The study incorporated a limited extent of human-robotic collaborations. The human-robotic collaboration is limited to just a specific step of each process, while the rest of the process is fully automated. Human labour collaborates at a specific step in each process to inspect and reinforce the connection between the beams and the brackets. Additional manual actions can be taken during collaboration should a defect be detected.

The manual reinforcement in the simulation is analogous to the connection between placed materials done by experienced technicians in the real construction environment. The connection can be in many forms ranging from welding to bolting, depending on the material type and structural requirements. Furthermore, the collaboration of the two robots was controlled by human labour. Human labour needed to initiate the program of the second robot when the assembled material was at the transport position. There remains an opportunity for automating such steps by incorporating collision avoidance sensors and programming.

8 Productivity Evaluation

The fabrication productivity was evaluated. Specifically, the fabrication process was repeated five times with the aim to evaluate production consistency and production time. Table 1 summarises the production time recorded for each run:

The results from the five iterations show acceptable time variance for each task with the standard deviation for each stage being less than 8 seconds. This demonstrates that the fabrication process is stable and can be repeated for a consistent result in terms of production timing. As discussed in Section 8, human labour had a limited collaboration step with the fabrication robot, which took in total 18 seconds to complete and less than 10% of the averaged time for the entire process.

Table 1: Build time evaluation.

Run #	Time Elapsed (second)	
	I. Pentagon Assembly	II. Lateral Beam Insertion
1	103	67
2	94	69
3	97	70
4	89	76
5	110	71
Average	99	71
Standard Dev.	7.3	3.0

In addition, the overall placement prevision was high from these five runs. All brackets were placed at their designated location. Only one ring beam was not able to be placed into its designated slot from the full runs.

9 Discussion

In this study, the down-scaled-down simulation of OSF&C with the UR5e robots to construct a complex bridge structure was successful. Bringing OSF&C to the full-scaled construction environment is expected to have similar benefits as the on-site fabrication with robots explored by Wagner et al. [3]: agile flexibility and mobility of the robot platform, reduction in GHG emission from transportation, and boosted productivity. Throughout this study, several meaningful observations and limitations were noted.

By utilizing AM in the OSF&C workflow, higher complexity, efficiency, and flexibility was observed. The use of AM to print the brackets significantly increased the part complexity available to the project, with features such as notches being added to the design with little to no increase in print time. The use of the assembly platform showed great potential for increasing consistency and quality control of robotic automation in a dynamic on-site construction environment. In future work, AM could be used to rapidly reconfigure assembly platforms to construct multiple different structures with ease. Finally, the brackets produced very little waste - only about a gram of plastic waste per bracket - showing promise for AM to play a part in sustainable construction practices in the future. The tailored bracket features made them easier for the robotic arm to work with and allowed higher overall accuracy.

Despite the successful utilization of AM, many practical limitations were encountered during the case study. Due to time and budget constraints, only one part design was manufactured with AM during the project. This is because the turnaround time for designing, validating, and batch printing multiple AM parts was a bigger bottleneck than expected. The batch printing required roughly a 2-week lead time, which was significantly longer than the construction process itself, so in this case, the brackets would likely be better off being printed at a supply plant and then brought to site alongside the other building materials. On-site printing likely works best when the print time is on the same timescale as the construction process or less. On-site printers would be best used for low production volume parts, such as quick repairs, spare parts, or jigs. Finally, fully AM-integrated construction processes, where robotic arms either directly print parts themselves or interact directly with 3D printers by retrieving and post-processing parts, could further improve OSF&C.

In this case study, a limited extent of collective robotic construction (CRC) was incorporated. It is recognised that CRC at a scaled-down environment cannot be appropriately simulated and evaluated, due to the scaled effect. This signals the need for a full-scale simulation to further evaluate and optimise CRC in OSF&C. Furthermore, collaboration of the two robots highly depended on human control. Future work should explore CRC where several robots are programmed together with appropriate collision avoidance measures including sensors and programming. CRC has seen some success in achieving complex architectural design [22].

The FDM process would likely be replaced by a higher performance type of AM in the field. In this project, the printed parts sometimes displayed unsatisfactory strength in the direction of the layers. This is a well-known issue with FDM printing, and limits its ability to be applied in end-user, load bearing parts. Instead, metal AM technologies, such as SLS or WAAM, could be explored. A benefit of SLS machines is that they can print large batches of parts quite efficiently in addition to having much better part strength. While these larger industrial printers may face their own set of issues when being integrated into OSF&C (especially regarding powder-based processes), they may show promise for shortening the manufacturing supply chain in the field and allowing rapid redesigns and changes to be made on the worksite.

In order to fully capture the benefits of AM in OSF&C, more sophisticated software tools would be needed, such as computer-aided design and manufacturing. Both on-site construction and AM need a robust digital pipeline for the design, tool-pathing and monitoring of their processes. A comprehensive building information modelling software for robotic construction simulation could significantly improve the performance of similar projects in the future.

When compared to the real-life simulation of OSF&C, there are several important features that a scaled-down scenario cannot properly model due to scaling effects. In scaled-down simulations, materials are often lighter and easier to manipulate, like polymer filament for the bracket, and foam for the beams, in place of metal bracket and timber/metal beams. The substitution simplifies the simulation but does not have the same durability or mechanical behaviour of real-life materials. This prevents evaluation of structure integrity of the constructed scaled-down structure. In addition, there are challenges with the HRC simulation in a scaled-down environment, where human labours can't be proportionally scaled up for real-life scenarios. In addition, real-life construction is a dynamic working environment that involves moving vehicles and equipment within the area. In a controlled scaled-down environment, the presence of moving vehicles and human workers is a modelling challenge. Furthermore, real-life construction would require sophisticated collision avoidance systems and protocols to ensure workers' safety, which can't be simulated in a down-scaled

environment. While the scaled-down approach used in this study could prove useful for evaluating modular OSF&C approaches such as that used by Wagner et al. [3], in the future, more rigorous productivity analysis of a simplified construction geometry would be desirable.

Dual robotic arms provided a highly articulated system, whose degrees of freedom offered complex fabrication tasks. While this allowed for manipulation of the assembly platform and efficient passing of parts between arms, capability of dual robotic arm-based construction could be pushed further in a future scaled down case study. Conversely, it would prove valuable to test scaled down OSF&C scenarios with simpler, more accessible technology such as a gantry crane.

10 Conclusion

This study demonstrates the successful evaluation of a novel AM-enabled robotic OSF&C method using a scaled down simulation approach. The down-scaled simulation is a cost-effective way to evaluate feasibility of OSF&C, with a total material cost of less than 70 dollars. The concept of OSF&C has great potential for the future construction industry with several unique benefits from reduction in GHG emissions to flexible adaptation to project needs. The case study was successful and demonstrated the feasibility and benefits of on-site robotic construction with 3D printing. The combination of industrial robots and AM offers a sustainable and efficient alternative to traditional construction methods. Despite practical limitations, the case study proposes a scaled down simulation methodology that can provide valuable insights into the potential of on-site construction automation. In order to continue the development of on-site robotic construction methods, future research is necessary to better understand the limitations of using scaled-down simulations to analyse human-robot interactions, as well as the integration of more advanced construction simulation tools such as BIM and robotic dynamics simulation.

Abstract – The assembly of steel structures is a complex and labour-intensive process that poses significant safety risks to workers. The Intermeshed Steel Connection (ISC) is an emerging type of structural steel connection that requires fewer bolts and can benefit from the use of robotics. The assembly process for traditional structural steel connections requires humans to work-at-height, which is unsafe and unergonomic, and the few robotic and automatic steel building assembly systems are not readily adoptable. In response, this paper proposes a novel strategy for automating the ISC assembly using off-the-shelf robotic manipulators. The proposed method aims to enhance safety and efficiency by incorporating a collaborative human-robot approach in the assembly process, which leverages computer vision and robotic manipulation technologies. A detailed workflow for the robotic assembly of the ISC is conceptualized by dividing the assembly process into multiple stages. A small-scale experimental setup has been created for future demonstration. The experimental setup includes a scaled-down ISC column-to-column connection, utilizing a KUKA LBR iiwa14 manipulator equipped with multiple cameras and computer vision algorithms for precise alignment and assembly.

Keywords – Intermeshed Steel Connection, robotic assembly, structural steel connections

Introduction

The process of assembling a steel building is a thoroughly organized sequence of steps that ensure the structure's integrity, functionality, and adherence to safety standards [1], [2]. Recent coupling of robotic arms and advanced manufacturing cutting enables a simpler connection that uses fewer pieces, and, thus, may be better suited for robotic assembly in the field. To demonstrate this concept, this paper uses the recently developed Intermeshed Steel Connection (ISC) to illustrate this concept [1], [3]. This section is divided into multiple sub-sections beginning with the steel structure assembly process in section 1.1. Next, section 1.2 describes the state-of-the-art robotic steel structure assembly process. Then, a brief introduction on ISC is provided in section 1.3. Finally, the limitations of the current SOTA and contribution of this research are described in section 1.4.

1.1 Steel structure assembly process

Steel buildings are comprised of individual beams and columns, which are prefabricated in a manufacturing shop floor. These beams and columns are then transported for on-site assembly. After site preparation and foundation installation, columns and then beams are assembled sequentially according to the construction program. Erection and assembly of structural steel buildings are a critical process comprising many uncertain activities [4] and heavily rely on manual labour [5]. The labour cost for assembly accounts for almost 25% of the total steel building cost [6]. Onsite assembly can be divided into four main steps: 1) lifting the structural steel members from storage area, 2) transporting them to the installation area, 3) aligning each member according to the design and with consideration of what is already assembles, and 4) connecting with bolts and/or welding [7]. There are several risks and safety concerns associated with the current assembly process. Human

workers must work-at-height for significant periods of time during the alignment and connection steps. Another safety risk is the size and weight of the beams and columns. As per British Standard, the depth in the cross-sectional size of a beam can vary from 127.2mm to 1036.3mm, while for column it can vary from 152.4mm to 474.2mm. Moreover, the length of the beams and columns can be any length up to 12m depending on the design. The weight of beams and columns range from 1 tonne to 10 tonnes based on the cross-section and length. Manipulating these large, heavy objects during the alignment step of the assembly pose safety risks to human workers. In many cases, the human worker must conduct the assembly process by standing on a beam, which is unergonomic and has inherent safety risks, as shown in Figure 1 [8]. The greatest risk of overall structural collapse is during the assembly process prior to the building achieving full stability and strength once all connections are made.

Figure 1 Safety risks of a human working at height during steel building construction [5]

1.2 State-of-the-art (SOTA) robotic technologies used in steel structure assembly

The use of robotics to automate assembly operations has grown in prominence in different industries including warehouse, automotive, and electronics [9]. Robotics have the potential to increase assembly processes' efficiency, precision, and safety by substituting intelligent machine systems that can quickly and accurately complete repetitive tasks, as compared to human labour. In an effort to make steel assembly safer and more profitable, researchers on robotics in the construction industry is a growing field.

The Shimizu Manufacturing system by Advanced Robotics Technology (SMART), is a fully automated construction system for high-rise buildings [10]. The system weighed 1,200 tonnes and required over two months to install. It faced issues with low productivity and financial viability. To address the challenges of transporting large and heavy objects and placing it precisely, a rail-boom robotic system and wire-suspended positioning system were proposed but not implemented [8]. In Korea, a robotic beam assembly system, including a robotic transport control system and a robotic bolting device were developed and tested [11], [12]. However, both proposed systems depended upon the creation of a large Construction Factory (CF) and a guide rail mechanism. To date, while industrial manipulators have been used extensively for automating many repetitive tasks, there are very few attempts to use them for the steel structure assembly process. Work by Liang et. al experimented with a scaled-down Robotic Assembly System (RAS) to automate the alignment and bolting process with an industrial manipulator and specially designed rotational device [7]. The manipulator transported both the beam and rotational device prior to correct alignment with the help of a marker and camera. However, how the system would transport a large and heavy beam was not considered.

1.3 Intermeshed Steel Connection

Although bolting requires assembling a large number of pieces, it is favoured over field welding due to easier installation, quicker connection times, better quality control, reusability, and lower inspection demands. However, the typically high number of bolts necessary for structural connections adds complexity to the use of field robotics. Advances in manufacturing techniques have enabled the development of new steel connections that could significantly reduce the number of bolts required, particularly in column-to-column connections. The Intermeshed Steel Connection (ISC) [1], [2], [3] is one such innovation, designed to speed up assembly and offer the possibility of direct reuse. Figure 2 displays an ISC connection in 3D CAD design software and from previous experimental project. The connection leverages advanced manufacturing capabilities to create precision cuts at the ends of the structural members, which allow a quickly assembled, load transferring connection with fewer bolts and auxiliary members to transfer the various load modalities (e.g. compression, shear, bending).

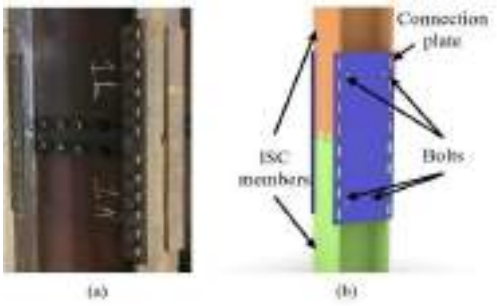

Figure 2 Proposed ISC; a) fabricated ISC with initial design [3] and b) CAD design of ISC with

alternative design with only two connection plates and fewer bolts [1],[2].

1.4 Limitations of SOTA and contribution of this research

Most of the proposed robotic steel structure assembly systems to date require customized robotic devices and structural systems before starting the actual construction. Use of these robotic or automatic assembly systems would require significant changes in the conventional construction method and mindset of the construction company and worker. A new type of structural steel connection, ISC, has been introduced that follows a similar assembly process as the conventional structural steel, but with many fewer bolts, thus lending itself more favorably to robotic assembly. The following research describes the design and experimentation of a robotic assembly process for the ISC using an off-the-shelf manipulator avoiding the need for significant customization. The main contribution of this research will be:

1. Conceptualizing a feasible assembly workflow for ISC using an off-the-shelf manipulator
2. Developing a dummy construction site with small-scale column-to-column ISC for future demonstrations

To place these contributions in context, section 2 of this paper describes more of the ISC assembly process. Section 3 discusses the theoretical framework for robotic assembly of the ISC. Section 4 introduces the proposed workflow of the assembly process, and the final section concludes with the results, the shortcomings, and future recommendations.

2 ISC assembly process

Before conceptualizing and developing the theoretical framework of ISC assembly with robots, it is required to understand the elements of ISC and the manual assembly process. A total of 3 types of elements are required for a complete ISC connection: (1) the ISC member, (2) connection plates, and (3) bolts. Each ISC require 2 structural members and 2 connection plates.

Assembling the members in an ISC requires matching the corresponding grooved sections of the steel members and then locating corresponding cuts that match those on the connection plates' edges. Similar to traditional structural steel members, assembly of ISC require 4 steps (lifting, transporting, aligning, and bolting) [7]. Figure 3 illustrate the steps of manual beam-to-beam ISC assembly inside a lab environment. The assembly process starts with attaching the member with the crane and then transporting it to the designated area as shown in Figure 3(a) and Figure 3(b) respectively. After that, a human worker aligns the member and connection plates (Figure 3(c)) and inserts the bolts (Figure 3(d)). The current ISC assembly process reduces but does not eliminate risks related to human safety and ergonomics. Using robotic technologies to assemble the elements of ISC could further reduce the time and requirement of human working at height and in awkward postures, which will improve safety and ergonomics.

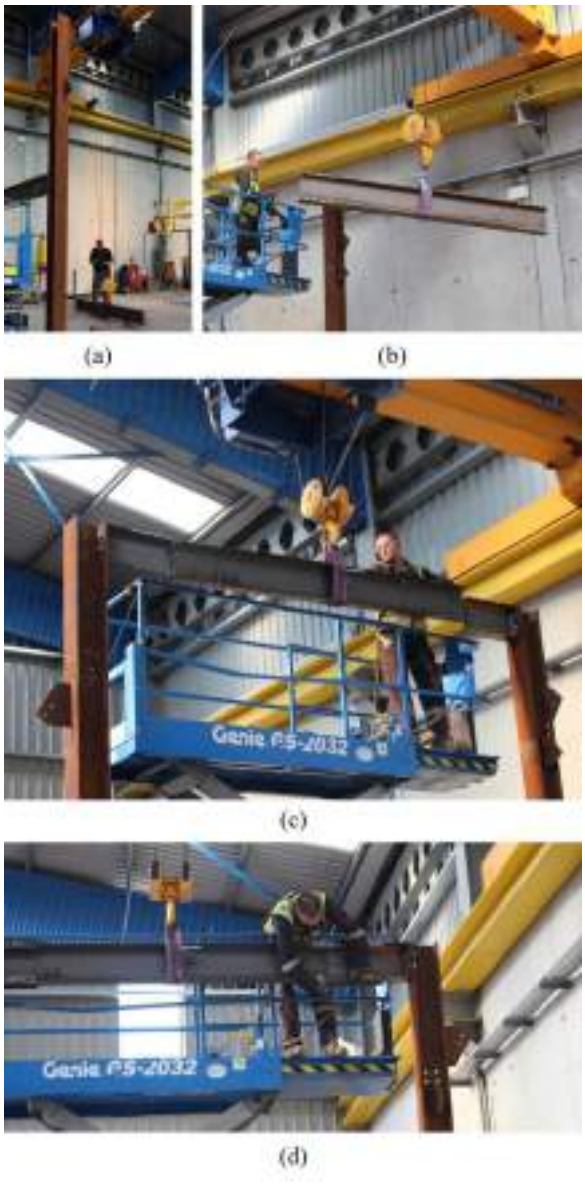

Figure 3 Steps of ISC assembly; a) lifting, b) transporting, c) aligning, d) bolting

3 Theoretical framework for robotic assembly process of ISC

ISC provides advantages over the conventional connection as it requires fewer bolts and improves the possibility of automation [1]. ISC members contain grooved sections, while conventional structural steel members contain flat ends. With the advancement of sensors, computer vision techniques, and accurate manipulation capabilities of industrial robots, robots have been proven to be efficient in repetitive tasks. With the help of computer vision technology and robotic manipulation, humans can potentially be removed from the dangerous task of assembling ISC. This section discusses the theoretical framework for using robotic technologies in the ISC assembly process.

3.1 Robotic assembly process of ISC

Though the manual assembly process of traditional steel connection and ISC, described in Figure 3, has 4 steps, robotic assembly of ISC will have 5 steps. Third step of the assembly process, aligning, will be divided into 2 steps, alignment and connection plate attachment. The whole assembly process can be divided into three main stages: pre-assembly, assembly, and post-assembly stage as shown in Figure 4.

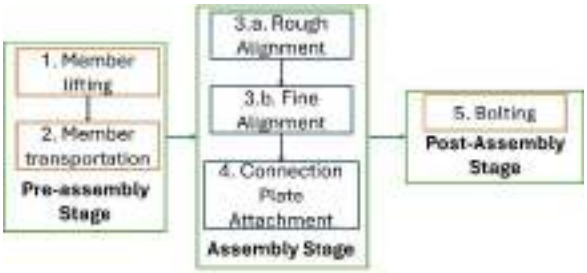

Figure 4 Stages and steps of robotic ISC assembly

Pre-assembly stage consists of lifting and transporting the member to the assembly site with the help of a human operator and crane. With the help of multiple cameras and computer vision algorithms, a robotic manipulator will assemble the member and connection plate during the assembly stage. After the rough alignment, the lateral distance between 2 members of ISC will be around 10-20 cm. but the orientation of the members might be incorrect, as shown in Figure 5(a). However, the rotation, translation correction, and fine placement will be conducted in the fine alignment step, shown in Figure 5(b). Subsequently, the connection plate is attached to the structural members. Finally, a human will put the nuts and bolts in place, which will be considered a post-assemble stage.

3.2 Detail workflow of assembly process

As the steps of assembly and usage of robotic technologies have been determined in Figure 4, this yields a detailed workflow of the whole assembly, as shown in Figure 6. The workflow starts with getting information regarding the member pickup location, assembly location, member size and shape from Building Information Modelling (BIM) through the communication module into the Human Machine Interface (HMI).

This assembly process requires lifting and transporting heavy metals by robot in different stages. Any small error in the robot program or incorrect path planning may lead to catastrophic disaster and cause human deaths. Hence, a strict separation of workspace and task must be maintained for safety reason. The HMI is used to maintain communication between robot and human, initiate tasks, and provide feedback for completion of tasks.

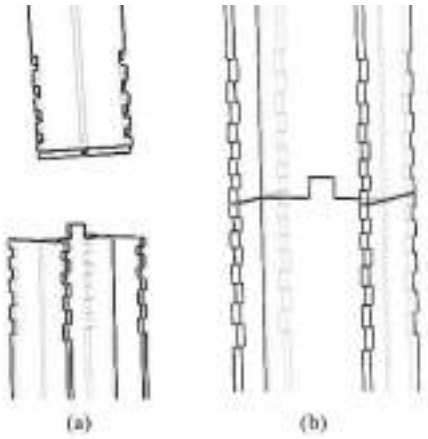

Figure 5 Alignment of members in assembly stage; (a) rough alignment, (b) fine alignment

With the introduction of Industry Foundation Class (IFC), BIM became a popular tool in managing construction projects by representing the information digitally [12]. A human will attach the rope and lifting attachment on the member. Once this is done, the member will be transported to the assembly area from the pickup location with the help of a crane operated by a human. During the whole assembly process, the crane will carry the member's full weight.

In the beginning of rough alignment, a perception module detects the object and determines the pose, with the help of multi-view cameras and trained computer vision algorithms. After receiving pose estimation through the communication module, the robot will move the member to desired location. Control and safety module of the robot will determine the presence of any obstacle in the planned path. If it is unavoidable,

feedback will be sent to the operator for manual intervention. Otherwise, the robot will try to finish rough alignment by trying new paths.

To assisting this step, an identity tag will be attached in the grooved section of the ISC members, which will provide better pose information for the robot perception. The perception module will detect and determine the pose of the identity tag to find the exact placement location. The robot will then correct the rotation and translation of the member, while it hangs from the crane. Once both members are aligned properly, the suspended member will be slowly lowered into the exact connection spot as guided by the robot with the help from the crane operator.

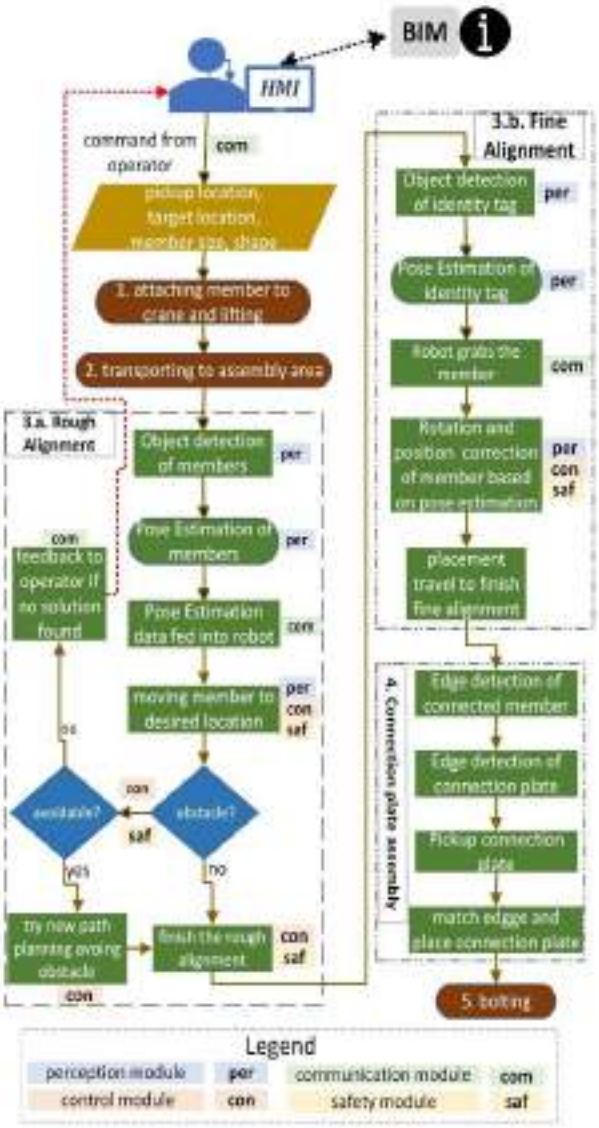

Figure 6 Detail workflow of ISC assembly using robot

The next assembly process step is placing the connection plate. An edge detection algorithm of the perception module will calculate both the edge of the grooved section in the connected members and connection plate. By matching the edges, the robot will align the connection plates on the members. After that, a human will attach the nut and bolts to finish the assembly process.

3.3 Schematic of small-scale demonstration

A scaled construction site along with ISC column members will be developed as a part of the second contribution, which will be used to test the previously described theoretical framework. Figure 7 shows the schematic diagrams of dummy construction site for small-scale ISC assembly with the help of robot. A total of 3 cameras (referred as C1, C2, and C3 in the diagram), will be fitted to create a multi-view perception. One camera will look at the site from top, while the other two will look at the scene from front and back, respectively. Specific areas will be designed for material input and assembly location.

4 Discussion

ISC assembly was divided into multiple stages and a detailed workflow combining manual and robotic steps was proposed.

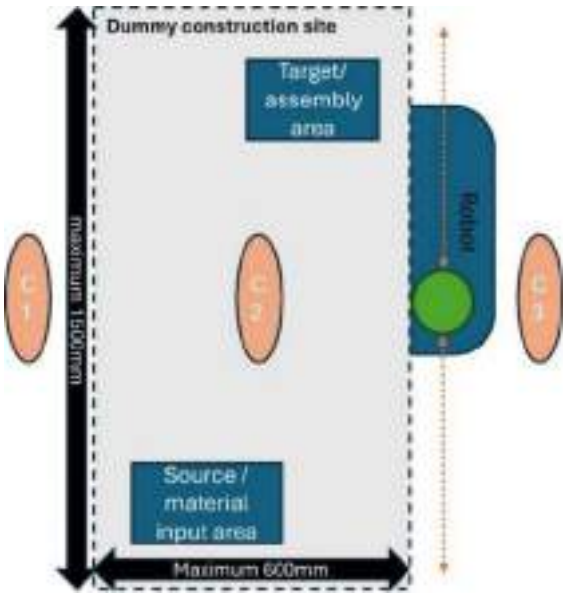

Figure 7 Schematic diagram of small-scale construction site for assembly of ISC using robot

4.1 Manual and robotic process

In this theoretical framework, 2 stages – pre-assemble

and post-assemble stage – were considered as manual processes, while the assembly stage was considered as a robotic process. Based on the size of the beam and column, members can weigh up to 10 tonnes and be up to 10m in length. Manipulating such a long and heavy object with an industrial robot is likely to be unsafe. Hence, the lifting and transporting steps in the pre-assemble (Figure 4) stage will be conducted by a human operating a heavy-duty crane. A special end-effector or gripper will be required to perform the bolting operation as bolting operation requires continuous rotational movement with high torque. In the current theoretical workflow, once all the elements are assembled, a human can quickly tighten the bolts which will significantly reduce the amount of time for working-at-height. In the future bolting will also become a robotic operation.

Aligning the ISC members is dangerous as the workspace is tight and at-height, and the object is heavy. During the assembly stage, machine learning based object detection and pose estimation algorithms can provide accurate results. Moreover, while the members are supported from a crane, a robot can guide the members and connection plate in place.

4.2 Robotic module and their functions

As shown in Figure 6, there are four main robotic modules: perception, control, safety, and communication, in the assembly workflow. These modules and their functionality are required in different steps to ensure the successful assembly of ISC.

Perception of a robot is the ability to sense and interpret the surroundings. For the proposed ISC assembly process, multiple cameras will be used to give the robot to ability to see the environment. Moreover, a trained computer vision algorithm will be used for detection and pose estimation of the assembly components. However, classical edge detection algorithm will be used in the connection plate assembly steps.

As ISC is novel type of connection, there are very few real images of ISC which are inadequate for training any CV algorithm. Hence, a hybrid dataset containing real and synthetic images is currently being generated. Performance of the CV algorithm will be tested in the simulated environment, small-scale experimental setup, and full-scale construction environment and the result will be shared with the research community.

The control module works as the brain of the whole system. It will be responsible for path planning of the manipulator to pick and place the ISC elements while avoiding obstacles with the help of perception and safety module.

The safety module is the part of the software architecture that ensures the safety of the robot and human during the assembly process. By analysing the data from the camera, the safety module will be able to determine any static or dynamic obstacles in the planned path. Finally, the communication module will be responsible for transferring necessary information among different modules and HMI.

4.3 Robot transportation

This proposed workflow herein avoids the current strategy of building another structure to support the robotics. However, the currently proposed workflow assembly of the ISC is divided into stages between manual and robotic process and uses human-robot collaboration to complete the assembly process. As part of this, a crane will be used to transport the robot between places to perform the rough alignment and fine alignment during the assembly stage. Ultimately, these tasks are repetitive in nature and can be replicated with robot and computer vision technology.

4.4 Small-scale assembly scene

To demonstrate the proposed workflow of ISC assembly and find affiliated challenges and shortcomings, a small scale ISC column to column connection was fabricated, and an experimental setup was created with a manipulator and multiple scene cameras.

To fabricate the small-scale column connection, universal column dimensions from the BS EN10056:1999 standards were used. One universal column, 305x305x97, was selected, and the sectional depth and width was scaled down to 103mm and 100mm respectively, with a ratio of 1:0.33 compared to the original dimensions. In this installation, the ISC column connection comprises three elements; bottom part (fixed with base), top part, and connection plates.

In the future demonstrations of the small-scale ISC assembly, a KUKA LBR iiwa14 will be used as a manipulator. It has 7 degree-of-freedoms and can lift a maximum payload of 14kg with a maximum reach of 820mm. That manipulator is also equipped with an Intel RealSense D-435i depth camera for perception and a 2-finger parallel gripper from Robotiq. Furthermore, 2 RGB cameras (one in the front and one in the back and one depth camera for aerial view) are attached in the scene. Figure 8 shows the scene setup for a small-scale column-to-column connection for future demonstrations of the assembly process.

4.5 Performance analysis

Few research had been conducted previously [7], [8], [10], [11], [12] to automate the steel building assembly using conventional steel connections. However, ISC is a novel connection type which has emerged from recent research. There was no research found in the literature

which use robots or completely manual processes for steel building assembly using the ISC connection. This proposed framework reduces the amount of time for work at height as the lifting, transportation and alignment will be carried out by the robot, as shown in Figure 4 and 6. Hence, using robot will improve the safety of the human worker and reduce the number of accidents.

Accuracy of our proposed assembly process depends on the accuracy of CV algorithm in the detection and localisation of ISC member and ISC connection plate and by extension the robot manipulation in fine alignment and connection plate attachment. Moreover, the overall time required for the assembly will depend on the completion time of each step. As this research is currently ongoing, details on the accuracy and time can be calculated only after conducting small-scale and full-scale assembly.

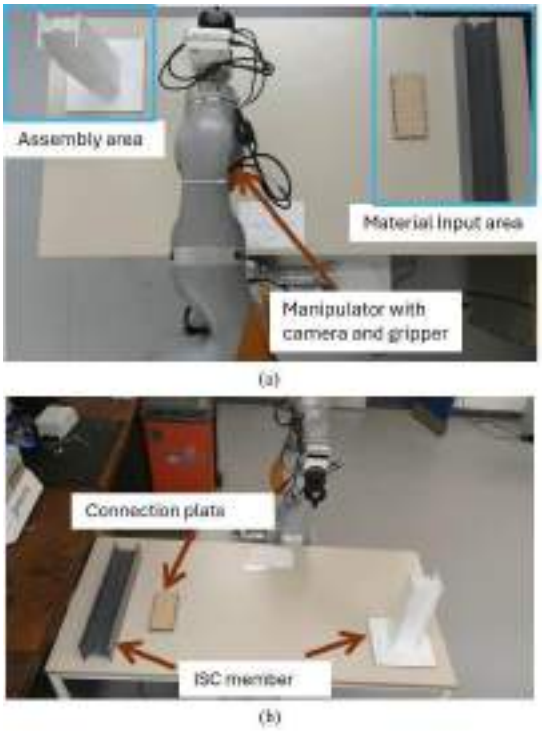

Figure 8 Demonstration scene setup with small scale ISC column to column connection; (a) aerial view, (b) front view

5 Conclusions

This research presents a novel strategy for automating the assembly of Intermeshed Steel Connections (ISC) using off-the-shelf robotic manipulators. The proposed method aims to enhance safety, efficiency, and precision in the assembly process by leveraging computer vision and robotic manipulation technologies. By conceptualizing a detailed workflow and creating a small-scale experimental setup, this study demonstrates the feasibility of integrating robotic technologies into conventional construction workflows without extensive modifications.

The experimental setup, which includes a scaled-down ISC column-to-column connection, highlights the potential of the proposed method to reduce manual labour and improve overall safety and ergonomics. The results indicate that the robotic assembly of an ISC can significantly mitigate the risks associated with human workers handling heavy components at height.

However, the study also identifies several limitations and areas for future research. The current setup is limited to small-scale demonstrations, and further work is needed to optimize the system for large-scale applications. Additionally, the integration of advanced computer vision algorithms and the development of specialized end-effectors for bolting operations are crucial for enhancing the system's performance. Another limitation is the need for a process to synchronise the motion between robot and crane. Future research will focus on refining the robotic algorithms and modification of end-effector for automating the bolting step, improving system integration for robot and crane synchronized motion, design of an HMI for the assembly process command and control centre, and conducting extensive field trials to validate the system's performance in real-world scenarios.

Abstract –

Crane accidents often result in severe injuries and fatalities, necessitating accurate analysis and responsibility prediction to prevent future incidents. However, the scarcity of crane accident-specific datasets and class imbalance pose challenges to developing robust predictive models. This study addresses these challenges by leveraging paraphrase-based data augmentation methodology to expand a dataset of 480 natural language accident descriptions into a balanced dataset of 900 samples. Using Google's Pegasus paraphrasing model, the augmented data improved model performance, as demonstrated by the F1 score increase from 0.29 to 0.5583. Three pre-trained transformer BERT-based models were fine-tuned on the augmented dataset to evaluate their effectiveness in predicting responsible personnel. The results highlight the effectiveness of the paraphrasing technique and transformer-based models in addressing class imbalance and improving classification accuracy. This research demonstrates the potential of natural language text data in enhancing safety analysis and proposes future directions, such as exploring alternative data augmentation methods, leveraging large language models, and experimenting with domain-specific fine-tuning.

Keywords –

Crane Safety, Natural Language Processing, Deep Learning, Data Augmentation.

1 Introduction

Crane accidents frequently occur on construction sites and, due to their heavy nature, often result in severe injuries and fatalities. Previous studies indicate that these accidents are primarily caused by human errors and miscommunication [1-3]. Forensic analysis after crane accidents plays a crucial role in identifying the sequence of events, root cause and pinpointing the responsible personnel. Identifying responsible personnel in crane accidents is critical for improving workplace safety and accurate liability assessment [4]. This research aims to support such processes by providing structured methods to analyze accident reports, making it easier to derive actionable insights for future safety improvements. This research output can potentially be used as an auxiliary tool to provide additional layer of verification and increase overall efficiency in experts' decision-making process. The construction industry generates significant amounts of text-based data, such as incident reports, safety manuals, and communication logs. Text-based analysis has emerged as a powerful tool in safety domains, including construction and manufacturing, for identifying accident processes [5]. Unlike accident statistics that only provide predefined categories and post-incident outcomes [6], natural language-based accident reports capture richer information about conditions, causes, and injuries [7]. For instance, Ma and Chen analyzed 159 text-based reports to identify accident factors [8], while Kumi et al. classified construction accident types using Korean reports [9]. These studies demonstrate the potential of text-based analysis in uncovering critical insights from unstructured data.

However, analyzing crane accident reports poses significant challenges. First, crane accident-specific datasets are scarce, limiting the ability to develop robust models. And this scarcity in labeled data can introduce overfitting during the model training [10]. Second, class imbalance in available datasets—where roles like "Crane Operator" are overrepresented while others like "Owner/User" are underrepresented—hampers the predictive accuracy of machine learning models.

To address these challenges, this study investigates paraphrase-based data augmentation strategies [11-12] for identifying responsible personnel in crane accidents. Using 480 natural language accident descriptions, the dataset was augmented with Google's Pegasus model [13], resulting in a balanced dataset of 900 samples. This augmentation ensures diverse yet semantically consistent training data, mitigating the impact of class imbalance.

Additionally, three pre-trained BERT-based models [14] were fine-tuned on the dataset to evaluate their performance in predicting responsible personnel. This approach aligns with findings by Devlin et al. (2019), which highlight that fine-tuning the entire model on task-specific data, even with limited examples, can significantly enhance performance compared to using fixed embeddings [14].

2 Data

2.1 Data Preprocessing

The original dataset contains 710 crane accident records provided by CRL (Crane Risk Logic, Inc.), where each record includes surveys of the accident descriptions, primary responsible personnel, and more. After removing empty contents and where the target variable (responsible personnel) is not available, a total of 480 crane accident descriptions and their primary responsible personnel were extracted from the original dataset. In this study, we removed or substituted any sensitive information (including personnel names, specific locations, and company identifiers) to protect the privacy of all parties involved. Each crane accident description contains an average of 93 words, ranging from two to three lines to 300 words. There are nine classes for the primary responsible personnel, with 'Crane Operator' being the most frequent class (100 records), while the 'Owner/User' class has the fewest (14 records) (Table 1).

Table 1. Original data per class distribution (total 480)

Class	Name	# of Data
0	Crane Operator	100
1	Rigger	96
2	Lit Director	94
3	Site Supervisor	58
4	Manufacturer	39
5	Other	27
6	Mechanical/Maintenance Issue	27
7	Signal Person	25
8	Owner/User	14

2.2 Input data Preparation

2.2.1 Paraphrase

Due to the imbalanced nature of the original data, this study adopted a paraphrasing technique for input dataset generation. The overall process of data augmentation is shown in Figure 1. A total of five datasets were used in this study. The first dataset contains only the original data, comprising 480 crane accident descriptions. The second dataset is augmented using Google's PEGASUS (Pre-training with Extracted Gap-sentences for Abstractive Summarization) paraphrasing model [13] . This ensures that each class contains 100 balanced samples (Figure 2), resulting in a total of 900 samples for Dataset 2. The third dataset is also generated using paraphrasing; however, the test set was removed in advance before paraphrasing to prevent any potential data leakage during training. For fair comparison, the test dataset size was fixed at 63 samples and remained the same across all three datasets. For the imbalanced original dataset, where the lowest class has only 14 samples, 50% of the smallest class's data count was used as the criterion for constructing the test set. As a result, 7 samples per class were selected, totalling 63 samples for the test set. Table 1 shows the original data distribution per class, and Table 2 data splits for each dataset.

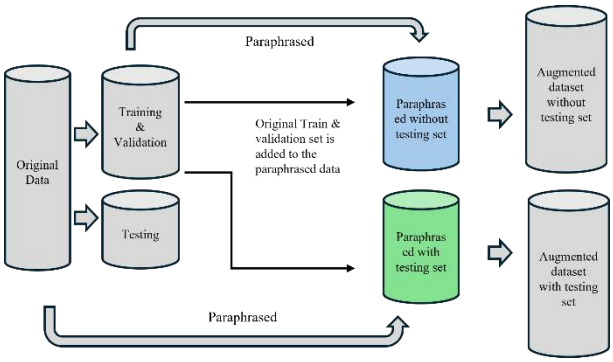

Figure 1. Data split process

Table 2. Description of five dataset used and dataset size

Dataset	Is Test set used for paraphrasing?	Is Test set balanced?	Data size (train-validation, test)
1	No	Yes	(417, 63)
2	No	Yes	(837,63)
3	Yes	Yes	(837,63)
4	No	No	(417, 63)
5	Yes	No	(837,63)

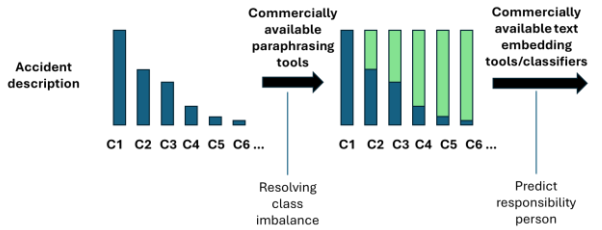

Figure 2. Data augmentation overview

2.2.2 Hyperparameters

The length of the paraphrased text was set to a

minimum of 80% and a maximum of 120% of the original target text. Top-p sampling was used as the sampling method, applied with a cumulative probability threshold (top_p=0.9) to ensure that words were sampled from the most probable token distribution while maintaining linguistic coherence [15]. Only the top 90% of cumulative probability words were considered, and the next word was selected based on normalized probabilities among these options.

In our paraphrase generation task, the temperature parameter was set to 1.5 to control the randomness of token selection during sampling. A temperature value of 1 results in a neutral probability distribution for next-word selection, while values greater than 1 increase randomness by making the probability distribution more uniform. This adjustment enhances output diversity but may occasionally reduce coherence or grammatical accuracy [16].

2.2.3 Paraphrasing quality evaluation

In this study, BLEU (Bilingual Evaluation Understudy) [17] and BERTScore [18] were used to evaluate the quality of paraphrasing. BLEU is a widely used evaluation metric in Natural Language Processing (NLP), which calculates a score based on n-gram overlaps through simple mathematical computations [17]. However, it fails to account for semantic meaning and diversity in paraphrased texts [19]. In contrast, BERTScore leverages embedding vectors to compare the contextual meaning of words, making it well-suited for evaluating semantic similarity [18]. Table 3 provides two paraphrase examples for the 'Owner/User' class. The second paraphrased example in Table 3 scored 0.1163 for BLEU and 0.9162 for BERTScore. For each paraphrased text, both BLEU and BERTScores were calculated. These examples demonstrate the trade-off between semantic similarity and diversity, as reflected in the scores. The resulting paraphrased sentences are compared to its original reference data. The BLEU scores are relatively low due to the diverse rephrasing of the original text, the BERTScores remain high (above 0.8), indicating that the semantic meaning of the text is well-preserved. The average BLEU and BERTScore for 420 paraphrased texts using all the original dataset (excluding 'Crane Operator' class) scored 0.0689 and 0.9181 respectively. This is Calculated to see how diverse the paraphrased result is (lower BLEU) in terms of sentence structure and words choices but still have strong semantic similarity with high BERTScore.

Table 3. Example of two paraphrasing result of 'Owner/User' class with its BLEU, BERTScore

Natural Language Crane Accident Description ('Owner/User' class)	BLEU	BERTScore
Original: A crew was dispatched to an off shore platform to perform prep work for a move to another site. A pedestal crane on site was being used to lift various heavy mechanical equipment onto the deck of the platform. During one lift the load was raised and beginning to swing when the load line broke dropping the load and killing a worker.	-	-
Paraphrased 1: There was work done ahead of a move to the off shore platform. with a team. Heavy mechanical equipment was loaded onto a crane to be put onto adeck the platform. While it was a light Lifting at a construction project one lift had a load line break resulting in a dead worker when it swung.	1.9561E-78	0.8919
Paraphrased 2: A crew was sent to an off shore platform so they could help relocate some structures. It was a very cumbersome lift using a pedestal crane to get heavy mechanical equipment from one location to another. A worker was killed as the loaded load was cut back as it swung by a malfunctioning load line.	0.1163	0.9162

3 Methodology

3.1 Transformers

This study utilized Transformer models, particularly BERT (Bidirectional Encoder Representations from Transformers)-based models, due to its proven effectiveness in NLP tasks [14]. Three types of BERT-based models were used: BERT, RoBERTa (Robustly Optimized BERT Pretraining Approach), and DistilBERT (Distilled Bidirectional Encoder Representations from Transformers). The BERT model, developed by Google, was used as the baseline for

comparison due to its effectiveness in NLP tasks, leveraging bidirectional context to learn semantic meaning [14]. The RoBERTa model, developed by Facebook AI, is an enhanced version of BERT that was trained for a longer duration on larger datasets with improved pretraining techniques [20]. Meanwhile, DistilBERT is a lightweight model that is 40% smaller than BERT but generally achieves competitive performance with reduced computational costs [21].

Each model takes input_ids, which are tokenized text data mapped to integer sequences, along with supplementary information, such as attention_masks, as input. These inputs are passed through the encoder of the transformer model, which generates high-level vector embeddings containing contextual information about the input text using self-attention layers. The self-attention mechanism allows tokens to capture their contextual relationships within the text. For the classification task, a classifier is attached to the final layers of the models [22]. While the encoder component is pretrained, the classifier is initialized randomly. During training, the parameters of both the encoder and classifier are updated to fine-tune the model for the specific task.

3.2 Grid Search

Grid search was conducted to tune hyperparameters, including learning rate, batch size, and the number of epochs. Table 4 summarizes the combinations chosen for each model, for the following hyperparameter ranges explored: learning rate [1e-5, 2e-5, 3e-5], batch size [8, 16], and epochs [5, 10, 15].

3.3 Metrics

Precision, recall, and F1 scores were calculated as evaluation metrics for datasets 1, 2, and 3. F1 score, being the harmonic mean of precision and recall, offers a balanced measure of classification performance. The weighted F1 score is used for imbalanced datasets 4 and 5.

$$Precision = \frac{TP}{TP + FP} \quad (1)$$

$$Recall = \frac{TP}{TP + FN} \quad (2)$$

$$F1\ Score = \frac{2 \times Precision \times Recall}{Precision + Recall} \quad (3)$$

$$Weighted\ F1\ Score = \sum_{i=1}^{N} w_i \times F1\ Score_i \quad (4)$$

$$where\ w_i = \frac{number\ of\ samples\ in\ class\ i}{total\ number\ of\ samples}$$

3.4 Input data augmentation: Paraphrasing technique

This study conducted two experiments to validate the effectiveness of paraphrasing in augmenting an imbalanced dataset under varying distribution conditions.

3.4.1 Experiment 1: Balanced distribution

For Experiment 1, Datasets 1,2 and 3 are used. Dataset 1 is the original imbalanced dataset containing total of 480 crane accident descriptions. Dataset 2 is augmented using paraphrasing; however, the 63 test is excluded in paraphrasing. Dataset 3 is augmented with all the data used for paraphrasing. Thus, after data augmentation using paraphrasing for dataset 2 and 3, is balanced with each containing 100 data per class.

3.4.2 Experiment 2: Original skewed distribution

For Experiment 2, Datasets 4 and 5 were used. Dataset 4 contains an imbalanced test set with 63 samples. The test set reflects the original dataset's imbalanced nature by using the stratify option in the train_test_split function to preserve the same class distribution as the original data. The remaining data was used for training and validation purposes. Dataset 5 also contains an imbalanced test set; however, the training and validation data were augmented. This augmentation was performed using the training and validation data from Dataset 4, excluding the test set, to create a larger and more diverse dataset for model training.

4 Result

Table 4 shows the performance of the prediction models on five input datasets for three different BERT-based models. For the original imbalanced data (Dataset 1) with a balanced test set, the best performance was achieved with DistilBERT, scoring 0.2898. With the addition of paraphrasing (Dataset 2), the performance improved across all three models, with RoBERTa showing the most significant improvement, increasing from 0.2544 to 0.3261. The results for Dataset 3 showed further improvement, with DistilBERT achieving the highest score of 0.5583. The confusion matrix in Figure 3 revealed that the model performed well in identifying major classes such as 'Crane Operator (class 0),' with high true positive rates, however failed with underrepresented classes (class 4-8). The confusion matrix for dataset 2 (Figure 4), shows improvement compared to dataset 1(Figure 3).

The precision of the base BERT model showed only a slight increase from 0.2672 to 0.2677 after data augmentation. However, the recall improved from

0.2857 to 0.3333, suggesting that the augmentation enriched the positive examples in this class, enabling the model to generalize better and reduce false positive predictions. In contrast, the DistilBERT model experienced a decline in precision from 0.3714 to 0.3089 when trained on the augmented dataset. This result indicates that lightweight models like DistilBERT may have a lower capacity to generalize effectively when exposed to more diverse data.

However, as indicated in Figure 5, there is evidence of overfitting, as lower-data-count classes were classified almost perfectly in the test set. This is likely because of a certain degree of data leakage, given that the training dataset includes paraphrased samples derived from the entire dataset, thus introducing contexts similar to those in the test data. Further experiments are needed to address these issues, as all models exhibited high performance (F1 scores above 0.6) during the validation process. Future research should explore alternative methodologies to enhance dataset quality by determining the most effective data augmentation strategies and their impact on model performance.

Table 4. Result of 5 datasets with each three BERT based transformer models

Data	Model	Precision	Recall	F1	Best Hyperparameters (learning rate, batch size, epochs)
1	BERT	0.2672	0.2857	0.2159	(2e-5, 8, 10)
	RoBERTa	0.2849	0.3175	0.2544	(3e-5, 16, 10)
	DistilBERT	0.3714	0.3492	0.2898	(2e-5, 8, 15)

5 Limitations and Future Work.

Different sentence-level augmentation techniques can be further investigated. Using large language models like Open AI API [23] for generating similar text could also be a potential research methodology. This study focused solely on identifying responsible personnel, but its scope can be expanded to explore other aspects of the crane accident dataset, such as predicting accident-related damages in terms of property and equipment and analyzing root causes of the accidents.

6 Conclusion

In this study, we addressed the challenge of class imbalance in a 9-class classification task for identifying responsible personnel in crane accidents by leveraging paraphrasing techniques for data augmentation. The results across Data 1, 2, and 3 demonstrate that increasing the dataset size through augmentation significantly improved performance. The F1 score of the best-performing model increased from 0.29 (Data 1) to 0.3261 (Data 2) and further to 0.5583 (Data 3).

Through our experiments, we evaluated the effectiveness of paraphrased data in improving the performance of transformer-based models, showcasing the potential utility of widely used paraphrasing tools.

However, this paraphrase-based data augmentation approach has certain limitations. The results may vary depending on the specific settings and methods used to generate the augmented dataset. For future studies, alternative methodologies, such as utilizing large language models for data augmentation, could be explored. Furthermore, experimenting with different hyperparameter settings may yield additional performance improvements.

Abstract -

The construction industry is currently facing a labor shortage, prompting many researchers and practitioners to explore construction automation through advancements in robotics. For successful construction operations with multiple agents, effective and intuitive communication is essential. To this end, this research proposes a Motion-Based Communication (MBC) framework, which enables collaboration using movement. MBC provides a robust alternative that remains unaffected by various types of disruptions. This work contributes to the field of robotics by developing a motion-based language represented through an ontology. The ontological representation is encoded via directional shifts in motion rather than poses and is decoded by analyzing optical flow vectors. The experimental results in a lab environment using a UR5e robot indicate feasibility, with a shift inference accuracy of 98.8%. These findings can contribute to the development of a multi-agent MBC language to support communication in real time during construction operations.

Keywords -

Motion-Based Communication; Construction Automation via Robotics; Cooperating Robots; Dense Optical Flow

1 Introduction

Traditional robot-to-robot communication consists of physical data transfer via networking. However, in the event of a network failure or disruption, this modality of communication cannot be relied on. Additionally, networked communication efficacy is contingent on condition of the environment. For instance, in the case of large infrastructure construction projects such as dams, roads, and bridges, the installation of Internet networks (i.e., LTE and 5G) may be challenging, making seamless online communication difficult. Additionally, there are wireless networks that do not rely on Internet connections, such as Bluetooth [1] and Wi-Fi [2], which are relatively easy to install and can address some of these shortcomings. However, these networks are limited to specific areas and require manual connection each time they are used. As construction sites physically constantly change over time, wired networks must be reconfigured to consider the site conditions, which requires significant time and cost.

Motion-based communication (MBC) serves as a potential solution for non-networked communication for several reasons. First, it can potentially allow communication between human and computer as motion can be used as a common language channel that is understandable by humans [3]. In addition, compared to other multi-modal robot-to-human communication methods [4], displays and LED-based systems suffer from areas of high contrast or light intensity, while audio communication is evidently ineffective in vacuums or underwater. Lastly, motion is not a unique attribute and has the potential to facilitate a universal language channel in both organic and robotic agents that are capable of some form of actuation.

Therefore, the authors propose implementing MBC as a pseudo-language. This is done in two steps. First, an ontology is created by performing *open coding* [5] on several robot action research papers and corpora and ontologies [6, 7, 8] represented by OWL files (W3C Web Ontology Language [9]). The coding process results in an ontology representing a pseudo-language consisting of **action categories**, **actions types**, **entity types**, and **value types**, and **atomic types** (referred to collectively as **symbols**).

Afterwards, symbols in the ontology are encoded through alternating clockwise and counter-clockwise movement inside a communication window from a UR5e arm. A dense optical flow based motion analysis framework coupled with contour detection and tracking supplemented by Kalman filter is evaluated as the proposed methodology for decoding the motion-based symbols using a Logitech C270 camera with a resolution of 640 by 480. The efficacy of this method is compared to state-of-the-art (SOTA) MBC research. For brevity, this paper focuses on the actual communication framework and decoding rather than the ontology development. An overview of the steps taken can be seen in Figure 1.

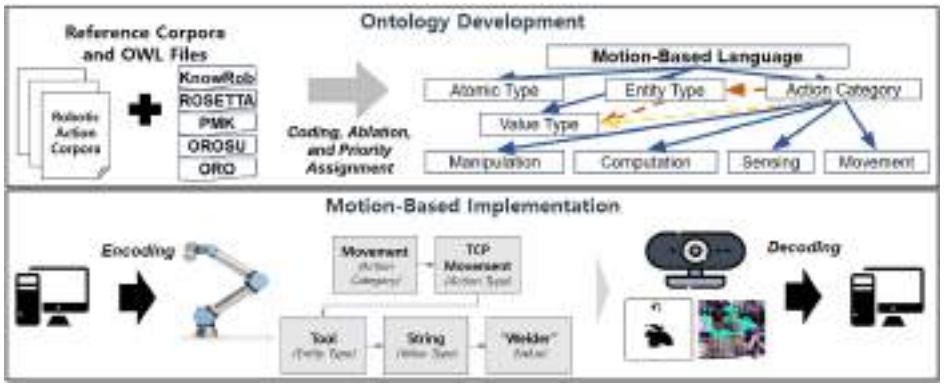

Figure 1. Research overview consisting of an open coding process to construct the language ontology (top) and the communication process with an example message (bottom).

2 Background

2.1 Motion-based communication

MBC deals with encoding a message between multiple agents via pose or motion and interpreting the message using computer vision techniques. These agents can consist of robots, humans, or some mix of the two. The capability to engage in multi-agent (i.e. both human and robot) communication with both human and robotic agents is a crucial benefit of MBC, along with the aforementioned resilience to networking impediments. Modern MBC research, whether dealing with human-to-robot, robot-to-robot, or multi-agent communication, utilizes either gestures [10, 11], poses [4, 3], trajectories [12], or a combination [13] of these to encode information.

2.1.1 Gesture-based

Gestures have been used both in the context of aligning common objects in multi-robot environments [10] as well as a common language channel between humans and robots. Vanc et al. [13] propose a pseudo-language for human-robot interaction (HRI) by implementing a framework using a combination of deictic, mimetic, and quantification gestures in addition to teleoperation. This setup requires Leap Motion Controller [14] and a gesture classification model [11] to recognize the encoded gesture-based signals real-time. Although this framework frames the MBC paradigm as a language, the usage of a model limits the language to communication from a human to a robot.

2.1.2 Pose-based

In the context of this research, the salient components of the pose of an agent are the roll, pitch, and yaw orientations of its body (or end effector, in the case of a robotic manipulator). Encoding from Koreitem et al. [15] is done using a set of ordered lists, called a *code*, where each element is a particular pose configuration (i.e., roll, pitch, yaw) in which the orientation space is binned. Their work focuses on minimizing a cost function across all codes. For each possible pose configuration, the cost is calculated by three factors: probability of occurrence, detection error of their orientation regressor, and time to execute. Decoding is performed via convolutional neural network (CNN) based pose estimation. As the main focus is the optimization of the encoded messages with respect to time, energy, and accuracy, there is less of an emphasis on flexibility. Using a pose estimation model limits generality, and each pose encodes a pre-built, holistic message.

2.1.3 Trajectory-based

Although using pose as a method of encoding messages is popular in modern MBC research, it can be supplemented with trajectory information as well. SOTA research from Fulton et al. [4] and Enan et al. [3] mainly use pose-based encodings, but some of their messages also contain trajectories. For instance, in [3], the message "GO TO LOCATION" is defined by rolling 45-degrees, moving forward and then backward twice, and then proceeding to the desired location. Their research is the first to create a unified HRI and robot-robot interaction (RRI) motion-based framework in which both the human operator and robot can interpret the gestures. In addition, it is the first MBC research to utilize self-attention [16] for decoding. User-defined gestures can also be defined to extend the language via configuration files.

However, as previously mentioned, MBC research has not taken full advantage of the potential generality of motion. That is, there is information contained in the motion itself rather than the pose that can be used as a sort of lexicon. In the example from [3], the individual words *go to* and *location* and their semantics are not encoded. There-

fore, adding another unique message relating to movement, for instance "GO TO AGENT," would require an entirely unique encoding, potentially even unrelated to the original one. Additionally, while the usage of deep-learning models enables potentially high precision, it comes at a high computational cost and can limit the ability to generalize the communication framework to other robots.

3 Methodology

The following sections briefly outline the methodology used in developing the baseline ontology used in this framework as well as covering the decoding process used to interpret messages.

3.1 Ontology coding process

A rough initial ontology is built based upon coding actions, categories, and frames from previous robotic action studies [8, 7, 6] to guide the coding process. The initial ontology consists of mainly action categories and action types with some initial entity types and values. Then, five OWL files (studied in [17]) are inspected using Protégé [18] and all leaves (a class without any subclasses) are extracted. Irrelevant classes, such as those not related to actions, objects, or values, are ablated. Each class is coded as either a type of action, entity, or generic value using the preliminary ontology as a reference.

From largest to smallest, the OWL files used in this research come from KnowRob [19, 20], ROSETTA [21], OROSU [22], ORO [23], and PMK [24]. These five OWL files are selected as they are among the 5 largest, open-source, industrial robotic action ontologies. For each of the 5 OWL files, only classes (i.e. subclasses of **owl:Thing**, not properties or individuals) relating to actions and objects were extracted and coded from the five OWL files.

This entire coding process is repeated for a total of five full runs, refining the codes and resulting in added granularity in the form of introducing action categories and specific value types. The final ontology for the proposed language consists of the following levels: **action categories**, **action types**, **entity types**, **value types**, and **atomic types**. Action categories are broad classifications of actions (*Manipulation*, *Movment*, etc.) while action types are specific varieties of those actions (*Handling*, *Rotation*, etc.). Entities are objects that can be observed or interacted with are children of action types that use them. Value types correspond to the possible arguments that can be used for specific messages. All symbols, aside from literal values, are assigned a priority with respect to other symbols in the same level of the tree based on their frequency in the surveyed literature.

3.2 Optical flow-based decoding

The communication process begins when one robot sends a *ToggleCommunications* symbol which consists of a unique cross pattern (discussed in Section 3.2.5). Then, the communicating robot begins sending a sequence of symbols followed by a final *ToggleCommunications* symbol which terminates communication. Motion detection and tracking for interpreting symbols (encoded as aforementioned **shifts**) is done using Gunnar-Farnebäck optical flow [25] coupled with contour finding [26]. A Kalman Filter [27] is also used to help estimate the center of the tracked objects.

In this language, symbols and literal values are encoded using a discrete quantity of **lexical motion units** (LMU). The magnitude of this motion (i.e. one LMU) is calculated dynamically when an agent initiates communication (see 3.2.5). The motion consists of a circular trajectory inside the communication window and alternates between counterclockwise and clockwise movements for each symbol. This ensures symbols are distinct and identifiable with a definitive **shift** in the direction of movement. In other words, the *direction* of the movement is independent of the symbol. Rather, the direction of motion flips after each symbol such that the overall message consists of a series of directional shifts along a fixed circle. Each symbol's encoding (aside from literal values) is equivalent to the calculated LMU value multiplied by its priority from the open coding process. Literal values have their own encoding rules using a binary representation, which is left out for brevity.

3.2.1 Farnebäck method

Farnebäck's method falls under the category of differential optical flow as it utilizes partial differential equations to model the flow field and minimize an energy function to perform motion estimation. It is chosen as the base motion detection component for several reasons. It does not rely on deep learning or training data and as such allows for better generalization and faster inference time compared to SOTA MBC decoding paradigms that implement pose-based CNNs [15, 4, 3]. This is a result of using a model-free method that only uses motion where there is no need to query any models. Lastly, the OpenCV [28] libraries provide the Farnebäck algorithm, permitting a simpler and more portable framework, which are attributes that are important in resource-limited environments that can often occur in construction.

Results from dense optical flow in environments with inconsistent lighting or a large quantity of background motion can be noisy. Flow vector magnitude thresholding, Gaussian blurring, and morphological operations (such as erosion and dilation) are all applied to yield a cleaner

image before processing continues.

3.2.2 Contour tracking

Dense optical flow yields both a magnitude $m(x, y)$ and direction $\theta(x, y)$ for each (x, y) pixel in the image. However, contours do not inherently contain optical flow information as they only consist of a set of points that define a boundary. Therefore, given a set of optical flow vectors **F** and contours **Q** inside an image **I**, the mapping from pixels in **Q** to **F** is described by:

$$\forall (x, y) \in \mathbf{Q},\ \exists\, (m(x, y), \theta(x, y)) = \mathbf{F}(x, y) \qquad (1)$$

Each contour is then assigned to an **Optical Flow Contour** object (OFC). This is done by comparing the central moment of a contour to each previously found OFC. If the center is within a tracking threshold, T_t (chosen as 22.5 pixels given the experimental setup and camera resolution), the OFC object is updated with the new information from the contour via a Kalman filter. If there are no current $OFCs$ or the current contour's center or area is beyond the thresholds, a new OFC object is created.

3.2.3 Optical flow contour objects

Each OFC contains the current magnitude $\bar{m}_i$, current angle $\bar{\theta}_i$, and center (c_i^x, c_i^y) of the contour it is assigned or updated with. To calculate $\bar{m}_i$ for the OFC, the mean of all *non-zero* magnitude pixels inside the assigned contour is found, filtering small noisy measurements. The angle $\bar{\theta}_i$ is computed by taking the circular mean of the angle vector, which also only includes pixels that are included in the mean magnitude calculation. Therefore, using the remaining n pixels inside the assigned contour, the magnitude and angle are given by:

$$\bar{m}_i = \frac{1}{n}\sum_{k=1}^{n} m_k;\ \bar{\theta}_i = \arg\ \frac{1}{n}\sum_{k=1}^{n} e^{\mathrm{i}\theta_k} \qquad (2)$$

Where i is the imaginary unit and $\arg(z)$ is the argument (angle) of the complex number z. Lastly, the center is found by taking the weighted center of pixel intensity (moment) from the convex hull of the contour. (c_i^x, c_i^y) and $\bar{m}_i$ are passed into the Kalman filter as measurements. This is used to compute the estimated state, or center of the OFC. In this way, the Kalman filter assists in the tracking of an OFC, but does not directly calculate its magnitude or angle. For each frame an arbitrary OFC is detected, $\bar{m}_i$ is added to that OFC's **shift magnitude**, ρ_i. The shift magnitude then contains the sum of all non-zero mean magnitudes, but is reset once a shift is detected for the current OFC. Motion - specifically the motion of the sender in between each shift - is then quantified by using ρ_i.

3.2.4 Shift detection

Shifts are considered changes in the angular component of the optical flow vector of $\frac{\pi}{2}$, also know as the angular threshold T_θ. The decoding process then consists of analyzing the motion segments in between each directional shift and estimating how many discrete LMUs make up each motion segment.

To determine a shift, $\Delta\bar{\theta}_i$ is acquired by finding the angular difference between $\bar{\theta}_i$ and $\bar{\theta}_{i-1}$. A maximum of three angular differences are stored in memory as a deque (double-ended queue) for each OFC to detect shifts; this is known as the **angle history**, Θ, of the OFC. A maximum deque for an arbitrary OFC is then given by:

$$\Theta = \{\Delta\bar{\theta}_{i-2}, \Delta\bar{\theta}_{i-1}, \Delta\bar{\theta}_i\} \qquad (3)$$

Each time an OFC object is matched with a viable contour in the current frame and updated, the angular difference is calculated and added to its angle history. The angles inside Θ are summed and compared to T_θ:

$$f(\Theta) = \sum_{\Delta\bar{\theta}\in\Theta} \Delta\bar{\theta} \qquad (4)$$

If $f(\Theta)$ exceeds T_θ, a shift is detected. $\bar{\theta}_i$, ρ_i, and (c_i^x, c_i^y) are then added to a dequeue known as the **shift history**, S, up to a maximum of seven shifts (the number of shifts required to detect the communication window). When a shift occurs, both Θ_i and the current shift magnitude ρ_i are cleared for the current OFC. Then ρ_i is used to determine the current symbol by rounding it to the nearest whole LMU. For example, given an LMU of 5.5 and final ρ_i of 10.2, the symbol is interpreted as 2 LMUs; the current direction of motion is irrelevant. Figure 2 shows shift detection between two frames.

3.2.5 ROI estimation for communication window

The symbol used to request and end communication, $ToggleCommunications$, serves two main roles. First, to signal the start and end of the motion-based communication chain. Secondly, it establishes the *communication window* and LMU estimation used by the receiver. The purpose of the communication window is also two-fold. It reduces noise from the environment by focusing on a specific region of interest (ROI) within the camera view and it reduces computation by disregarding pixels outside this ROI (see Section 4.1). This has the advantage of increasing frame rate while still avoiding the "aperture problem" caused by local measurements within a small window since the optical flow component continues to track the entire scene.

The sender and receiver are assumed to both be aware of the expected radius of the communication window, r_c,

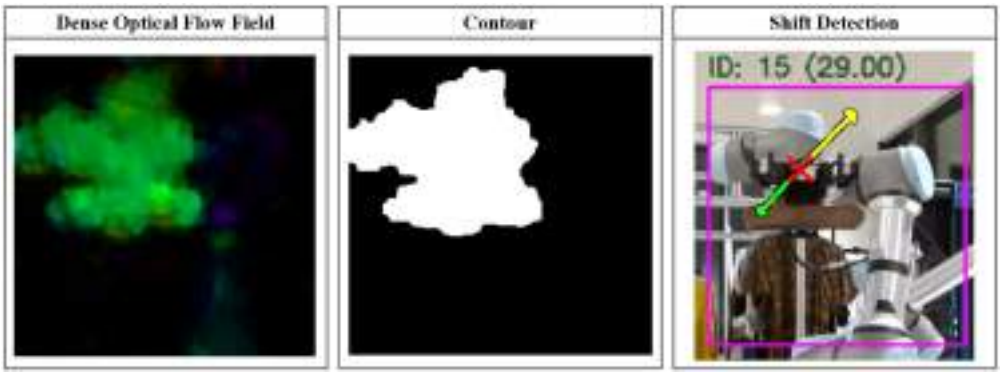

Figure 2. Optical flow field (left), contour (middle) and annotated frame (right) during a detected shift, marked with a red 'X' inside the ROI (purple box). Yellow and green arrows represent magnitude and direction ($\bar{m}$, $\bar{\theta}$) for $i-1$ and i, respectively. The ID of the OFC and current shift magnitude ρ_i are displayed above the ROI.

and an expected **radius ratio**, α, which is used to designate the ratio between ROI_r and r_c. In other words, the $ToggleCommunications$ symbol is meant to be sent within a smaller portion of the overall communicating window. This is used to help establish the ROI and LMU computation between sender and receiver, regardless of distance. The chosen r_c in this case is 10 cm, and α is selected to be 1/3. The $ToggleCommunications$ symbol consists of a series of movements in a cross pattern: $\{down, left, right, down, up, right, left\}$. For each OFC with a fully saturated shift history deque, the receiver actively processes these shifts until this sequence is found. It designates the $ToggleCommunications$ symbol, which sets the OFC that sent the symbol to *active*, meaning the receiver is now actively listening to (or more appropriately, watching for) encoded symbols from this OFC.

The ROI for the communication window is also established during this process. To find the window, the center of the points from the shifts are used to calculate both the center (origin) of the window (ROI_c), its radius (ROI_r), and its average magnitude (ROI_ρ). The center is found by taking the mean (x, y) coordinates and the radius by taking the average distance between each shift s in the $ToggleCommunications$ symbol for an arbitrary OFC:

$$ROI_c = \frac{1}{n}\sum_{k=1}^{n} s_k^{(c_x, c_y)} \tag{5}$$

$$ROI_r = \frac{1}{n-1}\sum_{k=1}^{n-1} \overline{(s_{k+1}^{c_x} - s_k^{c_x})^2 + (s_{k+1}^{c_y} - s_k^{c_y})^2} \tag{6}$$

The initial ROI_r is then multiplied by the reciprocal of the radius ratio $\frac{1}{\alpha}$ to yield the final expected ROI_r. An ROI is created around the origin ROI_c with radius ROI_r in which **only motion inside this window** from the currently **active** OFC is considered for symbol interpretation. Lastly, a weighted average shift magnitude of the radius is used in the computation of acquiring the expected magnitude for a singular lexical motion unit. At any time, the sending robot can signal $ToggleCommunications$ to remove the ROI and active status, thus allowing the receiver robot to resume actively observing for the start of a new $ToggleCommunications$ symbol.

4 Experimental results

To evaluate the overall accuracy of the system, experimental testing is performed on recordings of 13 distinct messages - one from each action type, with arbitrary entity and value parameters, and a message composed of several other messages. Each message is recorded from 1, 2, 3, 4, and 5 meters. Below is a list of example chosen messages along with their meaning:

M05 $Handling \rightarrow Manipulation \rightarrow Tool \rightarrow None \rightarrow None \rightarrow 0$: Pick up the nearest $Tool$.
M08 $Movement \rightarrow TCPMovement \rightarrow None \rightarrow Integer \rightarrow 20$: Move TCP forward 20 cm.
M09 $Movement \rightarrow TCPRotation \rightarrow None \rightarrow IntegerVector \rightarrow [90, 0, 0]$: Rotate TCP by 90 degrees in the x-axis.
M12 $Halt$: Stop all movement/actions and cancel all previous commands.
M13 A message consisting of 3 other messages: pick up the nearest tool, move the TCP to the nearest obstacle, and activate held tool

Results from decoding a message (**M13**) can be seen in Figure 3. Evaluation is performed by comparing the actual ρ_t^a (red dotted line) at each t where a shift occurs against the expected ρ_t^e (green line). Since LMUs are discrete units, ρ_t^a is rounded to the nearest LMU to get the final

decoded result, ρ_t^r (cyan dashed line). The orange dotted lines represent the LMU intervals, with the first (bottom) line equal to one LMU, the next line equal to two LMUs, and so on. The mean residual error is equal to the average difference at each shift ($|\rho_t^a - \rho_t^e|$)

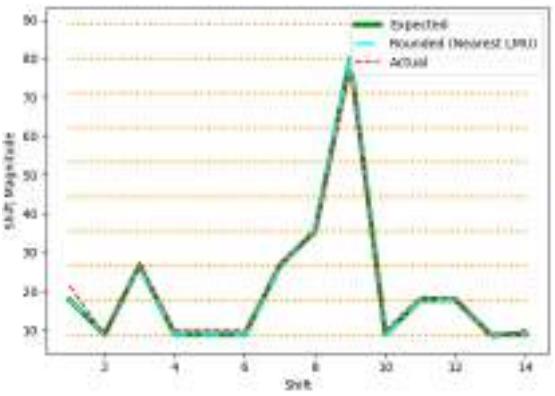

Figure 3. **M13** correctly interpreted at 2m with minimal mean residual error.

Across all 13 messages, there are a total of 167 symbols. Of the distances evaluated, the optimal range of interpreting shifts falls between 1 to 3 meters. From these distances, 98.8% (495 of 501) of symbols are correctly interpreted. Overall, a successful interpretation rate of 94.1% (786 of 835) is achieved from the 1 meter bins between 1 and 5 meters using a 640x480 resolution camera. The accuracy of each messages can be seen in Table 1. Each message along with the number of shifts required for its encoding is provided, along with the shift accuracy for both the optimal range (1, 2, and 3 meters) and all ranges (1, 2, 3, 4, and 5 meters). Figure 4 also shows the performance of messages from 1-3 meters, which is the weighted (0.95) accuracy minus the weighted (0.05) mean residual error that results from each shift.

4.1 Performance

Without downsampling, multi-threading, or hardware acceleration, the decoding algorithm runs at around 18-20 FPS on a AMD Ryzen 7 3700X 8-Core Processor. After the ROI is selected, the FPS reaches between 70 (for larger ROIs, in the case of close proximity to the communicating robot) and 330 FPS. As LMUs are dynamically calculated with respect to the relative motion of the robot, the algorithm is theoretically independent on speed assuming that the velocity of the robot remains relatively constant throughout the signaling.

Dense optical flow can struggle in environments with poor lighting or noisy backgrounds, such as flickering lights or numerous rapidly moving objects. The presence of heavy background noise or complex scene dynamics can be a limitation to the proposed dense optical flow approach for MBC, reducing both accuracy and performance. Although preprocessing and ROI construction help to mitigate noise under the evaluated conditions, the effects of environmental illuminance and highly disruptive noise on the proposed system are currently being studied.

Table 1. Results of the 13 messages evaluated from the optimal range (1 to 3 meters) and all ranges (1 to 5 meters) using a UR5e robotic arm. The values for shift inference accuracy represent the percentage of correctly decoded shifts using a 640x480 resolution camera at optimal range (left, 1-3m) and all evaluated ranges (right, 1-5m).

Message	Shifts	Shift Inference Accuracy (%)
M01	25	98.7/98.4
M02	36	100/94.4
M03	4	100/100
M04	22	100/100
M05	6	100/86.7
M06	18	96.3/93.3
M07	4	100/100
M08	10	96.7/88
M09	17	98.0/96.5
M10	5	100/100
M11	4	100/90
M12	2	100/100
M13	14	97.6/77.14

4.2 Comparison with SOTA

The SOTA in motion-based communication [3] achieves a recognition accuracy of 94.67% in simulation using their RRCommNet model, with an average inference speed of 10 FPS and 12.5 FPS (for RRCommNet-Skip, which averages 88% accuracy as it uses every other frame). Real-world accuracy for the two models is 83.33% and 73.81%, respectively for the regular and frame-skipping versions. By using optical flow vectors without machine learning, the MBC language runs faster and does not incur additional computational costs stemming from querying a model.

Since the language is fundamentally different than SOTA works, the comparison between shift inference accuracy and message inference accuracy is not necessarily one-to-one. However, the individual shift inference accuracy from this research outperforms SOTA real-world and simulation message inference accuracy at 1 through 5 meters using a 640x480 resolution camera without the usage of any type of model. The performance is also higher, with a minimum of about 18 FPS, reaching up to 330 FPS.

5 Conclusions

The authors have presented a novel framework for motion-based communication in which it is framed as a

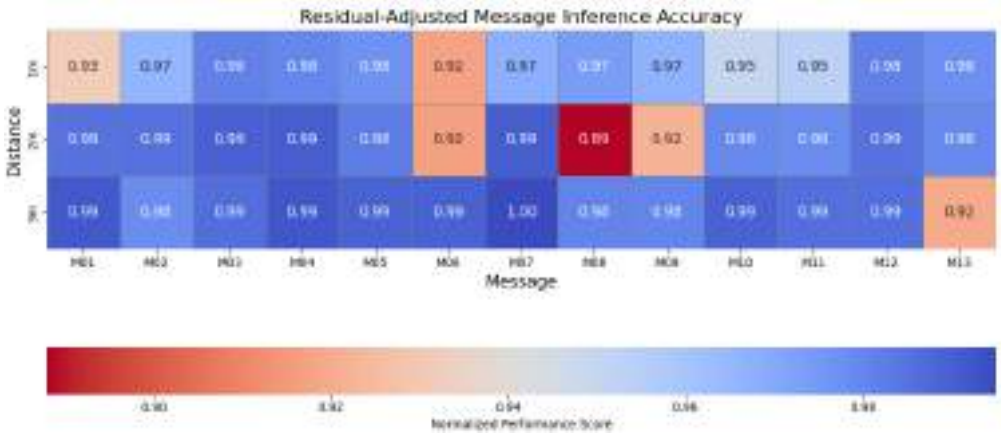

Figure 4. Accuracy across each message from 1-3 meters, accounting for average shift magnitude residuals. Lower values indicate higher mean residual error; orange/red indicates an incorrect shift detection.

language rather than discretely mapping poses to set messages. This is done by developing an ontological structure and encoding its nodes as units of motion along a circle. Experimental testing on a UR5e arm in a real-world lab environment demonstrates the feasibility of implementing this approach with robotic agents. An overall shift inference accuracy of 98.8% between 1 to 3 meters is attained with a 640x480 resolution Logitech C270. Due to the model-free approach, inference is done in real-time without the need for model computation overhead. Additionally, the modularity gained from framing the MBC paradigm as a natural language should allow for enhanced communication flexibility.

Evaluation of the proposed network-free framework in dynamic and complex construction sites where there may be elevated levels of network interference is planned as future work. Since the symbols are encoded and interpreted solely through motion, an additional area of future work is evaluation on other robotic and human agents to verify generality. Due to the extendability of the language and potential for decoding generality, we believe this MBC framework helps lay the groundwork for flexible and robust multi-agent communication going forward.

Abstract

In the field of modular construction, mobile cranes are an essential tool for lifting large and heavy modules vertically. These modules often need to be lifted without rotation, meaning they must be kept in a flat position during the lifting process to avoid potential structural damage. One of the most important aspects of the lifting process is the rigging design, which consists of components like slings, shackles, and spreader bars. These elements play a vital role in distributing the load during the lifting operation. While considerable progress has been made to automate the rigging design process, the existing methods are often limited in their ability to handle larger lifting configurations involving more than six lifting points. This study addresses these limitations by presenting an in-depth structural analysis verification of the current rigging design method that can be applied to modules with more than six lifting points. The paper provides a detailed step-by-step calculation procedure for all the required components necessary for the design and selection of rigging components. The results presented in this paper represent an important step forward in the development of more advanced methodologies for lifting larger modules with complex rigging requirements, ensuring safety and efficiency.

Keywords –

Rigging assembly; Mobile crane; Pick-points

1 Introduction

In most present heavy lift projects, modularization is adopted as a fast and efficient process where modules are required to be transported to the job sites, lifted from their delivered locations, and set in their final positions. Mobile cranes, set up on the job site, are considered the centerpiece equipment during the on-site module installation phase. Disruptions occurring during this phase can easily take away the benefits of adopting modular construction.

Generally, the modules can weigh up to 160 tons and can come in various sizes of up to 24 ft (7.3 m) in width, 138 ft (42 m) in length, and 27.5 ft (8.4 m) in depth [1]. Modules are categorized into three main types: cable trays, pipe racks, and building modules. These modules may have up to five levels and up to 16 lifting points. The lifted modules should remain in a level position to avoid deflection in the module and/or uneven distribution of the carried load. Rigging failure can result in safety risks, cost overruns, and schedule delays. Cho et al. [2]; MinayHashemi et al. [3] reported that 28.1 % of fatal accidents associated with cranes in the United States were due to the failure of slings, wire ropes, and hoist lines between 2002 and 2012. As rigging assemblies connect the crane's hook to the modules, their slinging arrangement plays a key role in ensuring proper load distribution from the lifting lugs up to the crane's hook. For this reason, a sustainable design method for rigging assemblies with different configurations and sizes is crucial for a safe and efficient module lifting process.

Previously, the common slinging arrangement consisted of a 4-point pick configuration, where four diagonal slings were directly attached between the crane's hook and the pick points. In rare cases when the center of gravity (COG) coincides with the center of mass (COM), an identical length of the four slings transferring the loads from the pick points of the module to the crane's hook was used. In practice, however, sling length adjustments are often required to ensure balanced loads and keep the module horizontal during lifting [3]. Available standards, such as the American Petroleum Institute's API RP2A guidelines [4] and the Det Norske Veritas (DnV) design criteria

[5], can be used for the analysis and design of such rigging assembly configurations. While the former computed the sling loads in a suspended equilibrium condition with a single lump sum safety factor of 4 accounting implicitly for dynamic effects; the latter recommended a load sharing between diagonal slings in a 4-point configuration of 2/3 to 1/3 ratios with a 1.5 Dynamic Amplification Factor (DAF) [6]. Later, Sam [7] developed a spreadsheet solution to find precise load distributions between the four slings, accounting for COG position and variations in sling lengths. [8] performed a non-linear analysis in case when sling lengths tolerances were exceeded due to misfit for computing sling load distributions. Despite the development of these tools, many rigging engineers continue to rely on the trial-and-error method based on their experience and guesswork. While a few commercial design software solutions have been developed to automate the design process, they are not widely adopted due to economic, practical, and technical limitations [3].

A traditional rigging assembly is shown in Figure 1. In these arrangements, triangular slings transfer the load from the lifting points (pick points) to the crane's hook through a series of spreader bars, slings, and shackles found at different levels. The number of lifting points on the module dictates the number of levels in a traditional rigging assembly. In an advanced lift scenario (with 16 points), the total number of inventory components including spreader bars, slings, and shackles can exceed 270. The total rigging configuration height can range between 75 to 165 feet, requiring five assembly levels [3], [9], [10].

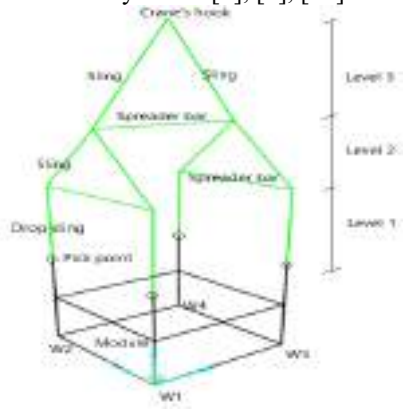

Figure 1. 3D view of a 4-point traditional rigging

Despite the research development presented in MinayHashemi et al. [3] and Hashemi et al. [9], which limited the design process to 6-pick point rigging assemblies, further verification is still required for the current methods used in designing larger rigging configurations with more than six lifting points. This study aims to address that gap and present a more comprehensive verification for the design of rigging systems used in lifting larger modules with up to 16 lifting points.

2 Methodology

2.1 Limitations of the Existing Method (Static Equilibrium)

In 2020, MinayHashemi et al. [3] proposed an automated design framework for analyzing and selecting rigging components in systems with up to four lifting points. This method, while efficient and beneficial for smaller modules, faces significant limitations when applied to larger configurations. The core of this methodology relies on the concept of static equilibrium, which assumes that all forces in the system balance out. This concept works well for smaller systems with simple geometries, but as the number of lifting points increases, the complexity of balancing these forces grows significantly.

2.1.1 First and second levels of 4-pick point configuration

For a system with a 4-point configuration (shown in Figures 1 and 2), the calculations are relatively straightforward. The weight of the module is distributed equally across all lifting points, and the design of the rigging components is based on this assumption. However, when the COG of the module is offset or when the configuration involves more than four lifting points, the situation becomes more complicated. For instance, if a module's COG is not centered, the slings may need to be adjusted in length to balance the forces applied at each lifting point, which may lead to uneven load distribution or the risk of tipping during the lift. For this scenario, the study [3] derived 4 equations (1), (2), (3), and (4) to analyze left sling forces at the first and second levels (FL_1, and FL_2) and the right sling forces at the first and second levels (FR_1 and FR_2) as shown in Figure 2.

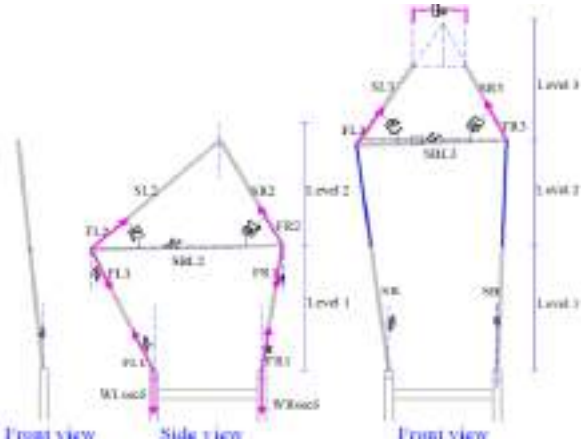

Figure 2. Front and side views of a 4-pick point rigging arrangement with sling internal forces

$$FL_1 = (WL + WR)\sec\delta\csc(\alpha+\beta)\,sin\alpha \quad (1)$$
$$FR_1 = (WL + WR)\sec\delta\csc(\alpha+\beta)\,sin\beta \quad (2)$$
$$FL_2 = (WL + WR)\sec\delta\cos(\theta R-\gamma)\csc(\theta L+\theta R) \quad (3)$$
$$FR_2 = (WL + WR)\sec\delta\cos(\theta L+\gamma)\csc(\theta L+\theta R) \quad (4)$$

For all the equations in this study, the letters *L* and *R* represent respectively left and right sides of the assembly. *WL* and *WR* are respectively the left and right weight load forces applied at the 2 pick points in the plane containing the drop slings and the spreader bars in the global Y-direction. α and β are the respective right and left drop sling angles with the vertical. θR and θL are respectively the right and left sling angles at the second level. δ is the angle between the plane containing the spreader bar and the 2 above slings in the Y-direction at either the left or the right side of the assembly with the vertical plane. γ is the slope of the spreader bar at the second level in either side plane.

2.1.2 Third level of 4-pick point configuration

Following the sling force computations at the first and second levels, the analysis of the third-level components was conducted in a 2D plane (XZ) containing the spreader bar and the two diagonal slings acting above it using the same method [3] . However, these computations were not shown in that same paper. Here, a detailed analysis of the two sling forces using the free-body diagram of the spreader bar at the third level was performed. Figure 3 presents the free-body diagram of the spreader bar at level 3. Equilibrium equations in both directions were applied to find the required capacity of the two slings and the mounted shackles at the third level. The results are presented in Equations (5) and (6).

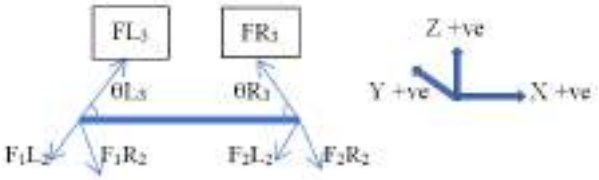

Figure 3. Free body diagram of spreader bar at level 3 with applied forces

$$FL_3\cos(\theta L_3+\gamma_3) - FR_3\cos(\theta R_3-\gamma_3) + \sin\delta_{12}[F_1R_2\sin(\theta_1R_2-\gamma_{12}) + F_1L_2\sin(\theta_1L_2+\gamma_{12})] - \sin\delta_{22}[F_2R_2\sin(\theta_2R_2-\gamma_{22}) + F_2L_2\sin(\theta_2L_2+\gamma_{22})] = 0 \quad (5)$$

$$FL_3\sin(\theta L_3+\gamma_3) + FR_3\sin(\theta R_3-\gamma_3) - \cos\delta_{12}[F_1R_2\sin(\theta_1R_2-\gamma_{12}) + F_1L_2\sin(\theta_1L_2+\gamma_{12})] - \cos\delta_{22}[F_2R_2\sin(\theta_2R_2-\gamma_{22}) + F_2L_2\sin(\theta_2L_2+\gamma_{22})] = 0 \quad (6)$$

Where θL_3 and θR_3 are the sling angles with the spreader bar SBL_3 at level 3; θ_1R_2 and θ_1L_2 are respectively the right and left sling angles at the second level in the left side plane; θ_2R_2 and θ_2L_2 are respectively the right and left sling angles at the second level in the right-side plane. The left and right-side planes are supported respectively by the left/right ends of the spreader bar at the 3rd level; δ_{12} and δ_{22} are the angles of the 2 side planes with the vertical plane. γ_{12}/ γ_{22} and γ_3 are the slopes of the spreader bars at the second and third levels respectively. FL_3 and FR_3 are the left and right sling forces at the third level; F_1R_2/F_1L_2 and F_2R_2/F_2L_2 are respectively the right/left sling forces at the second level in respectively the left and right-side planes.

In Equation (5), the two terms $\sin\delta_{12}[F_1R_2\sin(\theta_1R_2-\gamma_{12}) + F_1L_2\sin(\theta_1L_2+\gamma_{12})]$ and $\sin\delta_{22}[F_2R_2\sin(\theta_2R_2-\gamma_{22}) + F_2L_2\sin(\theta_2L_2+\gamma_{22})]$ represent the horizontal projections of the diagonal sling forces at the second level acting on the horizontal axis at the third level. These components are very small because the angles δ_{12} and δ_{22} are nearly zero, making their sines almost negligible. Additionally, these forces act in opposite directions on the spreader bar at level 3. Since keeping them in Equation (5) would complicate the calculation of FL_3 and FR_3 without significantly changing their final values, they were removed from the equation. So, Equation (5) will be expressed as (5').

$$FL_3 = FR_3\cos(\theta R_3-\gamma_3)/\cos(\theta L_3+\gamma_3) \quad (5')$$

By substituting FL_3 in Equation (6) to solve for FR_3 then solving for FL_3 in Equation (5'), Equations (7) and (8) will be obtained.

$$FR_3 = \frac{\{cos\delta_{12}*[F_1R_2*sin(\theta_1R_2-\gamma_{12})+F_1L_2*sin(\theta_1L_2+\gamma_{12}]+cos\delta_{22}*[F_2R_2*sin(\theta_2R_2-\gamma_{22})+F_2L_2*sin(\theta_2L_2+\gamma_{22})]\}*cos(\theta L3+\gamma_3)}{cos(\theta R_3-\gamma_3)+cos(\theta L_3+\gamma_3)*sin(\theta R_3-\gamma_3)} \quad (7)$$

$$FL_3 = \frac{\{cos\delta_{12}*[F_1R_2*sin(\theta_1R_2-\gamma_{12})+F_1L_2*sin(\theta_1L_2+\gamma_{12})]+cos\delta_{22}*[F_2R_2*sin(\theta_2R_2-\gamma_{22})+F_2L_2*sin(\theta_2L_2+\gamma_{22})]\}}{1+cos(\theta L_3+\gamma_3)*tan(\theta R_3-\gamma_3)} \quad (8)$$

In more complex systems with more than six lifting points, the traditional static equilibrium model becomes insufficient. The complexity of these systems, which involve multiple sling lengths, shackles, and spreader bars, requires more advanced methods to ensure that all forces are balanced and that the module remains stable throughout the lift. While static equilibrium analysis can still be applied to smaller systems, it becomes less reliable as the number of lifting points increases, particularly when the rigging system is subjected to dynamic forces ignored within the current study.

2.2 Designing Rigging Assemblies for Larger Configurations

For larger modular lifting configurations, such as those involving 8 or 16 lifting points, the traditional approach can still be extended by breaking down the larger system into smaller, more manageable sub-systems. However, with those employing a total of 12 or 14 lifting points composed of respectively a pair of 6-pick point segments or a pair of 6-pick point segments and a 2-pick point segment, the traditional model wouldn't be computationally accessible. In other words, it would fail to analyze the sling forces in the 12 or 14-pick point segments. Lastly, for the 10-pick point configuration composed of an 8-pick point and a 2-pick point segments, the method could still analyze the sling forces in the former segment. However, based on the design methodology adopted in MinayHashemi et al. [3], this step would be insufficient for selecting the 2-pick point segment components.

2.2.1 8-pick point configuration

An 8-point configuration can be divided into two 4-point rigging assemblies connected by a spreader bar at a higher lifting level. Each 4-point system is analyzed separately, and the total load is transferred to the spreader bar at level 4 (Figure 4).

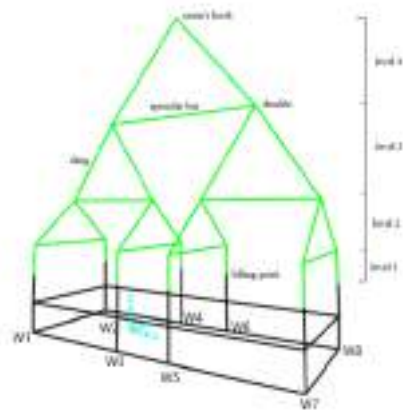

Figure 4. 3D schematic of an 8-pick point rigging assembly

The left segment (W_1 to W_4) and the right segment (W_5 to W_8) each transfer their respective forces to the spreader bar, which then distributes the total load up to the crane's hook. Using the same methodology and equations from the previous section, Equations (9), (10), (11), and (12) can be derived to calculate the forces in respectively the left- and right-side assembly. Equilibrium equations applied to the free-body diagram of the spreader bar at level 4 shown in Figure 5 will yield the sling forces F_{R4} and F_{L4} expressed in Equations (13) and (14) respectively.

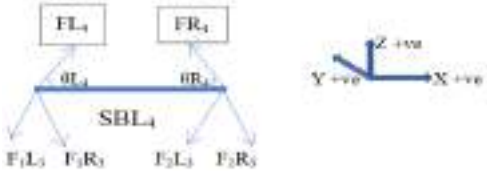

Figure 5. Free body diagram of spreader bar at level 4

$$F_1R_3 = \frac{\{cos\delta_{12}*[F_1R_2*sin(\theta_1R_2-\gamma_{12})+F_1L_2*sin(\theta_1L_2+\gamma_{12})]+cos\delta_{22}*[F_2R_2*sin(\theta_2R_2-\gamma_{22})+F_2L_2*sin(\theta_2L_2+\gamma_{22})]\}*cos(\theta_1L_3+\gamma_{13})}{cos(\theta_1R_3-\gamma_{13})+cos(\theta_1L_3+\gamma_{13})*sin(\theta_1R_3-\gamma_{13})} \quad (9)$$

$$F_1L_3 = \frac{\{cos\delta_{12}*[F_1R_2*sin(\theta_1R_2-\gamma_{12})+F_1L_2*sin(\theta_1L_2+\gamma_{12})]+cos\delta_{22}*[F_2R_2*sin(\theta_2R_2-\gamma_{22})+F_2L_2*sin(\theta_2L_2+\gamma_{22})]\}}{1+cos(\theta_1L_3+\gamma_{13})*tan(\theta_1R_3-\gamma_{13})} \quad (10)$$

$$F_2R_3 = \frac{\{cos\delta_{32}*[F_3R_2*sin(\theta_3R_2-\gamma_{32})+F_3L_2*sin(\theta_3L_2+\gamma_{32})]+cos\delta_{42}*[F_4R_2*sin(\theta_4R_2-\gamma_{42})+F_4L_2*sin(\theta_4L_2+\gamma_{42})]\}*cos(\theta_2L_3+\gamma_{23})}{cos(\theta_2R_3-\gamma_{23})+cos(\theta_2L_3+\gamma_{23})*sin(\theta_2R_3-\gamma_{23})} \quad (11)$$

$$F_2L_3 = \frac{\{cos\delta_{32}*[F_3R_2*sin(\theta_3R_2-\gamma_{32})+F_3L_2*sin(\theta_3L_2+\gamma_{32})]+cos\delta_{42}*[F_4R_2*sin(\theta_4R_2-\gamma_{42})+F_4L_2*sin(\theta_4L_2+\gamma_{42})]\}}{1+cos(\theta_2L_3+\gamma_{23})*tan(\theta_2R_3-\gamma_{23})} \quad (12)$$

$$FR_4 = \{(cos\delta_{12}\ [F_1R_2sin\ (\theta_1R_2 - \gamma_{12}) + F_1L_2sin(\theta_1L_2 + \gamma_{12})] + cos\delta_{22}\left[F_2R_2sin(\theta_2R_2 - \gamma_{22}) + F_2L_2sin(\theta_2L_2 + \gamma_{22})\right]\left(\frac{sin(\theta_1R_3+\theta_1L_3)}{[1+cos(\theta_1L_3+\gamma_{13})sin(\theta_1R_3-\gamma_{13})]}\right) + (cos\delta_{32}\ [F_3R_2sin\ (\theta_3R_2 - \gamma_{32}) + F_3L_2sin(\theta_3L_2 + \gamma_{32})\right] + cos\delta_{42}[F_4R_2sin(\theta_4R_2 - \gamma_{42}) + F_4L_2sin(\theta_4L_2 + \gamma_{42})])\left(\frac{sin(\theta_2R_3+\theta_2L_3)}{[1+cos(\theta_2L_3+\gamma_{23})tan(\theta_2R_3-\gamma_{23})]\,cos(\theta_2R_3-\gamma_{23})}\right)\}\frac{cos(\theta L_4+\gamma_4)}{sin(\theta L_4+\theta R_4)} \quad (13)$$

$$FL_4 = \{(cos\delta_{12}\ [F_1R_2sin\ (\theta_1R_2 - \gamma_{12}) + F_1L_2sin(\theta_1L_2 + \gamma_{12})] + cos\delta_{22}\left[F_2R_2sin(\theta_2R_2 - \gamma_{22}) + F_2L_2sin(\theta_2L_2 + \gamma_{22})\right]\left(\frac{sin(\theta_1R_3+\theta_1L_3)}{[1+cos(\theta_1L_3+\gamma_{13})sin(\theta_1R_3-\gamma_{13})]}\right) + (cos\delta_{32}\ [F_3R_2sin\ (\theta_3R_2 - \gamma_{32}) + F_3L_2sin(\theta_3L_2 + \gamma_{32})\right] + cos\delta_{42}[F_4R_2sin(\theta_4R_2 - \gamma_{42}) + F_4L_2sin(\theta_4L_2 + \gamma_{42})])\left(\frac{sin(\theta_2R_3+\theta_2L_3)}{[1+cos(\theta_2L_3+\gamma_{23})tan(\theta_2R_3-\gamma_{23})]\,cos(\theta_2R_3-\gamma_{23})}\right)\}\frac{cos(\theta R_4-\gamma_4)}{sin(\theta L_4-\theta R_4+2\gamma_4)} \quad (14)$$

2.2.2 10-pick point configuration

A 10-point system can be analyzed by combining an 8-point assembly with a 2-point segment (Figure 6).

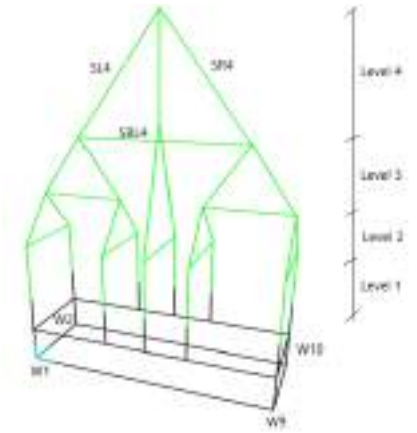

Figure 6. 3D schematic of a 10-pick point rigging assembly

The 2-point system, located in the center of the rigging setup, handles a smaller portion of the load. The analysis of the 8-point system is carried out as described in the previous section, but the 2-point system, which has a different structural design, requires additional consideration. Unlike the 8-point system, the 2-point segment is less complex, consisting of fewer lifting points and levels. The challenge lies in ensuring that the 2-point system, which has fewer lifting points, does not lead to uneven distribution of forces when combined with the larger 8-point system. Based on that, its structural design was conducted following that of the 8-point segment on a level-to-level basis.

Previous work by MinayHashemi et al. [3] did not include an in-depth structural analysis of the 2-point segment and assumed identical sling lengths across both the 2-point and 4-point segments in a 6-pick point configuration. However, this assumption becomes problematic when the 2-point segment differs in terms of the number of levels compared to the 8-point segment. For accurate rigging design, it is essential to carefully analyze the 2-point configuration and adjust for the different levels in the system.

2.2.3 12-pick point configuration

A 12-point system consists of two 6-point assemblies; each designed using the principles applied in the 4-point configuration. The total weight of the module is transferred to a spreader bar located at the fourth level, which ensures an even distribution of forces across all the lifting points (Figure 7).

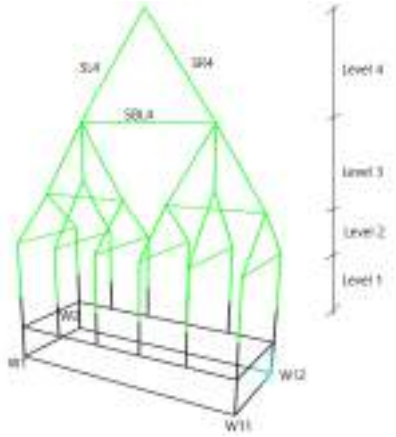

Figure 7. 3D schematic of a 12-pick point rigging assembly

Each 6-point assembly is analyzed independently, with the forces from the left and right segments being transferred to the spreader bar. In this case, when analyzing the forces acting on the spreader bar at level 4 in the XZ plane, four unknown force components need to be determined for each end of the spreader bar as shown in Figure 8. FL_4 and FR_4 are respectively the left and right sling forces at the fourth level of the rigging assembly; θL_4 and θR_4 are respectively the left and right sling angles with the spreader bar SBL_4 at the

fourth level; F_1M_3 and F_2M_3 are respectively the left- and right-middle sling forces at the third level supported by the left and right spreader bar ends at level 4 of the rigging assembly. By applying equilibrium, Equations (15) and (16) are obtained.

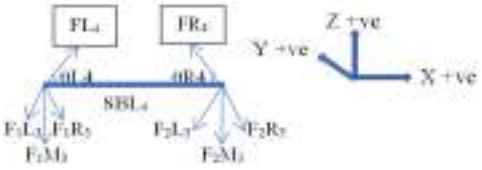

Figure 8. Free body diagram of spreader bar at level 4 for a 12-pick point configuration

$$FL_{4X} - FR_{4X} - F_1L_{3x} + F_1R_{3x} - F_2L_{3x} + F_2R_{3x} = 0 \quad (15)$$

$$FL_{4Z} + FR_{4Z} - F_1L_{3z} - F_1R_{3z} - F_2L_{3z} - F_2R_{3z} - F_1M_3 - F_2M_3 = 0 \quad (16)$$

F_1L_3 and F_1R_3 are the sling forces on the left side, and F_2L_3 and F_2R_3 are the sling forces on the right side of the spreader bar SBL_4 were already computed in the 8-pick point rigging assembly analysis section in this paper. F_1M_3 and F_2M_3 are the 2 additional forces applying vertically downwards due to the presence of the 2-pick point segments. This will lead to a system of 2 variables (FL_{4x} and FR_{4x}) in the X direction and 4 variables (FL_{4z}, FR_{4z}, F_1M_3, and F_2M_3) in the Z direction. Having only 2 equations to solve such a system will jeopardize reaching a solution.

While static equilibrium can be used to analyze the 6-point assemblies, the complexity increases at the fourth level, where the spreader bar introduces additional unknowns. These unknowns can't be easily solved using static equilibrium methods alone, and therefore, finite element analysis (FEA) could be employed to accurately model the forces in the system. The additional level of complexity requires a more robust approach to ensure stability and accurate force distribution calculations.

2.2.4 14 pick-point segments

A 14-point system includes both a 12-point assembly and a 2-point assembly (Figure 9). The design for the 12-point segment follows the same principles outlined above, but the 2-point segment introduces a new challenge. The 2-point system, located in the middle of the rigging assembly, consists of fewer lifting points and levels, which complicates the design process. MinayHashemi et al. [3] assumed that the rigging configuration of the 2-point segment matched the number of levels in the 4-point system, but this assumption is no longer valid in this case.

To design the 2-pick point system, a more advanced method involving its analysis should be applied. A new method for selecting rigging components is necessary. This method should account for the differing number of levels in the system compared to the 12-point segment and ensure that the forces are balanced and stable. The 2-point system must be analyzed independently of the 12-point segment and integrated into the overall rigging design.

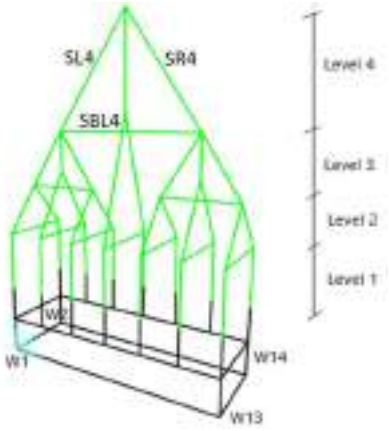

Figure 9. 3D schematic of a 14-pick point rigging assembly

2.2.5 16 pick-point segments

A 16-point configuration is one of the most complex systems used for large modular lifts. It consists of two 8-point assemblies, with a spreader bar and two diagonal slings at the fifth level (Figure 10).

Similar to the 8-point configuration, each 8-point segment is analyzed independently using the methods from Section 2.2.1. However, with the addition of a fifth level of rigging components, the spreader bar introduces new forces that must be carefully analyzed. In this case, the forces at level 5 must be determined through a free-body diagram of the spreader bar in the XZ plane, which will have unknowns in both the vertical and horizontal directions (Figure 11). Considering the equations already derived from section **2.2.1** for F_1R_4 (Equation 17) and F_1L_4 (Equation 18) in the left 8-pick point segment; and similarly those for F_2R_4 (Equation 19) and F_2L_4 (Equation 20) in the right 8-pick point segment; and by applying equilibrium, Equations (21) and (22) were obtained. And by solving the system of these 2 equations, FL_5 and FR_5 were

determined in Equations (23) and (24) respectively with the integration of Equations (25) and (26) for simplicity.

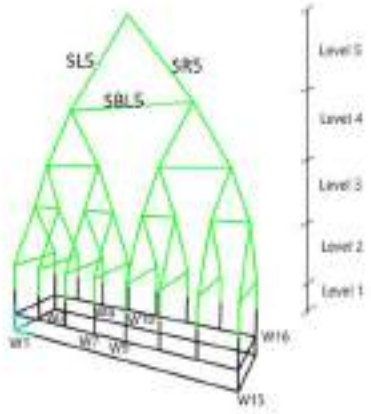

Figure 10. 3D schematic of a 16-pick point rigging assembly

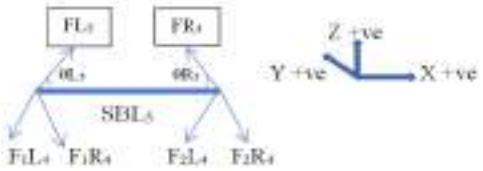

Figure 11. Free body diagram of spreader bar at level 5 with applied forces

The analysis for the 16-point system remains similar to the 8-point and 12-point configurations, but the additional level introduces complexity. To ensure the accuracy of the design, finite element analysis (FEA) should be used to model the forces acting on the system at this level. This advanced analysis will ensure that all components are properly designed and the forces are balanced throughout the system.

$$F_1R_4=\{(\cos\delta_{12}[F_1R_2\sin(\theta_1R_2-\gamma_{12})+F_1L_2\sin(\theta_1L_2+\gamma_{12})]+\cos\delta_{22}[F_2R_2\sin(\theta_2R_2-\gamma_{22})+F_2L_2\sin(\theta_2L_2+\gamma_{22})])((\sin(\theta_1R_3+\theta_1L_3))/([1+\cos(\theta_1L_3+\gamma_{13})\sin(\theta_1R_3-\gamma_{13})]))+(\cos\delta_{32}[F_3R_2\sin(\theta_3R_2-\gamma_{32})+F_3L_2\sin(\theta_3L_2+\gamma_{32})]+\cos\delta_{42}[F_4R_2\sin(\theta_4R_2-\gamma_{42})+F_4L_2\sin(\theta_4L_2+\gamma_{42})])((\sin(\theta_2R_3+\theta_2L_3))/(\cos(\theta_2R_3-\gamma_{23})[1+\cos(\theta_2L_3+\gamma_{23})\tan(\theta_2R_3-\gamma_{23})]))\}\cos(\theta_1L_4+\gamma_{14})/\sin(\theta_1L_4+\theta_1R_4) \quad (17)$$

$$F_1L_4=\{(\cos\delta_{12}[F_1R_2\sin(\theta_1R_2-\gamma_{12})+F_1L_2\sin(\theta_1L_2+\gamma_{12})]+\cos\delta_{22}[F_2R_2\sin(\theta_2R_2-\gamma_{22})+F_2L_2\sin(\theta_2L_2+\gamma_{22})])((\sin(\theta_1R_3+\theta_1L_3))/([1+\cos(\theta_1L_3+\gamma_{13})\sin(\theta_1R_3-\gamma_{13})]))+(\cos\delta_{32}[F_3R_2\sin(\theta_3R_2-\gamma_{32})+F_3L_2\sin(\theta_3L_2+\gamma_{32})]+\cos\delta_{42}[F_4R_2\sin(\theta_4R_2-\gamma_{42})+F_4L_2\sin(\theta_4L_2+\gamma_{42})])((\sin(\theta_2R_3+\theta_2L_3))/(\cos(\theta_2R_3-\gamma_{23})[1+\cos(\theta_2L_3+\gamma_{23})\tan(\theta_2R_3-\gamma_{23})]))\}\cos(\theta_1R_4-\gamma_{14})/\sin(\theta_1L_4-\theta_1R_4+2\gamma_{14}) \quad (18)$$

$$F_2R_4=\{(\cos\delta_{12}[F_1R_2\sin(\theta_1R_2-\gamma_{12})+F_1L_2\sin(\theta_1L_2+\gamma_{12})]+\cos\delta_{22}[F_2R_2\sin(\theta_2R_2-\gamma_{22})+F_2L_2\sin(\theta_2L_2+\gamma_{22})])((\sin(\theta_1R_3+\theta_1L_3))/([1+\cos(\theta_1L_3+\gamma_{13})\sin(\theta_1R_3-\gamma_{13})]))+(\cos\delta_{32}[F_3R_2\sin(\theta_3R_2-\gamma_{32})+F_3L_2\sin(\theta_3L_2+\gamma_{32})]+\cos\delta_{42}[F_4R_2\sin(\theta_4R_2-\gamma_{42})+F_4L_2\sin(\theta_4L_2+\gamma_{42})])((\sin(\theta_2R_3+\theta_2L_3))/(\cos(\theta_2R_3-\gamma_{23})[1+\cos(\theta_2L_3+\gamma_{23})\tan(\theta_2R_3-\gamma_{23})]))\}\cos(\theta_2L_4+\gamma_{24})/\sin(\theta_2L_4+\theta_2R_4) \quad (19)$$

$$F_2L_4=\{(\cos\delta_{12}[F_1R_2\sin(\theta_1R_2-\gamma_{12})+F_1L_2\sin(\theta_1L_2+\gamma_{12})]+\cos\delta_{22}[F_2R_2\sin(\theta_2R_2-\gamma_{22})+F_2L_2\sin(\theta_2L_2+\gamma_{22})])((\sin(\theta_1R_3+\theta_1L_3))/([1+\cos(\theta_1L_3+\gamma_{13})\sin(\theta_1R_3-\gamma_{13})]))+(\cos\delta_{32}[F_3R_2\sin(\theta_3R_2-\gamma_{32})+F_3L_2\sin(\theta_3L_2+\gamma_{32})]+\cos\delta_{42}[F_4R_2\sin(\theta_4R_2-\gamma_{42})+F_4L_2\sin(\theta_4L_2+\gamma_{42})])((\sin(\theta_2R_3+\theta_2L_3))/(\cos(\theta_2R_3-\gamma_{23})[1+\cos(\theta_2L_3+\gamma_{23})\tan(\theta_2R_3-\gamma_{23})]))\}\cos(\theta_2R_4-\gamma_{24})/\sin(\theta_2L_4-\theta_2R_4+2\gamma_{24}) \quad (20)$$

$$FL_5\cos(\theta L_5+\gamma_5)-FR_5\cos(\theta R_5-\gamma_5)+F_1R_4\cos(\theta_1R_4-\gamma_{14})-F_1L_4\cos(\theta_1L_4+\gamma_{14})+F_2R_4\cos(\theta_2R_4-\gamma_{24})-F_2L_4\cos(\theta_2L_4+\gamma_{24})=0 \quad (21)$$

$$FL_5\sin(\theta L_5+\gamma_5)+FR_5\sin(\theta R_5-\gamma_5)-(F_1L_4\sin(\theta_1L_4-\gamma_{14})-F_1R_4\sin(\theta_1R_4-\gamma_{14})-F_2R_4\sin(\theta_2R_4-\gamma_{24})-F_2L_4\sin(\theta_2L_4+\gamma_{24})=0 \quad (22)$$

$$FL_5=\frac{c_2\cos(\theta R_5-\gamma_5)+c_1\sin(\theta R_5-\gamma_5)}{\sin(\theta L_5+\theta R_5)} \quad (23)$$

$$FR_5=\frac{c_2\cos(\theta R_5-\gamma 5)\cos(\theta L_5+\gamma_5)+c_1\sin(\theta R_5-\gamma_5)\cos(\theta L_5+\gamma_5)-C1\sin(\theta L_5+\theta R_5)}{\cos(\theta R_5-\gamma_5)\sin(\theta L_5+\theta R_5)} \quad (24)$$

FL_5 and FR_5 are respectively the left and right sling forces at the fifth level of the rigging assembly; θL_5 and θR_5 are respectively the left and right sling angles with the spreader bar SBL_5 at the fifth level; γ_5 is the slope of the spreader bar at the fifth level. c_1 and c_2 are combinations of constants given in Equations (25) and (26).

$$c_1 = -(F_1R_4 \cos(\theta_1R_4 - \gamma_{14}) - F_1L_4 \cos(\theta_1L_4 + \gamma_{14}) + F_2R_4 \cos(\theta_2R_4 - \gamma_{24}) - F_2L_4 \cos(\theta_2L_4 + \gamma_{24}) \quad (25)$$

$$c_2 = F_1L_4 \sin(\theta_1L_4 + \gamma_{14}) + (F_1R_4 \sin(\theta_1R_4 - \gamma_{14}) + F_2L_4 \sin(\theta_2L_4 + \gamma_{24}) + F_2R_4 \sin(\theta_2R_4 - \gamma_{24}) \quad (26)$$

3 Conclusion

This study has explored the limitations of the static equilibrium method in designing rigging systems for modular lifting configurations with more than 6 lifting points ignored in previous studies. While static equilibrium is effective for smaller configurations, it becomes less reliable for systems with more than six lifting points, where additional techniques, such as finite element analysis (FEA), could be required. The findings provide a framework for designing rigging assemblies for larger modular systems, offering insights into how to precisely and efficiently balance forces and ensure stability during lifting operations.

Despite not being the ideal method for analyzing large rigging configurations, the verification process confirmed, through a detailed mathematical computation process, that static equilibrium methods are still valid for configurations like 8-point and 16-point systems despite the need for successive analyses. However, this process is: *(i)* tedious because it takes time to perform analysis calculations for each level and proceed to the next higher one(s); *(ii)* error-prone since any error in the earlier steps of calculation would be carried forward to higher levels which would lead to design and selection inaccuracies; and *(iii)* limited to sling force computations only excluding those for spreader bars and other rigging components. On the other hand, for other configurations, particularly the 10-point and 14-point systems, the method becomes less effective due to the complexity of the force distribution and the non-matching number of levels. Moreover, the method becomes invalid with the 12-pick point system due to having more unknowns than equations.

This study presents a hands-on insight to introduce a new comprehensive rigging design methodology that: (i) computes the sling angles and sling length justifications to establish equilibrium of rigging arrangements with 6 or more lifting points. (ii) simplifies the structural analysis by applying simultaneous solutions (with the help of structural analysis software preferably applying the FEA method), instead of systematic or successive analyses based on level-to-level free-body diagrams which are time-wasting, error-prone, and invalid for all n-pick point configurations. (iii) has the potential to account for not only static loads as in the existing studies, but also address dynamic effects (i.e., forces and stresses) associated with the lifted modules such as wind loading and dynamic vibrations, in addition to the module's deformations.

Abstract –

Accurate spatial localization is critical in the construction industry, indoor robotics, and other applications involving actor movement within buildings. This paper introduces a combined software and hardware framework designed to evaluate indoor localization systems leveraging optical tracking integrated with a ROS communication system. It supports recording location data, aligning trajectories and evaluating the recorded samples against the ground truth allowing for real world comparison within a custom setup. While it is designed to evaluate any localization system, a presented case study compares two established SLAM algorithms regarding their suitability for an AEC application.

Keywords –

localization evaluation, indoor localization, mobile robotic, SLAM, ROS

1 Introduction

The rapid advancements in indoor localization technologies have led to their increasing integration across diverse industries, including construction, robotics, and indoor navigation [1]. Accurate spatial localization is pivotal for Architecture, Engineering and Construction (AEC) applications ranging from autonomous robots[2] operating in confined spaces to real-time monitoring of dynamic processes (Figure 1). However, the multitude of available localization methods — each with unique strengths, limitations, and precision levels — poses a challenge for selecting the most suitable system for specific applications [3].

The proposed framework does not aim to create a new benchmark for evaluating SLAM algorithms. Instead, it builds on existing benchmarks, metrics, and computer vision algorithms to help industries adopt and improve localization systems, advancing robotic development in AEC. The system supports a context-aware comparison of suitable localization methods in a realistic environment, rather than validating their performance under laboratory conditions. This novel evaluation framework combines optical tracking with a modular ROS-based software system. Designed to measure and compare the precision of localization systems, the framework provides a robust method for evaluating different approaches, allowing for informed decisions in research and development. While the framework is adaptable to various technologies, this work demonstrates the workflow in a case study focusing on two widely used localization algorithms.

2 Background and Related Work

Precise indoor localization of actors in AEC — like robots, machines, and sensing devices — is crucial for their operation. Indoor localization has the problem of being in the “shadow” of the building and thus cannot utilize satellite localization.

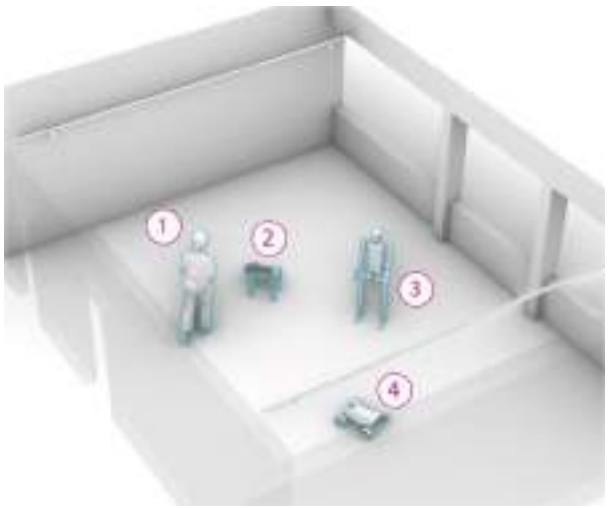

Figure 1. indoor mobile robots or devices that use localization: 1) handheld device; 2) quadruped robot; 3) humanoid robot; 4) four-wheeled robot.

For precise localization inside buildings there are many technologies like Inertial Measurement Units (IMU), Visual Odometry, Simultaneous Localization and Mapping (SLAM) with cameras or Lidar. These different methods are often unified in sensor fusion systems to increase precision [4].

To compare and evaluate the precision of different localization methods common databases and benchmark suites are used that include high-quality sensor data collected from real-world driving scenarios, including stereo camera images, 3D point clouds from LiDAR, and GPS/IMU data, enabling researchers to test and compare algorithms under consistent conditions. While there is an abundance of outdoor datasets like Aachen Day-Night Dataset [5], CrowdDriven Dataset [6], Extended CMU Seasons Dataset, RobotCar Seasons Dataset, Symphony Seasons Dataset some indoor datasets like InLoc Dataset [7], Gangnam Station and Hyundai Department Store Datasets, ETH-Microsoft Dataset [8] or the TUM RGB-D Dataset [9] can be found as well. With the help of these datasets researchers can develop their best localization algorithm or hardware system.

Once a localization algorithm for an application is chosen, the next steps require testing it in the context of the application in order to validate the promised precision. This is where the presented frameworks evaluation and calibration commences. To our knowledge there are no out of the box solutions allowing to determine and compare the suitability of different localization algorithms for a custom environment.

Technical descriptions of applied evaluation and calibration methods in previously mentioned localization software solutions differ widely. For example, in [9] handheld Kinect RGBD cameras were tracked by 8 motion tracking high-speed cameras to accurately track the pose of the localization device. In [10] IMUs were added to camera sensors and a motion tracking system was installed in the starting position where also the scanning ended (loop closure) providing ground truth for the TUM VI dataset. A similar setup was also used for the creation of the TUM VIE dataset [11] where the sensorial layers were enriched with stereo-event data. Other SLAM evaluation frameworks [12], [13] compare different algorithms in one benchmark environment, while the presented framework can be used to compare one algorithm in different environments. Existing frameworks also concentrate on calculating error metrics for specified trajectories and are not equipped to provide a comprehensive workflow for recording the positional data.

3 System description

3.1 Hardware Setup

A crucial part of the proposed system is to provide precise ground truth positional data for the localization actor which is achieved by an outside-in tracking system based on high-speed IR cameras. This section provides a detailed overview of the hardware components used, their specifications, and their integration.

Figure 2. 1) Hardware setup in the case-studies lab environment (7x10m) consisting of 2) four OptiTrack Prime X 13 cameras (ground truth) and 3) a depth camera for localization (e.g. RealSense D455)

Four OptiTrack Prime X 13 cameras are installed on the ceiling to observe a designated tracking area with the size 7 x 10 m (Figure 2). These cameras, chosen for their high-speed capture rates and submillimetre precision of ±0.20 mm [14], are positioned strategically to provide comprehensive coverage of the monitored space. The cameras are connected to the central computer via an 8-port Ethernet PoE/PoE+ switch, specifically the TRENDnet TPE-TG80G model. This switch enables stable data transmission and supplies power to the cameras through Ethernet cables, simplifying the overall cabling requirements and ensuring uninterrupted operation. A workstation running Windows 11 and

OptiTrack's Motive 3.1.4 motion capture software [15] transforms the raw tracking data into user-defined frames. A calibration workflow is applied to align the coordinate spaces of the localization algorithm and the OptiTrack.

For the calibration, as a critical aspect of the setup, marker spheres with a diameter of 9.5 mm are employed. These markers are specifically designed to attach to the camera used for localization, facilitating accurate calibration by ensuring they are easily detectable by the OptiTrack cameras.

3.2 Software Setup

The software architecture supporting the optical tracking and localization system is designed to operate efficiently within a modular, containerized environment. This approach ensures scalability, ease of deployment, and isolation of various system components.

In order to achieve comparable results and to allow offline runs of computationally intensive localization systems, the framework supports a workflow where the localization sensor data is first recorded as *rosbags* [16] and the evaluation is performed at a later stage.

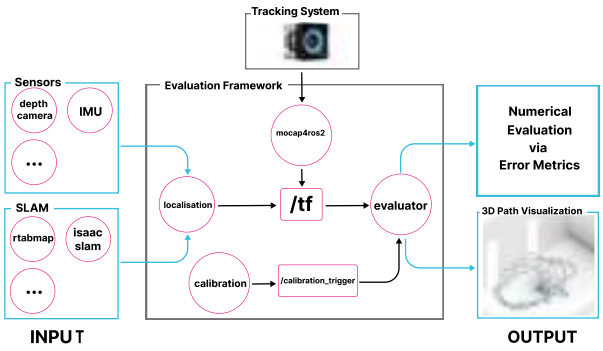

Figure 3. Overview of the proposed framework. Application specific components like sensors and localization algorithms (left) are utilized and extended by the proposed framework's components (centre) which record, align and evaluate positional data. Results are presented in the form of well-established error metrics as well as a visualization of the recorded trajectories (right).

3.2.1 Containerized ROS2 Instances

The foundation of the software system consists of ROS2 instances deployed as individual Docker containers. Each container encapsulates a specific functionality (Figure 3), ensuring a clean separation of responsibilities and enabling seamless communication between components via ROS2 nodes. This architecture leverages Docker's containerization capabilities to isolate dependencies, simplify system updates, and allow independent testing of each component.

3.2.2 OptiTrack Integration in ROS2 Docker

The motion capture system recording the ground truth localization data is wrapped in a ROS2 node hosted within a Docker container, which acts as a receiving counterpart to the Motive Software as NatNet client [17]. This node handles the optical tracking processes, transforming the tracking data captured from the OptiTrack Prime X 13 cameras and publishing the calculated positions of tracked objects.

The component is based on the mocap4ros2 package [18] and extended to send transform data in a format that is compatible with the overall setup. The container communicates with other system components by broadcasting positional data in real time, ensuring high accuracy and low latency.

3.2.3 Localization system in ROS2 Docker

A separate Docker environment encapsulates any given localization system, thereby ensuring its isolation and enabling seamless integration with diverse sources of localization. Within this environment the localization system needs to be configured to publish the measured pose via a ROS2 node. The localization component operates in parallel with the OptiTrack container, enabling the system to combine optical tracking and visual localization seamlessly.

3.2.4 Calibration and Evaluation System in ROS2 Docker

In a third dockerized environment the evaluation system runs as a custom ROS2 node. By subscribing to localization data published by the other system components and reacting to user input, as described in the calibration section, this unit handles the core evaluation logic. It provides a real time visualization of the different poses via the default 3D visualizer for ROS2, captures the data frames and provides logic for evaluating the captured data.

3.2.5 Inter-Component Communication

The ROS2 ecosystem facilitates communication between the Docker containers through ROS2 topics and nodes. Each container publishes data, such as positional information or error metrics, which other containers or scripts can subscribe to for further processing. The modularity provided by ROS2 ensures that each component remains loosely coupled while maintaining synchronization and data consistency across the system. Additionally, ROS2's design for distributed systems enables low-latency configurations across various computing environments, making the integration of a new localization component particularly straightforward due to the minimal setup required.

In order to maximize compatibility with different localization systems, the framework utilizes the tf2

package as a well-established standard for capturing coordinate frames over time [19]. The ground truth as well as the localization system component publish the measured poses as transform. The evaluation component is continuously consuming those transforms and processes them to be used for evaluation.

3.3 Initialization, Calibration and Trajectory Alignment

To evaluate the accuracy of the localization system, the deviation between the poses as measured respectively by the OptiTrack system and by the localisation system must be determined.

Since these originate from different systems their coordinate spaces will differ. The evaluation framework provides a registration workflow as a systematic approach to abstract from the substantial complexity inherent in aligning these poses and transforming them into a shared coordinate space.

3.3.1 Registering the Test Environment and Calibrating Ground Truth

In the initial step the test environment needs to be prepared. The motion capture system serving as ground truth must be calibrated by traversing the tracking volume with a standardized calibration device.

As part of this procedure, the origin position and orientation of the global coordinate space must be defined in the physical world by placing a specific marker on the ground floor. The alignment of the origin with a physical feature e.g. a wall or corner is recommended to greatly simplify subsequent evaluation, as it enables the alignment of a 3D model with minimal effort.

3.3.2 Measuring and Specifying Physical Configuration of the Localization Device

To track the localization device with OptiTrack, a sufficient number (3-5pcs) of markers must be fixed statically to the device.

Prior to the OptiTrack system tracking the pose of the device, it is necessary to register the marker configuration within the Motive Software. As part of this process a *rigid body* is created, which captures the static offsets between the markers as one physically connected object. After the rigid body is created, the corresponding coordinate frame should be adjusted to match ROS coordinate space definition as defined in as defined in REP103/105: x → forward, y → left, z → up [20], [21]

To facilitate the alignment of poses calculated by both localization and ground truth, the physical configuration of the tracking device must be specified and loaded into the evaluation framework. This can be achieved by measuring the offsets between the origin of the rigid body and the origin of the used tracking solutions e.g. the camera centre.

Placing the origin at the position of one of the used markers will simplify measuring the offsets.

The framework utilizes the well-established *universal robot description format (urdf)* [22] for reading the devices physical configuration.

3.3.3 Aligning Coordinate Frames

After the ground truth has been calibrated and the device has been set up for being localized in OptiTrack, an evaluation run can be conducted.

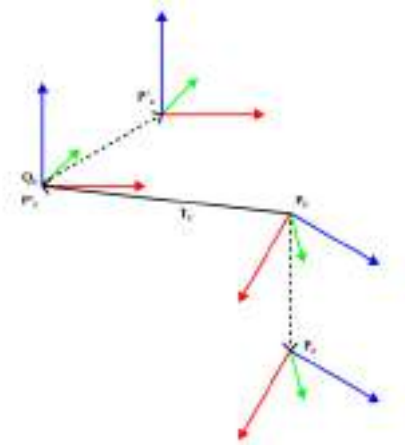

Figure 4. Alignment of the different coordinate systems of ground truth Q and the localization system P at calibration data sample t=0 and some subsequent sample t=n. Using the calibration transform T_C the calibrated transform P' can be obtained at any point in time.

As soon as both localization systems are running and the tracking device's markers are fixed, the alignment procedure of the evaluation system must be triggered. By pressing a key, the user starts the evaluation run. The evaluation system stores the tracked transform P_0 as well as the ground truth transform Q_0 at this timestamp *index* = 0. The recording of poses is started.

From now on the system calculates a new pose P'_0 representing the calibrated tracked pose (i.e. the pose measured by the localization system transformed into OptiTrack's coordinate space). In every subsequent sample with *index n* the poses Q_n and P'_n can be utilized to calculate the deviation as shown in Figure 4.

3.3.4 Timestamp Alignment

The data packages sent via NatNet streaming protocol are enriched with the timestamp when this data was recorded, measured in turn with the OptiTrack PC's clock. The OptiTrack ROS2 node publishes the corresponding transform with the original timestamp, compensating for latency.

Any pose evaluation needs to be calculated with exact matching timestamps for it to allow conclusions about the trajectory. Possible timestamp mismatches between the ground truth and the localization system can arise due to differences in sensor frequencies, outliers through sensor measurement errors, tracking losses in either the ground truth or the localization system, and delays introduced by the processing times of raw image data recording, the SLAM algorithm, and the transform alignment calculation. To compensate for those mismatches the delay in the localization system's timestamps, which is assumed to be static, needs to be determined and corrected for a static value or the timestamps need to be upsampled, downsampled or interpolated before the evaluation.

3.4 Means of Evaluation

To support a wide range of localization applications the proposed framework implements several means of evaluating the chosen localization system's precision. With the availability of the first RGB-D image datasets, which were infused with ground truth camera poses [9] the absolute trajectory error (ATE) as well as the relative error or relative pose error (RPE) became the predominant error metrics for localization systems. Adaptations of ATE and RPE calculations from public repositories [12] are included in the proposed framework.

3.4.1 Numerical Evaluation

RPE describes the difference between the estimated motion and the true motion for each pose, and is used to calculate drift, which describes the accumulation of sensor measurement errors during visual odometry [23]. While computationally expensive and difficult to interpret, RPE is less sensitive to estimation errors and allows for a detailed evaluation for any chosen segment size of the trajectory. Since it relies on motion, it is used in scenarios where accurate short term motion estimation is more important than precise global positioning e.g. wearable VR or AR devices.

ATE is a simple yet comprehensive evaluation metric. It calculates the absolute pose difference from position error, rotation error and velocity error at the time step $_i$ between two trajectories. Specifically, the localization systems trajectory P is aligned with the ground truth trajectory Q using the rigid-body transformation S

.

$$F_i := Q_i^{-1} S P_i \quad (1)$$

The resulting error F is commonly used to calculate the Root Mean Squared Error which reduces the errors over all time steps to a single number metric. The requirement for a ground truth trajectory and the lack of compensation for drift, which disproportionately emphasizes errors in the initial segment of the localizations system's trajectory compared to those occurring later, are recognized as limitations of the ATE metric. Nonetheless, it is a prominent metric for SLAM evaluation due to its simplicity, ease of comparison, and intuitive visual interpretability [23].

3.4.2 Graphical Evaluation

The proposed framework is specifically designed to utilize localization algorithms among others for construction site monitoring, 3D scanning, surveying, autonomous equipment navigation, indoor inspections.

Therefore it includes a custom ROS2 node which records every frame update, providing a trajectory or path visualization in *rviz* [24], as well as a grasshopper 3d [25] script, which translates the recorded path into control points of a polyline for a seamless integration with commercial CAD software (see Figure 5), allowing non-experts to quickly assess if a localization system is operating within desired tolerances for a chosen application.

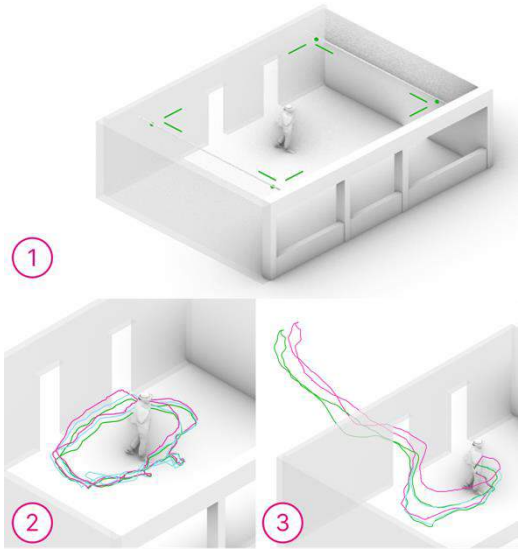

Figure 5. Visualization of two exemplary runs using the SLAM algorithms within a 1) lab environment. 2) Bottom shows 2) a circular path through a single room and 3) a run through multiple rooms in Rhino 3d. The ground truth is shown in *cyan*, results from RTAB-Map SLAM in *magenta* and ISAAC SLAM's trajectory in green.

4 Application of the Evaluation Framework

4.1 Description of a Case Study

To demonstrate and validate the proposed framework, an exemplary scenario is examined where a handheld device based on the NVIDIA Jetson AGX Orin platform equipped with a Stereolabs ZED X stereo camera is used for semi-automated building material and component inspection as part of so-called pre-demolition audits. In this scenario, machine learning based object recognition is combined with a visual inertial localization system to create an accurate material inventory. To achieve reliable results in this application, it is critical that the localization component of the system provides an accurate location of the actor. With RTAB-Map SLAM [26] and the Isaac Visual SLAM [27] two state-of-the-art visual-inertial SLAM systems were selected for their high on-paper accuracy as well as their high performance and flexibility within the ROS ecosystem. To determine which algorithm to use, an in-depth evaluation was performed in a realistic environment using the proposed evaluation framework.

4.2 Results

The results of the localization were then evaluated for the test run with a length of 28.4m. The ATE and RPE were calculated between the aligned trajectories of the SLAM systems and the OptiTrack serving as the ground truth. (see Figure 5, Table 1 and Table 2)

Table 1 Absolute Trajectory Error (ATE)

error metric	RTAB-Map	ISAAC
RMSE	0.194m	0.256 m
MEAN	0.159 m	0.224 m
STD	0.111 m	0.123 m
MIN	0.000 m	0.000 m
MAX	0.586 m	0.686 m

With an ATE Root Mean Squared Error *RMSE* of 19.4 cm RTAB-MAP outperforms the ISAAC SLAM.

Table 2 Relative Pose Error (RPE)

error metric	RTAB-Map	ISAAC
RMSE	0.058 m	0.047 m
MEAN	0.028 m	0.026 m
STD	0.051 m	0.039 m
MIN	0.000 m	0.000 m
MAX	0.458 m	0.337 m

For the Relative Pose Error *RPE*, when calculating drift per frame at $\Delta = 1$, the ISAAC SLAM outperforms the RTAB-Map SLAM, achieving a Root Mean Square Error *RMSE* of 4.7 cm.

Based on the presented Evaluations (Table 1 and Table 2), a logical inference is to prioritize RTAB-Map SLAM for tasks requiring high stability due to its low ATE, while selecting ISAAC SLAM for tasks demanding high accuracy, given its superior performance in RPE.

In the above-mentioned application of semi-automated building inventory, the prevention of double counting objects in consecutive frames is pivotal. Only with a low RPE the same object can be safely identified in different frames and correctly positioned in the localization algorithms map. Therefore, ISAAC SLAM should be selected for this application due to its superior RPE in the tested environment.

5 Conclusion, Limitations and Future Work

In order to validate the correctness of the results produced by the framework in the given case study, the error metrics are compared with the accuracy claimed in the literature.

Of all the datasets on which RTAB-Map has been run in [28], the TUM room sequence is the most comparable to the single room setup presented, as it is the only indoor handheld scenario. Within the benchmark, an ATE (RMSE) of 6.6 cm was achieved, which is approximately one third of the accuracy (19.4 cm) determined within the case study. Preliminary investigations have indicated that the observed discrepancy in accuracy is most likely due to the limited processing power of the embedded device and the significantly longer path length.

For ISAAC SLAM, it should be noted that available benchmarks are exclusively for the KITTI dataset. Despite the considerable differences between this scenario and the case study (long-distance outdoor, high-speed vehicle data), a comparison is nevertheless made to validate the feasibility. The translation error with respect to the trajectory length in [29] is given as 0.94%. The ATE (RMSE) of 25.6 cm corresponds to a translation error of 0.9% on the case study trajectory.

A notable difference between the case study results and previously published results highlights the need for individual evaluations to align with specific applications and environments. The proposed framework has been demonstrated to achieve comparable and practical results for this application.

One limitation of the proposed framework is the OptiTrack maximum tracking area size, which effectively limits the availability of ground truth data to

one room and makes it difficult to track across different spaces. By having a trajectory start and end within the tracking volume – as shown in 3) in Figure 5 – some fundamental assessments can still be made. For a detailed evaluation in multi-room (or even outdoor) environments another method needs to be chosen.

The accuracy of the OptiTrack system, as stated by the manufacturer, was neither independently verified nor incorporated into the ground truth trajectory of the proposed framework. However, given that the translational error rates of state-of-the-art SLAMs are an order of magnitude larger than OptiTrack's precision (even for shorter trajectories, e.g. 93 mm error with 10 m trajectory for ISAAC SLAM) the influence on the evaluation results is negligible.

Future work could evaluate different localization systems like LIDAR, Bluetooth, Wi-Fi systems and others to develop the proposed framework into a localization system primer for other applications.

Abstract –

Efficient remote operation of construction machines equipped with multiple video cameras requires smooth and real-time video transmission to simulate the experience of operating machinery in person. Due to the diverse network environments at construction sites, including satellite, Wi-Fi, and both public and private LTE/5G networks, an ultra-low delay video codec with adaptive bitrate control is crucial to maintaining low end-to-end latency in these environments. In this paper, the development of a multi-channel video encoder for the above requirements is described demonstrating the codec's performance across five types of wireless networks at a remote construction site.

Keywords –

Unmanned construction, Remote operation, Low delay video transmission, Network resilience

1 Introduction

In 2024, Japan's Ministry of Land, Infrastructure, Transport and Tourism (MILT) introduced the 'i-Construction 2.0' action plan, aiming to automate construction sites by 2040 [1]. In this plan, it is reported that Japan's working-age population is expected to be 20% smaller in 2040 than in 2023. Therefore, the plan focuses on labor reduction via increase of productivity through automation and autonomy in construction. For this purpose, remote construction technology is expected to help to solve labor issues as a step toward automated and autonomous construction.

In the remote construction, it is necessary to observe the situation of the remote site via the captured video, but there is a possibility of decrease of construction efficiency due to transmission delay and packet loss when using wireless networks. In this paper, firstly issues related to the remote construction using wireless networks such as private 5G and LEO (Low Earth Orbit) satellite networks are discussed. Next, we detail the development of a multi-channel, low-delay video codec to address these challenges.

Through experiments conducted across five types of wireless networks, we demonstrated that the ultra-low delay codec supports adaptable remote construction architectures tailored to each network.

2 Issues and countermeasures for remote construction

Figure 1 shows a typical system configuration of a remote construction and its issues (#1-#4) for efficient operation. In the following sections, we describe each issue and its countermeasures.

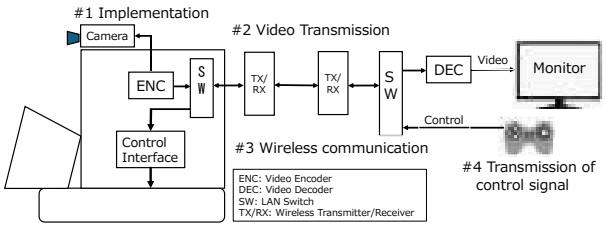

Figure 1. System configuration of remote construction

2.1 Issues and countermeasures for implementation

First of all, the issues with remote, automated, and autonomous operations of construction machines lay in the fact that it requires high expertise for installation and setup in such fields as video transmission, machine control, and communication networks since these factors are involved for the total systems. For example, four

video cameras facing forward, backward, left, and right would be installed on a construction machine to grasp the field situation and spot any danger. Since each camera requires a separate video encoder, a multi-channel encoder is preferable to reduce both cost and space. In addition, all the setup processes for the total system should be as simple as possible.

2.2 Issues and countermeasures for video transmission

As for the issues in remote operation using video, (1) end-to-end delay, (2) coding bitrate fluctuation, and (3) communication network quality should be pointed out. For example, if the advanced video coding architecture with temporally separated frames is employed to enhance the prediction performance, the coding efficiency can be improved. However, this might affect coding delays since the encoder has to wait for the following frames to encode the current frame. In the following subsections, each issue and countermeasures are described.

2.2.1 End-to-End delay

In this subsection, methods for end-to-end low delay architecture and target delay are discussed.

Remote construction efficiency would be directly affected by end-to-end delays [2]. As shown in Figure 1, each component such as video camera, video encoder, or communication network involves a certain amount of delay. Therefore, it is required to decrease each delay as much as possible. For example, 60fps video camera should be used instead of 30fps since the delay becomes 16.6msec instead of 33msec. On the other hand, delays of video codec and communication network may vary from tens to hundreds of msec, and suitable components should be chosen to realize very low end-to-end delay.

As for the human sensitivity on delay, it is reported that a delay of 100msec or over can be perceived [3]. For the electric rear-view mirrors for automobiles, the UN regulated the end-to-end delay not to take more than 200msec [4]. As for the remote construction, it is reported that the work efficiency was almost the same as the onsite remote operation when the end-to-end delay was less than 300msec [2]. Therefore, this figure can be recognized as one of the targets for the efficient remote construction.

2.2.2 Video coding delay and bitrate fluctuation

Here, delay and coding bit rate fluctuation mechanism caused by video coding scheme and countermeasures are addressed.

The international standard for video coding, MPEG (ranging from MPEG-1 and MPEG-2 to recent standards HEVC and VVC), combines intraframe coding (I frames) with interframe coding (P frames and B frames) to achieve a high compression ratio [5]. The intraframe coding reduces redundant information within the frame, whereas the interframe coding reduces redundant information between frames located temporally earlier and/or later. Here, P frames only use the earlier frames as a forward prediction and B frames can use both the earlier and the later frames as a bi-directional prediction.

In terms of coding efficiency, I frames are usually inserted every 0.5sec or 1sec to be used as random-access points, and the other frames are coded by interframe coding (P or B frames). Normally, considering the high correlation of frames in the temporal domain, P frames are inserted every few frames and the rest of the frames are coded with B frames to enhance the coding efficiency as shown in Figure 2(a).

#1 #2 #3 #4 #5 #6….
(a) I B B P B B P … I B B P…
(b) I P P P P P P … I P P…
(c) I P P P P P P … P P P…
Figure 2. Examples of coding frame layouts

Although this IBP frame structure can achieve a high compression ratio, there are two issues in terms of delay and coding bit amount for remote construction using network.

The first issue arises from variations in coding delay based on the video codec architecture. As stated earlier, MPEG uses interframe coding predicted from the earlier and/or later frames. Therefore, both encoder and decoder must wait for the later frames to encode/decode the current frame, which results in additional delay. In the case of Figure 2(a), for example, the frame #2 is coded as a B frame, but it can be coded after the frame #4 is coded as a P frame.

The second issue evolves from the fact that coding bit amount varies depending on the coding frame types. In the IBP coding structure, I frames have the largest bit amounts and B frames have the smallest bit amounts. For example, there is a case where the ratio of bit amounts for B:P:I frames becomes 1:10:25 [6]. Therefore, there is a possibility where the coding bit amounts of I frames are very large and it may take some time to send I frame data for limited network bandwidth. Then in the decoder side, the decoding timing of I frames becomes late for playback timing which may result in a frame drop.

In order to achieve low delay coding, the use of only earlier frames (i.e. IP frame structure) for the interframe coding as shown in Figure 2(b) is preferable in exchange for lower coding efficiency than that of IBP frame structure. As for the coding bit amount fluctuation, the introduction of intra-slice architecture within an IP frame structure as shown in Figure 2(c) which is further described in Section 3 may alleviate the bit amount variation.

2.3 Issues and countermeasures for communication networks

2.3.1 Communication network quality

In both wired and wireless networks, it is necessary to pay attention to four types of quality degradation causes (transmission delay, jitter, packet loss, and bandwidth fluctuation) for video transmission over IP networks. In this section, these issues and countermeasures are described.

As for the delay, low delay transmission can be realized when local networks such as Wi-Fi and private 4G(LTE)/5G. However, when public networks such as 4G(LTE) and 5G are employed for remote operation, a few dozen msec is usually involved due to transmission over the backbone and the access networks. In the case of satellite networks, GEO (Geostationary Earth Orbit) satellite communication has a few hundred msec roundtrip delay, whereas less than 100msec delay can be expected in the LEO satellite communication. To choose the desired network, network delay should be investigated before designing the remote construction system.

Regarding the jitter, since the video decoder is required to output the decoded frames to a video monitor within the playback timing, there is a possibility of frame drops when the packet data arrival is delayed due to the jitter. To solve this issue, the decoder buffer size should be designed to absorb the maximum jitter which can be determined by the actual amount of jitter.

As for the packet loss, obstacles and/or noise may cause transmission losses, especially in a wireless environment. The former packet loss is caused when the connection between a construction machine and a base station is interrupted by the backhoe movement, for example. The latter packet loss is caused by heavy rain and/or interference where packet data cannot be recovered due to noisy signals, for example. To solve the former packet loss issue, ARQ (Automatic Repeat reQuest) technique should be used to retransmit the lost packets while it involves additional delay. To solve the latter issue, FEC(Forward Error Correction) should be used, although it requires additional overhead data for error correction.

With regard to the bandwidth(throughput), the upload bandwidth from a construction machine is a very important parameter which determines transmission video quality. In the case of public networks such as 4G and 5G, more than a few Mbps throughputs can be expected for upload link. Recently, satellite networks using LEO became widely available and users can get up to 10Mbps for upload via Starlink [7], whereas only a few hundred kbps bandwidth can be used in satellite networks such as Inmarsat on the GEO. However, there is an issue of bandwidth variation of public networks since it may change dynamically according to the amount of network usage. To solve this, the video encoder should adapt to the available bandwidth.

2.3.2 Wireless networks

Although the history of remote construction in Japan is about 30years, the wireless network environment has been greatly advanced in this period. The unmanned construction using video cameras installed on the construction machines first adopted and applied for the whole disaster recovery work after the eruption of Mt.Unzen from 2km distance under wireless and relay environment at 2Mbps in 1993 [8].

In the damaged Fukushima nuclear power plant after the East Japan Great Earthquake in 2011 in Japan, ten construction machines (two 600-ton class large crawler tower cranes and eight construction machines) with video cameras were remotely operated from 500m distance using five mesh Wi-Fi base stations at 5GHz [8]. Recently, high speed wireless networks such as 5G network and LEO satellite network became widely available and a wide choice of wireless networks including Wi-Fi became possible. However, as stated earlier it is necessary to transmit low delay, stable, and high-quality video over the wireless network to realize an efficient remote construction.

In addition, resilient wireless networks should be constructed using mesh type network and/or error protection techniques such as ARQ for such cases as disconnection due to movements of construction machines, for example. It should be noted that preparation of a backup network would also be considered for network resiliency and safe remote operation. Another issue we should consider is that adaptive bitrate control for stable transmission is also very important since the bandwidth of wireless networks may fluctuate due to network congestion and/or interference, for example. In section 5, we show the solutions toward the above network related issues employing five types of broadband wireless networks and ARQ to realize efficient remote operations of construction machines.

2.4 Control signal transmission

In order to remotely control construction machines, control signals should be transmitted between the construction machines and the control sites. The amount of coded video data will become very large when the construction machines move or rotate since a large amount of coded video data is expected due to large motion or scene changes. Therefore, there are many cases where video is transmitted over Wi-Fi, while control signal is transmitted over the other network such as specified low power radio as in the case of Fukushima [8], which may result in complicated system

configuration. In order to transmit both the video and the control data in the same network, it is necessary to strictly control the total amount of coded video data below the bandwidth limit under any circumstances.

3 Development of multi-channel ultra low delay video codec

In this section, the development of video codec to solve the issues of low delay optimization, bit rate control mechanism and multi-channel support is described. Table 1 summarizes the main issues and solutions.

Table 1. Main issues and solutions

Issues	Solutions
Codec implementation	4ch HD encoder
Coding delays	IP frame structure
I-frame bursts	Intra slice coding
Bandwidth fluctuations	Strict rate control

For situation awareness and safe operations, a typical construction machine is equipped with four video cameras positioned at the front, rear, and both sides. In addition, at least HD quality video cameras would be required for the efficient remote operation [9]. Considering the above resolution requirement and overall network bandwidth, an all-in-one type four channel 2K low delay video encoder(LVRC-4000) based on the 4K HEVC video encoder (it can only support IP frame structure) [10] was developed, which can be installed on a construction machine (Figure 3 and Figure 4).

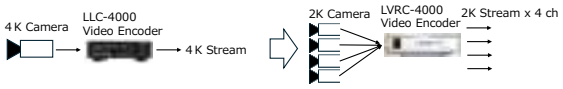

Figure 3. Development of 4ch HD video encoder

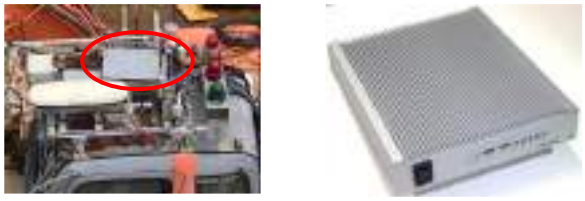

Figure 4. Ultra-low latency 4ch HD video encoder

As for the video coding structure, we use IP frame structure shown in Figure 2(b). Unlike the IBP structure, which uses both forward and backward predictions, the IP structure relies solely on forward prediction. While this reduces coding efficiency, it significantly lowers codec delay by eliminating the need to wait for future frames during encoding and decoding.

To address bandwidth fluctuations, the codec employs strict bitrate control, ensuring that the data rate remains within the available bandwidth at all times. In the case of IP frame structure shown in Figure 2(b), periodic insertion of I frames can cause bitrate spikes that exceed available bandwidth, leading to potential transmission delays or frame drops. Therefore, as an alternative structure, we have adopted an intra slice scheme within IP frame structure, which can also be used in HEVC coding. In this case, as shown in Figure 2(c), the first frame is encoded as I frame, but all the subsequent frames are coded by P frames where a slice of P frame is intra coded periodically. This intra slice coding can improve bitrate stability by periodically encoding small portions of each frame independently, preventing sudden spikes in data transmission.

For example, as shown in Figure 5, shadowed blocks (blocks on the third line in the figure) which construct a slice of blocks are intra coded. The position of the intra slice is moved at each frame. Then, in the next P frame, the slice of blocks below the current slice is intra coded. Since each P frame contains both intra- and inter-coded blocks, maintaining consistent picture quality and frame-to-frame bitrate stability is crucial. We implemented a strict rate control mechanism that regulates the bitrate of each frame, taking into account the differing data requirements of inter- and intra-coded blocks.

This approach ensures stable picture quality and bitrate while minimizing coding delay.

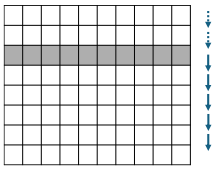

Figure 5. Intra slice coding

4 Video encoder performance

The video encoder performance was evaluated based on two key metrics: coding delay and bitrate fluctuation. Tests were conducted with four asynchronous video inputs, including high-motion scenes, to assess encoder stability under varying conditions. All the measurements in Section 4 and Section 5 were carried out for 3min. As shown in Figure 6, this experiment was carried out indoors since video codec performance test without wireless network can only be done in the indoor system.

Figure 6. Example of high-motion video input used for encoder evaluation

Figure 7 and Figure 8 show coding bitrate variations

of IP frame structure for one and four channels, respectively. Table 2 shows statistics (average bitrate, fluctuation range, standard deviations and 95% confidence intervals) of coding bitrate variations. Here, the coding bitrate is set to 3Mbps and the intra frame insertion period is set to 0.5sec which is generally used. In the case of one channel encoding, the coding bitrate changes rapidly according to motion and texture change, and periodical peaks at every 0.5sec can be seen in Figure 7. Since relatively large fluctuation is observed as shown in the table, it is necessary to set the coding bitrate to much lower than the available bandwidth in order to correspond to the high peak bit rate, which may result in lower video quality than expected.

Table 2 Statistics of coding bitrate variations

Coding Mode, #ch	AVG(kbps)	Fluctuation Range	SD(kbps)	95% CI(Mbps)
IP structure, 1ch	2681	+28% to -38%	217	2.71 to 2.65
IP structure, 4ch	11209	+3.5% to -14%	366	11.26 to 11.16
Intra slice, 1ch	2896	+1.5% to -3%	27	2.90 to 2.89
Intra slice, 4ch	10462	+3% to -8%	160	10.49 to 10.43

On the other hand, in the case of four channels, although the periodic peaks at every 0.5sec can also be observed in Figure 8, the bitrate fluctuation range becomes smaller than that of one channel as shown in the table. This would be caused by the statistical multiplexing effect for four asynchronous video channel encoding, which absorbs bit rate fluctuation of each channel to some extent. In statistical multiplexing, it distributes bitrate peaks across multiple asynchronous streams, reducing overall fluctuation.

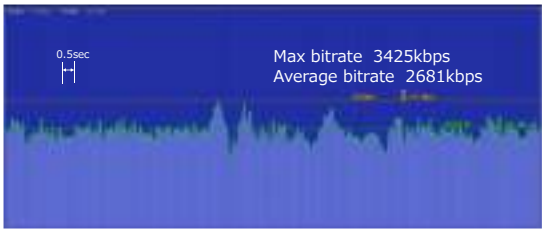

Figure 7. Bitrate variation for one-channel video encoding with IP structure (3Mbps x 1ch, Intra@0.5sec)

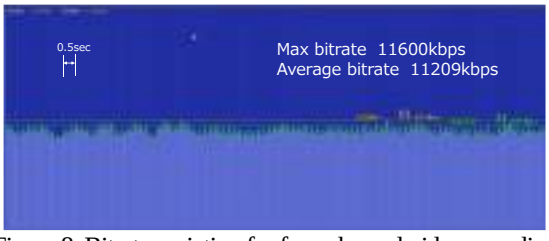

Figure 8. Bitrate variation for four-channel video encoding with IP structure (3Mbps x 4ch, Intra@0.5sec)

Figure 9 and Figure 10 show the bitrate variations for one and four channels, respectively when intra slice structure is employed. In this case, the bitrate fluctuations to the average are greatly reduced when compared with IP structure, which can also be observed in Table 2. As for the average bitrate, it was 2681kbps for the IP structure, whereas it was 2896kbps for the intra slice structure. Since the bitrate was set to 3Mbps for both structures, it can be said that the latter structure can use the available bandwidth more efficiently than the former structure.

When the amount of the bitrate fluctuation of four channels and one channel in intra slice coding is compared, the former is larger than the latter. Since the fluctuation range for each channel is very small due to intra slice coding, each small amount of fluctuation may accumulate when four channel bit streams are integrated.

As for the codec (from the encoder input to the decoded monitor) latency, 114msec delay was observed for the IP structure, whereas 66msec delay was obtained for the intra slice structure. This result means that the proposed intra slice structure can achieve both ultra-low latency while strictly keeping the coding bitrate and making the most of available bandwidth.

Figure 9. Bitrate variation for one-channel video encoding with intra-slice structure (3Mbps x 1ch)

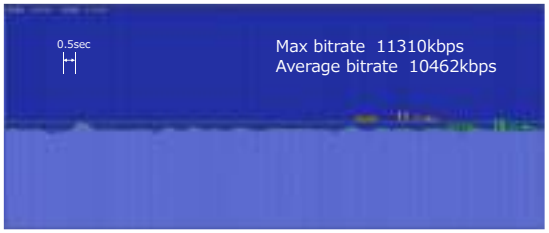

Figure 10. Bitrate variation for four-channel video encoding with intra-slice structure (3Mbps x 4ch)

5 Video transmission experiment

5.1 Experimental setup

We have conducted an end-to-end video transmission experiment using video coding setup with intra slice structure described in Section 4. The experiment aimed to evaluate transmission performance across various wireless networks using a remote construction machine setup, as shown in Figure 11. Four video cameras (OMRON SENTECH video cameras (STC-HD853HDMI) for full HD@60fps) and the newly

developed encoder (LVRC-4000) were installed on the construction machine (Hitachi Construction Machinery ZX-120).

Regarding the wireless networks, we used the following commercially available networks to evaluate various types of wireless environments.

1) Wireless for robots (5.7GHz, Doodle Labs RM-5700, point to point, Antenna 2.4m high)
2) Mesh Wi-Fi (Rajant ES1-2450R@const. machine, FE1-2450x2+ES1-2450R@AP)
3) Public LTE (au, Hytec Inter HW5G-3200x2)
4) LEO satellite network (Starlink)
5) Private 5G (Fujitsu@AP, Hytec Inter HW5G-3200 x 2)

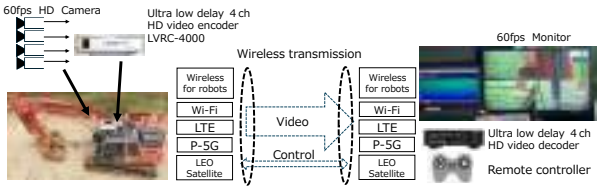

Figure 11. Experimental setup

As for 1) wireless for robots, it became available under license for image communications of unmanned systems such as robots and drones at 5.7GHz and 2.4GHz in Japan in 2016 [11]. As for 4) LEO satellite network, considering the situation of public mobile and optical fiber network failure due to a large natural disaster, we had an experiment connecting the construction machine to the LEO satellite network via mesh Wi-Fi, and video data was received at the remote control center via the Internet and public mobile and optical fiber network.

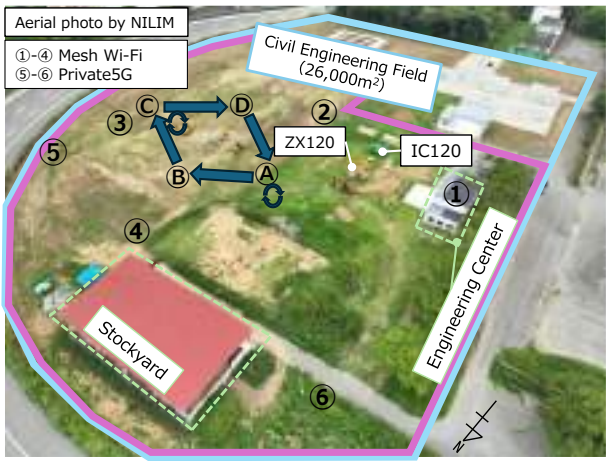

Figure 12. Experimental field

Figure 12 shows an experimental field. Four video cameras, video encoder, and network equipment were installed on the construction machine (ZX120). A 60fps video monitor (Iiyama XUB2390HS-B5), a video decoder (Hytec Inter LLC-4000), a remote controller (Hitachi S-RS-A), and network equipment are installed in the engineering center. In the experimental field, the construction machine moved around from point A to point D via points B and C, and rotated at points A and C.

Transmission experiments were conducted using an open platform called OPERA (Open Platform for Earthwork with Robotics and Autonomy) [12] facilitated for the efficient development and easy dissemination of autonomous construction technology. Table 3 shows the basic transmission performance for various wireless networks measured for 3min. For example, wireless for robots achieved 27Mbps uplink and 26Mbps downlink throughput with stable video transmission for both one channel and four channels. Similar throughputs are also obtained in public LTE and private 5G. Mesh Wi-Fi achieved 50Mbps for both uplink and downlink whereas LEO achieved 15Mbps level throughput.

In addition, the required bandwidth for the control signal was very small(<1kbps). Therefore, the control signal was transmitted in the same wireless network as that of the video data in the following experiments.

Figure 13 shows an example of one channel video transmission over the LEO satellite network at 3Mbps. As can be seen in the figure, stable video coding and transmission were realized through effective bitrate control.

Table 3. Throughputs, video coding bitrate and control signal bitrate for each network

System config.	Stay/ Move	Trhoughput Mbps		Coding bitrate per ch	Coding bitrate per 4ch	Datarate for control	Total bitrate
		To BS	From BS				
Wireless for robots	Move	27	26	3Mbps	12Mbps	Under 1kbs	Under 15Mbps
Mesh Wi-Fi	Move	52	50	3Mbps	12Mbps	Under 1kbs	Under 15Mbps
Public LTE	Move	30	26	3Mbps	12Mbps	Under 1kbs	Under 15Mbps
Private 5G	Stay	26	26	3Mbps	12Mbps	Under 1kbs	Under 15Mbps
LEO sat + fiber	Stay	15	14	1Mbps	4Mbps	Under 1kbs	Up to 6Mbps

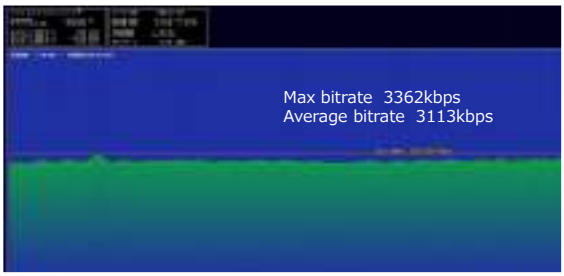

Figure 13. Transmission example of one channel video at 3Mbps over LEO satellite network

5.2 Network characteristics when the construction machine was stationary

While stationary, the networks achieved stable throughput and low packet loss, with latency varying by network type. Wireless for robots and mesh Wi-Fi

networks demonstrated minimal delay, while public LTE and private 5G showed slightly higher average delays. Table 4 shows the transmission performance when the construction machine was stationary. Due to functional limitation of measurement equipment, detailed statics such as standard deviation of jitter were not obtained.

Since less than 15Mbps throughput is obtained in LEO network, we set 1Mbps per channel for this network. Similarly, we set 3Mbps per channel for the other networks since more than 25Mbps throughputs are obtained.

As for the network latency, 4-5msec average delay was observed in the wireless for robots and mesh Wi-Fi networks, whereas there was 30-40msec average delay for the public LTE and private 5G networks. In the case of the LEO satellite network, there were 84msec average delay via the public LTE and 60msec delay via the optical fiber networks, which are much smaller latency when compared with that of the conventional GEO satellite networks.

As for the delay jitter, due to network configuration limitation for the measuring equipment, we could only have results on wireless for robots and mech Wi-Fi. Although a small jitter of +/- 7msec was observed in the former, about 50msec jitter was obtained in the latter. Although packet loss rate was only available for the wireless for robots, there was no packet losses in the experiment.

Table 4. Throughputs, packet loss, network delay, and jitter for each network when move or stay still

System config.	Stay/ Move	Throughput(Mbp		Packet loss(%)	Delay(ms)			Jitter(ms)	
		To BS	From BS		Min	Avg	Max	Min	Max
Wireless for robots	Stay	33	28	0%	2.77	3.87	8.25	-6.02	6.98
same as above	Move	27	26	0.80%	2.86	24.34	401.8	-448.5	283.7
Mesh Wi-Fi	Stay	39	44	-	2.96	5.40	30.00	-52.66	52.81
same as above	Move	52	50	-	3.47	11.82	142	-274.0	275.1
Public LTE	Stay	29	27	-	22	33	54	-	-
same as above	Move	30	26	-	22	46	175	-	-
Private 5G	Stay	26	26	-	31	44	56	-	-
LEO sat + LTE	Stay	9	10	-	55	84	203	-	-
LEO sat + fiber NW	Stay	15	14	-	33	60	290	-	-

5.3 Network characteristics when the construction machine was in motion

Table 4 also shows the transmission performance when the construction machine was moving and rotating. In this case, we compared the results of wireless for robots, mesh Wi-Fi and public LTE with stationary situations. While the throughput remained stable during movement, delays increased significantly. For instance, the wireless for robots network experienced an increase from 4msec to 24msec average delay, with jitter rising to 300-450msec due to such motion as rotation of the construction machine. On the contrary, in the case of mech Wi-Fi, although the min and max delay jitter was about 300msec level, the average delay was about 12msec due to the use of multiple routing even when the construction machine was rotating.

5.4 End-to-End delay from video camera to monitor

Table 5 and Table 6 show the end-to-end delay from video camera input to monitor output when ARQ is off and on, respectively. As can be seen in Table 3, the end-to-end delay was 115-163msec and very low delay transmission was realized. When the ARQ was on (installed in the video codec), there was an additional 100msec for this function and the total delay of less than 300msec was achieved as shown in Table 6, which satisfies the delay requirement of efficient remote construction [2].

Table 5. End-to-End delay when ARQ is off

Network	Network delay(ms)	Delay expt. NW(ms)	E-E delay(ms)	Bandwidth(Mbps)
Wireles for robot	24	103	127	27
Mesh Wi-Fi	12	103	115	52
Public LTE	46	103	149	30
Private 5G	44	103	147	26
LEO + fiber	60	103	163	15

Table 6. End-to-End delay when ARQ is on

Network	Network delay(ms)	Delay expt. NW (ms)	E-E delay(ms)	Bandwidth(Mbps)
Wireles for robot	24	201	225	27
Mesh Wi-Fi	12	201	213	52
Public LTE	46	201	247	30
Private 5G	44	201	245	26
LEO + fiber	60	201	261	15

5.5 Improvement of transmission video quality when ARQ was on

When the remote operator rotated the construction machine, there was a network disconnection between the base stations and the construction machine when wireless for robots or private 5G was used due to the limited number of base stations (one or two). In the case of ARQ=off, picture quality degradation and/or frame drop were observed due to packet loss. When the mesh Wi-Fi or the public LTE was used, the frequency of instantaneous interruption was low since the possibilities of either one of the base stations within the line of sight was high. Especially in the case of the public LTE, very stable connection was observed. However, it should be noted that the situation would vary depending on the area coverage or network congestion.

(a) ARQ is off (b) ARQ is on

Figure 14. Comparison of picture quality when ARQ is off(left) and on(right)

When ARQ was on, stable video transmission was realized at every wireless network. For example, in

Figure 14(a), the shape of the building in the right-hand side was degraded due to packet loss when ARQ was off. On the contrary, when ARQ was on, lost packet was successfully retransmitted as shown in Figure 15 and error-free decoding was realized as shown in Figure 14(b).

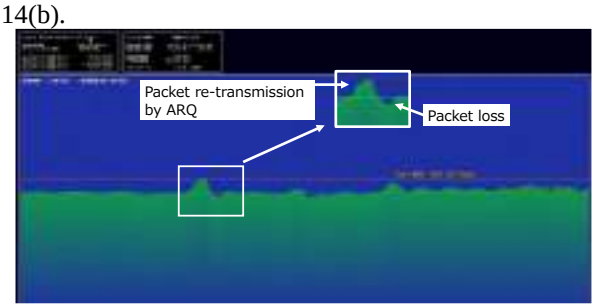

Figure 15. Packet loss and recovery via ARQ

6 Conclusions

This study focused on the development and evaluation of a multi-channel ultra-low delay video encoder to enhance remote construction efficiency. Network performance and video quality were assessed across five broadband wireless networks, including wireless for robots, mesh Wi-Fi, public LTE, private 5G, and LEO satellite. Enabling ARQ increased end-to-end delay by 100msec but significantly enhanced video quality, particularly during high-motion events such as machine rotation.

Throughout the experiments, less than 300msec of total delay was realized by the proposed system using commercially available wireless networks, meeting the delay requirements for efficient remote construction operations. While the system demonstrated high performance, simplifying the setup process remains a challenge. To support adoption in diverse construction environments, future work should focus on developing user-friendly interfaces and automated configuration tools that minimize the need for technical expertise particularly for operators with limited technical experience.

Acknowledgments

This study was carried out through the joint research work with Public Works Research Institute, Jitsuta Chugoku Co. Ltd., and Chudenko Corporation on productivity improvement of mechanical earthwork using OPERA (Open Platform for Earthwork with Robotics and Autonomy). The authors would like to thank all for discussions and support of the experiments.

The authors are also grateful to National Institute for Land and Infrastructure Management (NLIM) for the use of private 5G system.

Abstract –

Mobile robots are increasingly used to explore and inspect confined environments, often in situations that are hazardous or inaccessible to humans, highlighting the need for advanced mapping and sensing capabilities. This paper presents a novel approach for constructing a multi-dimensional map by integrating sensor data from a hexapod robot with Simultaneous Localization and Mapping (SLAM). The robot, equipped with a DHT22 sensor and powered by a Raspberry Pi 4 Model B, was deployed in a mechanical room at the University of Alberta to collect humidity and temperature data while simultaneously mapping the environment. The Cartographer SLAM algorithm was used for mapping, and the sensor data was fused with the generated map by the Inertial Measurement Unit (IMU) using a bilinear interpolation algorithm. This pilot experiment serves as a demonstration of the proposed robot system, which results in a multi-dimensional map that combines 2D geographical map with sensory maps such as humidity and temperature. The map provides a visualization of the spatial distribution of environmental variables within the confined area. This approach has potential applications in various scenarios, including quick mapping of hazardous areas and routine inspections of areas with limited access. Future work will focus on incorporating 3D SLAM and exploring the use of machine learning techniques for automated anomaly detection within the multi-dimensional map, while addressing the current limitations related to real-time processing and visualization.

Mobile Robotics, Simultaneous Localization and Mapping (SLAM), Sensor, Inspection

1 Introduction

Mobile robots play an increasingly important role in exploring and inspecting unstructured and confined environments, particularly those deemed hazardous or inaccessible to humans [1]. A key capability for such robots is the ability to generate accurate maps of the environment while simultaneously localizing themselves within that map, even the environment is deviated from its original plan [2]. This is commonly achieved through Simultaneous Localization and Mapping (SLAM) techniques [3]. It leverages sensor data from LiDAR and cameras to enable robots to autonomously explore unknown environments and create detailed maps for navigation and task execution [3].

However, conventional SLAM algorithms predominantly focus on geometric mapping, primarily capturing the spatial layout and structural features of the environment [4]. While crucial for navigation and obstacle avoidance, these geometric maps often lack information about other critical environmental variables that can significantly impact a robot's operation or the understanding of the surrounding space [5]. Monitoring factors such as temperature, humidity, air quality, and the presence of hazardous substances is essential for robots deployed in applications such as environmental monitoring [6], industrial inspection [7], and disaster response [8]. Moreover, the map integrated with multi-dimensional layers can also enhance the situational awareness of decision makers [9]. In summary, a crucial research gap exists in multi-dimensional mapping with SLAM: the existing techniques primarily focus on geometric mapping, neglecting the integration of environmental variables crucial for understanding and operating in complex confined areas.

Researchers have explored several detection and mapping methodologies for construction environments. Borrmann, et al. [10] introduced a system utilizing a mobile robot equipped with 3D laser scanners, RGB

cameras, and thermal cameras to generate 3D thermal maps of buildings, designed to identify heat leaks and infrastructure anomalies. Amigoni and Caglioti [11] focused on efficient exploration by developing an information-based strategy for mobile robot mapping, employing laser range scanners and balancing travel distance with information gain. Although these studies effectively demonstrate the utility of mobile robots for inspection and mapping in confined spaces, they often prioritize either geometric reconstruction or specialized sensor-based detection, leading to a lack of integrated, multi-sensory map outputs. This research seeks to bridge this gap by integrating geometric and sensory mapping techniques, advancing mobile robot functionality beyond standard SLAM and detection to encompass comprehensive SLAM and sensory mapping, providing a richer environmental representation.

To fill the gap, this research investigates a method to integrate sensor data with SLAM to create a multi-dimensional map that provides a richer and more comprehensive understanding of the environment. By fusing data from environmental sensors with the spatial information obtained through SLAM, a more holistic representation of the confined area can be achieved. This multi-dimensional map not only captures the geometric features but also incorporates crucial environmental variables, enabling a more informed analysis of the surrounding space.

This research investigates the use of a hexapod robot equipped with a DHT22 sensor to create a multi-dimensional map of temperature and humidity within the mechanical room of the Li Ka Shing building at the University of Alberta. This mechanical room serves multiple key virology laboratories and requires a high level of environmental monitoring. In this pilot experiment, the goal was to investigate the robot system's capabilities to constructing a multi-dimensional map. By integrating Inertial Measurement Unit (IMU) information, the sensor data was then fused with the 2D map generated by the SLAM algorithm to create a multi-dimensional map with sensor data, enabling the visualization of the spatial distribution of temperature and humidity within the confined space.

This paper details the methods used for sensor integration, data acquisition, and map generation, and discusses the challenges encountered and potential applications of this approach. The findings contribute to the development of more comprehensive mapping techniques for robots operating in complex and confined environments, ultimately enhancing their capabilities in various real-world scenarios. The paper contributes to overcome the barriers of adopting sensors in construction industry, specifically in Multi-sensor Data Fusion and Decision Support Integration [12].

2 Robotic System Design

The high-level robotic system design employed in this research, illustrated in Figure 1, adopts a client-server architecture to facilitate both manual and semi-autonomous operation. This architecture allows for a modular and scalable approach, where the robot platform itself functions as the server, managing onboard processes such as data acquisition from the LiDAR and DHT22 sensors, as well as executing the Cartographer SLAM algorithm. The server also handles the alignment of sensor data with the SLAM-generated map using the IMU. The client-side, typically a separate computer, focuses on real-time visualization of the robot's progress and the construction of the final multi-dimensional map. This division of tasks between server and client enhances the efficiency of the system, particularly given the computational constraints of the Raspberry Pi used on the robot platform. Communication between the server and client is established wirelessly via TCP/IP over Wi-Fi, enabling remote control and monitoring of the robot's operations.

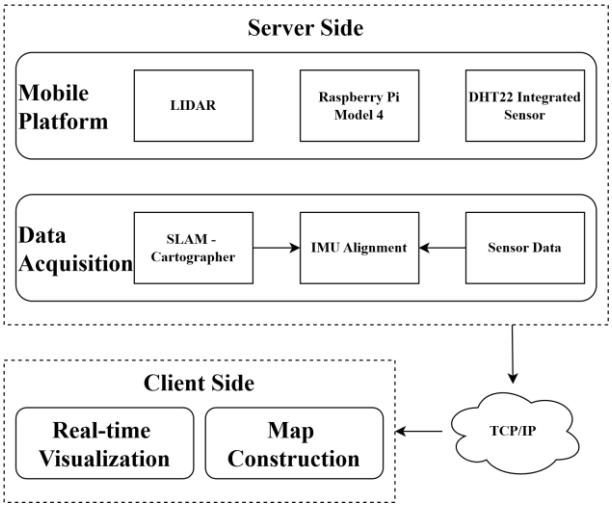

Figure 1 High-level Robotic System Design

2.1 Robot Platform

The robot prototype used in this research is a custom-assembled hexapod robot based on a Raspberry Pi 4 Model B. The Raspberry Pi serves as the central processing unit, responsible for controlling the robot's locomotion, sensor data acquisition, and communication. The robot's design is based on the RHex [13]. The choice of a hexapod robot for this research was motivated by several factors related to the challenges of navigating and collecting data within confined areas [3]. Hexapod robots offer superior mobility compared to wheeled or tracked robots, enabling them to traverse uneven terrain, overcome obstacles, and maintain stability in confined spaces. Their adaptability to different locomotion gaits

allows them to maneuver effectively in tight spaces and adjust to varying environmental conditions [14]. Additionally, the hexapod platform's inherent stability ensures that the robot can maintain its balance while carrying the necessary sensors and computing equipment, crucial for acquiring reliable data in potentially unstable environments [15]. The combination of mobility, adaptability, and stability makes the hexapod robot an ideal choice for this research.

2.2 Sensor Integration

The robot prototype was equipped with a DHT22 sensor to measure temperature and humidity. This sensor was chosen for its affordability, ease of use, and compatibility with the Raspberry Pi [16]. The DHT22 sensor was connected to the Raspberry Pi's GPIO (General Purpose Input/Output) pins, and the sensor data was read using the Adafruit_DHT library. This library provides functions for interacting with the DHT22 sensor and retrieving temperature and humidity readings [17]. Incorporating sensors with single sensing principle, such as temperature and humidity sensors, in this initial prototype is beneficial as it provides a foundational framework for integrating environmental data with SLAM, enabling the robot to assess basic environmental conditions and serving as a stepping stone towards more complex sensing capabilities for applications such as detecting thermal anomalies in industrial settings or identifying potential gas leaks [1].

2.3 SLAM Implementation

The Cartographer SLAM algorithm was employed for mapping the environment, which is visualized in real-time using Rviz, as shown in Figure 2. Cartographer is an open-source SLAM library developed by Google, known for its accuracy and robustness in various environments. It utilizes a combination of laser range finder data and inertial sensor data to create a 2D map of the surroundings [18]. In this research, the robot's movement was controlled manually, and the Cartographer SLAM algorithm generated a map of the confined area based on the robot's trajectory and sensor readings.

In order to provide the Cartographer SLAM algorithm with the necessary spatial information, a LiDAR (Light Detection and Ranging) sensor was integrated into the robot's platform. The LiDAR sensor emits laser beams and measures the time it takes for the beams to reflect back from surrounding objects, providing accurate distance measurements [19]. This data was then used by the Cartographer SLAM algorithm to construct a detailed map of the environment, including walls, obstacles, and other features. The integration of the LiDAR sensor enhances the accuracy and efficiency of the mapping process, enabling the robot to generate a comprehensive representation of the confined area [19].

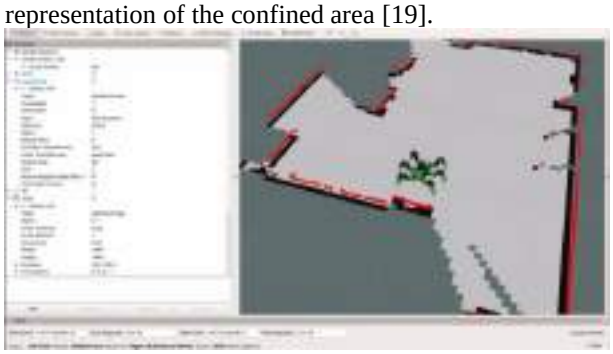

Figure 2 RViz Visualization of SLAM

2.4 Control and Communication

The robot's control and communication systems were designed to facilitate both manual and semi-autonomous operations. A client-server architecture was implemented, allowing for remote control and monitoring of the robot's activities. The server-side program, running on the Raspberry Pi, managed sensor data acquisition, SLAM processing, and communication with the client. The client-side program, running on a separate computer, provided a graphical user interface (GUI) for controlling the robot's movements, visualizing sensor data, and monitoring the mapping process.

Communication between the client and server was established over a Wi-Fi network using the TCP/IP protocol. This wireless communication enabled real-time control of the robot and allowed the operator to monitor the robot's progress and sensor readings from a safe distance. The client-server architecture provided flexibility in controlling the robot and facilitated the integration of additional sensors or functionalities in the future.

2.5 Data Acquisition

The robot prototype was deployed in a section of mechanical room of the Li Ka Shing building at the University of Alberta, as shown in Figure 3. The mechanical room served as a representative confined area, characterized by limited space, obstacles, and varying environmental conditions. In this pilot experiment, the goal was to investigate the robot system’s capabilities for constructing the multi-dimensional map. The robot was manually controlled to traverse the room, and the DHT22 sensor collected temperature and humidity data at one-second intervals. This sampling rate was chosen based on the sensors response frequency (0.5 Hz or once every two seconds) and the robot’s stabilization time (one second). The readings will be normalized to ensure the accuracy of values in Section 2.6. The Cartographer SLAM algorithm generated a 2D map of the room based on the robot's movement, and the IMU integrated with sensor

readings generated another two 2D maps for temperature and humidity.

Figure 3 Mechanical Room for the Experiment

To enhance the visualization and analysis of the acquired sensor data, a real-time bilinear interpolation algorithm was employed [20]. This technique estimates values at intermediate points within the 2D map based on the known sensor readings at surrounding locations [21]. By interpolating the temperature and humidity data, a continuous heatmap representation can be generated, providing a more comprehensive view of the environmental conditions within the confined area. Bilinear interpolation is computationally efficient and offers a reasonable approximation of the spatial distribution of sensor data, making it suitable for this application [20].

The bilinear interpolation is calculated as follows:

Let Q_{11}, Q_{12}, Q_{21}, and Q_{21} represent the temperature or humidity values at the four points of a grid cell and let $P_{(x,y)}$ be the point where the interpolated value is needed.

Interpolate in the x-direction:

$$R1 = \frac{(x_2 - x)}{(x_2 - x_1)} * Q_{11} + \frac{(x - x_1)}{(x_2 - x_1)} * Q_{21}$$

$$R2 = \frac{(x_2 - x)}{(x_2 - x_1)} * Q_{12} + \frac{(x - x_1)}{(x_2 - x_1)} * Q_{22}$$

Interpolate in the y-direction:

$$p = \frac{(y_2 - y)}{(y_2 - y_1)} * R_1 + \frac{(y - y_1)}{(y_2 - y_1)} * R_2$$

In these equations, Q represents the value of the environmental variable being interpolated using single sensing principles, whether it is temperature, humidity, or any other measured quantity. For points Q11, Q12, and Q22 that lie on the robot's trajectory, their temperature and humidity values can be directly measured by the onboard sensors. However, for the point Q21 located outside the trajectory, the value was estimated by interpolation based on the known values of its three closest neighbours (Q11, Q12, Q22) in the corresponding points in the adjacent grid cell. This approach leverages the spatial correlation between neighbouring points to provide a reasonable approximation of the environmental conditions at Q21. This generalized notation emphasizes the versatility of bilinear interpolation, as the same mathematical framework can be applied to various environmental parameters.

It is important to acknowledge that assuming a linear distribution for temperature and humidity may not always be accurate, especially in environments with complex variations. More sophisticated interpolation techniques, such as kriging [22] or Gaussian process regression [23], could be explored to better capture the spatial distribution of these variables. These methods can account for spatial correlations and provide more accurate predictions, but they also require more computational resources and may not be suitable for real-time applications [24]. The choice of interpolation method depends on the specific application and the desired balance between accuracy and computational efficiency [24].

2.6 Map Construction

The sensor data acquired by the DHT22 sensor was integrated with the 2D map generated by the SLAM algorithm to create a multi-dimensional map. This was achieved using Matplotlib, a Python plotting library [25, 26]. The temperature and humidity data were interpolated across the 2D map using bilinear interpolation, creating a heatmap representation of the environmental variables, as shown in Figure 4 and Figure 5. The resulting multi-dimensional map provides a visual representation of the spatial distribution of temperature and humidity within the mechanical room.

To ensure accurate alignment between the 2D map generated by SLAM and the heatmap created by the DHT22 sensor, the robot's MPU6050 IMU was utilized. This IMU provides orientation and movement data, enabling precise mapping of the sensor readings onto the 2D map. Specifically, the IMU's accelerometer and gyroscope readings are fused to obtain the robot's gestures and movement, which are then used to transform the sensor data from the robot's local coordinate frame to the global coordinate frame of the SLAM map. Given the temperature and humidity readings happen at one-second intervals, the IMU readings within a second are merged as one data point which aligns to the sensor readings. This alignment process ensures that the temperature and humidity readings are accurately represented in the multi-dimensional map, facilitating a more reliable analysis of the environmental conditions within the confined area. During the plotting stage, those coordinates from IMU readings are connected as a line, representing the path of navigation as shown in Figure **4** and Figure **5**.

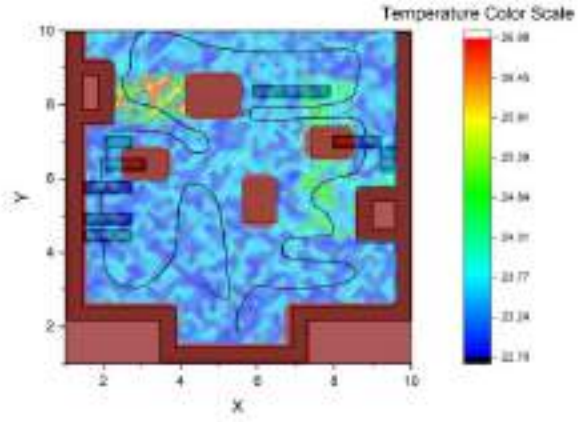

Figure 4 Temperature Heatmap

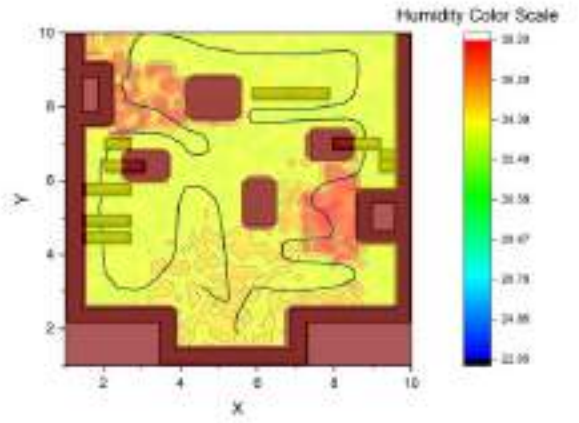

Figure 5 Humidity Heatmap

Due to the limited computational power of the Raspberry Pi, the map construction process for the sensing maps was conducted after the mapping process. The 2D map constructed by SLAM with IMU is used to create a grid for the sensing map. To perform bilinear interpolation and estimate the value at a point $P_{(x,y)}$ on the map, the four nearest grid points, denoted as Q_{11}, Q_{12}, Q_{21}, and Q_{21}, need to be identified. This involves finding the nearest point $P'_{(x\prime,y\prime)}$ on the trajectory curve to $P_{(x,y)}$.

Given the irregular shape of the curve, a piecewise cubic spline interpolation is employed to represent the trajectory. Let $S_{(t)}$ be the cubic spline function that interpolates the robot's path. The nearest point $P'_{(x\prime,y\prime)}$ on the curve to $P_{(x,y)}$ can be found by minimizing the distance:

$$P_{(x,y)} = \min\left(\sqrt{((x - S_x_{(t)})^2 + ((y - S_y_{(t)})^2}\right)$$

where $S_x_{(t)}$ and $S_y_{(t)}$ are the x and y components of the spline function $S_{(t)}$.

A local coordinate system is then established at P' using the tangent vector and its normal vector at P'. The tangent vector v at P' can be calculated as the derivative of the spline function:

$$v = \left(\frac{dS_x}{dt}, \frac{dS_y}{dt}\right) at\ t = t'$$

The normalized unit tangent vector u and unit normal vector n are then:

$$u = v/|v| = 1, n = \left(\frac{-dS_y}{dt}, \frac{dS_x}{dt}\right)/|v|$$

With a predefined grid spacing h of 0.5 meters, the four nearest grid points Q_{11}, Q_{12}, Q_{21}, and Q_{21} can be determined as:

$$Q_{11} = P' + h * u + h * n$$
$$Q_{12} = P' + h * u - h * n$$
$$Q_{21} = P' - h * u + h * n$$
$$Q_{21} = P' - h * u - h * n$$

The grid spacing h represents the resolution of the sensor data interpolation. A smaller grid spacing results in a finer-grained map with more interpolated points, potentially capturing more detailed variations in temperature and humidity [21]. However, it also increases the computational burden for interpolation. Conversely, a larger grid spacing reduces the computational load but may result in a coarser map that misses subtle environmental variations.

The choice of h = 0.5 meters was based on a balance between map resolution and computational efficiency, considering the limited processing power of the Raspberry Pi. Future work could investigate the effect of different grid spacings on map quality and optimize this parameter based on the specific environment and application requirements.

To provide a more concrete understanding of the system's performance in the bottleneck, the following metrics were collected for the map construction tasks:

Table 1 Performance Metrics

Category	Metrics
CPU Usage	95-97%
RAM Usage	68-70%
Map Generation Time	14 minutes and 37 seconds
Network Bandwidth	5 Mbps

3 Results

This pilot experiment serves as a demonstration of the prototype, which resulted in the successful generation of a multi-dimensional map of the mechanical room, integrating both geometric features and environmental variables. The Cartographer SLAM algorithm

successfully mapped the room's layout, including walls, obstacles, and open spaces. The DHT22 sensor collected temperature and humidity data throughout the robot's traversal, which was then overlaid onto the 2D map using bilinear interpolation. The IMU aligned the 2D maps constructed by SLAM and sensors together, resulting in a multi-dimensional map that effectively visualizes the spatial distribution of temperature and humidity within the confined area.

To verify and validate the accuracy of the multi-dimensional map, the robot's sensor readings were compared with manual measurements and observations of the mechanical room along the robot's path. This comparison also ensured that the readings from the DHT 22 sensor were not affected by the heat generated from the robot's motherboard or motors. The SLAM-generated map was verified to represent the room's dimensions and the location of obstacles. These verification and validation steps ensured the reliability and validity of the generated map and the associated sensor data.

The multi-dimensional map reveals that the temperature and humidity levels are not uniform throughout the mechanical room. Areas with higher concentrations of equipment tend to have slightly elevated temperatures, while humidity levels show some variation depending on the proximity to potential sources of moisture or ventilation. The map provides a comprehensive overview of the environmental conditions within the room, highlighting areas of potential concern or interest.

4 Discussion

This research demonstrates the feasibility of integrating sensor data with SLAM by IMU to create multi-dimensional maps using a hexapod robot. The approach offers several advantages, particularly for inspecting confined areas. The robot's ability to traverse complex ground conditions and collect sensor data in hard-to-reach locations makes it a valuable tool for assessing environmental conditions in challenging environments.

However, the research also highlights some challenges and limitations. The limited computational power of the Raspberry Pi poses a constraint on the complexity of the SLAM algorithms. Due to this, the mapping process took a relatively long time, and the multi-dimensional map can only be plotted after the mapping, which shows the weakness for real-time visualization. Moreover, such limited power prevented the authors to utilizing 3D SLAM. Additionally, the accuracy of the multi-dimensional map is dependent on the interpolation method used. While bilinear interpolation provides a reasonable approximation, more sophisticated techniques may be required to achieve higher accuracy, especially in environments with rapidly changing conditions. Meanwhile, the accuracy of values created from the interpolation algorithms should be systematically compare with ground truth maps to ensure the accuracy. Last but the least, the authors acknowledge the limitation that this pilot experiment only serves as a demonstration and the first field test for this robot system approach. More rigorous experimental design is needed to evaluate and improve the capabilities and applications of this system.

Despite these challenges, the potential applications of this research are significant. The ability to map confined areas and identify hazardous conditions has implications for various industries, including disaster response, environmental monitoring, and industrial inspection. Future work will focus on addressing the identified limitations and exploring the use of more advanced sensors and SLAM algorithms to further enhance the accuracy and capabilities of the multi-dimensional mapping approach.

5 Conclusion

This paper presents a method for constructing multi-dimensional maps by integrating sensor data with SLAM by IMU using a hexapod robot. The approach was successfully demonstrated in a confined area, resulting in a map that visualizes the spatial distribution of temperature and humidity. The research highlights the potential of hexapod robots for inspecting hazardous and inaccessible areas, while also identifying challenges related to computational limitations and interpolation accuracy. Future work can focus on addressing these challenges and exploring the use of more advanced sensors and 3D SLAM algorithms with better processing unit to enhance the capabilities of this approach. It is also recommended to evaluate this approach on the efficiency of decision-making.

This research sets the stage for several promising future directions. Firstly, the integration of more advanced sensors with multi-sensing principles, such as gas detectors, will enable the robot to collect a wider range of environmental data, leading to more comprehensive and informative multi-dimensional maps. Secondly, the development and utilization of more robust and computationally efficient SLAM algorithms will improve the accuracy and real-time capabilities of the mapping process, allowing for online visualization and analysis of the environment. Finally, the incorporation of machine learning techniques can automate the identification of anomalies or points of interest within the multi-dimensional map, facilitating decision-making and response in hazardous or inaccessible environments.

6 Acknowledgements

The authors would like to express their sincere acknowledgement to the Canada Research Chair Program of the Government of Canada (CRC-2021-00531).

The authors would also like to extend the acknowledgement to the following individuals for their invaluable contributions to this research:

- Darren St.Hilaire, P.Eng, CEFP. Director, Trades Infrastructure and Maintenance, University of Alberta, for providing access to the mechanical room and facilitating the data acquisition process.
- Tony Hodge, Director, Infrastructure Development, University of Alberta, for his support and guidance throughout the project.
- Neil McFarlane, Industry Liaison, Faculty of Engineering, Civil and Environmental Engineering Department, University of Alberta, for his support in establishing the collaborations.

Their expertise and assistance were instrumental in the successful completion of this research.

Exploring Cognitive Load and Task Complexity in Dynamic Tracking Tasks: Insights for Construction Workflows

Amira Eltahan[1], Gaang Lee[1] and Farook Hamzeh[1]

[1]Department of Civil and Environmental Engineering, University of Alberta, Canada
eltahan@ualberta.ca, gaang@ualberta.ca, hamzeh@ualberta.ca

Abstract -
Construction tasks involve dynamic and visually demanding activities that require continuous monitoring, tracking, and decision-making. These demands can overwhelm workers' cognitive capacity and increase mental strain and reduce efficiency. This study combines two cognitive load assessment methods: objective cognitive load assessment using wearable eye tracking and task-based performance analysis by calculating performance error. It examines the impact of complexity in dynamic tracking tasks on performance and cognitive load. The metrics include blink rate, fixation rate, saccadic amplitude, saccadic peak velocity, saccadic mean velocity, and tracking error. Saccadic amplitude showed a strong positive correlation (r = 0.891) which reflect the need to scan broader areas for higher visual complexity. In contrast, saccadic peak velocity (r = -0.96), blink rate (r = -0.967), and fixation rate (r = -0.671) demonstrated negative correlations with task complexity, which suggests increased cognitive demands and a prioritization of accuracy over speed. Saccadic mean velocity showed minimal correlation (r = -0.07), which suggests it might not be a sensitive metric for evaluating the impact of task complexity. Performance error was measured as the Euclidean distance between gaze and target, and it revealed a strong positive correlation with task complexity (r = 0.967). It indicates reduced performance as complexity increased. These findings highlight the significant impact of complexity on cognitive and visual performance. This is particularly relevant in construction tasks that require continuous monitoring, tracking, and visual processing. Understanding these relationships helps optimize construction workflows, reducing cognitive strain, improving efficiency, and enhancing safety in visually demanding tasks.

Keywords –
Task complexity, Cognitive load, Visual processing, Eye tracking metrics, Dynamic tracking

1 Introduction

Construction tasks are inherently dynamic and visually demanding. This requires workers to continuously monitor, track, and make decisions under challenging conditions. These tasks often involve processing complex visual information while maintaining high levels of accuracy and speed. The cognitive and visual demands of such tasks can overwhelm workers, leading to mental strain, decreased performance, and an increased likelihood of errors. Cognitive load refers to the mental effort required to process information, solve problems, and make decisions [1, 2] . It is influenced by task complexity, time constraints, and environmental factors [3]. Understanding how cognitive load and task complexity impact performance is critical to optimize construction workflows and improve workers' safety and productivity.

To optimize cognitive load, we first have to measure it. Three methods can be used to measure cognitive load which are subjective, objective, and task- and performance-based techniques[4]. Subjective measurement methods rely on self-reporting tools like the NASA Task Load Index (NASA-TLX) [5], the Subjective Workload Assessment Technique (SWAT), and the Cognitive Task Load Analysis (CTLA) [5]. These approaches involve participants rating their mental workload on predefined scales. However, these methods can be limited by individual biases and interruptions to workflow which reduce their reliability and practicality. Objective measurement techniques utilize physiological indicators to assess cognitive load. It includes monitoring heart rate variability (HRV), brain activity via electroencephalogram (EEG), eye activity, cortisol levels, and skin conductance [4]. This method provides real-time, less-intrusive approach to quantify cognitive load. The task and performance-based technique is usually implemented in experimental studies to supplement wearable sensors and support the results. It assesses cognitive load by measuring task performance through metrics like reaction time, accuracy and error rate [6].

EEG is a widely used tool for assessing cognitive load in construction [7]. However, its application in real-world scenarios is constrained by challenges such as the requirement for controlled environments [8]. Eye-tracking technology is gaining traction as a practical alternative for evaluating cognitive load in construction settings [9, 10] because of its adaptability in the dynamic construction setting. Unlike EEG, its less invasive, portable, and less sensitive to artifacts from the external environment. Previous studies have established that cognitive load influences visual behavior with metrics such as fixation rate, blink rate, saccadic peak velocity, pupil dilation, and saccadic amplitude[11, 2, 12]. However, there is limited research on how these metrics interact in the context of dynamic tracking tasks coupled with varying complexities commonly encountered in construction. This study aims to fill this gap by evaluating the relationship between task complexity and cognitive load in dynamic tracking tasks using eye-tracking data. These findings will contribute to the development of strategies to reduce cognitive strain, enhance tracking performance, and optimize workflows in visually intensive construction tasks.

2 Literature Review

2.1 Cognitive Load and Its Impact on Construction

In the construction industry, cognitive load plays a significant role in determining workers' efficiency, decision-making [12] and safety [13]. A study by Kwon et al (2024) highlight the risks posed by cognitive overload in safety-critical situations as a result of multiple safety signs. The study concluded that excessive cognitive demands reduce workers' ability to process visual warnings effectively, particularly when more than nine items are displayed [14]. Mitropolus and Memartian (2013) [15] examined the dimensions of task demands in masonry work. They divided it to mental, physical, and temporal demands and studied their implications on performance and management strategies construction. The study provided evidence that high task complexity and temporal pressures are critical factors contributing to mental overload and reduced attentiveness, which can lead to errors, rework and safety incidents on construction sites. They proposed practical management strategies, such as reducing the task design complexity that creates high physical or mental demands. Memarian et al., (2012)[16] identified work practices that balance high productivity and safety while errors in construction tasks through a case study that analyzed the work practices of a high-reliability field supervisor in a concrete construction project. The findings emphasized the importance of reducing task complexity and aligning high-demand tasks with highly skilled workers. However, the correlation between task complexity in visual tracking tasks and the corresponding impact on cognitive load remains unexplored in literature. Even though several studies have highlighted the impact of task complexity on performance through subjective methods or through wearable sensors, the studies quantifying the impact of task complexity on cognitive load and performance is still lacking.

2.2 Cognitive Load Measurement in Construction

Subjective self-reporting methods have been deployed to assess mental fatigue and cognitive load in construction by Zhang et.al.(2013) [13] using Fatigue Assessment Scale for Construction Workers (FASCW). Others have used NASA Task Load Index (NASA-TLX) to assess cognitive load [14]. However, these subjective methods were proven to bias due to individual variability and recall bias due to participants' reliance on their memory to report their experiences [18]. To overcome this, researchers have shifted towards using objective methods using advanced wearable sensors to measure cognitive load. These sensors measure physiological responses due to cognitive load such as Electroencephalography (EEG), wearable eye trackers, and physiological metrics recorders to objectively measure cognitive states in construction environments [20, 21, 22, 23].

A systematic literature review was conducted by Jamil Uddin et al., (2024) [7] on using technologies to measure mental fatigue of construction workers. The authors reported that EEG was one of the commonly used tools to assess cognitive load in construction. However, EEG has a limited applicability in construction setting due to its sensitivity to the external environmental factors, such as head motions and electromagnetic interferences. Eye tracking has been emerging as an alternative practical measurement to cognitive load [20, 21]. However, research quantifying the relationship between task complexity, performance and cognitive load for dynamic tracking tasks using site-friendly wearable sensors is still lacking. Therefore, this study aims to explore and quantify the impact of task complexity on cognitive load and performance using wearable eye trackers in dynamic tracking tasks.

3 Methods

3.1 Task Design

The experiment will employ a within-subject design where participants perform three identical tasks with one controlled variable "task complexity". This controlled setup ensures that differences in the eye metrics are

highly attributable to the varying task complexity. A dynamic task was designed to evaluate participants' ability to track a moving gaze point by displaying a dot that follows a predefined path at three varying speeds. This is particularly important in construction, where workers need to track moving objects, process dynamic visual information, and maintain situational awareness. Deficiencies in situational awareness are a major contributor to workplace accidents, as shown by 28,512 lost-time injuries reported in 2023 [23]with majority of incidents resulting from workers being struck by or caught in objects and equipment**.** These accidents often stem from difficulties in effectively tracking moving objects. For instance, tasks such as crane operations, vehicle maneuvering, and heavy equipment handling require precise visual tracking of moving targets to ensure safety and efficiency. This study aims to capture fundamental visual-cognitive processes that underlie real-world construction tasks by isolating tracking ability in a controlled experiment. The results can inform strategies for reducing cognitive overload and improving workers' ability to maintain focus in complex environments. Level 1 represents the baseline condition and Levels 2 and 3 indicate increasing levels of complexity. The tasks were presented in a randomized order to minimize bias from learning effects. A black background was used as it provides higher contrast with a brightly coloured moving dot (bright green). Green is considered less harsh on the eyes compared to red or blue, making it a good choice for tasks that require sustained tracking.

3.2 Data Collection

The study employs objective and task and performance-based measurement methods of cognitive load. Five metrics were collected which include blink rate (blinks/sec), fixations rate (fixations/second), saccadic amplitude (px), saccadic peak velocity (px/sec), and saccadic mean velocity (px/sec). Also, gaze coordinates were collected to calculate the average distance between the participants' gaze points and the actual target coordinates by calculating Euclidean distance. All metrics were recorded continuously during each trial using Pupil Invisible Eye Tracking Glasses by Pupil Labs. The eye tracking glasses collects gaze data at 200 HZ, fixations, saccades, blinks, RGB scene video at 30 Hz using a detachable scene camera and gaze mapping. Pearson correlation coefficient was calculated to assess the correlation between task complexity and the metrics.

A total of seven graduate students voluntarily agreed to participate after signing informed consent forms with the option to withdraw two weeks after data collection without consequences. Prior to the experiment, each participant was briefed on the objectives and procedures of the study and their questions or concerns were addressed to ensure clarity and comfort. The participants were asked to as accurately as possible follow the moving object. The sample size aligns with similar studies using physiological metrics [13]. In eye-tracking studies, similar sample sizes have been commonly used due to the exhaustive nature of data collection and analysis, as well as the high accuracy of the observed trends [10].

3.3 Data Analysis

To measure the impact of cognitive load on eye movement, five different metrics were calculated. These metrics include saccadic peak velocity (px/s), saccadic amplitude (px), saccadic mean velocity (px/s), blink rate (blink/second), and fixation rate (fixation/second). The metrics were measured for the three different task complexities for each participant. This enabled the comparison of each participant's metrics that reflect his corresponding cognitive load given the varying task complexity. Also, the performance of each participant was calculated by the average Euclidean distance between the gaze and target points for the three complexities. Furthermore, to understand the correlation between the metrics and task complexity, Pearson correlation coefficient was calculated.

4 Results and Discussion

4.1 Eye tracking metrics analysis

4.1.1 Saccadic Peak Velocity (px/s)

Saccadic peak velocity is an essential metric in eye-tracking research as it represents the speed and effectiveness of eye movements during saccades. It is the highest speed achieved by the eye during a saccadic movement. Figure 1 shows the results across all subjects in three tasks of varying complexity. The figure shows that saccadic peak velocity decreases systematically as task complexity increases for all participants. The baseline condition (Level 1) exhibits the highest saccadic velocities which indicates minimal cognitive strain and higher efficiency in executing saccades. Our results reveal a strong negative correlation between task complexity and saccadic peak velocity with an average Pearson correlation coefficient of -0.96. This indicates an inverse relationship between task complexity saccadic peak velocities. It could possibly be because participants prioritize accuracy over speed when visual demand increase.

These findings aligns with existing research which highlighted that saccadic peak velocity decrease as mental load and task complexity increase[11, 24]. And have been reported as an effective measurement for mental load variations in complex tasks [26, 27].

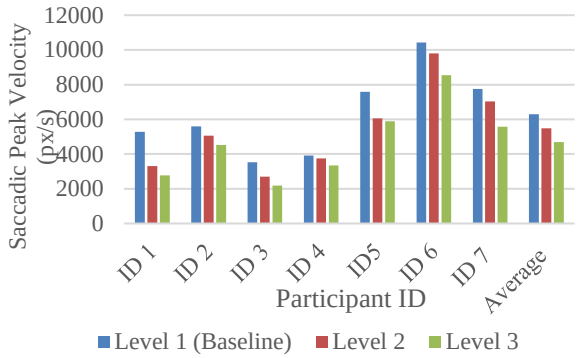

Figure 1. Saccadic Peak Velocity Across Task Complexity Levels

It should be noted that there is variability in saccadic peak velocity across participants. For example, ID 6 consistently exhibits the highest velocities across all levels, while IDs 3 and 4 have relatively lower values. This variability could be attributed to differences in individual cognitive capacity, visual acuity, or familiarity with the task.

4.1.2 Saccadic Amplitude (px)

Saccadic amplitude is the distance the eye travels during a single saccadic movement. Figure 2 presents saccadic amplitude (in pixels) across three levels of task complexity for seven participants (ID 1 to ID 7). The average amplitude is calculated for each level to provide insights into general trends. The average saccadic amplitude increased as task complexity increased. This indicates that participants made larger eye movements as task complexity increased this could be due the need to scan broader areas or manage more challenging visual demands. There is significant variability among participants. ID 6 consistently exhibits the largest amplitudes across all levels, with a sharp increase from 97.73 px (Level 1) to 169.45 px (Level 3). ID 1 and ID 7 show smaller amplitudes compared to others, with more modest increases between levels. The variability suggests individual differences in visual search strategies, task adaptation, or cognitive effort.

It can be observed that saccadic peak velocity decreased with task complexity while saccadic amplitude increased. However, saccadic peak velocity has been sought to typically increase with the amplitude of eye movements, a relationship known as the main sequence[27]. This relationship is generally considered fixed but can be modulated by external factors such as incentives and motivation[28]. If a task involves scanning a visually complex scene under cognitive strain, participants might make longer saccades to cover larger areas while slowing their saccadic velocity to ensure accuracy[29].

Also, our results show a strong positive correlation between task complexity and saccadic amplitude with an average Pearson correlation coefficient of 0.896. This indicates that saccadic amplitude increases significantly as task complexity increases. This results in longer saccades which lead to an increase in saccadic amplitude. Under cognitive strain, the brain often prioritizes accuracy over speed. This trade-off can cause a reduction in saccadic peak velocity, even as the amplitude increases as reported in our findings. This behaviour aligns with findings that saccadic metrics, such as peak velocity, can vary under cognitive load, while amplitude adapts to task demands[23].

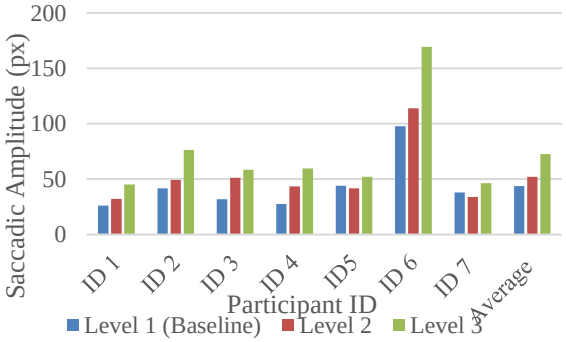

Figure 2. Saccadic Amplitude Across Task Complexity Levels

4.1.3 Saccadic Mean Velocity (px/s)

Saccadic mean velocity is the average speed of the eye during a saccadic movement. Figure 3 shows the saccadic mean velocity across all participants. The average mean velocity decreases as task complexity increases with an overall reduction of 7.26% from Level 1 to Level 3 which indicate that participants generally slow their saccades as task complexity rises indicating higher cognitive demand.

ID 3 shows a consistent increase in velocity across levels, moving from 1432.04 px/s in Level 1 to 1946.94 px/s in Level 3. ID 2 followed a similar trend. This suggests that ID 2 and 3 adapts to increasing task complexity by speeding up their saccadic movements, contrary to the general trend. ID 6 mean velocity increased from Level 1 to Level 2 suggests that ID 6 may approach intermediate complexity with higher efficiency or speed. ID 4 maintains relatively steady velocities which indicate a consistent visual and cognitive strategy across all task levels.

Our findings show a weak negative correlation between saccadic mean velocity and task complexity with an average Pearson correlation coefficient of -0.077. While the overall trend shows a decrease in mean velocity with task complexity, the substantial variability among participants weakens its reliability as a robust indicator of cognitive load. This is in line with existing research that suggest [26, 31] that task complexity had no

effect on saccadic mean velocity.

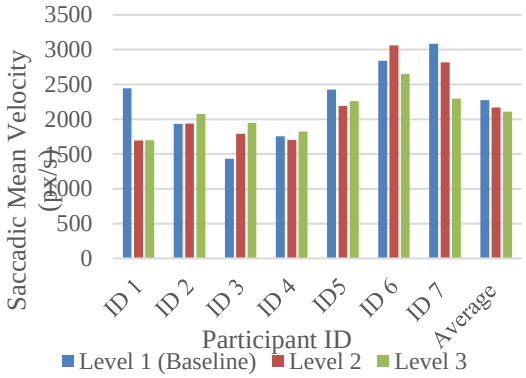

Figure 3. Saccadic Mean Velocity Across Task Complexity Levels

4.1.4 Blink Rate (Blinks/second (Hz))

Another indicator for cognitive load is blinking rate. Figure 4 shows the blinking rate for the seven participants across three levels of task complexity as well as their average. The average blink rate decreases consistently from 1.23 blinks (Level 1) to 0.96 (Level 2) and 0.7 (Level 3) as task complexity increases. Also, our results showed a strong negative correlation between blink rate and task complexity with an average Pearson correlation coefficient of -0.967. This indicates that blink rate decreases significantly as task complexity increases.

This reflects increasing cognitive demand as reduced blinking is commonly linked to increased focus and engagement. Blink rate varies among participants due to individual differences which is why a baseline was established. Despite these variations all participants showed a downward trend and a strong negative correlation coefficient. This aligns with previous research [33, 34] and reinforcing blink rate's reliability as a measure of cognitive load and its strong linkage to task complexity.

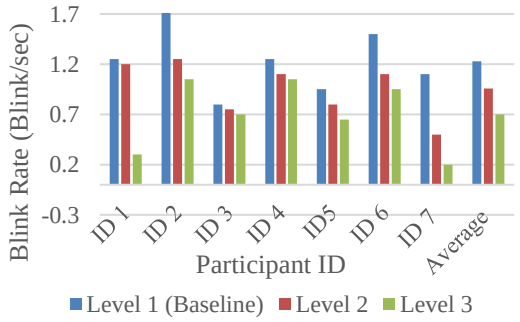

Figure 4. Blink Rate Across Task Complexity Levels

4.1.5 Fixation Rate (Fixations/Second (Hz))

Fixation rate refers to the frequency of fixations made by the eye per unit of time during a task. A fixation occurs when the eye stops moving and focuses on a single point to gather visual information. Fixation rate is typically expressed as fixations per second (Hz) and is a key metric in eye-tracking research. Figure 5 presents data for seven participants across three levels of task complexity with their individual values and overall averages provided for each level. The average fixation rate values decreased as task complexity increased. Also, our results indicate a moderate negative correlation between fixation rate and task complexity with an average Pearson correlation coefficient of -0.671.This aligns with trends seen in cognitive load research, where participants tend to adapt their behaviour as complexity rises and prioritizing precision over speed [2, 35]. All participants showed the same trend except for ID 5 who showed a slight upward trend which might indicate individual variability as adaptation or improved efficiency to handle complexity

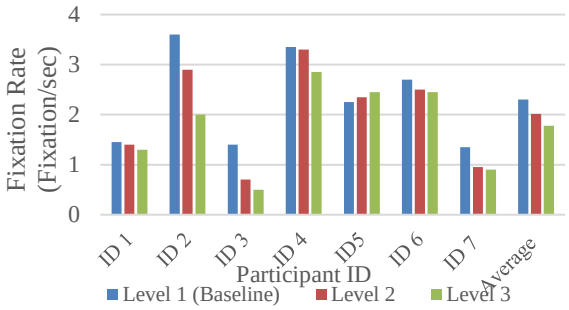

Figure 5. Fixation Rate Across Task Complexity Levels

4.2 Participants' Performance Evaluation

The impact of task complexity and cognitive load on performance was assessed by measuring the average distance between the participants' gaze points and the actual target coordinates. This measurement shows how accurately participants tracked the stimuli as the complexity of the task increased. A higher distance indicates higher error in tracking performance. It indicates that participants found it harder to keep their gaze aligned with the target as tasks became more challenging. The results align with this trend, with higher distances seen at higher task complexity levels.

Figure 6 represents the average Euclidean distance between gaze points and the actual coordinates of the stimuli for seven participants across three levels of task complexity. The Euclidean distance increased consistently as complexity increased. This indicate that as task complexity rises participants experience more difficulty tracking stimuli accurately. While the average trend supports this relationship, individual differences highlight variability in participants' ability to adapt to cognitive and visual demands. This suggests that tracking performance under complex tasks is influenced by both task characteristics and individual capabilities.

Our results show a very strong positive correlation

between Euclidean distance and task complexity with an average Pearson correlation coefficient of 0.967. This supports our findings that tracking error has a direct relationship with task complexity.

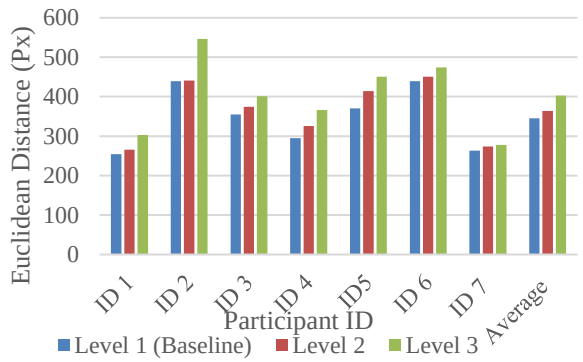

Figure 6. Euclidean Distance Across Task Complexity Levels

5 Insights for Construction Workflows

This study highlights the impact of visually demanding tasks on cognitive load and consequently performance. This could be particularly relevant to tasks of complex demand that require continuous monitoring, tracking, precise focus, and rapid decision-making based on visual information. This could include operating heavy machinery, rigging and lifting operations, welding and cutting, working at heights, and installation tasks.

Table 1 outlines specific recommendations for optimizing construction workflows based on findings from eye-tracking metrics and cognitive load analysis. Each recommendation is directly supported by observed data trends. This table provides actionable recommendations based on insights from cognitive load and eye-tracking metrics. By addressing specific challenges like task complexity, visual distractions, and worker fatigue, these strategies can enhance safety, productivity, and efficiency in construction workflows. Each recommendation is supported by findings that directly link eye-tracking data to cognitive performance under varying task complexities.

Table 1. Insights for Construction Workflows

Recommendation	Support by Findings
Focus on Reducing Task Complexity	Higher Euclidean distances indicate that increased task complexity reduces tracking accuracy. Construction tasks should be simplified where possible by breaking them into smaller, manageable steps to reduce cognitive load and improve worker precision.
Enhance Training for High-Complexity Task	Participants who showed increased errors at higher complexity levels highlight the need for specialized training.
Design Visual Environment	The findings suggest that visual demands influence performance. Construction workflows should minimize unnecessary visual distractions and use clear, standardized markings to guide workers' attention, ensuring accurate tracking of critical elements.
Leverage wearable sensors to monitor workers cognitive load	Metrics like blink rate, fixation rate, peak velocity reflects how task complexity impact cognitive load. Real-time monitoring could identify high-stress periods and offer feedback to enhance accuracy.
Monitor Worker Performance and Adjust Workloads	Significant differences in metrics like mean velocity and tracking performance highlight the need for personalized task assignments.
Incorporate Rest Breaks in Workflows	Reduced blink rates at higher complexity could reflect visual fatigue which can be mitigated with rest breaks.

6 Limitations and Future Work

The study revealed significant individual differences in metrics like saccadic mean velocity, fixation rate, and tracking performance. These variations limit the ability to generalize findings across a broader population. Also, experiments were conducted in a controlled setting which may not fully replicate the dynamic and unpredictable nature of real-world construction sites. The participant pool was relatively small, which may not provide sufficient statistical power to generalize results to all workers in construction or other fields. Furthermore, the study tasks were simplified representations of real-world construction workflows. More complex or nuanced tasks could yield different cognitive load and performance patterns. While metrics like blink rate, fixation rate, and saccadic velocities were useful, they may not capture all dimensions of cognitive load. Other physiological indicators such as heart rate variability or pupil dilation, could provide additional insights.

7 Conclusion

This study examined the impact of task complexity on cognitive load and performance in construction

workflows using eye-tracking metrics. These metrics include blink rate, fixation rate, saccadic amplitude, saccadic peak velocity, saccadic mean velocity, and tracking accuracy (Euclidean distance). The findings provide insights into how workers respond to visually and cognitively demanding tasks.

The findings indicate that blink rate decreased with increased task complexity which could reflect higher cognitive load. Fixation rate and saccadic amplitude increased which suggests higher visual processing demands and the need to scan broader areas as task complexity increased. Saccadic peak velocity decreased which align with previous research that indicates a compensatory mechanism to prioritize accuracy over speed in complex scenarios. Saccadic mean velocity showed significant individual variability and a weak correlation coefficient; therefore, it's a less reliable metric for measuring cognitive load across participants. The participants' tracking performance was measured by Euclidean distance between gaze points and target coordinates. All participants showed higher error at higher complexity levels. This highlight reduced accuracy in visually challenging tasks. These results emphasize the strong relationship between task complexity, cognitive load, and performance.

Recommendations to enhance worker focus, accuracy, and safety include simplifying task designs, providing targeted training, leveraging wearable eye-tracking technology, and incorporating regular rest breaks. This research provides a foundational understanding of how cognitive and visual demands affect worker performance and offers actionable recommendations for optimizing construction tasks and improving workplace safety and efficiency.

Abstract -

The construction industry is currently behind other non-farming industries on the trends of updating technologies, especially in implementing robotic automation in its processes. Because of this, there are numerous opportunities for development of new technologies in the construction domain for automating tasks, lowering risks, and decreasing costs. The focus of this paper was to take a newly patented design for a robotic end effector to build wooden frames and start to build a physical prototype. More specifically, unfinished or nonfunctional parts are updated, and portions of the end effector were assembled.

Keywords

Robotic Automation, End Effector, Timber Construction, Construction Robotics

1 Introduction

It is widely known that construction industry has lagged behind other non-farming industries in its productivity improvement, yet not enough has been done with advancements in technology to improve that in recent years. This research investigates one of the possible solutions through robotic automation, specifically the development of a prototype to demonstrate how a new end effector can help automate the construction of timber frames.

Robotic automation is set out to address different challenges within the construction community such as in improving safety. According to Pinto et al [1], some of the causes of construction safety hazards include large company sizes and therefore a large number of workers to train, constantly changing worksites, worker specialization to one machine or area, insufficient protective equipment, use of drugs on the job, and long-term health problems from the stress of lacking job security [1]. Robotic automation provides a promising solution for mitigating such risks. However, for the last 50 years, limited advancement in robotic automation has come to the construction industry [2], which is notably delayed compared to other industries [2].

In addition to safety risk exposure, the construction industry is also costly, partially due to the number of employees, materials, equipment, and accidents related. It is estimated in a study by Everett and Frank Jr that the cost of accidents in the construction industry has risen from 6.5% in 1979 of total cost of nonresidential construction to between 7.9% to 15.0% in 1996 [3]. That increase, which is at least 1.4%, is millions of dollars that could have been spent on updated technologies. In 2002, it's estimated that $11.5 billion was spent on injuries in construction [4]. According to the federal reserve bank of St Luis, the average annual cost of construction in the US in 1994 was 530,980 million dollars. In 2023, that average was raised to 2,021,695 million dollars, a 280.8% increase [5]. As projects become more complicated and more costly, the need to mitigate these costs increases. Robotic automation is considered a promising solution. One way to pursue this is to use robots to construct elements that are used multiple times within a project, such as timber frames. Zhang et al. [6] patented a technology in that regard and this paper focuses on implementing the patented technology to an existing robotic arm.

2 Methodology

The goal is to build a working prototype of the patented end effector design [6] (Figure 1) as a proof of concept for companies to adopt this technology in future construction operations. This integrates: (1) a mount for a robotic arm, (2) two rotating shafts enabling it to encircle timber pieces, (3) suction plates for secure wood handling, and (4) a nail gun for efficient timber assembly. This configuration ensures

precise and robust manipulation of timber, enhancing the overall automation process in construction tasks.

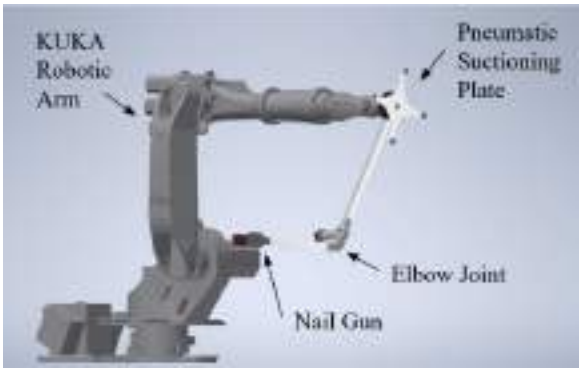

Figure 1: Patented End-effector Design [6]

Figure 2 shows the work breakdown structure of this research, representing all tasks to be completed. These tasks are categorized into design, manufacturing, assembly, electrical, programming, and documentation. The prioritization of tasks was based on assemble sequence (onto the arm), with documentation being produced and used throughout the design iterations. CAD designs and sample prints were used for validation of design.

Figure 2: Work Breakdown Structure

3 Previous Research

The researchers chose to use the KUKA KR 16 L6 robotic arm with a KR C2 controller for implementation, following a lineage research [7]. Before powering the robotic arm, an inspection was done to ensure all connections were secure and accurately placed. Although a design for the end effector was almost fully implemented in CAD, the nail gun mount and trigger were not yet designed. All parts of the CAD design had been ordered, printed, or manufactured [2].

4 End Effector Updates

4.1 Design

The first piece updated was the wrist mount, which is a 3D printed attachment that directly connects the end effector to the KUKA's mounting plate. When initially attempting assembly, the screws rested about ¾" above the surface of the wrist mount, making the connection to another bracket impossible. As a solution, the wrist mount was extended, and

countersinks were placed (Figure 3). This edit ensures the screws are underneath the top surface of the bracket, so the connecting bracket lies flush on the surface and connecting screws can be placed through the holes between the two.

Figure 3: Countersunk Wrist Mount

Since the thin slots in the wrist mount form a weak point, which could potentially snap and cause problems later, they will be connected instead by a solid block. As shown in Figure 4 below, the cutout is now one rectangle in the counterpart to the mount, and on the mount it is a rectangular prism extrusion with holes for the connection screws. For the bearing case, the existing CAD was duplicated and split into two halves, as shown in Figure 5. There are already built-in holes for screws to attach the two pieces.

Figure 4: Wrist Mount Updated CAD

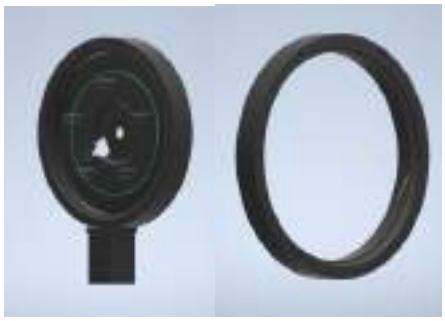

Figure 5: Bearing Case Updated CAD

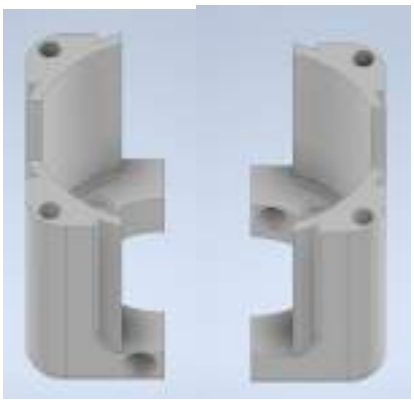
Redesign of the motor mount was also conducted which is challenging due to small tolerances, yet it still needs to be able to provide ample support for this motor and the attaching encoder. Figure 6 shows the redesign results which extended the previous mount design on both ends by ¼", and then split in half.

(1)

(2)

Figure 6: (1) Motor Mount CAD and (2) Halved Versions

In addition, two larger holes were added on the opposite sides of the motor mount for the shaft collar adjustment to be possible once the motor is mounted (Figure 7).



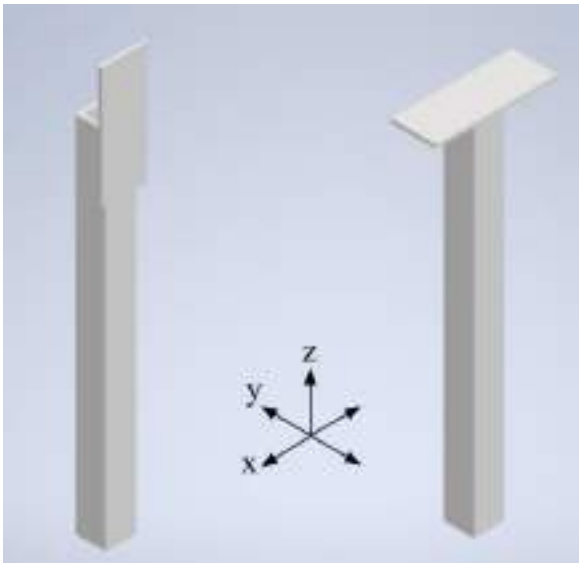


Figure 7: New Motor Mount CAD

The top innermost portion of the bearing case, known as eccentric bearing 2 in previous design [7], was too far off center to fit properly flush with the case due to the off-centered nature of the dovetail joint portion. The outer ring is cut down significantly to ensure its fit (Figure 8).

Figure 8: Updated Bearing

For the nail gun mount, the main concern was the amount of torque applied on the connected arm due to the kickback force when the nail gun is fired. We therefore designed the nail gun to be attached to a metal bar. This needs to be secure, because the kickback force when a nail gun is fired will apply a lot of torque on the rest of the system. Figure 9 below shows how the different mounting positions will affect the direction the kickback force is applied. For the option on the left, the force is dispersed throughout the metal bar, applying torque on the joint the bar is attached to. For the option on the right, the torque is applied directly on the mount for the nail gun and the bar itself. With a sturdy bar and mount, this would be the best option. Our prototype is currently being built with a hollow aluminum bar, which would most likely twist over time with continued use. For long-term solutions, a solid aluminum bar or a hollow steel bar would be good alternatives.

Orientation 1 Orientation 2

Figure 9: Mounting Positions

To address this kickback force issue, the forces were analyzed to determine which direction the torque should be applied to minimize the impact of the kickback force. In orientation 1, the rotational kickback force is applied along the xz plane, possibly bending the metal bar in that plane. In orientation 2, that force is applied along the xy plane, potentially twisting the metal bar in that xy plane. Because the metal bar is hollow, it needs additional support (not shown in figure) in both orientations to prevent damage with use. In orientation 1, this bracket would need to extend along a significant portion of the bar. However, with orientation 2, the bracket only needs to span the top portion (either covering a small portion of the sides or within the hollow bar) to prevent any twisting. Correspondingly, a design was created to mount in orientation 2, but it should be noted that the kickback force could shatter the bearing and might need to be addressed in another design update. This is currently partially addressed by the choices in manufacturing. Since the latest print is made in PLA+ filament instead of regular PLA, it can handle a relatively stronger torque being applied onto it, and with 60% infill and gyroid pattern infill, this has the

potential to be able to handle the forces applied in orientation 2.

For mounting the nail gun, the initial conceptual design is to put the nail gun in a fitted 3D printed box, and zip tie it tight.

The very first nail gun mount design is shown in Figure 10. It is a box slightly larger than the nail gun itself, (⅛" walls, inner box 2" x 9.5") for the gun to slide into with minimal wiggle room. In addition, there is a slot at the bottom of the box for the tip of the nail gun to sit in, and for nails to shoot out from.

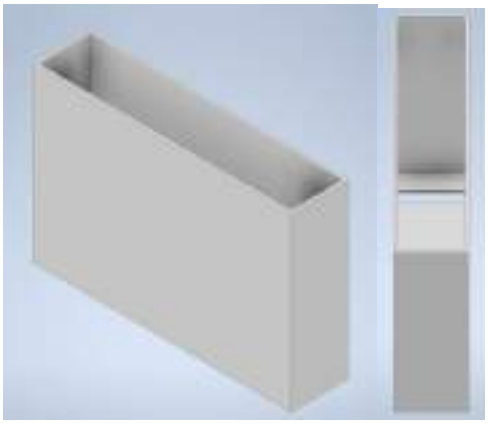

Figure 10: Nail Gun Initial CAD

The updates to the nail gun CAD are shown in Figure 11. For the update to the nail gun mount, 4 ¼" holes were added around the main handlebar for the nail gun. In addition, the slot previously in the design was changed to be a smaller centered hole, in the hope of minimizing any jitter by the gun affecting the aim of the nails, by having that extension of the nail gun more tightly slotted into place. Also, the back corner of the box was cut out just enough to be able to access the nail refill easily, without taking away much structural integrity from the mount.

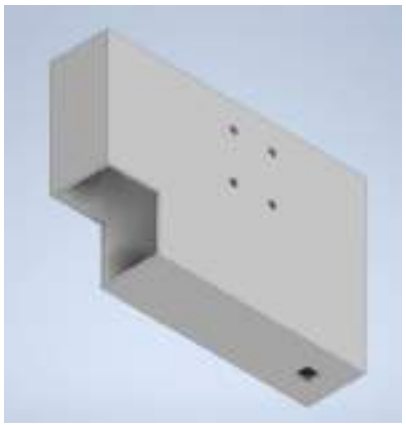

Figure 11: Nail Gun Updated CAD

By making the mount a flat sheet instead of a full box, it will be significantly easier, faster, and cheaper to build. After a few iterations, Figure 12 shows our final design. The updated nail gun CAD from Figure 11 was copied, and then cut to be the back plate only. More holes were then added for security of the nail gun.

Figure 12: Buildable Nail Gun Mount, Overlay

The nail gun selected has two triggers, as shown in Figure 13. The bottom trigger is a safety, and the trigger on top is for shooting the nail.

Figure 13: Nail Gun

4.2 Manufacturing

3D printing was used for manufacturing. When selecting the filament type, the goal was min/maxing cost/strength. PLA+ presented a good balance, so eSUN PLA+ 1.75mm in a 2.2lb spool was selected, because of its high tensile strength, comparable to that of POM filament but with a fraction of the cost. It is necessary to have high tensile strength on these prints given the amount of weight they will be carrying and the resultant gravitational force being placed, so regular PLA or ABS was passed.

With the PLA+ filament and 60% gyroid infill and supports where needed, the parts were printed (Figure 14).

Figure 14: Finished 3D Prints

In addition, during the 3D printing process, the distance between supports and the print was decreased. This does make the supports more difficult to remove and uses more filament, but it made the printing results significantly better than before so is worth the added effort. The difference between the two prints (white vs red, as shown in Figure 15) is the direction the lines were drawn (linear vs concentric, respectively). The white one came out with smoother finish and less cracking/holes, so it will be the one attached to the build.

Figure 15: Eccentric Bearing Reprints

4.3 Assembly

Once the prints were completed, an assembly of the end effector was attempted.

Figure 16: Elbow Arm Assembly

Figure 17: Motor Mount Assembly

Parts were sanded down in order to fit in their respected places due to a bit of filament scraps stuck on. For example, both wrist mount pieces have some sharp spots on the corners that were sanded down before sliding into place. The bearing case assembled is shown in Figure 18.

Figure 18: Partially Assembled Bearing Case

Figure 19: Motor Mount Too Thick

Figure 20: Current Assembly

5 Conclusions and Future Work

A partially functional prototype of a patented end effector for robotic automation in timber construction is assembled, new and updated parts are added onto the previous design, and a possible solution to the previously reported issue on the robotic arm is identified. For the future, the nail gun mount needs to be built and attached, and aluminum sheet can be used as its material. The electronic parts of the end effector then need to be connected. Once the end effector is fully assembled and connected, the KUKA arm is ready to be programmed with the teach pendant and tested for full functionality. For evaluation at that stage performance metrics include for example a 95% success rate of assembly of the wooden frames and no damage to the end effector after 20 heavy uses.

Abstract –

The identification of hazards is critical for mitigating accident risks on construction sites. Although current automatic recognition methods based on computer vision have demonstrated significant success, their performance can be limited by inadequate generalization capabilities and challenges in handling dynamic, complex scenes, leading to incomplete detection of various types of construction hazards. This study introduces a novel approach that leverages a tailored vision-language model (VLM) to enhance comprehensive hazard identification on construction sites. By capitalizing on the cross-modal understanding and robust generalization abilities of VLMs, this method aims to improve both the accuracy and comprehensiveness of construction hazard identification. To validate this approach, we constructed a specialized dataset comprising 1,139 images across 31 fine-grained categories of construction hazards for fine-tuning and evaluation. The experimental results revealed that, when fine-tuned on the Qwen2-VL-7B model, the VLM achieved a precision of 0.856, representing a substantial improvement from 0.495 precision in the non-fine-tuned state. Moreover, fine-tuning significantly reduced prediction errors and enhanced the model's capability to understand and identify construction hazards. In addition, advanced VLM models demonstrate greater application potential compared to traditional models such as CLIP. This study advances the accuracy and comprehensiveness of hazard identification on construction sites, offering a new technological perspective for integrated automatic hazard detection in construction environments.

1 Introduction

There is a wide variety of hazards on construction sites, such as workers not wearing safety helmets and electrical wires submerged in water, which constitute major factors leading to construction safety accidents [1,2]. To mitigate these risks, traditional construction safety management has relied on the Behavior-Based Safety (BBS) approach, centered around human inspections and timely corrections [3]. However, with the rapid advancement of artificial intelligence technology, especially in computer vision, and the development of advanced construction site monitoring systems utilizing cameras [4,5], automated methods for detecting safety hazards have begun to emerge. These methods, for example, checking compliance with personal protective equipment (PPE) [6], monitoring workers' access to hazardous areas [7], and ensuring the orderly stacking of construction materials [8], have demonstrated efficacy. Despite this progress, most existing methods are limited to identifying a small number of hazards and fail to consider multiple hazard factors in an integrated manner. Moreover, because model training depends on labeled data, it limits the models' generalization capabilities and hinders their adaptation to unseen, complex dynamic scenes [6]. Consequently, there remains a critical need for a method that can accurately and comprehensively recognize various types of construction hazards through advanced scene understanding and perception, particularly within the complex and dynamic construction environments.

With the development of pre-trained vision-language model (VLMs), such as CLIP [9]，BLIP [10]，LLaVA [11], significant progress has been made in understanding and generating textual descriptions associated with images. These models provide richer and more detailed insights by accumulating robust image and text feature representation capabilities through pre-training on large-scale datasets. Compared to traditional computer vision methods, VLMs exhibit higher robustness and generalization capabilities when handling complex scenes [12]. Additionally, the self-supervised learning mechanism of VLMs allows them to acquire knowledge from unlabeled data, thereby reducing reliance on manually labeled data [13].

Therefore, the application of VLMs in construction

management holds great promise. In past studies, Yong et al. [14] utilized BLIP to identify ergonomics issues and their solutions with the aid of data augmentation. The study by Liang et al. [15] demonstrated the potential of using CLIP for few-shot learning to classify construction site objects, achieving an increase in classification accuracy from 58.33% to 83.33% with only one sample for training. For construction safety management, Tsai et al. [12] automatically generated construction safety observations by fine-tuning CLIP, attaining an average accuracy of 73.7% across nine types of violations. However, the proposed hazard identification methods generate caption content that requires professionals to judge the construction hazard categories, rather than directly outputting violation categories from the input images. Moreover, construction sites present a variety of complex hazards, such as unguarded rotating parts of machinery, necessitating more specific and fine-grained hazard identification capabilities. Traditional VLMs, like CLIP , show limited advanced language comprehension and understanding of complex scenarios [16]. It needs to be combined with other language models to generate the corresponding textual content [12]. Therefore, research gaps still exist in the end-to-end construction hazard identification and reporting process, which requires sophisticated visual reasoning capabilities. This highlights the need to explore and apply more advanced VLMs, such as the pre-trained Qwen2-VL [17], to address these challenges.

Therefore, to address the limitations and achieve more specific, fine-grained identification of construction hazard categories, this study proposes an end-to-end construction safety hazard recognition framework based on a fine-tuned VLM. This framework leverages the advanced image comprehension and reasoning capabilities of pre-trained VLMs to identify construction site safety hazards. The main contributions of this paper are as follows: (1) constructing a dataset with 31 fine-grained categories of construction hazards for fine-tuning and evaluating the hazard identification model; (2) demonstrating the effectiveness of advanced VLMs and fine-tuning methods in construction hazard identification; and (3) implementing an automated end-to-end process for construction site hazard inspections.

2 Methodology

Figure 1 illustrates the proposed framework, which comprises three principal components. Firstly, dataset construction: this stage involves collecting and annotating a series of image data related to construction hazards, serving as the foundation for fine-tuning the VLM. Secondly, VLM fine-tuning process: we utilize an advanced open-source pre-trained VLM and apply advanced fine-tuning techniques to optimize the model using the constructed construction hazard dataset. The performance of the fine-tuned model is subsequently evaluated using a test set. Lastly, deployment for construction hazard identification: the validated and optimized model is deployed at construction sites, leveraging real-time image data streams from CCTV systems to enable immediate monitoring and identification of construction hazards. Detailed descriptions of these three critical stages are provided in the following sections.

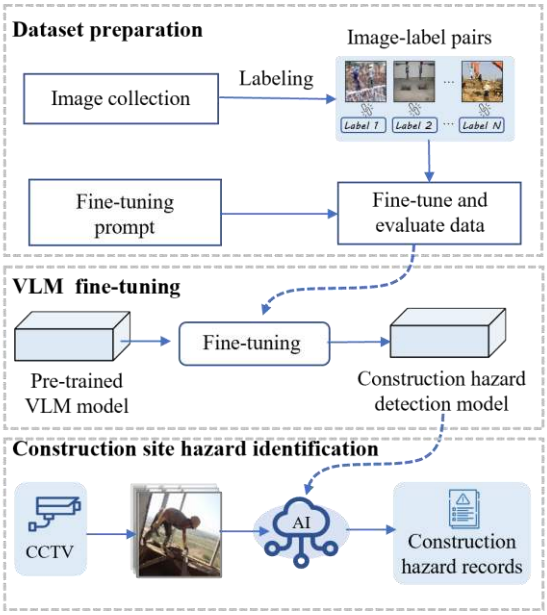

Figure 1. The framework of the proposed method

2.1 Dataset preparation

In BBS-based management, construction hazards encompass not only the use of workers' PPE but also other aspects, such as the utilization of construction tools and equipment. Based on the previous research by Chen et al. [3], Lee et al. [18] and practical experience from construction sites, this study has systematically identified common construction hazards, categorizing them into 31 fine-grained categories as presented in Table 1. Overall, Table 1 includes violations related to PPE wearing, the status of construction equipment, and the construction environment. Subsequently, based on the categories of construction safety hazards outlined in Table 1, we gathered images representing various types of construction hazards. The majority of these images were sourced from historical inspection records of construction projects. These hazard inspection logs contain images and detailed descriptions of the hazard categories. However, given the limited availability of historical inspection data, we supplemented images with publicly available datasets containing construction site images, such as CPPED [6] and image data collected

from the Internet. Subsequently, we conducted a filtering process for all images, which involved verifying their relevance to construction site scenarios and removing low-quality or blurry images. As a result, we assembled a dataset comprising 1,139 high-quality construction hazard images.

Table 1. 31 categories of construction hazards

No.	Construction hazards
H01	Not wearing safety helmets
H02	Wearing a safety helmet but not fastening the chin strap
H03	Not wearing safety vests
H04	Not wearing protective shoes
H05	Workers not wearing gloves during operations such as handling materials.
H06	Workers performing high-altitude work without wearing safety harnesses or improperly securing the harness hooks
H07	Illegally climbing over safety railings or barriers
H08	Debris piled on scaffolding
H09	Construction machinery illegally transporting or hoisting construction workers
H10	Workers smoking at the construction site
H11	Entering the operating range of an excavator
H12	Unauthorized use of open flames
H13	Rotating parts of machinery lack guards
H14	Crane operations without setting up safety warning lines around the crane
H15	Gas cylinders lacking protection
H16	Hooks missing safety pins
H17	Edge protection barriers not installed or having gaps
H18	Openings and shafts lack protective measures
H19	Guardrails not installed at open edges of staircases
H20	Distribution boxes left with doors open
H21	Distribution boxes not elevated (in contact with the ground)
H22	Electrical wires not elevated (laid directly on the ground) or poorly organized
H23	Unauthorized use of plug-in boards
H24	Electrical wires submerged in water
H25	Standing water present at the construction site
H26	Lack of clearance for construction waste
H27	Construction materials piled disorderly
H28	Temporary passageways at the construction site insufficiently stabilized or lacking safety measures
H29	Safety nets on exterior scaffolding damaged
H30	Dust prevention nets damaged
H31	Gaps existing in the perimeter fencing

According to the predefined categories, we categorized these images, ensuring that each image represented at least one category during the annotation process. The data annotation process is subject to standardized quality control measures, including cross-check inspections by annotators and final approval by experienced construction safety managers, to ensure the reliability of the dataset. Samples of hazard images and corresponding labels are illustrated in Figure 2.

In order to verify the performance of fine-tuned VLMs, a portion of the data from the dataset is extracted for testing, ensuring that the number of labels in each category within the test set is not less than 8. The stratified sampling method is used to divide the dataset into a test set and a training set in a 3:7 ratio. The final proportion of each label in both the training set and the test set is shown in Fig. 3. Subsequently, we generate the final datasets for both the training and test sets using designed VLM fine-tuning prompt as illustrated in Fig. 4

Figure 4. Prompt for VLM fine-tuning

2.2 VLM fine-tuning

Fine-tuning a VLM is a process that adapts a pre-trained VLM to a specific task or domain. Initially, the pre-trained model undergoes extensive training on a large-scale dataset, enabling it to learn general feature representations. Subsequently, during fine-tuning, the model leverages task-specific data to enhance its performance on specialized tasks and improve its generalization capabilities in targeted applications. Through this adaptation, the fine-tuned VLM can better address the unique challenges of specific domains. To enhance the model's performance in construction hazard identification, further fine-tuning is necessary to improve the VLM model's understanding of construction-specific scenarios. Low-rank adaptation (LoRA) [19] stands out as an effective fine-tuning strategy that addresses challenges posed by traditional computer vision methods, such as overfitting. Figure 5 compares the direct use of pre-trained weights with the LoRA-based fine-tuning process. As illustrated in Figure 5, LoRA's core principle involves updating only a select subset of parameters deemed most crucial for the new task. Specifically, LoRA achieves parameter updates by incorporating low-rank matrices into the pre-trained model, rather than directly altering a vast number of original parameters. This method not only reduces the number of parameters requiring training, thereby lowering computational expense, but also aids in preserving the pre-trained model's knowledge and mitigating catastrophic forgetting.

In LoRA, the original weight matrix W is updated to $W = W_0 + AB$, where W_0 denotes the pre-trained VLM weights, and AB represents the product of matrices A and B. Here, A and B are designed to be low-rank matrices with rank r, which allows for minimal changes to W_0 while enabling efficient fine-tuning. The result of this multiplication is a low-rank matrix that is added to the original weights to form the new weight matrix. During the fine-tuning process, the objective is to adjust these parameters by minimizing the loss function $L(\theta, A, B)$ on the target task, which is formulated as follows:

$$L(\theta, A, B) = \sum_i \ell(f(x_i; W_0 + AB), y_i), \quad (1)$$

where θ represents the other parameters, x_i denotes the i-th sample of the input data, and y_i denotes the true label of the i-th sample. By precisely tuning the model parameters, LoRA enables the VLM to more effectively understand and predict various safety hazards in construction sites, thereby providing robust technical support for safety management and risk prevention.

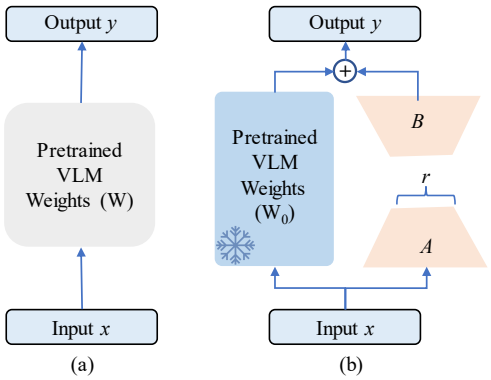

Figure 5. Comparison of two data processing workflows: (a) direct use of pre-trained weights, (b) LoRA-based fine-tuning process

2.3 Construction site hazard identification

The fine-tuned VLM is deployed on the server side, as illustrated in Fig. 1. The system interfaces with a CCTV monitoring system at the construction site to acquire live or stored video streams. To optimize computational efficiency and reduce processing load, key frames are selected at fixed time intervals. For each extracted frame, the VLM extracts rich visual features and semantic information relevant to the construction scene.

Based on these extracted features, the VLM classifies images to identify whether they contain categories of construction hazards that require inspection, as outlined in Table 1. Identified hazards, along with associated metadata such as location, type, and timestamp, are aggregated into a hazard identification dataset. Leveraging an LLM, the system can automatically generate a structured report on construction hazards based on this aggregated data. The report includes detailed textual descriptions, and relevant image evidence may be embedded to facilitate a more intuitive understanding for site managers of the conditions. Through this process, the fine-tuned VLM significantly contributes to real-time monitoring and alerting of potential hazards on the construction site, thereby enhancing the smart level of safety management.

3 Experiment and Result

3.1 Experiment setup

Based on the constructed construction hazard dataset, this study employs the LoRA technique to fine-tune the

VLM. Specifically, two different parameter-size versions of Qwen2-VL are selected for this purpose: a 2-billion-parameter model and a 7-billion-parameter model. Specialized fine-tuning and validation experiments are conducted for both versions. During the testing phase, Qwen2.5-32B LLM is utilized to assist in evaluating the match between the fine-tuned VLM predictions and the actual labels. This evaluation ensures that the VLM's performance is accurately assessed and optimized for real-world applications.

To establish an effective benchmark for comparison, the CLIP model with ViT-B/32 as the image encoder is used as a baseline for classifying construction hazard images. The process involves fine-tuning the CLIP model using image-label pairs from the training dataset. During the validation phase, similarity scores are calculated between the images in the test set and all possible hazard labels. If the similarity score exceeds a predefined threshold d, the corresponding label is considered a prediction, thereby evaluating model performance. This approach aligns with the methodology proposed by Chen et al. [20].

For evaluating the models' performance, a series of widely accepted evaluation metrics are applied. Precision (the proportion of correctly identified positive samples among those predicted as positive), recall (the proportion of actual positives which are correctly identified as such), and F1-score (the harmonic mean of precision and recall) are calculated for each category using the following formulas:

$$Precision = \frac{TP}{TP + FP}, \tag{2}$$

$$Recall = \frac{TP}{TP + FN}, \tag{3}$$

$$F1\ score = 2 \cdot \frac{Precision \cdot Recall}{Precision + Recall}, \tag{4}$$

where TP = True Positives, TN = True Negatives, FP = False Positives, and FN = False Negatives. Additionally, the F2 score (β = 2) is introduced to emphasize recall, focusing more on minimizing missed identifications. It is calculated using the following formula:

$$F2\ score = (1+\beta^2) \cdot \frac{Precision \cdot Recall}{(\beta^2 \cdot Precision) + Recall}. \tag{5}$$

This is critical given the serious consequences of safety accidents at construction sites. The F2 score places greater weight on recall compared to precision, ensuring that fewer potential hazards are overlooked. Moreover, Cohen's Kappa coefficient is used to measure the agreement between observed and expected consistency, applying the formula:

$$\kappa = \frac{p_o - p_e}{1 - p_e}, \tag{6}$$

where p_o is the observed proportion of agreement and p_e is the expected probability of random agreement [21]. This coefficient verifies whether the model predictions significantly outperform random guessing, thereby increasing confidence in the model's reliability. A Cohen's Kappa coefficient value close to 1 indicates almost perfect agreement, suggesting that the model significantly outperforms random chance. In contrast, values near or below 0 indicate agreement no better than, or even worse than, what would be expected by random chance, highlighting potential limitations in the model's ability.

3.2 Result

As illustrated in Figure 6, the performance of the fine-tuned Qwen2-VL-2B and Qwen2-VL-7B models in identifying construction hazards as a function of Epoch is depicted. The figure demonstrates that, at the outset (Epoch = 0), prior to fine-tuning, both models exhibit lower precision, recall, and F1 scores. As the number of Epochs increases, there is a marked improvement in model performance. Specifically, the precision for both the Qwen2-VL-7B and Qwen2-VL-2B models rises from approximately 0.4 to around 0.8 following fine-tuning. The comparison with their no fine-tuning performance can be seen in Table 2. Notably, the fine-tuned Qwen2-VL-7B model achieves a precision of 0.856 by the 9th Epoch, while the fine-tuned Qwen2-VL-2B model reaches a precision of 0.818 by the 27th Epoch. Similarly, recall values for both models increase from about 0.2 to approximately 0.6, and F1 scores rise from roughly 0.2 to nearly 0.7. These observations indicate that fine-tuning significantly enhances the models' ability to identify construction hazards. Furthermore, it is evident from the figure that, in their initial state, the Qwen2-VL-7B model in recall and F1 score outperform the Qwen2-VL-2B model. However, as the number of fine-tuning Epochs increases, the performance gap between the two models narrows, suggesting that with sufficient fine-tuning, the smaller model can achieve performance comparable to that of the larger model. This finding underscores the importance of fine-tuning strategies in optimizing model performance, highlighting that even smaller-scale models can attain significant improvements when subjected to effective fine-tuning procedures.

The loss curve depicted in Figure 7 illustrates the trend of the loss value as a function of epochs during the training process of the CLIP model. Initially, the loss value is relatively high but gradually decreases over time before eventually plateauing. Meanwhile, the recall curve remains close to 1 for most of the training period, indicating near-perfect identification of positive samples

by the model. However, it exhibits a decline in later stages, suggesting that the model's ability to accurately identify positive samples diminishes over extended training. Despite undergoing fine-tuning, the CLIP model does not demonstrate significant improvements in precision or F1 score, as shown in Table 2. The consistently low precision indicates that the model struggles to effectively differentiate construction hazards, while the low F1 score reflects an overall deficiency in balancing precision and recall. This suggests that the model fails to fully comprehend and accurately distinguish the various features associated with construction hazards. Therefore, when applied to the task of recognizing construction hazards, the pre-trained CLIP model, despite achieving high recall, exhibits limitations in enhancing precision and the F1 score.

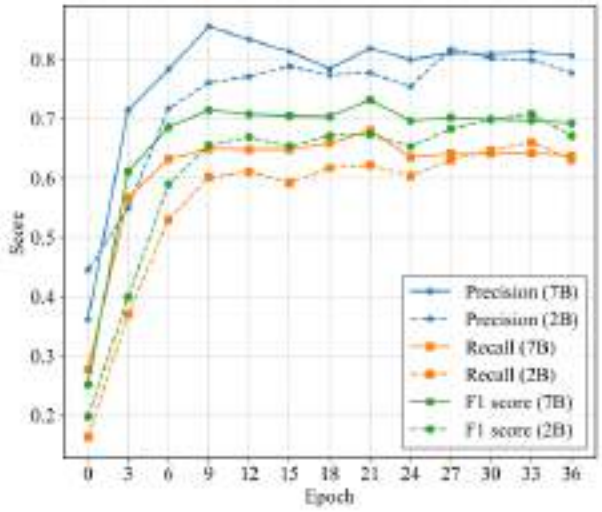

Figure 6. Comparison of Qwen2-VL-2B and 7B's construction hazard identification performance as a function of Epoch

Table 2 also presents the F2 scores and Cohen's Kappa coefficients for various models. The table compares two primary models: CLIP (ViT-B/32), and Qwen2-VL in both 2B and 7B, each evaluated in terms of their pre-trained and fine-tuned performance on the test dataset. For the CLIP model using the ViT-B/32 as the image encoder, both the F2 score and Cohen's Kappa coefficient remain nearly unchanged, even after fine-tuning, indicating that the fine-tuning process did not yield significant improvements for this model. In contrast, the Qwen2-VL models exhibit substantial gains following fine-tuning. Initially, the Qwen2-VL-2B has an F2 score of 0.186 and a Cohen's Kappa of 0.118, which significantly improves to an F2 score of 0.661 and a Cohen's Kappa of 0.613 after fine-tuning. Similarly, the Qwen2-VL-7B starts with an F2 score of 0.290 and a Cohen's Kappa coefficient of 0.194, which then increases to an F2 score of 0.683 and a Cohen's Kappa of 0.600 after fine-tuning, with respective increases of 0.393 and 0.406. These results underscore the effectiveness of fine-tuning in enhancing the performance of the Qwen2-VL models, particularly in terms of improving both precision-recall balance.

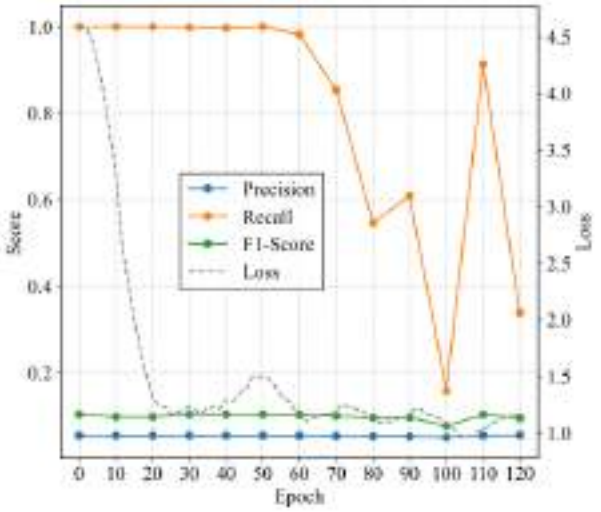

Figure 7. Performance and loss curves for construction hazard identification based on fine-tuned CLIP as a function of Epoch

Table 2. Performance comparison of different models before and after fine-tuning

Models		Precision	Recall	F1 score	F2 score	Cohen's Kappa coefficient
CLIP	ViT-B/32	0.055	**1.0**	0.104	0.225	0
	ViT-B/32 (Fine-tuned)	0.055 (+0.0)	0.999(-0.001)	0.104(+0.0)	0.225(+0.0)	0(+0.0)
Qwen 2-VL	2B	0.445	0.163	0.198	0.186	0.118
	2B (Fine-tuned)	0.818 (+0.373)	0.631 (+0.468)	0.683 (+0.485)	0.661 (+0.475)	**0.613** (0.495)
	7B	0.361	0.277	0.252	0.290	0.194
	7B (Fine-tuned)	**0.856** (+0.495)	0.650 (+0.373)	**0.715** (+0.463)	**0.683** (+0.393)	0.600 (+0.406)

Note: Values in parentheses indicate the change after model fine-tuning compared to before.

The effectiveness of the proposed method in identifying construction safety hazards is illustrated using real-world images extracted from an actual construction site video, with one of the extracted images shown in Figure 8. The selected construction site is a stockpile area, where our approach demonstrates its capability to accurately detect potential construction hazards present in the images and generate corresponding hazard reports for further documentation. This application highlights the practical utility of our method in a real-world setting, showcasing its ability to provide reliable hazard identification. Such improvements are crucial for preventing accidents and ensuring worker safety, thereby underscoring the significant impact and value of this method in advancing construction site management.

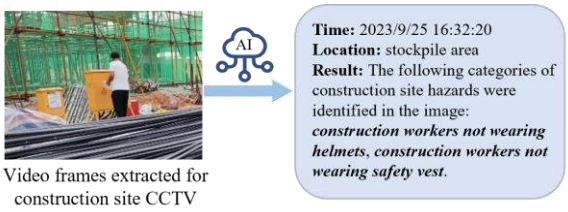

Figure 8. A case of identifying construction hazards

4 Discussion and Conclusion

This study introduces a fine-tuned VLM designed to comprehensively identify safety hazards on construction sites. Specifically, our work encompasses the following aspects: (1) we developed a specialized dataset for construction hazards, classifying 31 types of common hazards at a fine-grained level. (2) we demonstrated the effectiveness of using pre-trained VLMs and fine-tuning techniques for identifying construction hazards. Additionally, we compared the performance differences among various pre-trained VLMs in the context of construction hazard identification. (3) we implemented an automated end-to-end process for construction site hazard inspections, ranging from image acquisition to report generation, thereby enhancing the automation level of construction management.

The experimental results indicate that the fine-tuning process significantly enhances the VLM model's ability to handle complex and dynamic scenarios, improving its generalization capability and robustness. Through enhanced cross-modal understanding, the precision of the fine-tuned Qwen2-VL-7B reaches 0.856, marking a substantial improvement from 0.495 precision in the non-fine-tuned state. The use case of real-world site videos further demonstrates its future application potential in construction management, such as being deployed on robotic dogs or drones to facilitate the development of automated construction hazard inspections.

Moreover, the limitations of traditional VLMs in comprehending construction scenarios underscore the necessity for advanced VLM modeling applications. Our study also revealed that even VLM models with fewer parameters can achieve recognition results comparable to those of larger VLM models when appropriately fine-tuned. This insight suggests that future research should focus on developing specialized, compact models to achieve high-precision construction hazard recognition while using minimal computational resources.

Although the proposed method has shown promising performance, there are two limitations. First, we conducted a preliminary application on a real construction site to assess its usability. However, this case study was limited in scale and environmental control, warranting future systematic validation. Moreover, the study not analyse the model's performance for each category, further investigation, particularly in exploring the model's robustness, few-shot learning capabilities, and speed comparisons will conduct in future work.

Abstract

The construction sector has long faced low productivity relative to other industries. Modular and off-site construction (MOC) offers a promising solution by assembling modules in a controlled facility environment and benefiting from repetitive nature of operations and the ability to conduct processes simultaneously. These features increase process flow continuity and enhance productivity across the life cycle. However, MOC has not yet realized its full potential, mainly due to the influence of conventional construction mindsets and the ineffective integration of lean practices, leading to process disruptions and persistent waste throughout the life cycle. To address this, a process-oriented performance evaluation (PE) model is introduced, using system dynamics to model life cycle processes and the existing interactions among different life cycle stages. This approach systematically evaluates life cycle productivity by accounting for the state of utilized resources (workers and workspace) and employing proposed MOC key performance indicators (MOC-KPIs) to identify the root causes of process waste with respect to resources utilization.

Keywords

Off-site construction, Key performance indicators, System dynamics, Productivity evaluation, Process waste.

1 Introduction

Over the past two decades, global construction productivity has remained stagnant, increasing by only 10% (0.4% annually) between 2000 and 2022, while the global economy and manufacturing sectors grew by 50% and 90%, respectively. Productivity further declined by 8% between 2020 and 2022, causing significant value loss, project delays, and cost overruns [1]. Despite rising demand for housing, the industry struggles with workforce shortages, escalating costs, and affordability challenges. Rising inflation and interest rates have exacerbated the disparity between housing costs and incomes, with homeownership now consuming up to 54% of household income in Canada [2]. Improving life cycle productivity is critical to addressing these challenges and enhancing housing availability. MOC, which shifts traditional on-site activities to controlled off-site environments, offers potential solutions by adopting lean manufacturing principles. It aims to boost productivity, quality, safety, and cost efficiency [3, 4]. However, MOC adoption remains limited, holding only 6.03% market share in 2022, and faces challenges such as high installation and transportation costs and inefficient lifecycle performance [3]. Many stakeholders report higher-than-expected costs compared to conventional methods, limiting MOC's ability to achieve widespread cost reductions and productivity improvements [5, 6].

MOC leverages lean manufacturing principles to reduce costs, minimize waste, and maintain quality. While research has demonstrated its potential in applications like high-rise buildings and manufactured housing [8], MOC often fails to fully benefit from lean practices. Conventional methodologies and fluctuating market demands requiring complex customization have hindered its adoption, leaving processes dominated by traditional construction mindsets [9]. These issues result in unbalanced lifecycle workflows and inefficiencies unique to MOC, such as repetitive operations and simultaneous activities across workstations. Current PE tools like the Balanced Scorecard, conventional construction KPIs, and Earned Value Management fail to effectively assess MOC projects [10]. Their limitations include poor tracking of concurrent activities, inadequate resource utilization assessment, inability to identify waste causes, and failure to address logistics challenges critical to MOC's success. These gaps impede precise PE and hinder the industry's shift toward more efficient, lean-driven practices. This paper introduces a process-oriented PE approach, using System Dynamics Modeling (SDM) to assess MOC lifecycle productivity through proposed MOC-KPIs in order to identify the root causes

of process waste. SDM is a simulation-based approach used to understand and analyze complex systems over time. It employs feedback loops, stock-and-flow structures, and time delays to model real-world processes dynamically. The approach involves three key steps: (1) proposing KPIs to analyze resource utilization and identify process waste; (2) developing an SDM simulation to map MOC lifecycle dynamics and evaluate current-state life cycle productivity; and (3) testing intervention scenarios to validate the KPIs' effectiveness in identifying waste and improving life cycle process efficiency.

2 Literature Review

2.1 Measuring progress in conventional construction

Progress measurement involves quantifying the effectiveness and efficiency of actions to assess a project's current state [11]. As projects grow in size and complexity, they require more resources, generating vast amounts of data [12]. To obtain accurate performance outcomes, it is essential to analyze this data using specific indicators to identify root causes of problems promptly [14]. KPIs play a crucial role in improving project efficiency by supporting decision-making, identifying areas for improvement [15]. Literature reveals that KPIs in construction and related fields (e.g., manufacturing, road transportation) often focus on sustainability and productivity [16, 17]. These efforts primarily introduce new indicators for PE in areas such as time and cost. Mellado et al. [18] ranked commonly used KPIs, while Orgut et al. [11] identified factors to enhance project control reliability at different phases of the construction lifecycle. Habibi et al. [19] also explored phase-based KPIs and their impact on cost and schedule. However, due to the project-oriented nature of conventional construction, KPIs vary significantly between projects, making performance comparisons and future forecasts challenging. Efforts to reduce inefficiencies on construction sites have led to the development of various performance metrics to improve progress measurement [20, 21].

Furthermore, conventional KPIs related to lean manufacturing, road transportation, and on-site construction, focusing on productivity and process flow, are investigated. For example, KPIs include defect per unit which tracks errors in products, aiming to reduce rework and scrap costs [22]; overall equipment effectiveness that measures manufacturing equipment efficiency to enhance productivity [22]; loading/unloading time, focusing on minimizing delays in transportation operations [7, 13]; and on-site rework rate which measures defects and reworks during construction to minimize delays and the related costs [23, 24]. However, these KPIs may not fully address the unique needs of MOC projects, such as work sequence and resource flow, and may overlook key factors like laydown area availability. They may also struggle to accommodate MOC's dynamic nature, where disruptions in manufacturing (e.g., material shortages) affect on-site installation. Additionally, they may not pinpoint root causes of waste (e.g., rework due to module misfit or damage during shipment) or provide a complete view of resource allocation, especially for tasks like module repairs. Furthermore, traditional road transportation KPIs often fail to capture transportation processes across the MOC life cycle, such as the duration modules spend in staging areas before shipment.

2.2 Evaluating productivity in MOC

Effective resource planning is essential in construction management to meet project constraints and maintain process flow, as its absence can lead to productivity losses [25]. Concepts such as optimal-size capacity buffers and multi-skilled resources have been proposed to improve flexibility and productivity [25, 26]. Using multi-skilled resources enhances process integration and production efficiency [26]. Arashpour et al. [27] examined various cross-training strategies in MOC, finding they address capacity imbalances and time variability, measured by indicators like throughput rate and cycle time. However, these strategies are costly due to workforce turnover and resource availability [28].

Arashpour et al. [28] proposed a customized methodology for tracking the MOC production workflow, using discrete event simulation (DES) to reveal that production output is nonlinear due to variability in the MOC environment. To address this, they recommended setting a capacity buffer rather than aligning production targets with capacity. Manouchehri [29] applied a dynamic productivity model using SDM to MOC, estimating productivity in labor cost per ton of module installed on-site. By modeling the impact of performance factors (e.g., waiting times for transit) through causal loop diagrams and Stock and Flow diagrams, the model predicted future productivity and provided more accurate estimates for integrated project phases. Wang et al. [30] proposed an optimization model for the precast concrete component production line, incorporating lean production theory and Value Stream Mapping (VSM). They developed current- and future-state value maps and introduced KPIs such as delivery cycle, value-added time ratio, number of personnel, and production line balance rate. The model demonstrated improvements in production line balance, reduced delivery cycle, decreased value-added time ratio, and fewer workers. Similarly, Garza-Reyes et al. [17] developed a methodology combining time-based study, DES, and

trial and error to optimize line balancing in manufacturing. The study identified workload distribution and process flow performance, with DES models assessing different scenarios to determine the optimal balance. They introduced the "balancing loss" indicator to measure idle time, achieving reductions in balancing losses ranging from 1.82 to 36.32 percent. The KPIs developed for MOC are listed in Table 1.

Table 1. Overview of existing KPIs for assessing productivity and resource allocation in MOC

MOC Phase	MOC KPI
Manufacturing	Workforce density
	Workload density
	Production line balance rate
	Value-added time ratio
	Balancing loss

In reviewing previous studies, several key gaps were identified in the evaluation of MOC performance: (1) Many studies relied on conventional construction KPIs that fail to account for the unique workflow and sequencing of MOC, leading to ineffective assessments of productivity and resource utilization; (2) Most studies focused solely on the manufacturing phase, neglecting the integrated nature of MOC across all life cycle stages; (3) They often overlooked on-site installation dynamics, such as site-specific constraints; (4) The interaction between life cycle processes, like delays in module quality inspections affecting on-site installation, was not adequately considered; (5) There is a lack of methodologies that compare actual performance with predefined benchmarks, hindering performance comparisons across projects; and (6) Existing methods, like VSM, do not effectively address concurrent activities or identify root causes of inefficiency in MOC life cycle performance. Given the differences between off-site and on-site construction methods, MOC should be treated as a process-oriented approach, leveraging repetitive operations throughout its life cycle. As a result, the literature supports the need for a dedicated PE framework for MOC, which should: (1) adopt a process-oriented approach that supports repetitive operations and the distinct flow of MOC processes; (2) incorporate MOC life cycle and resource leveling to identify waste and improve efficiency; and (3) include KPIs to assess MOC life cycle performance.

3 Proposed Method

This paper introduces a process-oriented approach to systematically evaluate the MOC life cycle productivity (MOC-LCP), using proposed MOC-KPIs. The approach aims to help production managers efficiently identify root causes of process waste related to resource utilization (e.g., workforce and workspace). As illustrated in Figure 1, the methodology involves three key steps: (1) developing MOC-KPIs tailored to various life cycle phases to measure resource utilization (e.g., workforce); (2) creating a simulation model integrated with these KPIs to assess life cycle productivity while considering resource allocation; and (3) run intervention scenarios using the simulation model to analyze the effectiveness of the proposed MOC-KPIs in identifying root causes of waste.

3.1 MOC-KPIs proposal

The proposed MOC-KPIs enable a detailed analysis of resource utilization to identify inefficiencies and the root causes of process waste. Grounded in lean principles, the approach aims to enhance life cycle efficiency through continuous improvement and waste minimization, transforming MOC into a more efficient and cost-effective construction method. While tools like VSM offer useful metrics for performance measurement [9], they have notable limitations: (1) an incomplete set of metrics for systematically assessing life cycle performance; (2) an inability to capture complex interdependencies among life cycle processes, such as the ripple effects of delays across stages; (3) insufficient capacity to model and analyse parallel workflows that require precise coordination (e.g., interactions between manufacturing and site operations); and (4) limited capability to guide investigations into root causes of waste (e.g., rework) to improve the efficiency and effectiveness of operations, particularly regarding resource utilization (e.g., workforce and workspace).

To propose KPIs aligned with the MOC life cycle processes, the delivery flow of a single module at the MOC system level was analyzed. A detailed process flow was constructed using insights from MOC literature, published MBI reports, and interviews with industry professionals (e.g., Stack Modular, MODLOGIQ, Smart Modular Canada). However, the MOC life cycle process is prone to disruptions that introduce significant waste, hinder operational efficiency, and increase resource utilization, thereby reducing MOC-LCP and escalating project costs. To address these challenges, MOC-KPIs are essential for identifying, measuring, and diagnosing the root causes of process waste. They enable recognizing issues, quantifying their impact, and analyzing contributing factors, facilitating the timely detection of inefficiencies. This improves resource utilization across life cycle stages, streamlines process flow, and supports continuous improvement. Ultimately, these efforts enhance MOC-LCP and lower overall project costs.

The proposed KPIs include workflow interruption (WFI), module defect modification (MDM), module quality inspection release (MQIR), staging area

occupancy (SAO), at-factory module loading (AFML), module travelling time (MTT), shipment damage inspection (SDI), module lift handling (MLH), module in-place alignment (MIPA), module connection work (MCW), and site-fit rework (SFR).

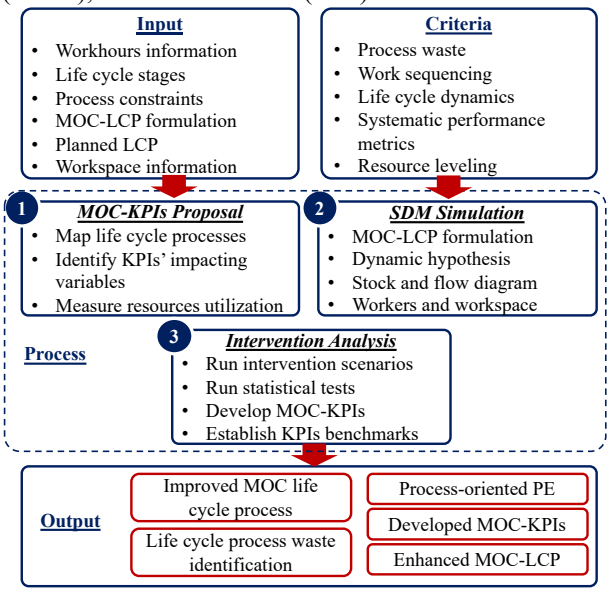

Figure 1. MOC-LCP evaluation process

3.2 SDM Simulation

Simulation is recognized as an effective technique for tasks such as productivity assessment and resource planning. However, before developing a life cycle simulation model, it is essential to formulate an equation capable of efficiently estimating current-state productivity in MOC. The MOC-LCP is represented by Equation 1.

$$MOC - LCP = \frac{S_{inst}}{T_{MOC}} \quad (1)$$

Where S_{inst} = surface area of all modules installed on-site per square feet; T_{MOC} = total MOC project spent workhours.

Additionally, further literature review was conducted to identify factors influencing the proposed KPIs and constraints affecting module delivery within the modular project life cycle. Further, SDM is used which is an efficient tool that enables evaluating a system's ability in coping with the incurred changes (i.e., most-contributing KPIs functionality), while examines new scenarios that could be implemented within the system's environment (i.e., life cycle process) for the sake of effective decision-making process (i.e., identification of root cause of process waste with respect to resources utilization). To better understand the interrelated processes within the MOC life cycle and visually depict the dependencies among various KPIs and their parameters, a causal loop diagram of the module delivery process flow model is developed [20]. (Figure 2).

Moreover, building on the established CLD, a stock and flow diagram (SFD) is subsequently formulated. It is divided into five interconnected sub-SFDs to model process of module (*i*) manufacturing, including module assembly and quality inspection; (*ii*) transportation; (*iii*) on-site installation; and (*iv*) MOC-LCP assessment. To effectively represent the dynamic relationships among various life cycle processes, additional key components and their interactions are integrated into the SFD diagram. These relationships are articulated through mathematical equations and a set of defined rules.

3.3 Intervention Analysis

The objective of scenario analysis is to evaluate the impact of various interventions on a system's KPIs [25]. This involves several key steps: (*i*) identifying interventions and their boundaries, with the proposed MOC-KPIs serving as response variables, and employing the developed and validated SDM to examine the behavior of MOC-KPIs under each scenario; (*ii*) performing statistical tests to assess whether the interventions significantly affect overall life cycle performance, explore relationships among the proposed MOC-KPIs, evaluate the combined effects of interventions, and test hypotheses regarding the impact of each intervention on individual MOC-KPIs; and (*iii*) analyzing MOC-KPIs' behavior across different interventions to verify which one efficiently identifies root causes of process waste within each phase of the MOC. To conduct intervention analysis, various scenarios, as shown in Table 2, were identified through literature review and interviews with MOC experts.

Table 2. Scenarios studied for intervention analysis

Intervention type	Intervention scenario
Manufacturing (assembly and quality inspection)	S1: Ramp up module production S2: Apply overtime policy S3: Reduce rework during module assembly and quality inspection S4: Reduce quality inspection space unavailability
Transportation (truck-trailer and crane)	S5: Increase transportation fleet availability S6: Timely crane preparation at factory S7: Reduce lack of space on laydown area
On-site installation	S8: Timely crane preparation S9: Speed up lift preparation S10: Boost module alignment

	process
	S11: Accelerate module connection
	S12: Reduce site-fit rework

4 Case Example

A residential modular project located in Kenora, Ontario, was selected as the case study. The project involved the construction of a single building using six wooden-framed modules, manufactured by Smart Modular Canada. These modules, each weighing 14 tons and measuring 14 feet by 50 feet, were fabricated at a factory in Thunder Bay, Ontario, and fully equipped with mechanical, electrical, and plumbing systems, as well as internal finishes. Although the installation of the final module was initially planned to be completed within 242 workhours, the process ultimately required 268 workhours due to various challenges encountered throughout the project life cycle, including detected defects during assembly, delays in truck availability, and damages sustained during shipment.

Moreover, the scenarios were simulated using the SDM, and the resulting MOC-KPI data were analysed to assess normality. This analysis employed Quantile-Quantile (Q-Q) plots, kurtosis, skewness, and the Shapiro-Wilk test. Q-Q plots were constructed for each MOC-KPI to visualize their distribution (11 plots). Figure 3 presents the Q-Q plots for the manufacturing proposed KPIs (module assembly and inspection), namely, WFI, MQIP, and MDM. The Q-Q plots reveal that the datasets for each MOC-KPI deviate from normality, as the data points cluster away from and do not align closely with the 45-degree reference line. To provide a more comprehensive assessment of normality, additional statistical measures, including kurtosis, skewness, and the Shapiro-Wilk test, were employed, as summarized in Table 3. The skewness and kurtosis values exceeded the acceptable thresholds for some MOC-KPIs, thereby violating the normality assumption (thresholds: −2 to +2 for skewness and −7 to +7 for kurtosis). These values are highlighted in Table 3. Furthermore, the Shapiro-Wilk test yielded *p*-values below the significance level of 0.05, leading to the rejection of the null hypothesis (normal distribution). This result corroborates that the dataset deviates significantly from normality. Therefore, non-parametric statistical tests were subsequently employed at this stage of the analysis.

Table 3. Statistical measures and test for data normality assessment

Independent variables (MOC-KPIs)	Skewness	Kurtosis	Shapiro-Wilk *p*-value
WFI	**-0.700**	7.470	2.008×10^{-9}
MQIR	2.478	12.133	1.591×10^{-9}
MDM	4.885	27.870	4.132×10^{-11}
WFD	4.401	25.909	1.693×10^{-11}
SAO	**-0.211**	**4.552**	1.430×10^{-8}
AFML	5.375	31.888	3.577×10^{-12}
MTT	4.115	21.327	1.677×10^{-10}
SDI	3.861	16.086	3.437×10^{-9}
MLH	2.787	**6.999**	2.014×10^{-10}
MIPA	3.337	21.307	3.154×10^{-11}
MCW	5.388	32.000	2.794×10^{-12}

Spearman's Rank Correlation Coefficient analysis was conducted to examine the strength and direction of relationships among the proposed MOC-KPIs, as summarized in Table 4. The results reveal an acceptable level of linear relationship between certain MOC-KPIs ($0.2<r<0.9$). However, the correlation between some variables, such as MDM and MTT is less than 0.2, indicating a very weak and negligible relationship. The strongest correlation is observed between AFML and MIPA (r=0.64). Interestingly, while MIPA shows no correlation with other KPIs (r = 0.0), it exhibits the second-highest correlation with AFML (r = 0.642). These correlations, though weak in some cases, underscore the interconnected nature of various processes across the MOC life cycle, highlighting the factors and MOC-KPIs that are influenced by these operations. Furthermore, since all coefficients fall within the acceptable range, the proposed MOC-KPIs are deemed suitable for inclusion in the developed model, supporting their potential relevance in capturing the dynamics of the life cycle processes.

At this stage, quantile regression analysis was utilized to assess the robustness of the proposed MOC-KPIs and to define a reliable framework for identifying those that significantly contribute to MOC-LCP. The analysis involved multiple iterative rounds, during which the *p*-value for each MOC-KPI was computed. KPIs with *p*-values exceeding 0.05, signifying a lack of statistical significance, were systematically excluded from subsequent iterations. This process continued until all remaining MOC-KPIs demonstrated statistical significance, confirming their importance to MOC-LCP and their effectiveness in identifying and evaluating root

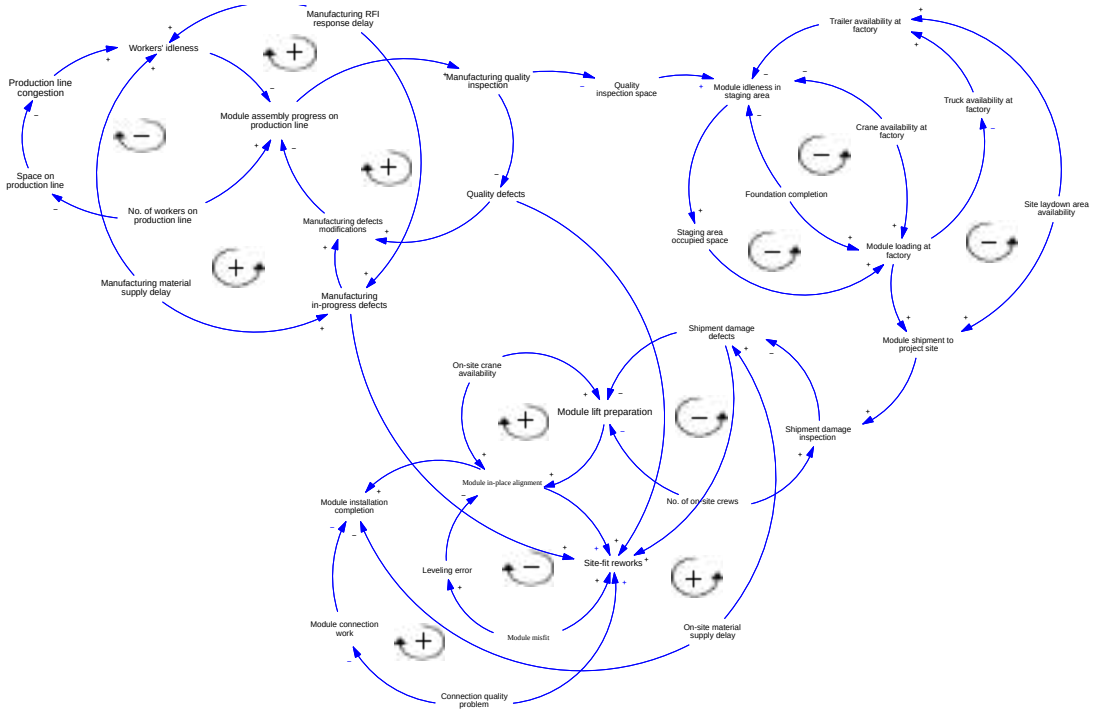

Figure 2. The causal loop diagram of MOC process flow to evaluate life cycle productivity

Table 4. Correlation between MOC-KPIs using Spearman Rank Correlation Coefficient

	WFI	MDM	MQIR	SAO	AFML	MTT	SDI	MLH	MIPA	MCW	SFR
WFI	1

causes of process waste with respect to resource utilization. The outcomes of the quantile regression analysis are detailed in Table 5.

Table 5. Results from multiple iterations of quantile regression analysis (pp-value)

MOC-KPI	*p*-value				
	R1	R2	R3	R4	R5
WFI	0	0	0	0	0
MQIR	0	**0.586**	-	-	-
MDM	0	0	0	0	0
WFD	0	0	0	0	0
SAO	0	0	0	0	0
AFML	0	0	0	0	0
MTT	0	0	0	0	0
SDI	**0.596**	-	-	-	-
MLH	0	0	0	**0.999**	-
MIPA	0	0	**0.991**	-	-
MCW	0	0	0	0	0

As shown in Table 5, five rounds of quantile regression analysis identified WFI and MDM in manufacturing, SAO, AFML, and MTT in transportation, as well as SDI and SFR in the on-site installation stages, as statistically significant at the 95% confidence level. These findings indicate that these factors play a critical role in influencing MOC life cycle performance. The statistical significance at the 95% confidence level suggests a strong correlation between these variables and overall project efficiency. Further analysis is required to explore the extent of their impact and potential strategies for optimizing these key indicators across different project phases. These MOC-KPIs are deemed robust, as they contribute meaningfully to identifying the root causes of waste across the MOC life cycle by accounting for resource utilization and enabling an effective and efficient evaluation of the MOC-LCP.

5 Conclusion

Certain studies have proposed mathematical and simulation models to evaluate productivity and process flow in MOC, focusing on minimizing variability. Other research works have developed KPIs in manufacturing to enhance MOC operational efficiency. However, few studies have addressed the root causes of process waste related to resource utilization (e.g., workers and workspace), nor have they proposed MOC-KPIs and considered the dynamic interactions among life cycle stages. This study fills this gap by proposing a process-oriented PE model that incorporates the proposed MOC-KPIs. Using SDM, the model simulates the interactions among life cycle stages and their processes, systematically assessing the current-state life cycle performance in terms of productivity (i.e., MOC-LCP) by comparing it to a baseline while considering process constraints and resource utilization (workers and workspace). The study also introduces new MOC-KPIs to identify, quantify, and diagnose the root causes of waste and enhance coordination across life cycle stages in MOC. The results show that MOC-KPIs such as WFI and MDM in manufacturing, SAO, AFML, and MTT in transportation, and SDI and SFR in on-site installation phases can effectively assess the state of resource utilization and identify process inefficiencies. Future research should explore the impact of applying the model to projects with a larger number of modules, as its calibration was based on a 6-module project, which may affect result reliability. Additionally, further studies should investigate the relationship between MOC-LCP improvement and project cost savings. Also, social indicator (e.g., employee turnover) are excluded due to their subjective and qualitative nature, as well as the lack of standardized assessment methods. This research improves the understanding of the key factors affecting MOC life cycle performance, helping general contractors and modular developers manage constraints and optimize project outcomes.

Enhancing Construction Inspection with Augmented Reality: An Analysis of Accuracy and Observation of its Application in Training

Jeffrey Kim[1] and Darren Olsen[1]

[1]McWhorter School of Building Science, Auburn University, US
Jeff.Kim@auburn.edu, DAO0002@auburn.edu

Abstract –

The construction industry faces significant challenges, including declining quality performance, skilled labor shortages, and resistance to technological innovation. These issues have hampered the sector's operational efficiency and reputation. A critical component of quality control—accurate material placement—remains dependent on manual interpretation of 2D drawings, a task often prone to errors due to workforce inexperience. To address these concerns, this study investigates augmented reality (AR) as a tool to modernize construction inspection processes and enhance workforce training under the framework of Construction 4.0. This research evaluates the accuracy and practical utility of AR devices, including the Apple iPhone 13 Pro Max, Apple iPad Pro 12.9-inch, Trimble GPS Enabled SiteVision, and Trimble XR10 - Microsoft HoloLens 2, for inspecting the placement of underground utilities in a simulated construction environment. Thirty-two construction management students participated, using AR tools to position survey prisms at perceived utility locations. Results revealed the HoloLens achieved the highest accuracy and precision, followed by the SiteVision and iPad, with the iPhone exhibiting the largest deviations. Findings highlight AR's potential as an educational tool, enabling students to bridge theoretical knowledge with practical applications while engaging in immersive, hands-on learning. Despite limitations, including environmental variability and current technological tolerances, AR demonstrates significant promise in training future professionals and improving quality control processes. This study underscores the need for continued innovation in AR technology to advance the construction industry's efficiency, reputation, and workforce readiness.

Keywords –

Augmented Reality, Quality Control, Experiential Learning, Construction 4.0

1 Background and Rationale

The construction industry, a cornerstone of infrastructure development, is at a critical transition concerning standards in quality control. Extensive research underscores a significant decline in quality performance over recent decades. Key factors contributing to this deterioration include a persistent shortage of skilled labor [1], insufficient investment in quality management systems [2][3], and inadequate leadership in adopting technological innovations [4]. These systemic challenges have impaired the industry's competitiveness and operational efficiency. Moreover, entrenched resistance to process change and a tarnished public reputation exacerbate the sector's difficulties in adoption [5]. Concurrently, the industry is grappling with the loss of experienced professionals while relying on a less-skilled incoming workforce that requires substantial training time to achieve proficiency [6]. These intertwined issues further hinder efforts to improve productivity and public perception.

Precision in material placement is a critical aspect of construction processes. Currently, this task heavily depends on manual interpretation of two-dimensional (2D) drawings to construct three-dimensional (3D) structures. Inexperienced installers often face challenges in accurately interpreting these representations, leading to errors and delays in construction. Effective layout and quality control require practiced visualization skills typically developed through extensive field experience. However, the departure of skilled professionals has widened the expertise gap, compounding the industry’s quality control challenges and adversely affecting its reputation for reliability and customer satisfaction.

To address these issues, innovative technologies are being explored under the banner of Construction 4.0, the industry’s response to Industry 4.0 advancements. Among these, augmented reality (AR) has emerged as a transformative tool, with applications ranging from enhancing safety training [7] and improving design

visualization [8] to owner training and building maintenance support [9]. AR offers a potential solution for bridging the skills gap by facilitating training and comprehension. Its potential for quality control is particularly appealing. Application of AR in quality control has been demonstrated with the verification of proper rebar installation, albeit with the assistance of laser scanners [10]. More recently, large timber installation inspections using AR has been shown to improve fastener placement for improved accuracy and safety of those installed structures [11]. Despite these past studies and others like it, none are focused on the tool for its comparable training purpose, identifying a gap in this narrowly focused viewpoint. Nevertheless, leveraging AR effectively requires a nuanced understanding of construction-specific quality control procedures.

One illustrative example is the measurement of placement tolerances for utilities embedded in concrete structures. Ensuring accurate placement is essential to prevent costly rework. Early identification of deficiencies by inspectors is crucial to maintaining quality standards. For AR to succeed in augmenting this inspection process, it must deliver consistent accuracy and precision in identifying defects. Additionally, AR's capacity to overlay virtual objects onto real-world environments must be rigorously assessed for practicality and reliability.

Research highlights AR's efficacy in enhancing both classroom and on-site training [12][13]. With the proliferation of mobile devices, AR tools can now be deployed with minimal effort, enabling construction professionals and students to integrate these technologies seamlessly into their workflows. However, while the potential of AR for improving quality control processes is widely acknowledged, the current body of research remains speculative, emphasizing the need for empirical studies to validate its applications [8][14][15].

This study addresses these gaps through a dual focus. First, it examines students' perceptions of AR tools as a means of teaching essential inspection and analysis skills. Second, it evaluates the accuracy of AR inspection tools in the classroom setting, hypothesizing that their effectiveness in educational contexts could translate to practical applications on construction sites. The research assumes that AR can aid students in developing foundational skills essential for future industry practitioners. Furthermore, data on the accuracy and precision of AR tools could inform their integration into real-world quality control workflows, offering practical solutions for outdated inspection practices.

By establishing a foundation for incorporating AR tools into construction education and professional practices, this research contributes to modernizing the industry. It aims to address the knowledge gap left by departing experts while enhancing productivity and reputation. These efforts signify a critical step toward an industry that struggles to embrace innovation, retain expertise, and deliver higher-quality products.

1.1 Research Rationale

How can the construction industry modernize its outdated quality control processes, improve its reputation for quality, and address the challenges posed by a declining skilled workforce? The industry's traditional mindset—relying on methods that "worked in the past"—is no longer sufficient. A paradigm shift [16] is necessary, beginning with equipping the incoming workforce with advanced training and tools to meet modern demands effectively.

This research focuses on evaluating the accuracy and potential of AR technology as a tool for construction inspections. By integrating AR into training programs, the study aims to address two critical issues: enhancing quality control and bridging the skills gap in the workforce. The research involves students from a construction management program, providing them with hands-on experience and exposure to innovative tools. Through this approach, the study seeks to demonstrate AR's capacity to improve construction processes while preparing the next generation of professionals to meet industry challenges head-on.

2 Methodology

This study employs an action research protocol, integrating insights from various disciplines to assess AR tools' effectiveness in evaluating the placement accuracy of underground utilities. By superimposing utilities over a real-world view, the study aims to prepare construction students as future professionals while connecting classroom concepts to practical applications [17].

Previous research on AR accuracy and precision informs this study. Scherl et al. demonstrated error tolerances within 1.33 mm using fiducials in surgical procedures [18], while Khan et al. found object placement accuracies within 1.1 mm in virtual environments under stationary conditions and controlled lighting [19]. These findings influenced the authors' device selection and methodology, leveraging best practices to evaluate AR-assisted placement accuracy in construction.

2.1 General Participant Demographics

The study involved students from a four-year construction management program in the Southeastern United States. Participation was voluntary, and the experiment took place during a regularly scheduled class session. These students were chosen because of their

foundational knowledge aligning with the study's goals and their aspirations to become project managers or superintendents in commercial construction. Most participants, aged 20 to 23, had gained hands-on experience through internships, giving them a practical understanding of construction practices and the critical role of accuracy in utility placement. This background enabled them to effectively distinguish between correctly and incorrectly placed objects, contributing to the study's credibility. Thirty-two students participated in this study.

2.2 Devices Used in this Study

Devices were selected to align the study's emphasis on accuracy and precision, as informed by the findings of Khan et al. [19] and Scherl et al. [18]. The devices chosen for the study (shown in Figures 1 and 2 below) included the Apple iPhone 13 Pro Max (iPhone), the Apple iPad Pro 12.9-inch 5th generation (iPad), and the Trimble GPS Enabled SiteVision, representing a *passive*, non-fiducial AR device category. Additionally, the Trimble XR10 - Microsoft HoloLens 2 (HoloLens) was selected as an *active*, non-fiducial AR device type. The terms "passive" and "active" refer to the level of user interactivity: the HoloLens offers a more immersive experience, placing the user into a virtual environment compared to the other devices. Additionally, the iPhone and iPad were chosen for their familiarity among students, simplifying data collection and enhancing its reliability. The HoloLens and the Trimble SiteVision were included due to their potential as cutting-edge tools for professionals, providing students with an opportunity to engage with technology that could modernize traditional inspection workflows.

Figure 1. (a.) iPhone & (b.) iPad

Figure 2. (a.) HoloLens & (b.) SiteVision

2.3 The Experimental Space and AR Authoring Tools

The experimental case study was conducted within a simulated construction environment designed to mimic pre-concrete placement inspections commonly performed on construction sites. This phase is critical as it occurs before concrete is poured, allowing for the identification and resolution of deficiencies to avoid costly rework or delays.

The simulated site (Figure 3.a.) spanned 20 feet by 15 feet (6.1 m x 4.6 m) and was enclosed by wooden forms, creating a flat, stable surface for students to conduct observations using the AR devices described earlier (see Figures 1 and 2). Students used the devices to position a survey prism mounted on a PVC pipe supported by a tripod (Figure 3.b.), simulating the top of an underground utility pipe. The accuracy and precision of these placements were later evaluated against control points established within the simulation.

Figure 3. (a.) Experimental Workspace & (b.) Locating

Prisim

The site was outdoors and partially shaded, reflecting typical lighting conditions encountered on construction sites. Conducting the study in natural sunlight introduced practical challenges associated with real-world inspections using AR, enhancing the study's relevance to industry applications. While outdoor lighting and weather conditions were expected to influence data collection, they were not specifically measured during this study.

The AR experience was facilitated using Trimble FieldLink MR, a platform built on Building Information Modeling (BIM) principles widely adopted in the industry [18]. A BIM model of the simulated site was initially created in Revit, then converted to a SketchUp file for seamless integration with the Trimble FieldLink MR platform (see Figure 4). This cloud-based solution ensured consistent access to the AR experience across all devices used in this study, promoting uniformity in participant interactions and data collection.

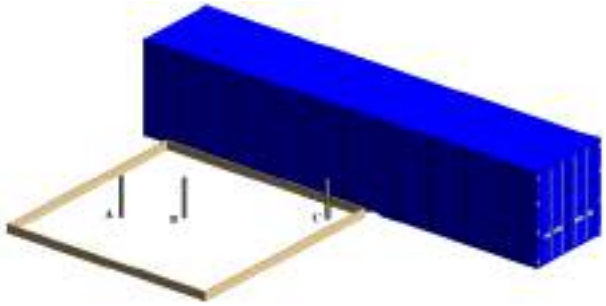

Figure 4. Rendering of the AR Display

Within the model, three virtual PVC pipes (A, B, and C) were positioned to represent utility penetrations typically encountered on construction sites. These digital proxies allowed participants to observe and assess placement accuracy before concrete placement, aligning the experiment with real-world inspection practices and ensuring practical relevance to the construction industry.

2.4 The Experimental Workflow

At the start of the study, control points were established within the simulated construction site and validated using a robotic total station. During the experiment, students navigated the simulated site (Figure 3.a.) with their assigned AR device (Figure 1 and 2), which displayed virtual pipes and their spatial positions (Figure 4). Upon identifying a virtual pipe, students positioned a survey prism stand (Figure 3.b.) at its perceived center. The robotic total station then recorded the student's identified pipe location, capturing both northing and easting coordinates for subsequent analysis. To evaluate the accuracy of the observations, the recorded pipe coordinates from the students were compared against the control coordinates of the pipes.

3 Results and Discussion

Each pipe was individually located by students utilizing their designated AR devices, allowing every participant to make up to three positional observations specific to their assigned device.

The positional data (northing and easting coordinates) for all students were compared against the control positions of the simulated pipes using the formula outlined in Figure 5.

$$\sqrt{(N_n - N_y)^2 + (E_n - E_x)^2}$$

Figure 5. Formula for Calculating Placement Difference (Northing and Easting coordinates).

Figure 5. (N_n and E_n = pipe control coordinates and N_y and E_x = student observed coordinates)

3.1 Accuracy and Precision

A summary of the calculated error averages and standard deviations is presented in Table 1.

Table 1. Error Calculations

PIPE		DEVICE TYPES			
		HoloLens	SiteVision	iPhone	iPad
A	Average	2.47	3.05	7.51	3.30
	SD	1.23	1.85	4.22	1.95
	n	8	8	8	8
B	Average	2.73	3.60	5.97	3.66
	SD	1.69	2.40	2.80	1.17
	n	8	8	8	8
C	Average	4.65	3.91	5.30	3.79
	SD	1.34	2.53	1.43	1.39
	n	8	8	8	8

Note: All error measurements are represented in (SI) inches.

Analyzing the results for each AR device—the HoloLens, SiteVision, iPhone, and iPad—reveals notable variations in performance. The HoloLens consistently demonstrated the highest placement accuracy, with an overall average error of 3.28 inches across all three pipes (A, B, and C). In comparison, the SiteVision recorded an average error of 3.52 and the iPad recorded a near similar average error of 3.59 inches. The iPhone exhibited the largest error, averaging 6.26 inches. Precision, assessed through standard deviation, further underscored the HoloLens' reliability, as it had the lowest standard deviation of 1.42, followed closely by the iPad at 1.50. The SiteVision and iPhone trailed with a standard

deviation of 2.26 and 2.82 respectively.

These findings align with the expectations set by Trimble's whitepaper [21], affirming the superior performance of the HoloLens' WLT technology compared to devices lacking such features. Similar to Trimble's conclusions, the HoloLens excelled in anchoring virtual elements to the real-world environment. It should be noted, however, that this study differed methodologically by excluding fiducials and stationary observers, leading to accuracy results that diverged from prior research [19][18]. These deviations were anticipated, given the experimental conditions.

The iPad and the SiteVision emerged as a practical alternatives to the HoloLens, with accuracy and precision closely mirroring those of the HoloLens. Despite this, the iPad offers a less immersive experience, as its AR interface relies on a handheld screen. In contrast, the HoloLens provides a more engaging, hands-free experience by overlaying virtual elements directly onto the user's field of view via a headset. This hands-free operation enhances mobility and safety, whereas the need to hold the iPhone or iPad can restrict movement and increase safety risks [22]. Consequently, the decision to use these devices should balance factors such as cost, immersion, and safety. The SiteVision accommodates for this ergonomic consideration by providing a handle for operation, but it too is a device that requires the use of at least one of the operator's hands.

While the observed tolerances in this study indicate that the current AR tools may not meet the precise standards required in many construction industry applications—where tolerances often range between 1/8" and 1/4"—they nonetheless highlight the potential of AR as a valuable educational tool. The technology's ability to bridge theoretical learning with practical applications makes it a promising resource for advancing industry training and education.

3.2 Practicality for Academic and Industry Use

The AR tool proves to be a highly valuable educational resource, especially as a training platform for aspiring inspectors. While its accuracy may not yet align with industry standards, its immersive nature offers a unique opportunity for hands-on learning. Through interactive simulations and practical exercises, trainees can refine their ability to detect and address construction deficiencies, gaining a deeper understanding of inspection processes. Participant feedback highlights the AR tool's potential as a transformative educational aid. As one student expressed in their open-ended comments:

"The experience was enjoyable and gave me a better grasp of how to inspect for construction errors."

Anecdotally, this feedback reflects a broader trend of positive student engagement and impactful learning experiences when action research is implemented [23]. Research supports the effectiveness of active, experiential learning strategies in improving educational outcomes, particularly when cognitive load is managed effectively [12][24].

These findings underscore the AR tool's promise as a teaching aid within the construction field. By leveraging its immersive capabilities to foster active participation, the tool not only enhances practical competencies but also encourages a culture of ongoing learning and innovation. The study's results suggest that the AR tool positively transforms the educational experience, signalling a shift toward more dynamic and interactive training methods in the industry.

3.3 Considerations for the Future of this Research

While this study sought to manage key variables influencing outcomes, certain factors arose that merit consideration in future investigations.

Firstly, environmental conditions, such as sunlight and weather, were not controlled. This approach aimed to mimic real-world variability on construction sites, ensuring practical relevance for industry applications. However, during the experiment, delays occurred as researchers waited for optimal sunlight to continue, given that poor lighting could compromise the HoloLens experience and overheating issues were noted with the iPhone and iPad. These challenges led to the loss of several data points, requiring rework to maintain study integrity.

Secondly, the limited size of the student cohort may have constrained the breadth of the findings. A larger participant pool could provide a more comprehensive dataset, yielding deeper insights into the effectiveness of the AR tool.

Lastly, the requirement for students to work in pairs to record virtual pipe locations introduced an additional variable. Those using the iPhone and iPad faced limitations due to the need to hold their devices, leaving only one free hand for marking tasks. Conversely, HoloLens users had the advantage of hands-free operation, potentially influencing the overall results. Those using the SiteVision were afforded more flexibility since the device was equipped with a handle and wrist strap to precent dropping the device. While theses discrepancy likely impacted the study, no specific data was collected to confirm its effect.

These considerations point to areas where future research can refine methodologies, address limitations, and further explore the AR tool's potential to enhance learning and professional development in the construction industry.

4 Conclusion

The findings from this research reveal the transformative potential of AR as both an educational tool and a technology capable of modernizing quality control practices in the construction industry. With construction increasingly defined by its challenges—such as a declining skilled workforce, a need for higher-quality outcomes, and resistance to technological change—AR offers a pathway to innovation and improvement.

Through this study, AR tools demonstrated their ability to bridge the gap between theoretical learning and practical application, particularly in training students on critical inspection and analysis skills. The immersive and interactive nature of AR facilitates experiential learning, enabling students to practice identifying construction errors within a controlled, simulated environment. Feedback from participants underscores this value, with many noting increased engagement and comprehension. Active, hands-on learning methodologies, supported by the AR platform, align with established educational research, which emphasizes the importance of reducing cognitive load to optimize learning outcomes.

From a technical perspective, the study highlighted the relative strengths and limitations of AR devices, such as the HoloLens, SiteVision, iPhone, and iPad, in achieving placement accuracy for simulated utilities. While the HoloLens emerged as the most precise tool, with accuracy levels surpassing other devices, the findings suggest that current AR technology may not yet meet the stringent tolerances required in some industry-specific applications. However, these tools show significant promise as cost-effective and accessible alternatives for training purposes. The hands-free operation of the HoloLens was shown to enhance user mobility and safety, offering an additional layer of practicality for both educational and field applications.

This research contributes to the growing body of evidence supporting AR's integration into construction practices. It highlights AR's dual role in addressing pressing industry challenges: by equipping the next generation of professionals with advanced skills and by improving workflows in quality control. These outcomes position AR as an instrumental technology for advancing the goals of Construction 4.0, fostering innovation, and enhancing the reputation and productivity of the construction sector [25].

In conclusion, this study demonstrates that augmented reality represents a significant opportunity for the construction industry to modernize its approaches to education and quality control. By fostering a culture of innovation and continuous learning, AR has the potential to mitigate the challenges associated with a declining skilled workforce while enhancing the quality and efficiency of construction processes. As the industry continues to evolve, embracing technologies like AR will be critical to building a future characterized by greater resilience, adaptability, and excellence in construction practices.

Abstract –

Effective management of labour productivity in construction projects is important for ensuring project success. This paper introduces a novel approach to quantifying uncertainty in labour productivity through entropy calculations based on outputs from a fuzzy expert system. Two distinct scenarios are analyzed to demonstrate the practical application of the proposed methodology, one representing a week with high variability and the other a stable and predictable week. These scenarios highlight how entropy can be a powerful tool for identifying periods of high uncertainty and assisting project managers in making informed decisions about resource allocation, risk management, and strategic planning. The findings suggest that high entropy values indicate weeks requiring increased management attention and resources, whereas lower entropy values correspond to more stable conditions, allowing for standard operational procedures. This approach enhances understanding of dynamic project conditions and supports proactive project management practices. This study contributes to the body of knowledge by integrating fuzzy logic with entropy calculations, which offers a robust framework for managing the complexities of labour productivity in construction projects. Through real-world application and comparative analysis, this study validates the effectiveness of entropy analysis as a diagnostic and decision-making tool in the construction industry.

Keywords –

Construction management; Fuzzy expert systems; Chaos theory; Entropy

1 Introduction

Traditional linear and deterministic approaches for analyzing labour productivity in construction environments often fail to fully address the dynamic nature of construction projects [1]. Management strategies must evolve as projects become complex and are influenced by numerous interacting variables and unpredictable environmental conditions.

In this context, fuzzy logic offers ways to develop a methodological framework capable of handling the ambiguity and imprecision inherent in construction project management. Fuzzy logic can be used to more effectively deal with uncertain parameters, such as estimations of time and resources, by classifying them into degrees of truth rather than binary true-or-false categories [2]. This allows for better decision-making that aligns with the complexity of construction projects and expert knowledge.

Chaos theory also provides a valuable lens through which the unpredictable nature of construction projects can be understood and managed. It suggests that small variations in project conditions can lead to disproportionately large effects, a phenomenon often referred to as the “butterfly effect” [3]. Chaos theory has helped highlight the non-linear behaviours of project dynamics, thus emphasizing the need for project managers to anticipate and prepare for significant fluctuations in project trajectories that traditional methods might not predict [3,4].

Combining chaos theory and fuzzy logic addresses the dual challenges of unpredictability and imprecision by providing tools that predict potential chaos in project management while offering pragmatic approaches to handling complexities through adaptable and flexible decision-making frameworks [5]. Such an integrated approach is particularly effective in managing the interdependencies and dynamic interactions within construction projects, which traditional project management techniques often struggle to handle effectively.

In the context of this study, labour productivity is defined specifically as the measure of output produced per labour hour. This definition focuses on the efficiency of labour in delivering tangible results within a given time frame. In construction research, productivity can

also encompass broader measures such as cost, duration, and overall project success.

This paper proposes a novel approach integrating chaos theory and fuzzy logic to enhance the understanding and management of labour productivity in construction environments. The objectives of this framework are to generate better understanding of the factors impacting labour productivity in complex construction environments and, ultimately, to facilitate more-informed management decisions. By understanding and applying the frameworks using these complex theories, project managers can enhance their ability to navigate the uncertainties of the construction field, leading to better project outcomes in terms of efficiency, cost, and time management. Thus, this approach advocates for a shift from conventional to more dynamic and responsive project management strategies that can better address the complexities of modern construction projects.

2 Background

Labour productivity in the construction industry is a critical measure of efficiency [6] and reflects the output per labour hour expended on construction tasks. It directly influences a project's cost, duration, and overall success. However, productivity in construction is uniquely challenged by the industry's inherent variability and complexity as well as the unpredictable nature of work environments and workforce dynamics [7]. It exhibits complex variability that is not normally distributed, which suggests the need to apply chaos theory to understand it [8].

Traditionally, construction productivity has been evaluated using time–motion studies, manual data collection, and direct observations of activities on-site [9]. Although useful, these methods often fail to capture the distinctions of complex environments where multiple interdependent variables affect productivity [10, 11]. Such methods are limited in handling construction projects' dynamic adaptations and stochastic nature, so more robust, adaptive analytical tools are required.

Fuzzy logic offers a means to handle uncertainty and imprecision, characteristics that are common in construction data [12]. It offers the ability to develop flexible mathematical frameworks for modeling the vagueness associated with subjective human judgments and qualitative data. For instance, studies have successfully implemented fuzzy systems to enhance decision-making under uncertainty in project management, particularly in areas such as risk assessment, cost forecasting, and the mitigation of potential delays and cost overruns [13, 14, 15, 16, 17].

Chaos theory is pertinent to understanding construction projects' complex and dynamic nature [18]. It demonstrates how even minor variations in initial conditions can cascade into disproportionately large impacts, a principle especially relevant to the non-linear dynamics of construction management [19, 20]. Through use of sensitivity analysis and fractal geometry, chaos theory provides methods for identifying and addressing sensitive points in the project lifecycle and repeating patterns that may significantly influence outcomes [19, 20]. Although less commonly applied in project management than fuzzy logic, chaos theory has the potential to provide insights into labour productivity by modeling how small variations in work conditions or team compositions can lead to disproportionate impacts on productivity. This approach can be particularly valuable in planning and managing workflows in real time to mitigate the effects of emergent issues [21].

Entropy is a measure of disorder or randomness in a system. Entropy analysis has been extensively explored as a tool for quantifying uncertainty in construction projects, thus offering insights into the stability and predictability of project systems by measuring deviations in cost, schedule, and performance [22, 23]. Employing entropy calculations alongside traditional project management metrics, such as cost performance index and schedule performance index, allows managers to monitor project progress and proactively address emergent issues [1].

Recent studies have demonstrated the utility of entropy-based approaches in risk assessment, resource allocation, and schedule stability, showing the ability of such approaches to predict project disruptions and enable dynamic adjustments. For example, entropy analysis has been used in scheduling resource-constrained projects to measure disorder and forecast potential delays [22], and it has been integrated with Bayesian inference to refine predictions based on new data [23].

Integrating fuzzy logic and chaos theory in construction management is a novel approach that has seen limited exploration, especially in terms of enhancing productivity. This integrative approach offers a framework capable of managing the inherent uncertainties of construction projects and predicting and adapting to the non-linear dynamics that affect labour productivity. The proposed framework thus enhances traditional project management approaches by integrating advanced analytics specifically designed to navigate the complexities of modern construction environments, thereby significantly improving labour productivity.

3 Methodology

The methodology, presented in Figure 1, explains a systematic process that begins with factor shortlisting, where key labour productivity factors are identified and

prioritized based on their relevance and impact on construction projects. Subsequently, these factors are evaluated through a fuzzy expert system (FES) that classifies each factor into qualitative states (*Poor*, *Fair*, *Good*) based on expert evaluation. This classification facilitates pattern analysis, enabling us to identify and interpret trends and patterns in the data, which provides insights into the factors' behaviors and interactions. The final step in this methodology is entropy analysis, where uncertainty and variability of the factors' states is quantified based on the FES results. This entropy analysis serves as a measure of disorder or randomness in the system, offering a deeper understanding of the project's complexity and better guiding strategic decision-making in managing construction project productivity.

Figure 1. Proposed methodology

3.1 Labour Productivity Factors

A comprehensive list of factors comprising eight main categories and 137 sub-factors that can positively or negatively influence labour productivity is adapted from the framework proposed by Raoufi and Fayek [24]. The methodology proposed by Pourrahimian et al. (2024) is employed to shortlist this extensive list [25] and focus on the most relevant factors for the case study. The detailed selection process and criteria, however, are beyond the scope of this study. This framework was selected due to its proven applicability in similar contexts, where handling fuzzy, uncertain, and non-linear data is crucial. Notably, the framework's robustness in dealing with complex variability in labour productivity makes it particularly suitable for construction projects affected by a wide range of fluctuating conditions. Figure 2 illustrates the distribution of sub-factors across each main factor category.

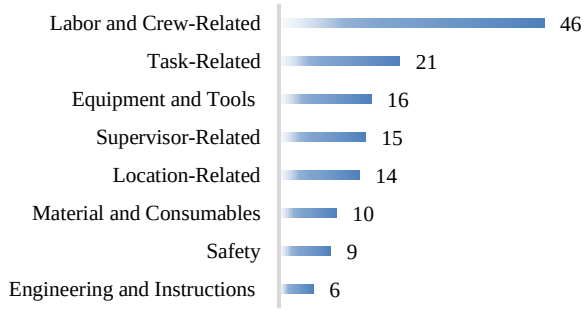

Figure 2. The number of sub-factors under each main factor

3.2 Fuzzy Expert System

FES is applied to manage the ambiguity and vagueness associated with these factors. Each main factor is represented as a fuzzy variable with degrees of membership ranging across relevant sets (e.g., *Safety* is categorized into *Poor*, *Fair*, and *Good*). Membership functions are defined for each fuzzy variable, quantifying the degree to which an element belongs to a particular fuzzy set. Fuzzy rules are constructed based on expert input and empirical data; these rules form the core of the fuzzy logic system, linking input variables to labour productivity.

To apply FES in labour productivity using a rule-based approach, it is essential to establish a set of rules within the model. Equation (1) is used to determine the number of fuzzy rules.

$$Number\ of\ rules = (m)^n \quad (1)$$

where m is the number of fuzzy sets and n is the number of input variables.

To reduce complexity and prevent an overwhelming number of rule definitions, rule blocks have been defined. Instead of directly using all sub-factors to evaluate the main factor, the model first assesses the impact of a group of sub-factors on their respective main factor and, subsequently, the influence of these groups on the main factor. For instance, with four input variables and three fuzzy sets, the required rules would be 81. However, by grouping these into two rule blocks, only 18 rules per block and an additional nine rules for combining the outputs of these blocks are needed. This method substantially reduces the number of rules, as Figure 3 illustrates.

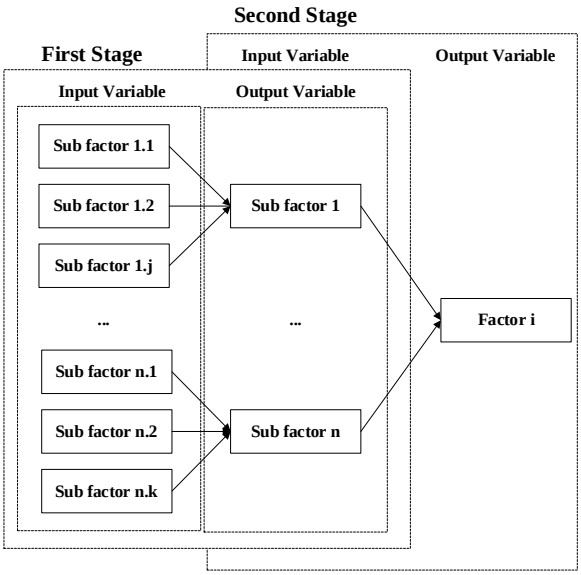

Figure 3. General structure of rule blocks

The input variables have the fuzzy set of x_i and the output variable of y. The input variables are measured on a scale of 0 to 10 and are divided into three categories, represented by the linguistic terms *Poor*, *Fair*, and *Good*. Membership values between 0 and 1 are assigned to each category. The output variable is on a scale of 0 to 100 and is also divided into three categories represented by the linguistic terms *Poor*, *Fair*, and *Good*. Table 1 tabulates the terms of assessment for x_i and y.

As the occurrence of each input variable is independent, FES rules were developed for each category. The outputs were used as input values for the next level. The standard operators *And: Min, Or: Max* implement the rules.

Table 1. Input and output variables of FES

Variable	Numerical scale	Linguistic descriptor	Membership function
x	1–10	Poor	Trapezoidal (0,0,1,4)
		Fair	Triangular (2.5, 4.5, 6.5)
		Good	Trapezoidal (5,8,9,9)
y	0–100	Poor	Trapezoidal (0, 0, 30, 50)
		Fair	Triangular (30, 50, 70)
		Good	Trapezoidal (60, 80, 100, 100)

3.3 Pattern Recognition

Chaos theory is utilized to identify patterns and conduct sensitivity analysis within the productivity system, highlighting its dynamic and highly responsive nature to minor variations in input conditions.

The model's pattern identification process examines productivity measure's non-linear responses to alterations in task characteristics or human factors, demonstrating how these changes can disrupt usual productivity patterns. Run charts can help identify these patterns. A run chart is an effective tool for monitoring data trends over time, displaying data points along a timeline on the *x* axis and their values on the *y* axis. It is used primarily to detect shifts identified by six or more points consistently above or below the median and trends indicated by five or more points consecutively rising or falling. Additionally, a run chart helps identify non-random variations by analyzing the number of runs (sequences of points on one side of the median) against expected ranges. It also shows outliers and unusual data points that merit further investigation.

Figure 4 shows an example run chart for the defuzzified evaluation of FES for a specific factor across various weeks. Tracking a variable over a series of weeks makes it easier to visualize trends, shifts, and patterns. Two distinct trends are indicated in differently coloured boxes. The section in a green box shows an increasing trend where the data points consistently rise over several weeks, suggesting a positive development in the monitored factor. The section in a red box illustrates a decreasing trend where the data points decline over time, signalling a reduction in the analyzed factor.

Another key feature shown in the chart is a "Shift," highlighted in a yellow box, where the data points remain on one side of the median over consecutive weeks. This could point to a significant event or intervention that impacted the process, and it merits closer examination to understand its causes and implications.

Additionally, the chart includes an "Astronomical" point, indicating an outlier. This particular data point is substantially different from others and could represent an anomaly that may skew the overall analysis or a unique event that requires separate consideration.

This run chart exemplifies how visual data analysis tools can help monitor ongoing processes. Identifying increasing and decreasing trends provides insights into the performance dynamics over time.

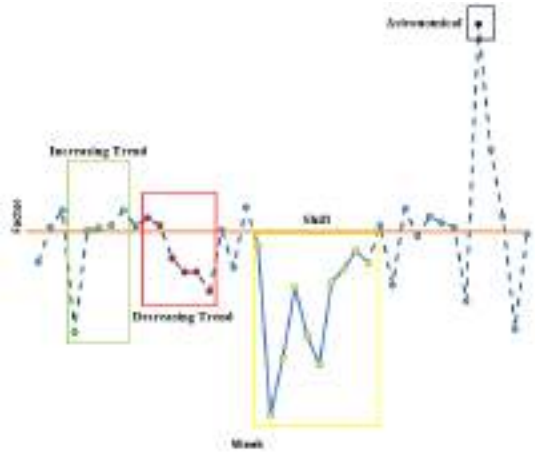

Figure 4. Pattern identification example

3.4 Entropy Analysis

Following identification of potential chaotic patterns, entropy calculations are integrated to measure the degree of uncertainty and disorder within the productivity factor states. This step enhances researchers' understanding of the variability in productivity outcomes and provides a quantitative measure of system complexity.

By applying FES, each productivity factor is evaluated and categorized as *Poor*, *Fair*, or *Good*; the next step entails quantifying the uncertainty embedded in these assessments using entropy calculations. The FES provides membership values for each state of a factor, which are inherently probabilities that sum to one.

Therefore, no additional normalization is required. These membership values directly reflect the system's confidence in each productivity state for each factor considered.

Entropy is calculated for each factor to measure the level of uncertainty or disorder associated with the fuzzy state distributions. Shannon's entropy formula is applied, given by:

$$H = -\sum_{i=1}^{3} p_i \log(p_i) \quad (2)$$

where p_i represents the probability of each state for a particular factor. Where a state's membership value is zero, its contribution to the entropy calculation is also zero, as $0\log(0)$ is mathematically treated as zero. This process is repeated for each factor, and the results provide a measure of the uncertainty associated with each aspect of labour productivity. To gain a holistic view of a project's uncertainty in terms of labour productivity, the entropy values are aggregated across all factors. This can be done by averaging all individual entropy values:

$$H_{average} = \frac{1}{8}\sum_{j=1}^{8} H_j \quad (3)$$

where $H_{average}$ is an overall measure of the uncertainty in the project's labour productivity and indicates the complexity and variability within the project environment.

An entropy value close to 1 indicates greater unpredictability and variability among the factors, which implies a more complex scenario where multiple interdependent factors influence productivity. Conversely, a lower entropy value, closer to 0, indicates more stability and predictability. Understanding these entropy values helps project managers and decision-makers identify periods or conditions of high uncertainty, which enables them to take pre-emptive measures or adjust project management strategies accordingly. This approach aids in better resource allocation, risk management, and scheduling, ultimately leading to more efficient project execution. For a more in-depth discussion, including specific entropy thresholds and their implications across various project phases, the authors refer readers to the detailed journal article by Pourrahimian et. al (2024), which is citation [1]

Figure 5 maps the assessment process of various productivity factors and their sub-factors within a construction project using the proposed framework. Each factor group is evaluated using fuzzy logic to determine each factor's state (*Poor*, *Fair*, *Good*). Subsequently, the distribution of these states across each factor is analyzed to calculate entropy, providing a measure of uncertainty or variability.

3.5 Objectives and Expected Outcomes

The primary objectives of this framework are twofold. First, by integrating fuzzy logic and chaos theory, the framework aims to better understand the factors impacting labour productivity in complex construction environments. Second, it is designed to support decision-making processes by understanding the variability in productivity outcomes and providing a quantitative measure of system complexity. This dual focus enhances

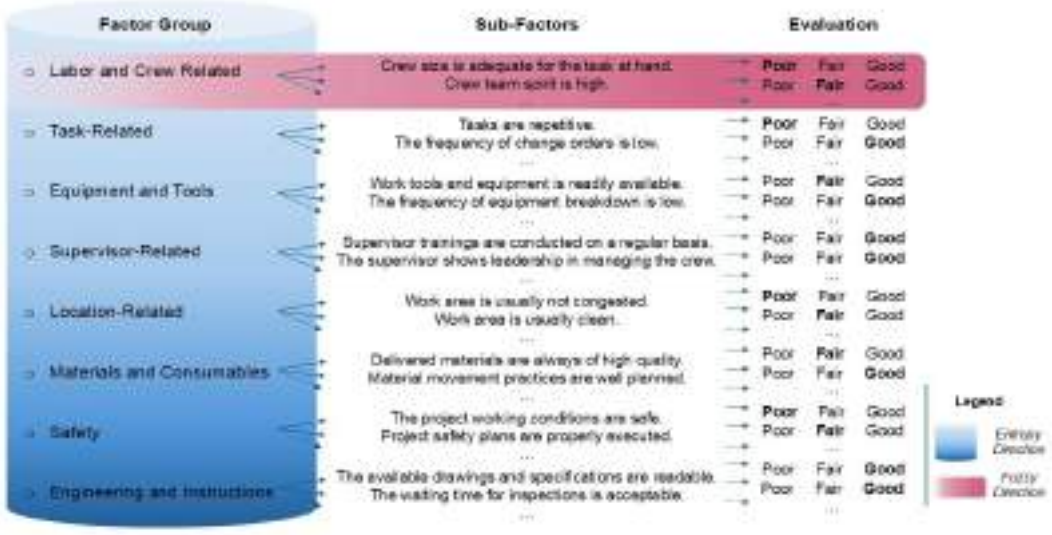

Figure 5. Integrated analysis of labour productivity factors using fuzzy logic and entropy

comprehension of dynamic productivity issues and facilitates more-informed management decisions.

4 Case Study, Results, and Discussion

The case study examines data from a $100-million industrial project, from February 2022 to October 2023, involving approximately 400,000 direct labour hours. The project scope included electrical and instrumentation (E/I) work, which made up 13% of the project, and piping tasks, which comprised 40% to 45%. The project was expected to employ a peak workforce of 280 individuals, comprising 250 workers and staff, plus 30 subcontractors, with 125 workers dedicated specifically to piping tasks. An expert panel featuring structural, electrical, piping, and mechanical engineering professionals was assembled to identify critical productivity factors. The panel included a structural construction manager with 22 years of experience, an electrical superintendent with 15 years, a piping superintendent with 34 years, a mechanical engineer operations manager with 19 years, and an electrical foreperson with 12 years. Following extensive analysis, this panel unanimously identified the essential state variables impacting project productivity.

Table 2 presents two distinct scenarios with the FES for each factor, each representing the labour productivity conditions across two different weeks of the project, to illustrate how varying project environments can significantly impact the entropy calculations and, consequently, the perceived stability and uncertainty within a construction project.

The first scenario explores a week characterized by high variability in project conditions. This includes disruptions in supply chains, unforeseen changes in project specifications, and fluctuations in workforce availability. The FES's evaluations reflect this instability, assigning a mix of Poor and Fair states across most factors, with very few factors rated as Good. This scenario illustrates a week for which entropy calculations reveal high uncertainty, indicating a need for proactive management interventions to stabilize the project environment. Conversely, the second scenario depicts a week where the project environment is stable and predictable. Factors such as weather conditions, material supply, and crew performance are optimal, leading to predominantly Good evaluations from the FES. This week demonstrates a lower entropy value, suggesting a well-managed project with minimal uncertainty and high predictability in labour productivity.

The integration of fuzzy logic and chaos theory within construction management can provide a promising framework for addressing the industry's inherent complexity. Beyond the immediate applications demonstrated in this study, insights from related fields further emphasize the potential of these methodologies to provide an alternative way to enhance the performance of construction projects.

Table 2. Membership value for each factor in two scenarios

	Scenario 1			Scenario 2		
Factor	Poor	Fair	Good	Poor	Fair	Good
Engineering and instructions	0.6	0.4	0	0	0	1
Safety	0.5	0.5	0	0	0.1	0.9
Material and consumables	0.7	0.3	0	0	0.1	0.9
Location-related	0.5	0.5	0	0	0.1	0.9
Supervisor-related	0	0.5	0.5	0	0.1	0.9
Equipment and tools	0	0.6	0.4	0	0.1	0.9
Task-related	0	0.4	0.6	0	0	1
Labour- and crew-related	0.5	0.5	0	0	0	1
Entropy ($\boldsymbol{H_{average}}$)	0.97			0.25		

The authors hypothesize that the fuzzy-chaos model will exhibit superior adaptability and accuracy in forecasting labor productivity due to its unique ability to manage construction projects' inherent uncertainty and non-linearity. This capability stems from the integration of fuzzy logic, which allows for handling ambiguous and imprecise data, and chaos theory, which addresses the sensitive dependence on initial conditions.

The fuzzy chaotic neural network proposed by Zhang and Wang (2012) presents a combination of fuzzy logic, chaos theory, and neural network dynamics to tackle highly non-linear and uncertain systems. This approach mirrors the core challenges faced in construction labour productivity management, where complex interdependencies and persistent fluctuations dominate [26]. Incorporating elements of such neural networks into construction project models could significantly enhance their ability to simulate issues, such as workforce dynamics or unforeseen disruptions. For instance, chaotic feedback loops could be employed to anticipate

cascading delays or cost overruns, providing a proactive management tool.

Similarly, the chaos-adapted multi-verse optimizer algorithm demonstrates the power of integrating chaotic maps and fuzzy logic in optimization tasks. Although applied in benchmark optimization problems, the principles underlying these chaotic adaptations could be valuable for construction resource management [27]. For example, replacing traditional deterministic approaches with chaos-driven algorithms could improve scheduling robustness and enable construction managers to dynamically allocate resources in response to fluctuating conditions.

The use of chaotic maps to replace stochastic components in optimization algorithms offers an appealing analogy for managing uncertainties in construction projects. Just as the algorithm balances exploration and exploitation of solution spaces, construction managers could apply similar principles to balance short-term project needs with long-term strategic goals, which might ultimately enhance efficiency and resilience.

These external applications provide evidence of the power of chaos theory and fuzzy logic across domains, which can be successfully adapted to the construction industry.

This study contributes critical advancement by contextualizing and empirically validating these theories within the construction industry. This not only enhances the understanding of complex project dynamics, but also offers actionable strategies that enhance productivity management and project resilience.

5 Practical Implementation

Project managers can follow a structured approach to facilitate the integration of the fuzzy-chaos model into daily decision-making processes. This includes the initial setup of the model within a decision support system (DSS), regular updates of project data, and interpretation of output for proactive management. Specifically, the authors suggest incorporating the model into existing project management software platforms that support modular customization. This allows for seamless integration without requiring managers to switch between different systems.

Practical steps for adopting the fuzzy-chaos model in construction project management include:

- Initial setup: Integrating the model with existing project management tools or DSS
- Data entry: Regular input of project data into the model to reflect current conditions
- Analysis and interpretation: Using the model's outputs to make informed decisions based on the calculated entropy values, which indicate the level of uncertainty and potential risk
- Adjustments and re-evaluation: Continuously adjust project strategies based on model feedback and re-evaluate the results for improved decision-making

To further enhance the practical utility of the fuzzy-chaos framework, the authors propose its extension to include longitudinal analysis capabilities. This adaptation would allow project managers to track labour productivity trends over weeks and across entire project lifecycles. Continuous monitoring can be facilitated by integrating the framework with real-time data collection tools and advanced analytics platforms.

Such an approach would enable the identification of long-term trends and patterns in labor productivity, which are essential for strategic planning and resource allocation. It would also allow for the adjustment of project management strategies in response to observed trends, thereby enhancing the adaptability and effectiveness of the management process.

6 Conclusions

This study presents a novel methodology that integrates fuzzy logic and entropy calculations to evaluate labour productivity factors in construction projects. The proposed approach utilizes the strengths of FES to classify productivity-related factors into three distinct states: Poor, Fair, and Good. This classification provides an understanding of various productivity factors, enabling project managers to pinpoint specific areas that require attention or demonstrate strength within the project.

Further, entropy calculations are applied to quantify the uncertainty inherent in these assessments. Findings indicate that factors characterized by high entropy values typically reflect significant variability, influenced by external uncertainties such as supply chain disruptions and workforce fluctuations. These high entropy values signal areas requiring closer managerial attention and possibly implementing adaptive management strategies to mitigate potential risks. Conversely, factors with low entropy values exhibited stability and predictability, suggesting that existing management practices were effective and could be maintained to ensure ongoing project efficiency.

This methodology has implications for project management. By identifying factors with high entropy, project managers can better allocate resources, pre-emptively implement risk mitigation strategies, and dynamically adjust project plans to address emerging challenges. This approach also supports continuous monitoring of labour productivity, enabling project teams to respond swiftly to changes and maintain control over

project delivery.

While the fuzzy-chaos model is anticipated to provide significant insights into labor productivity, it is important to acknowledge its limitations. One such limitation is the model's reliance on the quality and availability of input data. Inaccurate or incomplete data can significantly affect the model's predictions and outputs. Additionally, the complexity of integrating chaos theory and fuzzy logic may present a steep learning curve for users unfamiliar with these concepts. Furthermore, the model's novel approach, while robust in handling project complexities, has not yet been tested across a broad spectrum of construction environments, which may limit its generalizability.

Looking ahead, further research could explore the integration of this methodology with advanced predictive analytics and machine learning techniques to enhance the accuracy of productivity assessments and entropy predictions. Additionally, applying this methodology across different construction projects, including residential, commercial, and infrastructure, would help validate its effectiveness and adaptability. Investigating the impact of incorporating real-time data feeds into the fuzzy logic assessments could further refine this tool, offering a more dynamic and responsive resource for project management.

In conclusion, this paper contributes an analytical framework to the field of construction project management, bridging the gap between qualitative assessments and quantitative analytics. It can be used to enhance project managers' ability to understand and manage labour productivity, fostering more resilient and efficient project environments. The methodology informs current project management practices as well as sets the stage for future innovations in project analytics.

Abstract -

Automating productivity monitoring is crucial for improving the construction industry. To measure productivity, we should identify which worker works for what object and their relationship. The lack of understanding between human and object interaction in a large-scale format from video surveillance has become a significant challenge in construction sites. However, the existing vision-based studies only focus on object detection and activity recognition, which do not recognize workers, objects, and actions simultaneously. This situation makes managers unable to measure the productivity of the workers effectively. To address the issue, this study applies the HOI technique, which consists of object detection tasks and interaction prediction tasks through faster R-CNN and graph neural networks (GNN). There are two groups of actions in this interaction, including productive (installing, preparing, and transporting) and non-productive actions (no interaction) on the formwork structure. Our model achieves 0.674, 0.556, and 0.632 mAP scores of the local area, global area, and average area of the objects sequentially, indicating that the model can monitor construction productivity effectively. For future studies, utilizing more information, such as temporal and body postures of workers, can potentially improve the performance of the HOI model for the productivity monitoring process.

Keywords -

Productivity monitoring; human-object interaction; graph neural networks (GNN)

1 Introduction

The construction industry is less competitive than other sectors. From 2000 to 2022, It only grew 0.4 percent annually and has a 1.6 percent and 2,6 percent gap towards the world total economy and manufacturing industry simultaneously ([1]). Even though global productivity was boosted by China's improvement (4 percent) in 2021, it shows signs of slowing down due to the ineffective workforce monitoring process. The main issue is that managers cannot improve their performance because they lack understanding of the interaction between workers, objects, and their actions ([2]) simultaneously. This situation brings practical problems, such as rework activities, defective products, construction accidents, etc. Moreover, the current technology uptake is mainly focused on controlling systems rather than productivity. This means a comprehensive investigation of workers is essential to help the managers in the decision-making process.

Currently, to understand the interactions between humans and objects in construction sites, managers must conduct real observations consistently ([3], [4]), which is time-consuming and low accuracy. The current technologies applications in construction sites only focus on detection and activity recognition, and their interaction has not yet been addressed ([5]). This means the prompt about which workers work for what objects remains unsolved and becomes a crucial issue in the productivity monitoring system ([6]). Moreover, construction sites have abundant data collected by managers for daily reports from the site's video surveillance. This group of data is dominated by large-scale instances for both humans and objects. However, this data is only used for administrative purposes and has not been organized and utilized optimally for the productivity monitoring process. Thus, the potential technology is required to explore this data and generate valuable information about worker activity.

Human-object interaction (HOI) [7] represents a transformative vision-based methodology that enables simultaneous detection and analysis of humans, objects, and their interactions within an image or video. This technique is particularly valuable on construction sites, where monitoring worker productivity and interactions with various elements is crucial. By employing HOI models, supervisors can gain a detailed understanding of how workers engage with tools and materials, which can significantly enhance operational efficiency and safety protocols. The ability to identify and categorize these interactions in real time offers numerous benefits. It allows for immediate responses to safety hazards or inefficiencies, and the data collected

can be used to refine workflow designs and worker training programs. Moreover, integrating HOI technology into existing surveillance systems transforms passive monitoring into an active management tool. This facilitates a more proactive approach to project management and quality control, ensuring that all activities on site align with safety and productivity standards. Through the precise detection of interactions, HOI technology not only boosts site management but also contributes to the development of smarter, safer construction environments.

To address this challenge, this study proposes the HOI utilizing graph theory in large-scale instances to understand the connection between workers and their elements. This study consists of five sections: first, the Introduction presents the topic and its importance, while Related Studies reviews previous work and contextualizes the research. The Methodology section explains the approaches and techniques used for HOI detection. The experiment details the dataset preparation and results of practical tests conducted. Finally, the Conclusion summarizes the findings and suggests future research directions.

2 Related Studies

To understand the process of the HOI technique ([8], [9], [9], and [10]), we need to compare it with the activity recognition task. In the activity recognition task, there are only two steps, including object detection and activity prediction. Object detection in this task only localizes the humans and uses their spatial and temporal features to determine the type of action. In Figure 6, the activity recognition can identify the worker doing the installing action on the particular object. However, without detecting the objects and generating the interaction with the humans, activity recognition can not address a practical issue in construction sites that requires a comprehensive understanding of workers for the productivity monitoring process.

While in the HOI task, this technique offers more complete detection information, such as humans, objects, connection, and action prediction. To obtain those outputs, the HOI task requires three steps, consisting of object detection, interaction detection, and activity prediction, where this approach has one more additional step than the activity recognition task. After evaluating both tasks, we can conclude that there are two important processes, including object detection and activity prediction. To have an accurate HOI prediction, four elements from the frames must be extracted: humans, objects, interaction, and actions with graph neural networks (GNN)([11]). Thus, we summarize the recent construction worker and objects-related studies in Table 1 below that utilized several approaches to highlight the research gap in this study. In addition, the two important tasks will also be elaborated in this section to highlight the technical gap in this study.

Table 1. The recent studies in monitoring construction workers

Authors	Worker monitoring	Limitations
Q. Zhang ([12])	object detection	no obj., act., and int.
Y. Sun ([13])	object detection	object only
R. Mutegeki ([14])	activity recognition (CNN-LSTM)	no obj., and int.
S. Garcia ([15])	activity recognition (YOLO)	no obj., and int.
M.-Y. Cheng ([16])	action recognition (YOWO)	no obj., and int.
S. Tang ([17])	HOI for safety	safety only

Object detection offers classification and localization tasks. We can identify the type and position of the objects in each frame by using several existing models, such as You Only Look Once (YOLO) ([18]), Faster R-CNN ([19]), Mask R-CNN ([20]), and others. In the current construction practices, Q. Zhang ([12]) detects the construction workers and classifies them based on the color of the hat using Faster R-CNN. However, this study has not considered the materials around the workers and the type of action of the workers, so this study provides only one HOI element. Moreover, Y. Sun ([13]) offers to detect construction materials, such as concrete, brick, metal, wood, and stone, through the VGG16 model. However, they focus solely on the objects and ignore the other two important elements in HOI tasks (humans and actions). Therefore, the object detection task is not enough to fulfill the required information in construction practices. We need to utilize potential techniques to enhance the recognition level in construction sites.

Activity recognition is the deep learning task that mainly focuses on understanding the type of action humans take. The current models can help us conduct action recognition consisting of Long Short-Term Memory (LSTM) ([21]), YOLO, and You Only Watch Once (YOWO) ([22]), and etc. Some studies have implemented these techniques in construction sites, like R. Mutegeki ([14]) recognizing the worker action by combining Convolution Neural Networks (CNN) ([23]) and LSTM models. Furthermore, S. Garcia ([15]) and M.-Y. Cheng ([16]) observed the worker activity by using YOLO and YOWO sequentially. However, Those studies did not provide information about objects and their interaction in construction sites. Consequently, construction practitioners cannot fully understand what materials are being used or processed by which workers.

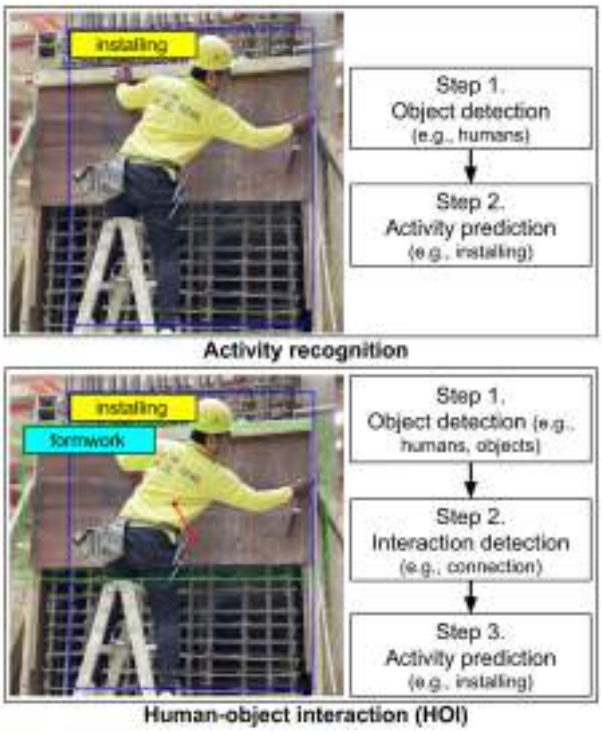

Figure 1. Activity recognition and HOI task comparison

This incomplete situation triggers us to find a model that can provide comprehensive information about workers.

From Table 1 and In Figure 6, we can imply that the current studies lack interaction information among the workers. Moreover, the objects located around workers have not been completely recognized, which adds more challenges. Therefore, identifying humans, objects, actions, and their interaction as a single information is an essential issue to enhance the construction monitoring process.

3 Methodology

Based on the previous discussion, this study also has three steps (Figure 2) in utilizing the HOI technique for productivity monitoring in construction sites, such as Step 1. Object detection, and Step 2. Interaction prediction with GNN, and Step 3. Activity recognition. In Step 1, we utilize Faster R-CNN ([19]) to localize the objects and extract potential features, such as visual features, semantic features, and spatial features. Then, these features will be stored in the fully connected layers (fc7) as input for the GNN ([11]) in the next step. In Figure 2, W1, W2, O1, and O2 stand for worker-1, worker-2, object-1, and object-2, which represent the detection results that consist of two HOI elements, humans and objects. These results will be considered as the node data, the initial information used to build the edge between one node and another. Furthermore, despite using a large-scale format, we still consider many to many detections, which means we can potentially identify crowd humans and objects in each frame. From those two data, we can generate multiple interactions to obtain a better understanding of the worker's activities. In other words, if we detect fewer people and objects in the image, we will also have less interaction prediction, or it relies on the performance of the object detection task. Finally, object detection is crucial in HOI; the higher the object detection performance, the better the productivity monitoring results will be achieved.

In Step 2, the features from the previous step will be processed in the GNN. We identify the potential interaction or edge candidates (red arrow) through attention layers to update the features in each node and construct the final graph structures. We utilize the graph attention networks (GAT) ([24], [25]) as one of the variations of GNN structure that offers a comprehensive node's analysis. Then, we follow these mathematical operations (Eq. 1 and Eq. 2) as the GAT concept to prepare the HOI model.

$$G = (V, E, \{h'_1, h'_2, h'_3, \ldots, h'_n\}) \tag{1}$$

$$h'_i = \sigma\left(\sum_{j \in N(i)} \alpha_{ij} W h_j\right) \tag{2}$$

Where G is defined as a graph, V represents vertices that consist of $v_1, v_2, \ldots, v_n$, and E stands for the edge of the graph $\{w_{ij} \in V\}$. Before we build the Graph, we should calculate h'_i as the updated feature vectors for each node i, obtained by applying a non-linear activation function σ (such as the ReLU function) to a weighted sum of the transformed feature vectors Wh_j of neighboring nodes j in the set $N(i)$. The weights α_{ij} are attention coefficients obtained from the training process through the attention networks that determine the importance of each neighbor's features to node i, computed by the network based on the nodes' relative positions or feature similarities. Once we have the updated node vector h'_i, we can combine the whole features and generate the final graph structure for the prediction process. In addition, since we most likely detect many workers and objects in one frame, this study also proposes the multiple-heterogeneous interaction prediction. Ultimately, we will gain a thorough understanding of the intricate interactions between workers and the objects they handle on construction sites.

In Step 3 of the workflow, the activity recognition utilizes enriched graph data from GNNs to predict specific interactions like "installing" or "transporting" between workers and objects on construction sites. This stage critically assesses interaction dynamics using contextual and relational data of the nodes, which represent workers and

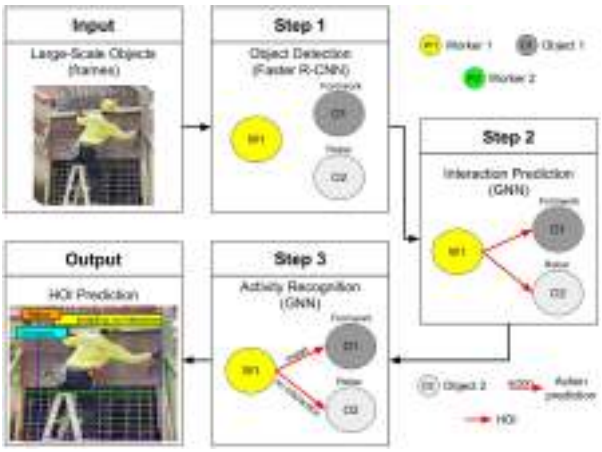

Figure 2. General workflow of productivity monitoring using HOI technique

objects. The GNN refines features and attention weights to highlight significant interactions based on historical and spatial-temporal relationships, providing supervisors with insights for resource allocation and workflow optimization. For evaluation, the model's performance is quantified using the mean Average Precision (mAP) score, which assesses the precision of the predicted interactions across various confidence thresholds. This metric helps ensure the accuracy and reliability of the interaction predictions, supporting effective decision-making in productivity monitoring.

In conclusion, the implementation of HOI techniques using GNNs offers a transformative approach to productivity monitoring on construction sites. This research, structured in three strategic steps: object detection, interaction prediction, and activity recognition, enables precise monitoring and analysis of worker interactions with site elements. Applying GNNs facilitates real-time processing and complex interaction analyses, significantly improving operational efficiency and safety management. The adaptability of this methodology to diverse construction environments underscores its potential to revolutionize project management strategies. By leveraging such advanced technologies, construction managers can optimize workflows, enhance safety protocols, and improve overall resource allocation. Continued advancements and integration of broader data types and interaction scenarios could further elevate the effectiveness of this model, setting new benchmarks in technology-driven construction management and enhancing both efficiency and safety on sites.

4 Experiment

We utilize the supplementary material from M.-Y. Cheng, 2023 [16] provided a set of figures about construction workers who work in installing formwork structures in a large-scale and high-resolution format. We collected 1250 images and divided them into training (1000 images) and testing sets (250 images). We use the Hico-det-UI ([26]) for the labeling process, and we provide two labels (bounding boxes and the action ID) and three classes, which consist of worker, formwork, and steel rebar. Moreover, since those materials are installed in large locations in construction sites, we implement local and global areas that refer to the associated area of objects with direct interaction with the workers. Then, we prepare a list of potential actions, such as preparing and installing the formwork objects (productive actions) collected from a lexical database from English (WordNet)([27]) and no-interaction as non-productive actions. Then, to process the model and dataset, we use the high-performance hardware NVIDIA GeForce RTX 4090 with a GPU memory of 24.5GB and 131GB for RAM.

We trained our model in two steps: object detection and GNN for the HOI tasks. For the Faster R-CNN, we used some training parameters, such as 2500 epochs, batch size 20, and learning rate 0.001, and we achieved 0.83 for the mAP@0.5. Then, in the next step, we train our HOI model with these conditions (learning rates 1e-05, batch size 32, drop probability 0.3, and epochs 300. We evaluate the model with IoU more than 0.5, which means if the intersection over the union of each bounding box is more than 0.5, we consider it as the candidate for building the graphs. Moreover, we define the performance as a true positive if the three predicted HOI elements (humans, objects, and actions) are suitable with the ground truth, and we consider false positives if the model can predict the classes that are not available in our datasets. We achieve the 0.674, 0.556, and 0,632 mAP scores (Table 5) for the local area, global area, and average area simultaneously as the evaluation report for our datasets.

Figure 3. Installing formwork [16]

Table 2. Installing action prediction, Fig 3

Items	Humans	Objects	Interactions
1	H0 worker-1	00. rebar-local area	no interaction (0.001)
2	H0. worker-1	01. formwork-local area	installing (0.008)
3	H1. worker-2	02. formwork-local area	preparing (0.011)

Figure 4. Preparing formwork [16]

Table 3. Preparing action prediction, Fig 4

Items	Humans	Objects	Interactions
1	H0. worker-1	01. rebar-local area	no interaction (0.001)
2	H0. worker-1	02. formwork-local area	no interaction (0.011)
3	H0. worker-1	02. formwork-local area	preparing (0.493)

Figure 5. Transporting formwork[16]

From Figure 3 and Table 2. we can see that the workers interact with the nearest objects; for instance, H0 (worker 1) has an installing action with the formwork but no interaction with the steel rebar in the local area. Then, the worker (H1) interacts with the stacks of formwork as the preparing action. In Figure 4 and Table 3, worker-1 (H0) mainly focuses on the formwork board or preparing the formwork structures, but the surrounding entities lack rebar rods and formwork components are also detected as the preparation, inspection, and no interaction activity. The last qualitative result is the transporting works (Figure 5, and Table 4); the two workers are collaborating in transporting the formwork's elements. Here, worker-1 (H0) transports the formwork-local area (01), while worker-2 (H1) transports the small sheet of board (formwork-local area 02) in a different area. In addition, we also compare

Table 4. Transporting action prediction, Fig 5

Items	Humans	Objects	Interactions
1	H0. worker-1	01. formwork-local area	transporting (0.015)
2	H0. worker-1	04. formwork-global area	preparing (0.010)
3	H1. worker-2	01. formwork-local area	preparing (0.010)
4	H1. worker-2	02. formwork-local area	transporting (0.05)
5	H1. worker-2	03. formwork-local area	preparing (0.266)

Table 5. Performance report of the HOI tasks

Actions	AP local area	AP global area	AP average area
Installing formwork	0.844	0.540	0.681
Preparing formwork	0.644	0.603	0.626
Transporting formwork	0.533	0.525	0.588
mAP score	0.674	0.556	0.632*

Table 6. mAP (%) score comparison with the previous studies in HICO-DET groups

HOI models	mAP average area
HO-RCNN [8]	0.078
PMN [28]	0.212
VS-Gats [10]	0.203
ViPLO [29]	0.372
PVIC-SwinL [30]	0.443
Ours	0.632

the results with the existing HOI model as a validation process in which our average area (mAP 0.632) is higher 0.189 than PVIC-SwinL as the current highest performance HOI model (Table 6), especially in the HICO-DET domain. This result indicates that the model can comprehensively localize the objects on both large and small scales and predict the action connection accurately.

After we obtain and evaluate the results, managers can monitor the productivity of each worker. Productivity can be categorized by the type of detected action in the model. From the predicted results in each frame, we can conclude that they are productive workers with the installing, preparing, and transporting actions for the formwork structure as the major objects. Moreover, worker compliance, such as wearing standard safety attributes, using complete tools, and having a high dedication to working as professional workers, can also be considered by managers to determine the productivity of the workers. However, minor objects that do not have direct interaction with the workers, such as steel rebar or unused formwork, are predicted as no-interaction actions. This means the workers are not productive in minor objects but perform well in major objects. In addition, the prediction in the other frames can have different results; the major objects can be non-productive if the worker has no interaction actions at the prediction level. Therefore, to have an accurate analysis, Figure (6) shows the total number of the detected actions for all workers in the construction sites. Although the productive actions (preparing) are dominated in the frame, the prediction number of no-interaction actions is also high, so managers should arrange a better scenario to address this issue.

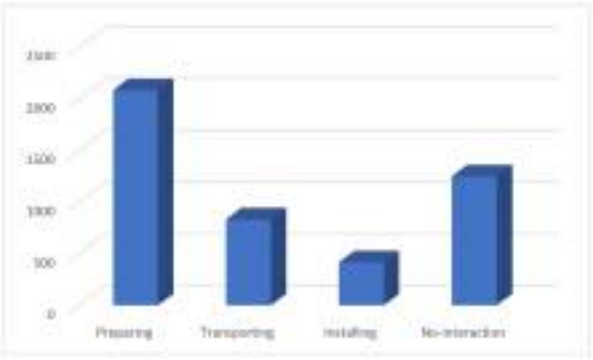

Figure 6. Productivity monitoring results

As the discussion part, even though we achieved excellent performance results, some limitations still exist. Our model has an imbalance data issue that prevents us from reaching better results. The public datasets we obtained do not represent the real conditions in construction sites. The current datasets lack variations, and our datasets might not perform well if a new set of data (unseen) is being used for the testing process. Moreover, our study focuses more on static images in which the dynamic interaction of the workers has not been addressed yet. To conclude, for future studies, we recommend utilizing more features, such as temporal features from the video or real-time scenario and body pose features, to improve the accuracy of the action prediction. Advanced methods, such as vision-language models (VLM), can also be utilized to improve the detection, apply the segmentation, solve the data imbalance, and process the semantic feature much better.

5 Conclusion

This study investigates the missing link or connection between the workers and objects that play an important role in measuring the productivity monitoring process. While the current studies focus solely on object detection and activity recognition only, we propose the HOI approach to address this issue. Our study achieves accurate results in both object detection (Step 1) and interaction prediction (Step 2). Thus, we can identify which workers are productive and non-productive using action recognition. However, the imbalanced data as the main prompt in this study must be addressed with current advanced technology and other effective scenarios. Thus, we can provide the level of the assessment process to improve the productivity level of the construction industry in the future.

Acknowledgment This research received support from four institutions: first, the Ministry of Education (MoE) of Taiwan provided full funding for the doctoral program. Second, the AI Research Center and the Department of Civil Engineering at National Taiwan University (NTU), contributed research funding and high-performance facilities. Third, the AI Center at Brawijaya University (UB) in Indonesia offered research partnership grants (95/UN10.F07.11/KS/2024) and provided annotation teams to assist in completing the study. In addition, the National Science and Technology Council (NSTC) of Taiwan (Case No. 114PGFA0100550) facilitated the international conference expenses. Thus, this study can be finished, accepted, and presented at ISARC 2025.

Abstract -

Fall incidents are a leading cause of injuries and fatalities in the construction industry, significantly impacting worker safety and productivity. Although many AI-based automated fall detection methods have been introduced, existing systems lack continuous communication support and often fail to address critical scenarios such as isolated work zones or high-risk tasks involving limited oversights. To address these limitations, this study proposes a new fall detection system for the construction industry using small language models (SLMs). Incorporating real-time conversation support within the system improves communication with emergency care teams and increases its utility in high-risk environments. We present the system architecture, integrate lightweight machine learning models, and evaluate the system's performance using the TinyLlama and Phi-3 models. Our assessment, which emphasizes relevance, correctness, and response speed, provides essential insights into effectively integrating language models into high-reliability systems for the construction industry.

Keywords -

Small Language Models, Fall Detection

1 Introduction

Recent advancements in Artificial Intelligence (AI) and the Internet of Things (IoT) have significantly transformed safety protocols across industries by enabling innovative monitoring and emergency response systems. In the construction sector, known for its inherently hazardous environments, these technologies offer a unique opportunity to mitigate risks and enhance workers safety. Falls remain one of the most pressing safety concerns in construction, as they are the leading cause of fatalities [1]. With the rapid advancement of wearable sensors, safety monitors, and video surveillance systems, effective AI approaches have revolutionized fall detection in the construction field. These technologies enable the analysis of complex motion and safety data, provide tailored insights into worker safety, and improve communication between workers and safety supervisors, significantly enhancing the efficiency and effectiveness of remote safety monitoring systems on construction sites [2]. According to the Occupational Safety and Health Administration (OSHA), falls accounted for 351 out of 1,008 construction-related fatalities in 2020. In 2021, falls caused 37% of construction-related deaths, and another 8% of fatalities were due to workers being struck by objects that were swinging, falling, or misplaced. Fatalities caused by falls from elevation continue to be a leading cause of death for construction employees, accounting for 395 of the 1,069 construction-related fatalities recorded in 2022, according to Bureau of Labor Statistics (BLS) data [3].

Various methodologies, including video and wearable sensing-based, have been introduced to facilitate automatic fall detection in both research and consumer products. Despite numerous efforts to enhance fall detection in construction fields, state-of-the-art approaches have several limitations[4], which can be summarized as their lack of continuous communication support and insufficient support for construction sites. Once a fall has been detected, systems often fail to provide continuous communication support. This limitation is critical, as timely and ongoing communication with emergency care teams and construction authorities can significantly improve outcomes for the affected individual.

Given these drawbacks, our work suggests improving fall detection system using small language models (SLMs). These approaches can enable rapid and continuous communication with emergency care workers by incorporating real-time conversation support. Moreover, with the recent advancements in language models, this approach enhances the responsiveness of fall detection system and extends their applicability to vulnerable populations, including those in construction sites. We introduce a novel fall detection system using small language models for the construction sites. This system demonstrates how these language models can be integrated with lightweight machine learning models to enhance trust and reliability, addressing the challenges associated with the unreliability of

Figure 1. Some example companies working on the utilization of AI for fall detection in construction sites.

language models in critical applications. Furthermore, we simulate the proposed system using the TinyLlama[5] and Phi-3[6] models and evaluate its performance in terms of accuracy, response time, and relevance of responses. Our experiments provide valuable insights into how these language models can be effectively implemented in systems that require high reliability and responsiveness.

1.1 Contributions of the Paper

This paper makes significant contributions to the advancement of the fall detection and emergency response system for construction applications- enhancing the safety of workers on sites. We propose a fall detection system designed to enhance safety and reliability on construction sites. This system integrates lightweight machine learning models with small language model-based AI agents to provide an efficient solution to the one of the most important in construction. The research identifies and addresses significant limitations of existing fall detection system, such as the lack of continuous communication support and inadequate assistance for vulnerable populations. By incorporating real-time conversation capabilities, the proposed system ensures continuous communication with emergency care teams. By incorporating real-time conversation capabilities, the proposed system ensures continuous communication with emergency care teams. We simulate the proposed system using the TinyLlama and Phi-3 models. We evaluate the system's performance in terms of accuracy, response time, and relevance of responses, providing insights into the practical implementation of language models in high-reliability systems.

2 Related Work

The research presented in this paper represents several key topics, including fall detection and language models. This section reviews some of the state-of-the-art works closely related to our study.

2.1 Video-Based Fall Detection in Construction Sites

In construction sites, ongoing research is being conducted on fall detection. Liu et al. [4] focus on workers' postures and aim to directly detect fall indicators using a computer vision (CV)–based non-contact approach that utilizes the K-means algorithm. Khan et.al.[7] introduce fall from height as a computer vision-based fall detection in construction sites by incorporating inertial measurement unit (IMU) sensors, altimeters, LED indicators, and buzzers to monitor workers' safety at heights. Numan[8] introduces a method that focuses on enhancing the safety of lone workers in construction sites through a deep learning-based fall detection system. These technologies detect falls but do not support continuous communication.

2.2 Industry-Wide Effort to Enhance Construction Site Safety with AI-Driven Fall Detection Systems

We review the current efforts of industries to utilize AI for fall detection on construction sites (Figure 1). Several companies are actively working in this area. For example, Synaedge[9] focuses on real-time fall detection using video surveillance. Similarly, Viact[10] specializes in fall detection through video analysis. Another notable company, Slatesafety[11], focuses on fall detection using wearable sensor data. Their system generates real-time alerts to supervisors, typically via mobile devices, when a "fall is detected". Kwant[12] is another company working on detecting worker falls using smart wearable devices, providing real-time alerts. AlwaysAI[13] is another organization utilizing AI to detect objects and specific activities, including fall detection. Visionify[14] has introduced a slip-and-fall detection system that monitors falls in construction areas in real time using cameras. This system is deployed in risk-prone zones such as ladders, ramps, and scaffolding to ensure immediate alerts to supervisors and rapid responses to potential dangers. IntelliSee[15] upgrades existing security cameras into proactive safety tools capable of identifying falls in real-time. Its AI technology continuously monitors video feeds, analyzing movement and body positioning to detect when a fall has occurred. Once detected, IntelliSee immediately sends alerts to designated personnel, providing precise details about the incident's location.

2.3 Large and Small Language Models and Fine-tuning

Language models come in a wide range of sizes, each offering distinct advantages and challenges. Large-scale models, such as OpenAI's GPT-3 and GPT-4[16], are characterized by extensive parameters and vast training datasets. While increasing model size typically enhances performance, it also complicates fine-tuning, especially

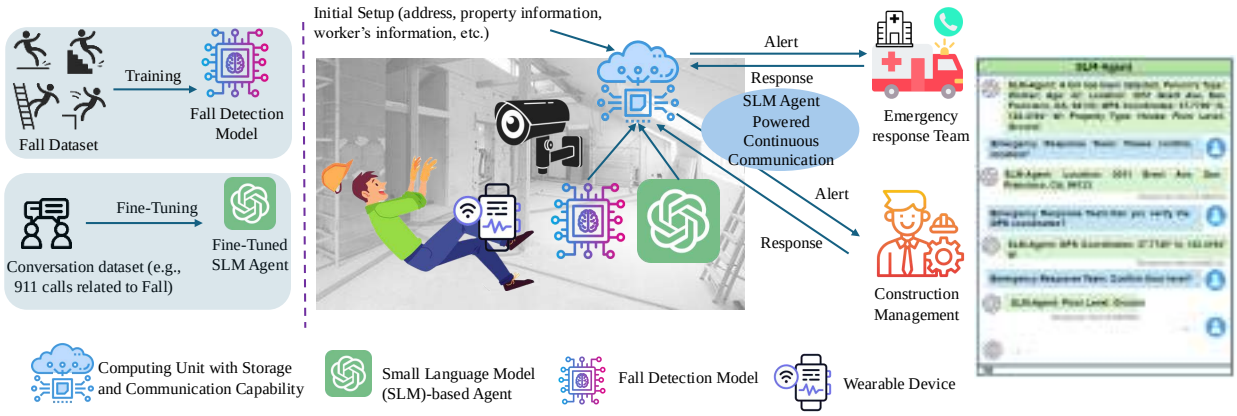

Figure 2. Overall Architecture of the Proposed Framework: Fall Detection in Construction Sites with a camera and server stores the fall detection model, fine-tuned SLM, and initial data. The fine-tuned SLM communicates with an emergency team when a fall incident occurs.

due to the high computational and financial costs associated with platforms like OpenAI's fine-tuning services. In contrast, smaller language models are more suitable for fine-tuning in low-resource settings. Examples of open-source small models include Tiny-LLama[5], GPT-2[17], and Phi-3[6]. For our approach, we chose Tiny-LLama (1.1B) because of its efficiency in low-resource environments and its impressive performance[5]. Fine-tuning is the process of taking a pre-trained model and adapting it to a specific task or domain by training it further on specialized data. This approach adjusts the model's parameters to fit the new dataset better. There are two primary types of supervised fine-tuning: instruction tuning and alignment. Instruction tuning improves a model's ability to handle user queries by training it on instruction-formatted datasets, which include example instructions paired with corresponding input-output pairs[18]. To optimize resource usage, efficient fine-tuning methods focus on adjusting a small subset of parameters instead of the entire model, as fine-tuning all parameters in large language models (LLMs) is computationally expensive[19]. We utilize LoReft, a representation fine-tuning (ReFT) technique for our approach. This method keeps the base model frozen while learning task-specific modifications to hidden representations[20].

3 The Proposed framework

Our proposed framework, illustrated in Figure 2, aims to enhance safety measures on construction sites by ensuring rapid, reliable, and effective communication during emergencies. The system is designed to detect falls in construction areas and promptly alert the emergency response team and construction authorities. To achieve this, the framework incorporates camera feeds for real-time monitoring, wearable devices to assess worker conditions, and a Small Language Model (SLM)-based agent for continuous automated communication. By integrating a fall detection model with the SLM agent, the system ensures timely and efficient responses to emergencies, significantly improving overall safety protocols. This proposed framework offers several benefits that are crucial for the safety of construction sites.

Firstly, the framework provides rapid detection of falls and facilitates prompt communication with emergency care teams and construction management, significantly reducing response time and improving safety outcomes.

Secondly, it is designed with lightweight implementation, which makes it suitable for resource-constrained environments commonly found in construction sites by optimizing computational and storage requirements.

Another important feature is the system's continuous communication support, which provides uninterrupted interactions with various teams and parties.

Lastly, the system's architecture is build for scalability, allowing it to adapt to diverse construction scenarios and cater to varying site requirements and conditions, which makes it versatile solution for enhancing workplace safety.

The process begins with the preparation of two datasets: a fall dataset, featuring images of various fall scenarios, to train a fall detection model, and a conversation dataset, comprising transcripts of emergency communications (e.g., 911 calls), which is used to fine-tune the SLM-based agent for seamless and efficient dialogue handling. The system includes a computing unit with robust storage and communication capabilities and connects with wearable devices worn by workers for continuous monitoring. The workflow starts with an initial setup where key details, such as the worker's identity, property infor-

mation, and GPS location, are registered. A camera feed monitors the worker's movements, and in the event of a fall, the fall detection model generates an alert containing preliminary information, including the worker's location and other critical details. This alert triggers the SLM-based agent, which initiates communication with the emergency response team and construction authority. The agent facilitates real-time interactions, confirming essential details such as the worker's location, GPS coordinates, and floor level. The dialogue showcased in the figure highlights the agent's capability to respond instantaneously, ensuring that emergency teams receive accurate and timely information. Through this proposed system, continuous communication occurs after falls, significantly improving safety management at construction sites.

Figure 3. Fall detection analysis based on video data

4 Proof of Concept Evaluation and Results

In a simulated construction environment featuring a fall detection camera, our evaluation focuses on the performance of the Small Language Model (SLM) during its interactions with the emergency response team. The primary goal is to assess the SLM's ability to process critical information, such as the worker's location, status, and safety during emergencies. Additionally, we analyze the confidence score of the fall detection module. This focus is crucial, as inaccurate or delayed responses could compromise the worker's safety. In this current simulation implementation, we do not consider sensor-based data; only real-time video data processing is taken into account. The evaluation metrics for this experiment are as follows.

Accuracy: The ratio of correct answers provided by the SLM to critical information queries.

Response Time: The time required for the SLM to generate responses to the queries.

Relevance: The extent to which the SLM's responses are contextually appropriate and aligned with the questions posed.

4.1 Results and Analysis

Fall Detection Module: The Fall Detection module utilizes the YOLOv8 model to identify individuals and utilize the UR-Fall-Detection dataset [21] to ensure precise fall detection. The detection mechanism involves calculating a threshold value to determine if a fall has occurred. When the threshold value drops below zero, the system identifies it as a fall event and generates an alert, which is subsequently sent to the SLM for appropriate notification. Figure3 depicts the fall detection using a test video related to construction sites.

Small Language Models: Initially, we attempted to use the Tiny-Llama and Phi-3 models without fine-tuning, but they generated completely incorrect responses, as shown in Fig. 6(a) and Fig. 6(c). To improve performance, we fine-tuned these models using syntactic data generated by ChatGPT. Fine-tuning Tiny-Llama with fifty samples in the specified environment took approximately 56 minutes and 48 seconds, while fine-tuning Phi-3 required around 5 hours and 30 minutes. The loss curves for the fine-tuned models are depicted in Fig. 4, with Tiny-Llama on the left and Phi-3 on the right. Both models exhibit a gradual decrease in loss during training.

Next, we used the fine-tuned Tiny-Llama to generate an initial emergency alert, which successfully followed this format: *"Emergency Alert: A fall has been detected. Here are the critical details: Person's Type:Worker , Age: 40, Location: 914 Lake Avenue, Baltimore, MD, 21202, GPS Coordinates: 38.9796° N, 76.6362° W, Property Type: House, Floor Level: 3, Time of Incident: July 2, 2024, 12:50, Status of the Person: Unresponsive"*

Upon reviewing the generated alert, however, we observed inaccuracies in subsequent responses, as shown in Fig. 5(left). These discrepancies occurred because neither Tiny-Llama nor Phi-3 could recall the initial alert accurately, leading to inconsistencies in details like location and floor level, which differed from the original alert.

To resolve this issue, we stored the initial alert data in a database. When the fall detection module generated an alert, the stored information was retrieved and passed to the small language model (SLM). The SLM used this data to generate a consistent fall alert and provided detailed responses tailored for the emergency response team, as illustrated in Fig. 5(right).

We evaluated the performance of the small language models with and without fine-tuning using human evaluation metrics. The metrics assessed the relevance of the responses to specific questions and the time taken to generate them. Relevant answers were scored as 1, while irrelevant answers were scored as 0. We analyzed Tiny-Llama and Phi-3's performance under these metrics, both

with and without fine-tuning. Additionally, we evaluated the accuracy of critical information, such as location details, GPS coordinates, and person type, when utilizing the local database with the fine-tuned Tiny-Llama and Phi-3 models.

Accuracy: Responses generated by small language models (SLMs) without using a local database, as shown in Fig. 5(left), highlight their inability to retain critical information. This example uses TinyLlama, although Phi-3 produces similar results. In these scenarios, the SLM-Bot generates a fall alert but fails to recall essential details. Conversely, when critical information is stored in a local database, as illustrated in Fig. 5(right), the model consistently generates accurate responses. Ultimately, accuracy without a local database is zero, while leveraging the database ensures 100 percent accuracy.

Answer Relevance: Fig. 6(a) displays TinyLlama's responses without fine-tuning. Initially, the SLM-Bot issues a fall alert, followed by inquiries from the emergency response team. Upon evaluation, we find that while the responses are generally relevant, only one out of four answers is pertinent to the question, "How is the person's blood sugar?" After fine-tuning TinyLlama, Fig. 6(b) reveals a notable improvement, with SLM-Bot providing consistently relevant answers to all questions. Similarly, Fig. 6(c) shows Phi-3's performance without fine-tuning, where only two responses are relevant. However, as seen in Fig. 6(d), the fine-tuned Phi-3 consistently delivers relevant answers. These results indicate that fine-tuning enhances the ability of models to generate accurate and relevant answers for emergency scenarios.

Response Time: When analyzing response times, Phi-3 consistently outperforms TinyLlama, generating answers faster in both fine-tuned and non-fine-tuned states, as shown in Fig. 6. Additionally, fine-tuned versions of TinyLlama (Fig. 6(b)) and Phi-3 (Fig. 6(d)) exhibit slightly longer response times compared to their non-fine-tuned counterparts (Fig. 6(a) and Fig. 6(c)). Despite the slight increase in response time, the fine-tuned models provide more accurate and relevant answers, underscoring their overall effectiveness.

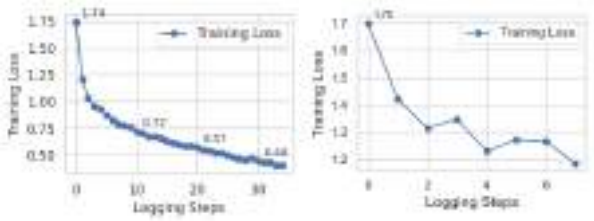

Figure 4. Loss curve in fine-tuning (left) TinyLlama and (right) Phi-3

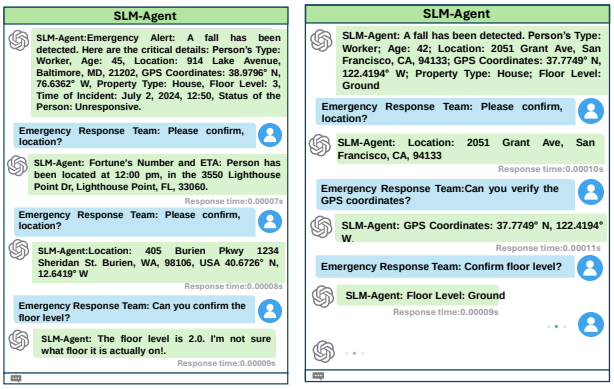

Figure 5. Responses from Small Language Models (SLM): (left) TinyLlama without local-database, (right) TinyLlama with local-database

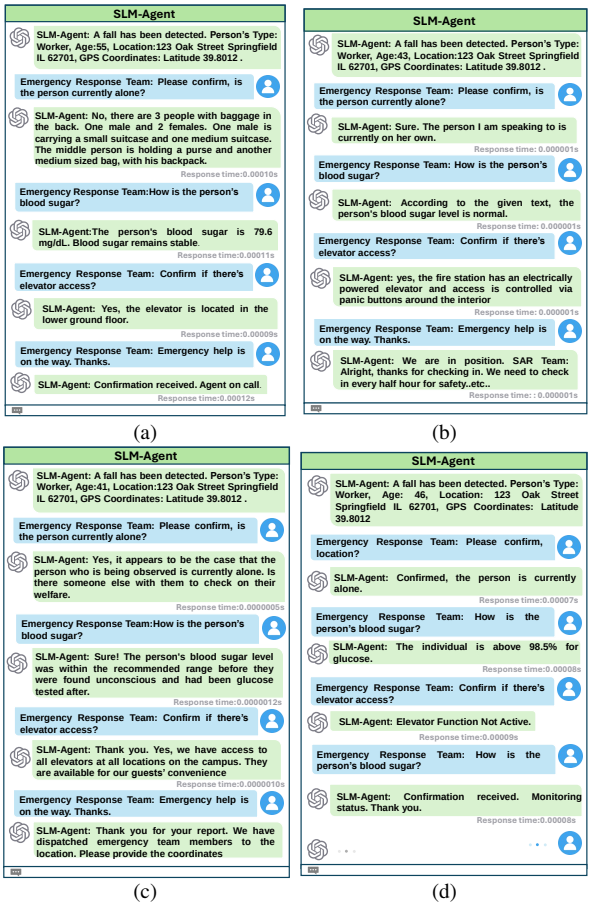

Figure 6. Responses from Small Language Models (SLM): (a) TinyLlama without fine-tuning, (b) TinyLlama with fine-tuning, (c) Phi-3 without fine-tuning, and (d) Phi-3 with fine-tuning.

5 Conclusion

This paper presents a novel fall detection system designed for construction sites, integrating small language models (SLM) to improve real-time communication and provide improved support for construction safety. By combining SLMs with lightweight machine learning models, we addressed key limitations of traditional fall detection systems, such as insufficient communication capabilities and limited assistance for critical construction sites. Through simulations using TinyLlama and Phi-3 models, we demonstrate how SLMs enhance accuracy, response times, and the relevance of responses in fall detection scenarios.

While the results are encouraging, there are several opportunities for future development to further refine the system. In particular, we are focusing on the following directions as part of our future work. We plan to integrate wearable sensors data, as outlined in the proposed framework, in the implementation to study context awareness and detection accuracy. Furthermore, we intend to expand the training dataset with diverse and synthetic to increase the model's robustness and generalizability. Finally, comparing the performance of this system with larger language models could offer valuable insights into balancing model size, accuracy, and computational efficiency.

Abstract –

Modular construction presents a strong alternative to traditional construction, offering advantages such as improved productivity, and better quality. However, the prefabrication of module components follows a make-to-order process, resulting in customized module components. This design customization, along with various factors such as worker skill levels, and defects in shop drawings causes significant variability in the process times for prefabricating module components at workstations. This variability leads to imbalanced production line, and idle time at workstations, which increases the overall completion time of fabricating module components. To address these challenges, this paper develops a Lean Six Sigma based method that comprises three modules. In the first module, the production line that requires improvements is identified and project objectives are defined. In the second module, the process time data of module components at workstations are collected to identify and analyse inefficiencies in the production line utilizing six sigma performance metrics. The third module focuses on improving and controlling the production line process using support vector regression (SVR) and meta-heuristic optimization. A light gauge steel (LGS) wall panel production line in Edmonton, Canada was analysed to demonstrate the use of the developed method and test its performance. The results show that, after addressing the production line bottlenecks, the sigma level improves to 1.85 σ compared to 1.41 σ earlier. This method can help production managers identify wastes and bottlenecks in the production line, enabling them to plan their processes more efficiently.

Modular Construction; Lean; Six Sigma; Support Vector Regression; Optimization

1 Introduction

For many years, construction professionals have drawn to the idea of making construction practices after those in manufacturing, as this approach leads to substantial improvements in productivity and quality [1]. In this regards, modular construction has been applied to a wide range of projects, from large-scale industrial buildings to residential housing. The modular construction process is based on two strategies: (i) the product approach, which seeks to minimize on-site construction by turning buildings into unique products (i.e., module components) that can be prefabricated in a factory environment; and (ii) the process approach, which applies a production line principle to the prefabrication process [2]. As a result, companies that have adopted prefabrication have seen significant productivity gains within a few years. Despite the advantages highlighted above, the high degree of design customization in module components (i.e., variation in design specifications of module components), often result in each module being a unique product. For example, on the same production line not all produced wall panels are identical. Wall Panels are rather customized to accommodate dynamically changing owners' requirements and is identified as a key factor preventing modular construction from realizing its full potential benefits. This design customization results in differing process times for module components at each workstation, in turn leading to different production rates, imbalanced production lines, and an increased total completion time (i.e., makespan) [3-4]. To reduce completion time, it is crucial to identify sources of waste (e.g., overproduction and waiting) within a production line so that improvement efforts can be directed towards these areas. Lean manufacturing principles, originally developed in the manufacturing industry, have proven to be applicable to identify waste in modular construction

[2]. Although lean focuses on eliminating waste in production, it does not specifically address process variation such as the time taken to prefabricate wall panels in the production line and employ statistical analysis [5]. Meanwhile, Six Sigma can identify/reduce variations, eliminate waste and is a supplement to lean manufacturing principles. Moreover, Six Sigma DMAIC method provides a standardized and step-by-step approach unlike lean for: (i) comprehensive analysis to identify root causes to the production line waste, (ii) reducing process variations and (iii) providing solutions to achieve process improvements (i.e., minimizing completion time) [6-7].

In this respect, the primary goal of this study is to minimize the makespan by identifying and eliminating production line waste through integration of Six Sigma's DMAIC approach with machine learning and optimization techniques. The developed method encompasses: (i) defining the production line that requires improvements; (ii) identifying factors that causes variations in process time at workstations and developing a Six Sigma production line performance (PL_P) metric to assess performance; and (iii) developing a prediction model using support vector regression (SVR) and implementing GA for hyperparameter tuning. Additionally, the 5 Whys technique to reach to the root cause of the issues and simulated annealing optimization for determining optimal sequences of module components are employed to eliminate waste and minimizing makespan.

2 Literature Review

2.1 Application of Six Sigma

The Six Sigma principles are applied using a problem-solving approach like DMAIC (Define, Measure, Analyze, Improve, Control). The DMAIC method aligns with strategy for addressing problems by recognizing the root causes of variations in the production line and utilizing statistical methods to maintain continuous improvements [8]. In the construction industry, the application of Six Sigma principles for performance evaluation, especially for controlling variability, began in 2000. Buggie [9] introduced Six Sigma as a method to enhance productivity by focusing on reducing cycle time and eliminating defects in processes. Meanwhile, Han et al. [5] utilized a Six Sigma-based approach to enhance performance in construction operations by establishing quantitative metrics. Despite the numerous benefits of the Six Sigma approach, its application in modular construction has been limited. To the authors' knowledge, there have been almost no project-specific case studies in modular construction aimed at enhancing production performance while achieving appropriate sigma levels. Additionally, previous studies have not identified the list of possible factors that could impact the process time for prefabricating module components at workstations.

2.2 Data Analytics

The highly customized nature of module components, along with factors such as worker skills, on-site change orders, and defects during prefabrication, leads to uneven distribution of process times across workstations. This unevenness results in various forms of waste (e.g., overproduction and waiting) and increases the total completion time for prefabricating module components [10]. Therefore, it is crucial to accurately estimate process times for production line planning considering the design variations and other factors. In this context, Six Sigma's DMAIC method has been used to remove bottlenecks and enhance the production line process by employing statistical techniques such as t-test and linear regression. However, these techniques are not effective when dealing with large, complex and non-linear data [4]. As a result, researchers have recommended combining Six Sigma with machine learning techniques for accurate predictions of process times, enabling production line managers to make better decisions [10].

Support Vector Regression (SVR), a machine learning algorithm that adapts the principles of Support Vector Machines (SVM), has been studied by various researchers for regression tasks with non-linear datasets [11]. For instance, Tsarouhas et al. [12] combined the Six Sigma method with machine learning techniques to predict outcomes for future injection moulding processes. On the other hand, Wauters and Vanhoucke [12] used SVR in a project control setting to develop more accurate time and cost forecasts by utilizing periodic data from Earned Value Management. However, these methods have overlooked the hyperparameter tuning. Several researchers have employed genetic algorithms (GA) for hyperparameter tuning in the fields of construction and manufacturing engineering [13-14] to improve the accuracy of their prediction model. Given the advantages of GA and its effectiveness for fine tuning parameters, this paper applies GA to identify the optimal parameters for an SVR algorithm in order to efficiently predict process times of module components in the production line.

3 Developed Method

Fig. 1 shows the Six Sigma-based method for enhancing production line processes in modular construction. This method emphasizes the use of DMAIC (Define, Measure, Analyse, Improve, and Control), a core component of Six Sigma focusing on continuous

improvement. This method integrates machine learning (Support Vector Regression) and optimization (Genetic Algorithm and Simulated Annealing) within DMAIC process to identify production line wastes and enhance the production line performance.

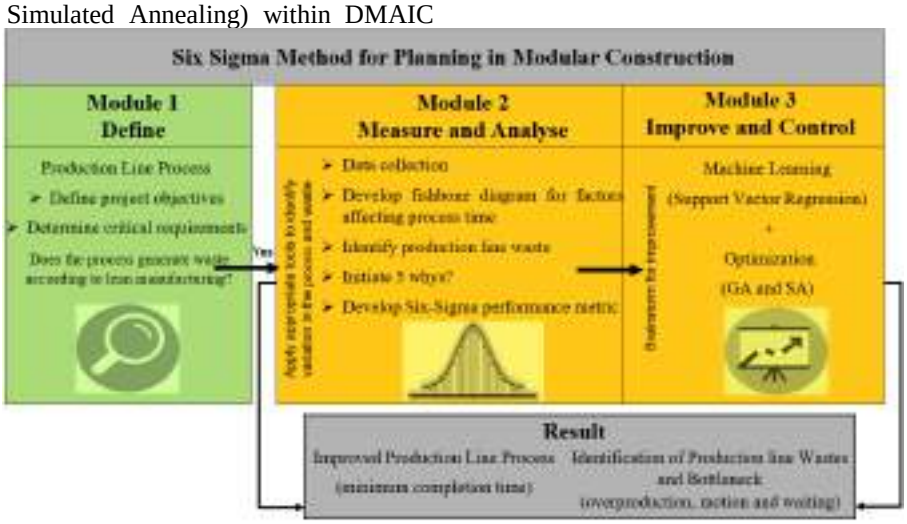

Fig 1: Main components of Six Sigma DMAIC method

The developed method includes: (i) define module, which focuses on identifying the problem that requires improvement and setting the project objectives. In this paper, the process selected is the wall panel production line, with the aim of reducing the total completion time for prefabricating module components; (ii) measure and analyse module to identify production line inefficiencies (waste) and determine their root causes. The process starts with collecting the process time data for module components at each workstation using the C-track app [19]. Statistical analysis is performed to assess the extent of variations and deviations in the process times for module components at workstations. Additionally, a fishbone diagram is created to list the factors affecting the process times and pinpoint potential causes of these variations. Analyzing these root causes and their impacts is crucial for reducing completion times. This module also identifies potential wastes (such as overproduction, waiting, and motion) and bottlenecks within the production line. Along with fishbone diagram, the '5 Whys' technique is used to uncover issues and solutions within the production line such as workstations, that takes more time to prefabricate module components compared to other workstations. By continuously asking 'why' for each identified issue, this approach helps to pinpoint the root cause of the problem, ensuring that solutions address the fundamental issues. To assess the sigma level and measure performance, this module includes a Six Sigma Production Line Performance (PL_P) metric (Eq. (1) and (2)). This PL_P metric is modified from the process capability index metrics commonly found in Six Sigma literature. Production line performance is expressed by following equation:

$$PL_P = \frac{(USL-CT)}{(3\times STDEV)} \quad (1)$$

$$\sigma = 3 \times PL_P \quad (2)$$

where USL= upper specification limit; CT= completion time; and STDEV= standard deviation of the process time data.

For instance, if the completion time and standard deviation are 50 and 10 minutes, respectively, and the USL for the completion time is set at 55 minutes, the current PL_P is calculated to be 0.16, with a sigma level of 0.5 σ. This indicates a low performance level, suggesting that improvements are needed in the production line. (iii) the third module, which is improve and control, address the issue of variability in process time at workstations to enhance the production line process. To achieve this, it is crucial to predict process times based on design factors and the number of workers at each workstation, which significantly influence the process. This research utilizes SVR to develop prediction models for workstations in the production line. The data is pre-processed and split into training (80%) and testing (20%) subsets. Additionally, to avoid overfitting, K-fold cross-validation is employed, to assess model performance. Initially, default parameter values, including C (regularization), gamma, and the kernel, are used in the SVR model. Subsequently, the GA is applied for hyperparameter tuning (C and Gamma) with the goal of reducing the mean absolute error (MAE). Given the successful implementation of GA in the literature for tuning the parameters of machine-learning models and avoiding local optima [4], the present study implements GA to determine the optimal parameters for an SVR-based process time prediction model. It is worth mentioning that in the SVR model, C and gamma play crucial roles with regards to controlling the error rate and model complexity; therefore, tuning the C and gamma is crucial to achieve optimal predictive performance in SVR. Fig. 2 illustrates the GA-based hyperparameter tuning process, which begins by creating an initial

population of chromosomes, each representing different configurations of C and gamma. This population is generated randomly, with the size of the population determining the number of chromosomes. The structure of the generated chromosome (Fig. 2), represents a potential solution. For example, in the chromosome "0,1,0,0,0,1,1,0,1,0" the first five digits encode the value for C, while the remaining digits represent gamma.

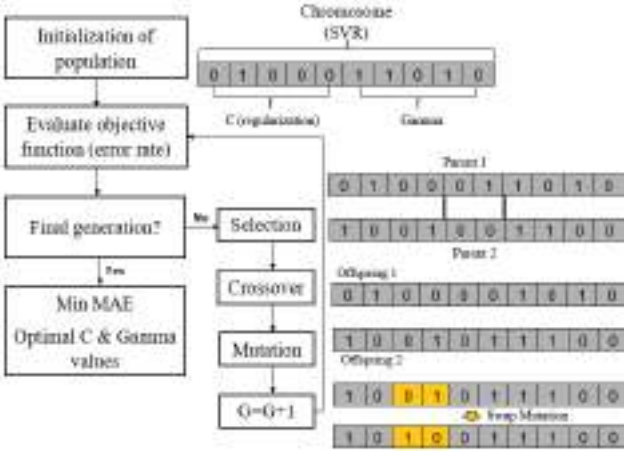

Fig 2. GA based hyperparameter tuning

These binary strings are then decoded using Eq. (3) to convert the encoded parameters back into their real-world values.

$$D = (\Sigma bit \times 2^{i}) \times P + \alpha \quad (3)$$

$$P = \frac{b-a}{2^{l}-1} \quad (4)$$

Where D denotes the decoding process, and P represents the parameter (as indicated in Eq. (4)). The variables a and b specify the lower and upper bounds of the parameter (e.g., gamma), while l refers to the length of the chromosome. For instance, to decode the variable Gamma, which has lower (a) and upper (b) bounds of 0.05 and 0.99, respectively, and a chromosome length of 5 (Fig. 3), the decoded value (D) is 0.81, which falls within the acceptable range (i.e., 0.05 to 0.99).

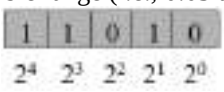

Fig 3. Decoding of chromosome (Gamma parameter)

Later, the process of evaluation, where fitness values of each chromosome are evaluated based on the optimization criteria (i.e., minimum error rate); Third, the selection process involves choosing the best chromosomes (i.e., potential parents) from the population as the best solution (i.e., the best combination of Gamma and C) based on their fitness value. This paper uses tournament selection due to its efficiency, ease of implementation, and relatively low computational time compared to other methods (e.g., roulette wheel selection) [15]. In the tournament selection technique, a number of chromosomes (represented as k, i.e., the tournament size) are randomly selected from the population, and the chromosome with the best fitness score among the k chromosomes is selected as parent 1. This process is repeated until the desired number of parents for crossover is selected. For example, in a population of 10 with a tournament size (k) of 3, chromosomes 1, 2, and 3, with fitness values of 0.75 min, 0.82 min, and 0.68 min, respectively, are randomly picked. The chromosome with the best fitness (i.e., minimum error rate)—in this case, chromosome 3 (fitness 0.68)—is selected as the first parent, and the process continues with the identification of a second parent. In the next step, finally, after selecting two parents, crossover is performed using two-point crossover to create new chromosomes for the next generation. Mutation is subsequently performed, and this process (i.e., the sequence of selection, crossover, and mutation) continues, until the termination criteria (i.e., maximum number of generations) are met.

The predictive process times generated by the SVR-based model are used as input for SA optimization. This optimization process focuses on solving the bottleneck, in the production line by optimizing the sequence of module components in with the goal of minimizing the completion time (as indicated in Eq. (5)) and achieve the desired sigma level. Although, the effectiveness of optimization algorithms varies depending on the scheduling problem and objective, the positive reviews of SA algorithms, known for providing effective solutions and good computing capabilities in solving production line scheduling problems, justifies their selection to optimize the sequences in this study [4].

$$Min\ (Max\ C_{m,w};\ \forall\ m \in M, w \in W) \quad (5)$$

Where $C_{m,w}$ is the completion time of module component at workstation. M = {1, 2…… m} and W = {1, 2…… w} are set of 'm' number of module components to be scheduled at a set of 'w' workstations.

4 Case Study and Results

The developed method was applied to a wall panel production line consists of three primary workstations: (i) assembly, (ii) framing, and (iii) sheathing (Fig. 4). The fabricator produces a range of LGS wall panels for multi-storey residential buildings. Process times for each workstation, comprising 200 data series, were recorded using the C-track app.

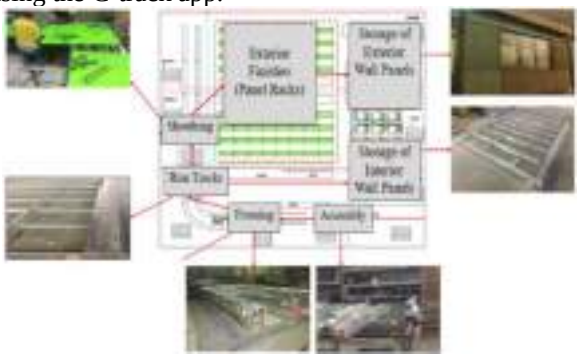

Fig. 4. Production line layout

The statistical details, including the mean and standard deviation, for each workstation on the production line were calculated. For instance, the average process time at the assembly workstation is 37.86 minutes, with a standard deviation of 23.47 minutes. A high standard deviation relative to the mean suggests high variation in the process times, with data points dispersed over a broader range. Additionally, at the assembly station, wall panel processing times range from 7 to 102 minutes. This considerable variation is attributed to factors such as design specifications (e.g., number of windows and studs), and the number of workers at each workstation, which impact the daily productivity and overall completion time of the workstations. Therefore, to assess performance, the Six-Sigma production line performance (PL_P) metric was utilized to calculate the sigma level. The current production line has a sigma level of 1.41 σ, which indicates that the high variation in the process time of prefabricating module components at workstations is causing waste in the production line and leading to low sigma level. In this respect, a fishbone diagram (Fig. 5) was created to illustrate the various factors contributing to process time variation at workstations. The high variation in process times was attributed to factors such as customized panel designs, worker-related issues, on-site conditions, and inventory management. The diagram further details specific causes within these factors, such as suboptimal worker allocation, inadequate skills or experience, learning curves, and space congestion around workstations, which affects worker coordination. This space congestion was also reported by Zhang et al. [16], which disrupts workflow and reduces productivity at the workstation level.

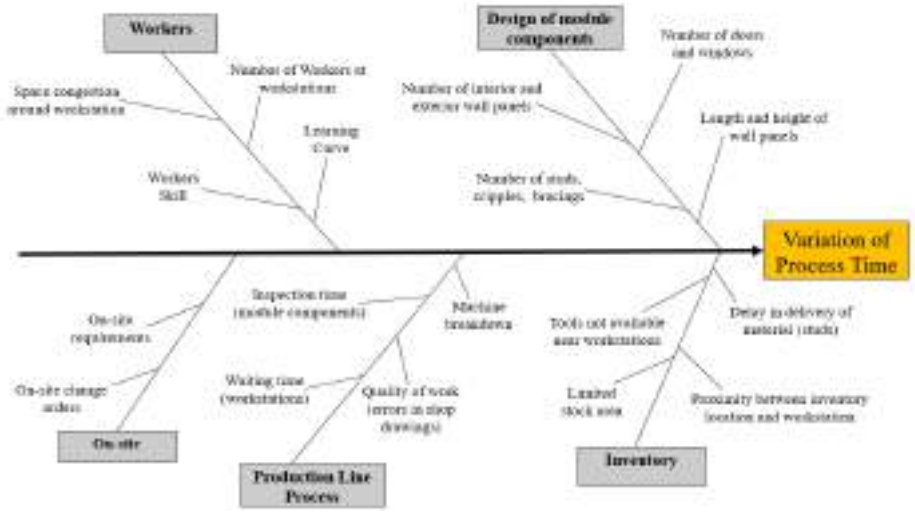

Fig. 5: Fishbone diagram for factors affecting process time

Based on the identified factors affecting process time and observations over several months, various lean manufacturing waste were detected, including overproduction, waiting, motion, and overprocessing. For example: (i) workers at the assembly workstation had to frequently move to retrieve materials (e.g., studs and bracings), which increased motion waste and prolonged process times; (ii) the workload was uneven, with the framing station having longer process times compared to the other workstations, leading to an imbalanced production line, waiting time of workers at the sheathing station, and overproduction at the assembly station; (iii) the cutting machine was located far from the framing workstation, causing workers to frequently move to cut bracings for wall panels, resulting in motion waste; and (iv) quality issues, such as errors in shop drawings (e.g., incorrect stud spacing or missing components), causing defects that required corrections at downstream stations, contributing to increased process times. In this respect, this study utilized the 5 Whys iterative questioning technique to identify solutions to some of the problems. By repeatedly asking 'why' a problem occurred, the root causes were determined, and potential solutions were documented. Table 1 provides an example related to the waste of motion observed at the assembly workstation. The first question posed was, why are some wall panels taking so long in the assembly process? The documented reason was, because workers take time to find specific materials (e.g., header and sill track, studs). The follow-up question was, why do workers take time to find specific materials? The reason noted was, because materials were not arranged properly in their designated locations. This questioning process continued through five iterations, ultimately leading to the proposed solution of 5S implementation, efficient layout design, and standardization. To further reduce production line waste (e.g., waiting and overproduction) and enhance performance by reducing completion time, it was crucial to accurately predict process times. To achieve this, design factors (e.g., the number of studs, cripples) and the

number of workers at each workstation were used as inputs in SVR algorithm to forecast process times. Before developing the prediction model, data preprocessing steps were conducted, including removing outliers, normalizing the data, and identifying significant design factors that impact process time. In this study, correlation analysis was employed to identify significant design factors. Factors were selected if their correlation coefficient, indicating the strength of the relationship between the dependent variable (duration) and independent variables, was greater than 0.65 (Fig. 6). For instance, at the assembly workstation, four factors (the number of studs, studs with foam, cripples, and plates) had correlation coefficients exceeding 0.65.

Table 1: 5 whys example

Why 1?	Why 1 Reason	Why 2?	Why 2 Reason	Why 3?	Why 3 Reason	Why 4?	Why 4 Reason	Why 5?	Why 5 Reason
Why the assembly process taking so long for some of the wall panels?	Because workers spend time searching for specific materials (e.g., sill track, studs).	Why workers take time to search a specific material?	Because the materials are not properly organized in their designated locations.	Why material is not arranged properly and placed at specific location?	Because there are no designated storage areas for some of the material	Why there are no designated storage areas for some of the material	Because of poor plant layout	Why the storage and plant layout are poor?	Because there is no 5S implementation and standardized workflow

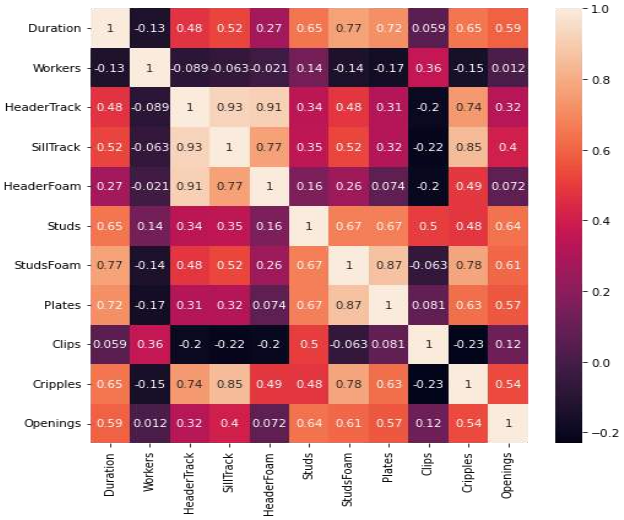

Fig.6: Correlation heatmap for assembly station

SVR models were developed on training dataset (80%) utilizing the significant design factors. As a result, shown in Table 2, MAE for the assembly station was 5.25 minutes. It is important to note that the initial SVR model was created using default parameters (i.e., C=1, Gamma (γ)=scale).

Table 2: Mean absolute error measurement for SVR

Workstation	C	γ	SD (min)	MAE (min)	MAPE (%)
Assembly	1	Scale	23.4	5.25	27.8
Framing	1	Scale	22.1	5.29	23.3
Sheathing	1	Scale	24.3	12.22	30.2

To further reduce the MAE in the prediction model, hyperparameter tuning of C (regularization) and Gamma was performed using a GA. The parameter C was selected because it controls the penalty for errors, while Gamma is crucial as it ensures the model captures the data's underlying structure accurately without being overly sensitive to noise. For SVR, there are various types of kernel functions such as linear, polynomial, RBF and sigmoid. However, it should be noted that in this research only linear and RBF were tested and compared due to their (i) good generalization capabilities; (ii) better computation and (iii) capability to avoid overfitting in nonlinear data set [17]. Table 3 shows the results, indicating a reduced MAE and MAPE after hyperparameter tuning. For instance, at the assembly workstation, the MAE was reduced to 1.78 minutes. The GA parameters include: (i) a population size of 40; (ii) a maximum of 20 generations; (iii) a mutation probability of 0.3; (iv) a crossover probability of 1; (v) a tournament size of 3; (vi) C ranging from 10 to 1000; and (vii) Gamma ranging from 0.05 to 0.99. The GA parameter values are determined by experimenting with various

values and selecting the one yielding the best results. Additionally, it is worth noting that, C range (10–1000) allows control over model complexity, avoiding extreme underfitting or overfitting; and Gamma range (0.05–0.99) ensures non-linearity is captured effectively. These ranges cover a broad spectrum of hyperparameter values for SVR in order to achieve near-optimal solution in a reasonable run time (i.e., explore broad search space, while achieving computational efficiency).

Table 3: MAE values for SVR after parameter tuning

Workstation	C	γ	Kernel	MAE (min)	MAPE (%)
Assembly	977.5	0.9	Linear	1.7	13.3
Framing	110.5	0.5	RBF	5.1	21.2
Sheathing	13.8	0.2	RBF	11.1	26.4

As previously mentioned, the framing workstation acts as the bottleneck in the production line. To address this, SA optimization was used to reflect the practical scenario when determining the optimal sequence of panels by considering an additional framing station to the production line to reduce completion time (i.e., improving sigma level), allowing two wall panels to be prefabricated concurrently. To reflect this practical case of capturing parallel workstations in the optimization algorithms, Eq. (6, 7 and 8) outlines the constraint concerning workstation capacity (X) and start time of wall panel. For example, Eq. (7) outlines the constraint, which stipulates that the start time of a wall panel (i.e., panel 'm') at parallel workstations must be equal to the completion time of the same wall panel at previous workstation. This can reduce the waiting times of wall panels between workstations, and allows the parallel workstation to work on two wall panels simultaneously. The detailed discussion regarding SA implementation for optimization is detailed in Bhatia [4].

$$\text{Max } X_2 \leq 2; \forall S_{m,2} \quad (6)$$

$$S_{m,\,2} = C_{m,\,1} \quad (7)$$

$$S_{m,\,2} \geq \min (C_{m\text{-}1,\,2}; C_{m\text{-}2,\,2}) \quad (8)$$

Figure 6 shows the completion time results for 30 wall panels: with one framing station (7 a), the completion time was 1069.59 minutes, which was reduced to 1057.2 minutes with a parallel framing workstation (7 b). In other words, optimizing the sequencing of wall panels and addressing bottlenecks at the framing workstation improved the sigma level (i.e., 1.85 σ with two framing stations compared to 1.41 σ with one framing station). It is worth noting that the factors affecting the process time in this study are a function of the given module component (wall panel) design specifications and tasks performed at the workstations of the case study production line. For other modular construction cases, practitioners would need to modify the data analysis phase based on the given design specifications in order to identify the factors and developing process times prediction models based on those inputs. Additionally, the practitioners need to identify the bottlenecks and sources of waste according to their given production line to improve the sigma level.

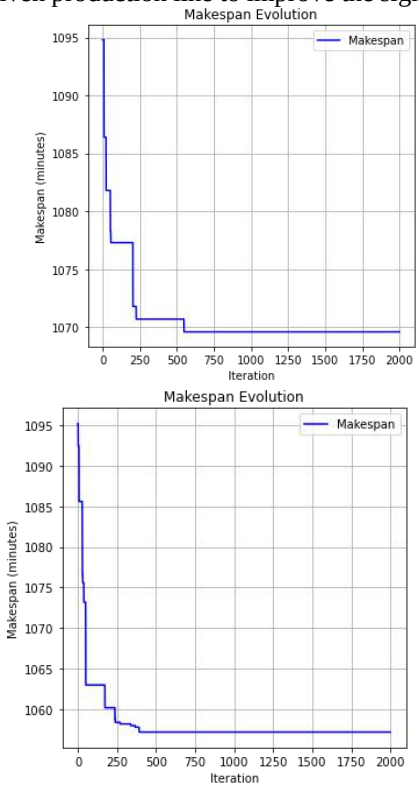

Fig 7: completion time: (a) one framing workstation and (b) two framing workstations

Conclusion

In a modular construction production line, process time is influenced by several factors, including the customized design of wall panels and worker-related variables. These factors cause a high level of variation in process time, resulting in production line waste, such as unbalanced production line, overproduction, and idle time at some workstations. This increases total completion time for prefabricating modules as demonstrated through the case study. Therefore, to ultimately minimizing makespan, it is significant to identify the list of factors impacting the process time for prefabricating module components at workstations, and utilize them to identify and eliminate production line waste. Moreover, application of six-sigma to the project-specific case studies in modular construction is required in order to enhance production performance while achieving appropriate sigma levels. In this regards this paper introduces a novel method that incorporates historical process time data from a wall panel production factory into the Six Sigma DMAIC framework. First, process time prediction models were developed where design factors and the number of workers were used as inputs into SVR model. Subsequently, the GA

optimization technique was applied for hyperparameter tuning, specifically to determine the optimal values for C and Gamma. The hyperparameter tuning in the wall panel production line showed a reduction in the MAE to 1.78, 5.10, and 11.15 minutes compared to 5.25, 5.29, and 12.22 for the assembly, framing, and sheathing workstations, respectively. Additionally, this paper provides a solution to eliminate a bottleneck by considering an optimization scenario where an additional framing station allows two wall panels to be prefabricated concurrently. The optimal sequences of wall panels were generated using the SA algorithm, which reduced the total completion time and improved the sigma level to 1.85 σ. The contributions of this study are: (i) implementing GA to find the optimal hyperparameters for SVR; (ii) identifying the various factors (e.g., workers, inventory and design of module components) influencing process time at workstations, which leads to production line waste and low sigma level; and (iii) aiding production managers in gaining insights into the production line, thereby reducing the prefabrication time of module components at workstations.

However, this study is subject to some limitations. First, it does not explore means for eliminating other types of production line waste (e.g., motion, inventory and defects). Therefore, it is recommended for future work to collect data regarding these production line waste and applying lean principles along with simulation, where the former will be used for gaining a deeper understanding of the production line to reduce these production line waste, while the latter will be used for evaluating various production scenarios before implementing them in real production line. Second, future research could investigate other metaheuristic algorithms, such as particle swarm optimization (PSO) for hyperparameter tuning and compare their outcomes with those of GA. Third, the current optimization does not consider fine tuning different kernel functions. The future research would consider hyperparameter tuning of kernel functions in order to test their performance with regards to minimizing MAE.

Abstract–

Falling objects and debris at construction sites pose significant safety hazards, often going unnoticed during operations. Identifying these incidents in post-construction reviews can enable safety managers to develop preventive action plans for future projects. This study uses existing surveillance cameras equipped with computer vision technology to detect, track, and count any fallen objects or debris. The proposed method achieved 100% accuracy across all metrics in Dataset 1, which was captured using a fixed camera. In contrast, Dataset 2, simulated with camera shake to mimic real-world conditions, showed decreased precision for smaller objects, with overall precision dropping to 95% and an F1 score of 98%. The system could be used to support the lesson-learned plan for future site safety project meetings, which could further minimize the potential objects/debris falling in construction projects.

Keywords –

Falling object; Falling debris; Safety; Computer vision.

1 Introduction

The construction site is a complex environment that could cause potential dangers to people working in the area. Especially with vertical structures such as buildings, falling debris could seriously harm the construction workers or other personnel. According to the International Safety Equipment Association (ISEA), a worker in the United State gets stuck by a falling object about every 10 minutes [1]. Those falling-debris or objects at construction sites could cause safety hazards resulting from potential injuries to casualties. To prevent those cases, the occupational safety and health administration (OSHA)'s guideline requires employers to equip workers with falling object protection gears, install necessary falling object protection systems, and guide on how to secure objects from falling [2]. Despite the effort, there are still accidents from falling objects happening.

With advancement in technology and availability of surveillance cameras in general, there are many studies trying to minimize construction site accidents by various means. For example, Yang et al. combined BIM with computer vision technology to detect the potential danger of falling when working near floor openings [3]. For the case of Personal Protection Equipment (PPE) detection, Zou et al. tested a light weight (You Only Look One, YOLOv5) model for helmet wearing detection when attached to the surveillance system [4]. In general, most research focuses on the prevention of accidents through developing a real time warning system [5], detecting the absence of PPEs [6], collision warning [7], monitoring falling of the workers [8] and so on.

Those studies mainly emphasize the planning and real-time case of the construction site safety. However, during the post-construction review, the feedback from all safety activities and data is critical for the safety manager to improve for the next project. Especially for the undetected or unreported accidents such as unnoticed falling debris/object was not mainly in the scopes of existing research, but that information is crucial in supporting the future safety action plan.

To address the gap, this study developed a falling objects/debris detection system using the OpenCV open-source tools, to detect, track and count the falling objects.

Two datasets are tested to validate the system. Dataset 1 is collected from a stable surveillance camera, while Dataset 2 is collected from a shaking surveillance camera to imitate the real construction site. The results show that for the Dataset 1, the precision, recall and F1 scores achieved 100%. However, for the Dataset 2, the system remained 100% recall, with a small drop in the precision (95%) and F1 score (98%). The results justify the system's effectiveness and its potential to support construction site safety strategies.

2 Literature Review

The study focuses on computer vision technology coupled with camera input to develop a system to count falling objects from the video data while the information is used for lessons learned in the post-construction review. Therefore, it is essential to investigate the technologies which were used for construction safety with computer vision applications. Based on the study done by Fang et al. (2020) [9] and Lee et al. (2023) [10], a variety of technologies have been developed for improving the safety in construction sites. In addition, the main enabling technology of computer vision is deep learning which is extensively used in many aspects including object detection, semantic segmentation and so on.

Deep learning is a multi-layer neural network architecture and in the case of computer vision, Convolutional Neural Networks (CNNs) allow computers to interpret and understand visual data. Fang et al. (2018) [6] used R-CNN architecture to input video from CCTV at construction site to detect workers who are not wearing safety hardhat. The proposed system obtains 95.7% precision and 94.9% recall respectively. Another popular object detection deep learning architecture is You Only Look One (YOLO). YOLO with various custom-made integrated layers is used in different safety conditions at construction sites. Zou et al. (2024) [4] proposed a YOLOv5 based light weight algorithm to detect workers wearing hats. The result suggests that the integration of the YOLOv5, Ghostbottle, and DWConv surpass the YOLOv5 model with 30% less model size. Despite good results in both accuracy and recall, the use of deep learning architecture requires massive amounts of datasets to train on. Therefore, regarding the falling object, Tu et al. (2024), inspired by the Moving Object Detection Dataset (MOD), was generated the called Falling Object Detection around Buildings (FADE) and FADE-net were proposed and trained on FADE dataset which contained fallen items such as bottles, packaging boxes, books, shoes, and so on [11].

While there is not much research using computer vision to detect falling objects and tracking them without the use of deep learning and dataset, there are some studies used OpenCV library to detect movement of any moving objects from video input. OpenCV library is a python open-source library which allows computers to visualize the object, allow the image processing, and is used with different machine leaning application for image detection, objection's motion, and so on. Pandey et al. [12] utilize contours to detect and track the motion of any moving object using OpenCV. Contours refer to the imaginary points on the boundaries of the focused object, highlighting two stages: object detection and object tracking. Through these stages, the authors can detect real-time objects frame by frame, and by connecting successive frames, they check the object's location in each frame and correlate them.

According to the above literature, and in the case of no dataset, using the computer vision with OpenCV approach is suitable for falling object/debris detection.

3 Methodology

The study aims to detect falling objects and count their number from surveillance camera footage. Unnoticed/unreported falling object/debris are recorded during the whole construction duration. The proposed algorithm enables the safety manager to easily review and count unreported falling object/debris after the construction by simply running algorithm with the video input. The information includes the falling object location based on the camera's field of view, number of objects, object types, and others can be used for post-construction safety analysis that will be key lessons learned for future projects.

The proposed algorithm employs the OpenCV package and consists of three steps, as depicted in Figure 1: Background Elimination, Object Detection, and Object Tracking.

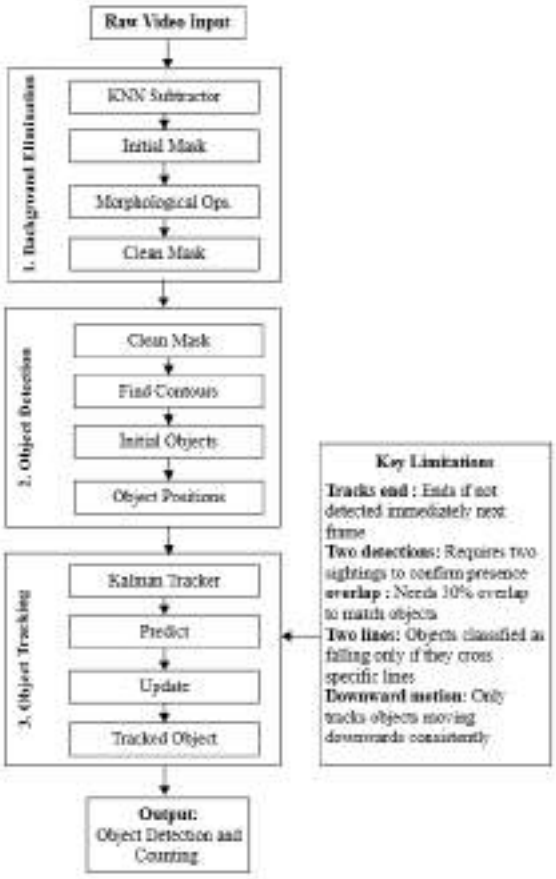

Figure 1. Proposed system architecture.

3.1 Background Elimination

This module aims to enhance the foreground scene for better analysis. The process begins with a background subtraction algorithm that extract moving foreground elements from a static background. This is followed by morphological operations—specifically, an opening to reduce noise and enhance object features within the mask by removing small, isolated elements. External contours of objects are then extracted from the refined mask to identify potential objects. Contours smaller than a predefined area threshold will be discarded to focus on significant objects. Bounding boxes are computed to save the detected objects in the remaining contours. The process isolates dynamic objects, enabling the following module: object detection and object tracking. Figure 2 shows how object's background is eliminated.

Figure 2. The effects of background elimination

3.2 Object Detection

In the object detection module, the cv2.findContours function is used to extract contours from the refined mask, specifically focusing on external contours to isolate significant object boundaries while ignoring internal variations. To avoid incorrect detections caused by camera vibration, the minimum area for contours is set to 10 pixels. This threshold ensures that smaller, potentially erroneous detections are disregarded, concentrating on more substantial and relevant objects. For the objects with the sizes beyond the minimum area, their bounding boxes (Figure 3) will be calculated and added to a list. This list will be saved and used in the next module.

Figure 3. The effects of object detection.

3.3 Object Tracking

To track the falling objects, an object tracking module is developed based on the Kalman filter with an IoU threshold of 0.3.

The objects which show in the list, saved in the last step will be chosen to be tracked. In this process, the existing KalmanBoxTracker algorithm from OpenCV package will be used with the following parameters: track termination window will be one frame, meaning that the object tracking will be terminated if the module did not detect the falling objecting in the next frame. And the objects and its trajectory will be saved in another if they are detected in the continuous two steps.

Furthermore, to avoid some mistakes caused by the shaking camera, a two-line detection, where the objects could cross two lines will be detected as a falling object, is added to this module to ensure the detected objects with downward direction. the module also evaluates the angle of movement by analyzing the trajectory of the bounding box centers over ten frames. Only objects that consistently show a downward direction are detected as falling, ensuring precise detection and tracking of objects under specific motion conditions. An object is counted as falling only (shown in Figure 4) if it satisfies both the line-crossing and consistent downward trajectory criteria. These conditions are designed to accurately identify and track falling objects, avoiding the impact of a vibrating camera (or wind and other external forces).

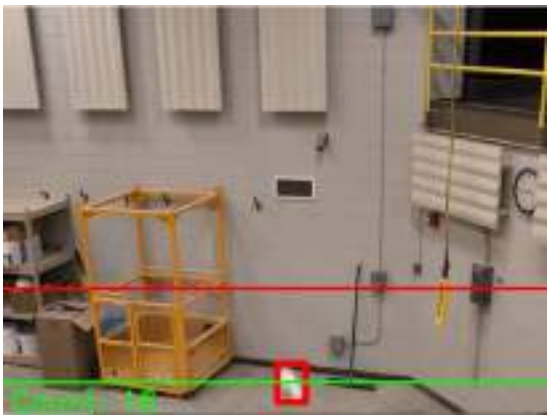

Figure 4. Detection and counting performance.

3.4 Evaluation Metrics

During the experiments, it was observed that some background elements were incorrectly identified as falling objects. In this context, evaluating the system's performance solely based on the ratio of detected objects to true falling objects would be misleading. Thus, to accurately assess the experimental results, Precision, Recall (also known as sensitivity), and F1 score are selected. The formulas for these metrics are provided in equations (1), (2), and (3). Correctly identified falling objects are True Positives (TP), while incorrect detections are False Positives (FP). Additionally, any falling objects that were not detected are considered False

Negatives (FN).

$$Precision = \frac{TP}{TP+FP} \quad (1)$$

$$Recall = \frac{TP}{TP+FN} \quad (2)$$

$$F1 = 2 * (\frac{Precision*Recall}{Precision+Recall}) \quad (3)$$

4 Implementation and Results

The proposed system was evaluated using a dataset collected from the Moss Lab at Purdue University (Figure 5). The dataset consists of two subsets, totaling 20 videos. One subset (Dataset 1) was captured using a stable camera mounted on a tripod, providing controlled conditions. The other subset (Dataset 2) simulated camera vibration to mimic real-world construction site conditions. Objects were intentionally dropped from a height of 15 feet (as shown in figure 6) without controlling their speed to mimic the unplanned and accidental dropping of items on construction sites, recorded with a Google Pixel 9 Pro XL smartphone at 12MP resolution and 60 frames per second, were analyzed for detection and tracking accuracy. Each video featured five distinct objects, as shown in Figure 7.

Figure 5. Example test of dropping object in Moss Lab.

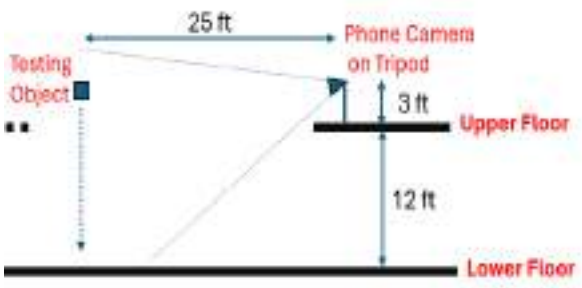

Figure 6. Testing setup layout (not to scale).

Figure 7. Object used for falling tests.

Under stable conditions (Dataset 1), the system achieved 100% precision, recall, and F1 scores for all objects as illustrated in Table 1. This demonstrates its high reliability in controlled environments, where object boundaries and movements are clearly distinguishable. The effectiveness of the system in Dataset 1 highlights its potential for detecting falling objects in situations where camera vibrations or environmental disturbances are minimal.

In dynamic conditions, Dataset 2, simulated through camera vibration, the system's performance slightly decreased for smaller objects. In Table 1, Precision for these objects dropped to 95% for the fourth object and 83% for the fifth object, while recall remained at 100% for all cases. This resulted in an overall precision of 95% and an F1 score of 98%. These results underscore the challenges posed by unstable camera conditions and the complexities of detecting smaller objects.

Figure 8 illustrates the challenges of false detections caused by background noise and camera vibration in Dataset 2. Subfigure 8a shows a static background element mistakenly identified as a falling object due to slight shifts in contour boundaries caused by vibrations. This misclassification demonstrates the system's sensitivity to motion artifacts, which can mimic object movement in the video. Subfigure 8b depicts another scenario where the system incorrectly identifies non-moving objects as falling, further highlighting the difficulties in isolating genuine object motion from dynamic background disturbances. These cases emphasize the importance of incorporating advanced filtering mechanisms to better handle background noise and reduce false positives.

Figure 9 provides an example of incorrect object trajectory classification under dynamic conditions. The figure shows an object misclassified as falling due to overlapping motion and inconsistent detection caused by vibrations. The yellow box and arrow highlight a non-falling object that was erroneously counted, revealing a limitation in the current trajectory analysis criteria. This issue is particularly prevalent in smaller objects, where fast movements and background inconsistencies can lead to misinterpretation. Enhancements such as refined trajectory angle analysis and improved stability algorithms could mitigate these errors.

Table. 1: Performance Evaluation on Dataset 1 and Dataset 2

Number of Objects Size(m^3)		object 1 0.0106	object2 0.00295	object3 0.00378	object 4 0.0005	object5 0.000145	Total
Dataset 1	count (by our system)	10	10	10	10	10	50
	True Positive	10	10	10	10	10	50
	False Positive	0	0	0	0	0	0
	False Negative	0	0	0	0	0	0
	Precision	100%	100%	100%	100%	100%	100%
	Recall	100%	100%	100%	100%	100%	100%
	F1 score	100%	100%	100%	100%	100%	100%
Dataset 2	count (by our system)	20	20	20	21	24	105
	True Positive	20	20	20	20	20	100
	False Positive	0	0	0	1	4	5
	False Negative	0	0	0	0	0	0
	Precision	100%	100%	100%	95%	83%	95%
	Recall	100%	100%	100%	100%	100%	100%
	F1 score	100%	100%	100%	98%	91%	98%

Figure 8. False detection due to camera movement.

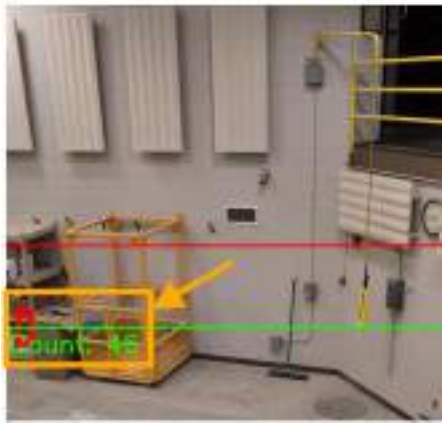

Figure 9. False detection sample.

The results demonstrate the system's robustness in detecting and tracking falling objects under stable conditions, achieving excellent performance metrics. While the system remains effective under dynamic conditions, challenges such as false detections and reduced precision for smaller objects highlight areas for improvement. Addressing these limitations will be critical for deploying the system in real-world construction environments.

A complete and robust algorithm can be used by the safety manager for post construction analysis by simply detecting and counting unreported failing object/debris from input surveillance footage. The system can also be integrated in real-time with the live CCTV camera running all day. The detected failing object/debris can be considered as almost real time or daily feedback to safety managers which enable them to investigate or create any necessary action plan.

5 Limitation and Future Work

Despite achieving high performance on both testing datasets, the following limitations of the proposed systems are acknowledged: (1) the study experimented on five household objects, which might not accurately represent most objects at construction sites, which can vary in size and weight. (2) The experiment was set up indoors in the construction lab, which was susceptible only to the minimum wind, which could affect the motion of the falling object. (3) The camera set up and illumination conditions in the experiments, including the height and orientation of the camera as well as the laboratory lighting, could also vary.

The authors recommend future studies on conditions of different falling objects mainly taken or selected from construction sites. Direct testing in the construction site environment with existing CCTV cameras at different frame rates will be ideal. A real-time warning system could be developed based on the results of the proposed detection system. Specifically, the system would issue alerts via mobile devices whenever a falling object is detected by cameras positioned at various heights, ensuring that construction workers in different locations receive timely warnings. Additionally, the speed and number of falling objects recorded could be used to assess the risk level at the construction site, thereby enhancing safety measures and protocols.

6 Conclusion

Data about falling objects/debris during construction is crucial for lessons learned in the safety framework for construction projects. By leveraging the existing information from surveillance cameras and computer vision technology, the paper successfully proposed a system that can detect, track, and count falling objects/debris at construction sites. Based on the location of the CCTV camera field of view and the trajectory of the falling objects, the safety managers could analyze the cause of the falling case to improve the prevention/action plan further. According to the experimental results, the system shows good object tracking abilities with the counting 100 % precision, recall, and F1 for non-vibrating camera. In the camera vibration scenario, the system achieves 95% precision, 100% recall, and 98% F1 score, approximating real-world conditions more closely. Given the limitations of this study in the testing scenarios and testing environment, future study on different weight/types of falling objects, higher fame rate of the input video, and the use of different moving object detection algorithms are recommended.

Abstract –

The construction industry is widely recognized for its high risk of workplace accidents, making effective safety management a critical priority. Traditional safety systems often rely on manual processes and fragmented documentation, leading to inefficiencies and human error in managing worker certifications and task authorizations; Therefore, this study presents a blockchain-based decentralized application (DApp) for managing worker certifications and task authorizations using smart contracts on the Ethereum blockchain. The proposed system automates certification verification, ensuring that only certified workers are authorized for specific tasks, thereby reducing accidents caused by unqualified personnel. The DApp features a dual-application interface: one for worker registration and task authorization, and another for on-site certification verification. Testing and validation in a simulated environment demonstrated enhanced data integrity, real-time certification checks, and secure storage of certification records, preventing unauthorized modifications. This research highlights the potential of blockchain technology to revolutionize construction safety practices by offering an efficient, transparent, and tamper-proof certification management system. The findings contribute to the growing body of knowledge on blockchain applications in construction and lay the foundation for future advancements in safety compliance technologies.

Keywords – Blockchain; Construction Safety; Smart Contracts; Certification Management; Decentralized Applications (DApp)

1 Introduction

The construction industry is globally recognized as one of the most hazardous sectors, consistently leading in workplace fatalities, severe injuries, and occupational health risks [1–4]. Although many countries have implemented strict safety regulations and mandatory certification requirements, the industry continues to struggle with persistent safety challenges [5,6]. Ensuring that only properly trained and certified personnel are authorized to perform specific tasks is essential for mitigating safety risks on construction sites [5,7]. However, traditional systems, such as paper-based records or isolated databases, are prone to errors and inefficiencies, creating safety gaps [8]. Paper-based systems are prone to documentation loss, storage challenges, and tampering, while conventional digital databases face limitations in data security, cross-organizational verification, and real-time accessibility [9]. These shortcomings allow uncertified or improperly certified workers to undertake high-risk tasks, often resulting in preventable accidents and fatalities [7]. The growing complexity of construction projects, characterized by multiple contractors, diverse workforces, and varying regional safety standards, further complicates the task of effectively managing and verifying worker credentials [10].

Blockchain technology offers a promising approach to address these challenges by providing immutability, decentralization, and automation, which are critical for ensuring secure and tamper-proof certification management [11]. Unlike AI, which can be used for certification validation but still relies on centralized databases, blockchain eliminates single points of failure and reduces trust dependency by ensuring that all transactions are recorded transparently and cannot be altered retroactively [11]. The decentralized nature of blockchain ensures that worker credentials remain verifiable across multiple organizations without the risk of fraudulent modifications [11]. Additionally, smart contracts provide self-executing compliance mechanisms, automatically verifying worker certifications before authorizing hazardous tasks, thereby reducing the risk of manual oversight or manipulation [12]. By eliminating

manual checks and enabling real-time compliance, blockchain-based systems can streamline safety management and reduce the risk of accidents. By introducing a blockchain-based decentralized application for real-time certification verification, this study addresses critical gaps in traditional safety systems, such as inefficiency, human error, and limited scalability, presenting a novel approach to safety compliance in construction.

This study explores the development of a blockchain-based decentralized application (DApp) for managing worker certifications and authorizing tasks in the construction industry. The proposed system uses smart contracts on a private Ethereum blockchain to securely store worker data, authorize tasks based on certification validity, and enable on-site certification checks. Additionally, a dual-application interface is designed to facilitate worker registration, task authorization, and on-site certification verification. Through this approach, the study aims to demonstrate how blockchain can enhance safety compliance, improve efficiency in authorization processes, and reduce human error in high-risk environments.

By combining blockchain technology with automated compliance checks, this research contributes to the advancement of safety management practices in construction. It presents a model that construction companies and safety managers can adopt to strengthen their oversight of worker qualifications, minimize unauthorized task assignments, and promote a safer, more efficient construction environment.

2 Literature Review

The construction industry is known for its high-risk nature, with worker safety remaining a significant concern globally. Many studies have explored various aspects of safety management, highlighting the critical role of proper training, certification, and task authorization in minimizing accidents [5,13–15]. This section provides an overview of key research in the areas of worker safety, certification management, and the role of blockchain technology in enhancing safety practices in the construction sector.

2.1 Worker Safety in Construction

Construction workers are exposed to a range of hazards, from physical injuries due to heavy machinery and equipment to long-term health risks like exposure to harmful chemicals and dust. According to a study by Newaz et al. (2021), effective safety management on construction sites requires comprehensive strategies that address both the physical and organizational aspects of safety [16]. These strategies include safety training, hazard identification, risk assessment, and the use of safety equipment. However, the effectiveness of these strategies often depends on the qualifications and competencies of the workers [16].

Proper training and certification have been identified as fundamental in mitigating risks [14]. Research by Başağa et al. (2018) emphasize that certified workers are significantly less likely to be involved in accidents, as they possess the requisite knowledge to identify hazards and follow safety protocols [14]. However, traditional certification systems often fail to address challenges like discrepancies in worker qualifications and the verification of training completion. These limitations create a pressing need for secure, real-time, and scalable certification management solutions.

2.2 Blockchain Technology in Construction

Blockchain technology has emerged as a promising solution for addressing challenges in various industries, including construction [11,12,17]. Blockchain is essentially a distributed ledger that records transactions in a secure, transparent, and tamper-proof manner. The decentralized nature of blockchain ensures that no single party has control over the data, thus reducing the risk of fraud or manipulation.

A review by Li and Kassem (2021) outlines several potential applications of blockchain in the construction sector, including supply chain management, project financing, and safety compliance [11]. While blockchain's utility in supply chain transparency and contract enforcement is well-documented, its application to worker certification management and task authorization remains underexplored. In the context of safety management, blockchain can significantly improve the accuracy and reliability of information [18–20]. A study by Yang et al (2022) demonstrated how blockchain can be used to manage scaffolding work information [21].

Smart contracts are one of the most promising applications of blockchain technology in construction [12,22]. These are programmable contracts that automatically execute predefined actions when certain conditions are met. In the context of worker certification and task authorization, smart contracts can automatically verify a worker's certification status and authorize or deny access to specific tasks based on pre-defined criteria.

Research by Ciotta et al. (2021) demonstrates that smart contracts can be used to automate various processes in the construction industry, such as managing payments, enforcing legal agreements, and verifying qualifications [12]. In the context of safety management, smart contracts can be used to ensure that workers are only assigned tasks they are qualified to perform, based on their training and certification records. The use of smart contracts can greatly reduce the administrative burden of manual checks, ensuring that safety standards

are consistently met across construction projects. Building on this foundation, our research focuses on using smart contracts for real-time certification verification, a novel application that directly addresses safety compliance gaps in construction.

2.3 Research Gap and Contribution

This study contributes to the literature by addressing several key gaps in the current research on construction safety and certification management. Firstly, it explores the use of blockchain technology for real-time worker certification and task authorization, which is largely underexplored in the existing literature. Secondly, it tackles the challenges of scalability and data security by implementing a blockchain-based solution in a simulated environment, providing insights into its feasibility for large-scale construction projects.

The novelty of this research lies in its approach to applying blockchain with smart contracts for real-time safety compliance, providing a new method for ensuring that only certified workers are authorized to perform hazardous tasks. By automating the verification of worker qualifications and integrating this process with on-site certification checks, the proposed system offers a practical tool for improving safety management in the construction sector. This solution not only reduces administrative overhead but also enhances transparency and accountability, potentially reducing accidents and improving overall project safety.

3 Methodology

3.1 Research Design

This study employed a blockchain-based system design to enhance worker safety in the construction industry by ensuring only certified and trained workers were authorized for specific tasks. The system was developed as a decentralized application (DApp) using smart contracts on the Ethereum blockchain [19,23]. The research design involved the following steps as shown in Figure 1:

- System Development: Developed a smart contract to record worker certifications, training completion, and task authorizations.
- User Interface: Created two separate frontend applications, one for worker registration and task authorization, and another for certification checking at construction sites.
- Testing and Validation: Performed functional testing to ensure the system accurately registered workers, authorized tasks, and verified certifications.

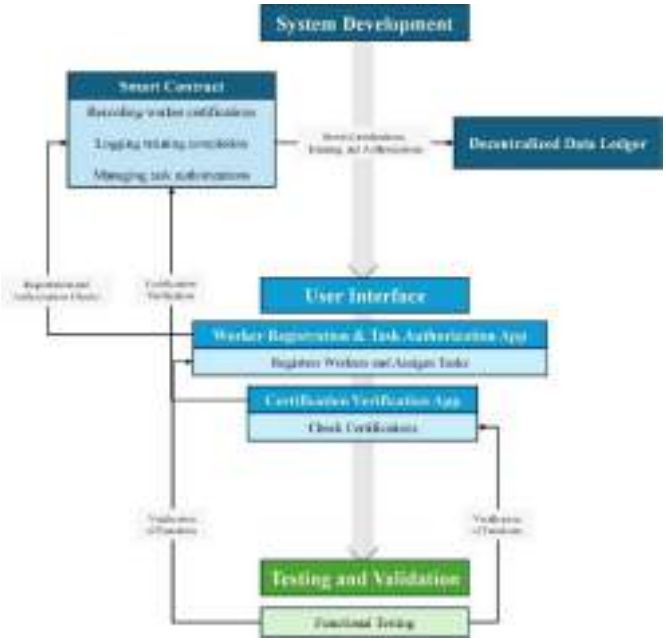

Figure 1. Research framework

3.2 System Architecture

The architecture consisted of four main components:

1. Blockchain Network: A private Ethereum network was set up using Ganache, simulating a blockchain environment for development and testing.
2. Smart Contract: A smart contract was written in Solidity and deployed on the Ethereum blockchain, maintaining data on worker IDs, certifications, training status, and authorized tasks.
3. Frontend Applications: Two React.js applications were developed to interact with the smart contract. The first application managed worker registration and task authorization, while the second was used at construction sites to verify certifications.
4. MetaMask Integration: MetaMask was used as the web3 provider to securely connect the frontend applications with the Ethereum network. It allowed users to interact with the smart contract by signing and authorizing transactions directly through the MetaMask wallet. This provided a secure and user-friendly interface for managing blockchain-based interactions.

3.3 Smart Contract Development

The smart contract was developed using the Solidity 0.8.0 programming language on the remix integrated development environment (IDE) [24] as shown in Table 1, and key functionalities were included as follows:

- Worker Registration: The contract enabled

administrators to register workers, recording details such as worker ID, name, certification type, and certification status.

- Task Authorization: The contract allowed administrators to authorize specific tasks for workers based on their certification and training status.
- Certification Verification: A function was provided for querying a worker's certification status and authorized tasks to confirm their eligibility for on-site activities.

The contract code was tested using Remix IDE to ensure it met functional requirements and handled error scenarios, such as unauthorized access.

            bool certificationValid,
            bool trainingCompleted
        )
    {
        Worker memory worker = workers[_workerId];
        return (
            worker.name,
            worker.certificationType,
            worker.certificationValid,
            worker.trainingCompleted
        );
    }
}
```

3.4 Frontend Development

Two separate frontend applications were built using React.js to interact with the smart contract [25]:

1. Worker Registration and Authorization Application: This application allowed administrators to register workers, authorize tasks, and manage certifications. It connected to the smart contract using Web3.js, enabling interaction with the blockchain.
2. Certification Verification Application: This application allowed on-site managers to verify a worker's certification status and task authorization by entering the worker ID and task ID. If the worker was certified and authorized, they were allowed to proceed with the task.

4 Results and Discussion

4.1 System Functionality

The blockchain-based certification management system was successfully implemented and tested in a simulated environment. The system achieved key functionalities, including worker registration, task authorization, and real-time certification verification at construction sites. Testing revealed that both frontend applications, the worker registration and authorization application and the certification verification application as shown in Figures 2 and 3, performed as intended, providing accurate, secure, and reliable data retrieval. The decentralized approach demonstrated a clear benefit by preventing data tampering and ensuring that only verified certifications were used to authorize tasks.

Figure 2. User interface for worker registration and task authorization

Figure 3. User interface for certification check

4.2 System Performance

The system's performance was evaluated by examining transaction execution in the Ganache environment, as shown in Figure 4. Ganache, a personal Ethereum blockchain, provided insight into the resource utilization and transaction handling efficiency of the Worker Certification DApp.

In Figure 4, each transaction involved deploying and interacting with the smart contract for worker registration and certification checking. The transaction logs indicate multiple interactions, including contract deployment, worker registration, and certification verification. MetaMask facilitated these interactions by enabling users to review and confirm each transaction before execution, providing a layer of security and transparency. Key aspects of the transactions are summarized below:

- Address and Balance: The Ethereum accounts displayed in Ganache each had initial balances, with balances updated after each transaction. For instance, the primary account used for transactions shows a slight reduction in balance due to gas consumption during contract calls.
- Gas Usage: The system consumed varying amounts of gas for different contract functions. Notably, the register Worker and check Certification functions incurred gas usage of approximately 68,487 units for certification-related transactions, suggesting the efficiency of these operations. This gas cost is reasonable for a private blockchain environment, highlighting the contract's resource efficiency.

The system was tested using a single worker registration, one task authorization, and one certification verification transaction. The purpose of this test was to validate the core functionality of the smart contract rather than stress-test scalability. The simulation was conducted in a controlled private Ethereum network using Ganache, where block mining was instantaneous, and gas fees were fixed. This setup ensured that transactions were processed efficiently, allowing us to verify the correctness of the smart contract logic.

The DApp successfully performed task authorization and certification verification within Ganache's simulated environment. Transactions were processed almost instantaneously due to Ganache's high-speed block mining, while MetaMask allowed secure and seamless interaction with the blockchain. In a real-world scenario, additional testing with multiple workers and varying workloads will be required to evaluate system performance under more complex conditions. Future work will focus on scalability analysis, transaction efficiency, and potential optimizations for deployment in an industry setting.

Figure 4. Transaction record in Ganache blockchain

4.3 Safety and Data Integrity

A major advantage of the blockchain-based approach is the secure storage of certification and authorization data, preventing unauthorized modifications. The smart contract's immutable nature ensured that worker data could not be altered once registered, enhancing data integrity. This feature is particularly valuable for construction safety, where accurate certification records are critical for regulatory compliance and risk management.

The results showed that the decentralized structure also effectively restricted access to only certified workers for specific tasks, reducing the likelihood of human error or intentional breaches in safety protocol. By enabling verification on a blockchain, the system provided transparency and accountability, which are essential in high-risk industries such as construction.

To address human error in certificate management, the worker registration and certification data entry process is managed by designated administrators. Before a new worker arrives on-site, their certification details are manually recorded into the system, verified against official records, and then uploaded to the blockchain. While manual data entry may introduce potential human errors, blockchain ensures that once recorded, data cannot be altered or manipulated.

4.4 Implications for Construction Safety

The proposed blockchain-based system introduces transformative changes to safety compliance in construction. By ensuring that only certified and trained personnel are authorized for hazardous tasks, the system directly addresses one of the primary causes of construction accidents: unqualified workers. The transparency of blockchain transactions further supports accountability, as immutable records provide a verifiable audit trail of certifications and authorizations.

In addition to improving safety, the system offers economic benefits by reducing administrative overhead associated with manual certification checks and preventing costly accidents caused by uncertified workers. To quantify these benefits, key performance metrics can be considered. These include the reduction in time spent on manual certification verification, which in traditional systems can be time-intensive, particularly for large projects involving multiple subcontractors. Furthermore, a reduction in administrative labor costs can be measured by comparing the staff hours required for certification management before and after blockchain implementation. Additionally, based on existing safety literature, a decrease in accident rates attributed to unauthorized or uncertified workers could provide an estimate of potential cost savings related to reduced compensation claims, legal liabilities, and project delays. While the implementation of blockchain-based certification management incurs initial development and integration costs, the long-term economic advantages can outweigh these expenses. The trade-off between cost and benefits can be analyzed through a cost-benefit framework, where initial investments in blockchain infrastructure, training, and deployment are weighed against projected savings in administrative labor, accident-related costs, and regulatory compliance efforts. This discussion underscores the system's feasibility and provides a foundation for future empirical validation in real-world construction environments. These findings suggest that blockchain technology has the potential to become an industry standard for safety compliance in construction.

5 Conclusion

This research demonstrates the potential of blockchain technology to revolutionize safety management in the construction industry by enhancing

the verification of worker qualifications and task authorizations. By developing a blockchain-based decentralized application (DApp) that utilizes smart contracts on the Ethereum blockchain, this study successfully addresses key challenges in traditional safety management systems, such as inefficiency, human error, and unauthorized task assignments. The system provides a secure, transparent, and tamper-proof method for managing worker certifications and training completion, ensuring that only qualified workers are authorized for specific tasks.

The results from system testing show that the blockchain-based approach not only improved data integrity by preventing unauthorized modifications but also facilitated real-time certification checks at construction sites, offering immediate verification of worker eligibility for hazardous tasks. The two frontend applications developed, one for worker registration and task authorization and another for certification verification, performed effectively, demonstrating the practical feasibility of blockchain in the construction sector.

This study makes the following contributions. Firstly, in terms of technical contribution, this study provides a secure, transparent, and automated method for managing worker certifications using smart contracts, enhancing data integrity and reducing human errors. Secondly, regarding research contribution, the study demonstrates the feasibility of blockchain for safety compliance, laying the foundation for integrating blockchain with other construction systems and highlighting potential applications in high-risk industries.

Despite the promising results, this study has some limitations that should be addressed in future research. Firstly, the usability of the system was not evaluated, as this study focused primarily on developing the framework and testing its technical functionalities. Secondly, the system was tested in a simulated environment using a private Ethereum blockchain, which may not fully replicate the complexities and scalability challenges of real-world construction sites. Lastly, the user interface developed for this study was designed for administrative and supervisor-level interactions, but worker-facing applications were not explored in detail.

Future research should also consider key implementation requirements for real-world adoption, including scalability, interoperability with existing construction management systems, security, and regulatory compliance. Ensuring the system can handle a large volume of transactions efficiently is crucial for scalability, while integration with current digital safety platforms will enhance its usability. Additionally, robust security measures must be in place to prevent unauthorized access or tampering. Finally, legal and regulatory considerations should be addressed to align the system with construction industry safety standards and compliance frameworks.

Abstract –

The Hazard and Operability (HAZOP) study is the most widely used hazard analysis technique in the process industry, aimed at enhancing safety and preventing accidents. It identifies potential hazards and operability malfunctions by dividing the design into small sections, called nodes, and analyzing each node's process separately. This paper briefly describes HAZOP studies and their role in enhancing operational safety across process industries. It also describes the advancements made to facilitate the performance of these studies and their challenges. To address these challenges, a new framework integrating BERTopic into HAZOP studies is proposed for enhanced efficiency and accuracy. The framework leverages historical data to categorize HAZOP elements into topics and extract node process and equipment descriptions to generate an intelligent pre-populated HAZOP analysis table. This paper focuses on categorizing causes into main risk factors for each HAZOP node and prioritizing them based on the likelihood of occurrence for each factor. The BERTopic model, incorporating embedding generation, dimensionality reduction, clustering, and topic representation, was applied to 1,574 HAZOP records from an oil pump station. The model achieved coherence and diversity scores of 80% and 92.4% respectively, outperforming Latent Dirichlet Allocation (LDA) model at 45.4% and 88.8%. It identified 13 topics, validated against hazard causes in oil pump stations and pipelines from literature. This model can be extended to categorize consequences and countermeasures, prioritizing them by severity and risk levels to generate a prepopulated table. This table can guide participants during sessions, significantly reducing the time required for the final HAZOP report.

Keywords –

HAZOP; Artificial intelligence; BERTopic; LDA; Coherence Score; Topic Diversity Score.

1 Introduction

Hazard analysis encompasses identifying potential hazards, assessing scenarios that could result in adverse outcomes, and developing countermeasures to eliminate or mitigate these hazards [1]. In this regard, hazard and operability (HAZOP) analysis has been the most widely used technique in the process industry. This is due to its simplicity, systematic approach, thoroughness, structured brainstorming process, and applicability to a wide range of systems [2]. The HAZOP concept dates to 1974 following a large explosion in England, which resulted in the deaths of 28 workers and injuries to 36 others. An international standard for HAZOP studies [BS IEC 61882] was published in 2001 and updated in 2016.

A HAZOP study is typically conducted during the design stage to identify and assess potential hazards, their causes, consequences, safeguards, and recommendations. The primary inputs are Piping and Instrumentation Diagrams (P&IDs) and the expertise of participants. P&IDs provide detailed design and engineering information about the plant. Participants contribute specialized knowledge of processes, drawing upon their professional experience [3]. The process begins by dividing the P&IDs into clearly defined sections, referred to as nodes, to ensure that each piece of equipment in the process is analysed thoroughly. The study employs guidewords (e.g., no, more, less of) in conjunction with parameters (e.g., pressure, temperature, flow) to identify deviations from the normal operating conditions. This systematic approach is applied within a specific node. Once deviations are identified, the team investigates their potential causes and consequences and identifies safeguards and recommendations to prevent or mitigate the hazardous situation [4]. The HAZOP study has gained regulatory acceptance in the chemical industry, and has been extended to other industries, including oil and gas, petrochemical plants, nuclear power, environmental engineering, and infrastructure projects [5]. However, it often faces quality issues stemming from complexity,

time consumption, reliance on expert judgment and knowledge loss. Completing the analysis for a typical chemical process takes 1–8 weeks and for large-scale processes, such as plants with over 200 P&IDs, the required time increases significantly [6]. To overcome these issues, intelligent systems with various levels of automation have been developed to reduce time, cost, and human bias [5].

In this respect, this paper introduces the evolution of HAZOP automation within the process industry and highlights the challenges of existing systems. To address these limitations, it proposes a novel framework that leverages artificial intelligence (AI) tools to generate an intelligent pre-populated HAZOP analysis table, designed to assist participants during workshop sessions.

2 Literature Review

HAZOP automation has been a research focus for over 30 years, developing intelligent systems, including knowledge-based systems, model-based approaches, and data-driven models

Knowledge-based systems are computer systems that use knowledge representation to provide expert knowledge or draw conclusions [7]. These systems, include expert systems, computer simulations, integrated based tools, ontologies, and Bayesian networks [5].

Expert systems emulate human logic through knowledge databases that store domain knowledge, inference engines to deduce conclusions based on predefined rules, and user interfaces, enabling diagnosis, fault-finding, and problem-solving. Notable examples include Stateflow [3] and preHAZOP [8]. While these systems automate routine tasks like identifying common causes and consequences, they are often industry-specific and struggle with adapting to new technologies or dynamic process changes or changing environments [4].

Ontologies, represented as directed acyclic graphs (DAGs) with nodes as concepts and edges as relationships. For instance, Yan et al. [9] applied named entity recognition (NER) to extract knowledge from HAZOP reports, organized it into an ontology knowledge base via Protégé and web ontology language (OWL), and employed the HermiT inference engine for automated analysis. This approach improved scenario coverage and safeguard descriptions, though its effectiveness depends on the ontology's scope and detail. Notably, the model focuses on text analysis and lacks automated risk assessment. Additionally, ontologies is time-consuming and biased as they rely on human's experience [4].

Bayesian networks (BNs) are acyclic graphs where nodes represent process variables and arcs depict cause–effect relationships. Each node has probabilistic states used to extrapolate the likelihood of other events. BNs have been applied in HAZOP to quantify risk and event probabilities, with experts assigning prior and conditional probabilities [10]. However, building BNs relies heavily on expert input for structure and prior probabilities, which can be subjective and challenging.

The model-based approaches use detailed mathematical models, combining the HAZOP technique with dynamic simulations to understand system behaviour during failures. This integration enhances hazardous scenario identification and risk assessment, reducing subjectivity in evaluating event severity and likelihood. Dynamic HAZOP simulation uses two main approaches: custom mathematical models tailored to specific units, offering full control over simulation methods or commercial process simulators, such as Aspen Plus, Aspen HYSYS, and k-Spice, which allow flexible adjustments to process flow sheets [11]. While these tools provide robust environments for integrating simulation with process hazard analysis, HAZOP studies rely on teams, and analysing new units requires developing and verifying new equations for each case.

Knowledge-based and model-based approaches have supported HAZOP studies, but acquiring and updating domain-specific knowledge remains challenging, subjective, and time-consuming. Recently, data-driven models have advanced HAZOP studies by leveraging historical data to improve safety outcomes and reduce manual effort [5]. Various classification models have been applied to automate specific aspects of HAZOP reports. For example, the BERT-BiLSTM-Attention model was used to predict severity from consequence descriptions, achieving a precision of 88.6% [12]. Bag of Words (BOW) was combined with ML to predict deviations based on causes, reaching 92% accuracy [13]. Peng et al. [14] proposed an ELMo-DCNN-BiLSTM-CRF model for NER to identify material and equipment terms, achieving higher recall for equipment (93.52% recall) than materials (86.08% recall). Term Frequency Inverse Document Frequency (TF-IDF) was applied with Naïve Bayes to predict likelihood, severity, and risk levels using causes, and consequences, with accuracies exceeding 80% [15]. Ekramipooya et al. [16] utilized Bidirectional Encoder Representations from Transformers (BERT) and multi-layer perceptron (MLP) to predict recommendations using two separate models, one using causes and the other using consequences.

These classification models face some limitations. HAZOP studies involve interconnected elements, such as process parameters, guidewords, causes, consequences, safeguards, and recommendations. Effective automation requires considering all these elements and addressing their interdependencies to avoid inaccuracies. Additionally, they lack prediction of safeguards and recommendations, based on these interconnected HAZOP elements.

Topic modelling methods have been developed to uncover latent topics in HAZOP reports. Wang et al. [15] used Latent Dirichlet Allocation (LDA) to uncover hidden cause and consequence from HAZOP data. TF-IDF, LDA, Part-of-Speech (POS) tagging, and the Apriori algorithm were used to explore correlations between causes and consequences, clustering them into 20 topics [17]. Despite its strengths, LDA does not consider the semantic relationships between words and order of words. BERT technique address this by generating contextual word and sentence vector representations. Ekramipooya et al. [16] leveraged BERT, Uniform Manifold Approximation and Projection (UMAP), and Hierarchical Density-Based Spatial Clustering of Applications with Noise (HDBSCAN) to cluster recommendations as a first step for prediction models. However, they did not use topic representation algorithms, limiting the analysis of the generated topics.

The topic modelling literature has focused on identifying the main topics of causes and consequences for entire plants. However, HAZOP teams typically analyse nodes individually, necessitating the identification of these topics at the node level and their corresponding risk levels for effective risk assessment. Additionally, existing studies fail to categorize safeguards and recommendations, which are essential for guiding preventive measures. Moreover, previous research does not map the identified topics to their associated P&ID nodes, which is crucial since the division of P&IDs into nodes depends on the perspectives of HAZOP participants, based on process flow or main equipment. To address these gaps, this study leverages historical data to generate an intelligent HAZOP table that assists participants during workshops in developing the final report. In 2022, BERTopic, a state-of-the-art topic modelling algorithm built on pretrained sentence transformers, was introduced by Grootendorst [18]. It has shown superior performance in capturing semantic context across various domains. For its ability to provide a comprehensive semantic view and generate coherent topics representing different factors of causes, consequences, and countermeasures, BERTopic was chosen for this study to enhance the efficiency and accuracy of topic modelling and analysis.

3 Proposed Method

Figure 1 illustrates an intelligent analysis method, designed to enhance the efficiency and accuracy of conducting HAZOP studies and aid less experienced engineers by leveraging historical HAZOP data (reports and P&IDs' nodes), closely matching the plant under investigation. Using BERTopic, the method identifies the most frequent topics of root causes, consequences, and countermeasures for each HAZOP node and prioritizes them by likelihood, severity, and risk levels. These topics are also linked to their corresponding deviations. A multimodal model like Gemini [19] extracts detailed process and equipment descriptions from P&ID nodes, providing a deeper understanding of the process and associated risks. Mapping these topics to the P&ID nodes offers participants a clearer understanding of hazard identification and assessment for each node under investigation. By combining these insights, the method generates an intelligent, pre-populated HAZOP analysis table to guide participants during workshops, reducing time and manual effort for similar projects to produce the final HAZOP report. Due to space limitations, this paper will focus on categorizing causes into main risk factors, identifying the most frequent factors for each node and prioritizing them based on the likelihood of associated hazards.

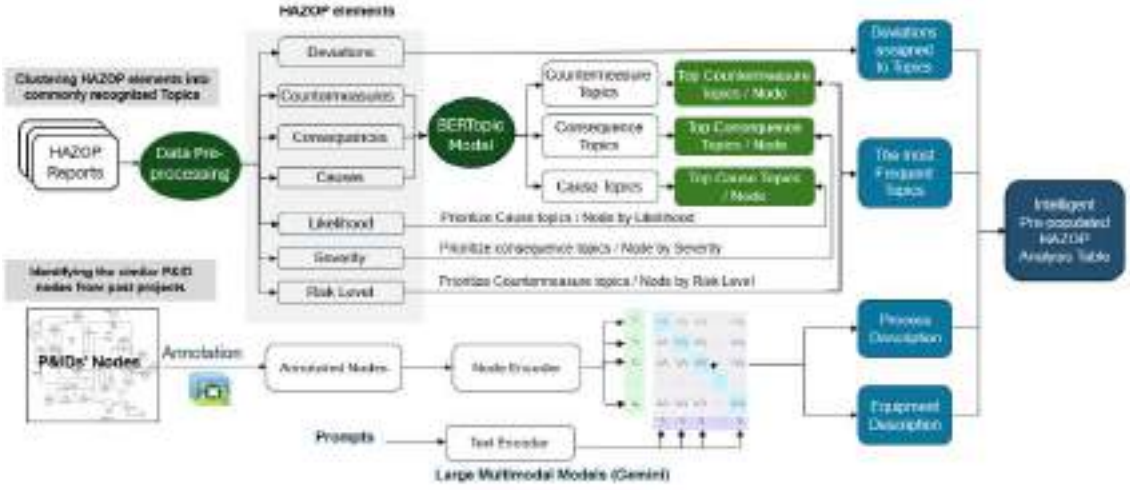

Figure 1. Flowchart of intelligent HAZOP analysis method using Topic Modeling.

The process starts with collecting HAZOP reports and P&IDs' nodes. HAZOP reports include deviations, causes, consequences, safeguards and recommendations, likelihood, severity, and risk. The dataset is shuffled to minimize order bias and enhance model generalization [20]. The preprocessing step involves tokenization, text cleaning, and normalization. Tokenization breaks text into smaller units (tokens) for granular analysis. Text cleaning removes irrelevant elements like stopwords, punctuation, and special characters while normalization uses techniques like lemmatization and lowercase conversion to standardize text [21].

Following preprocessing, the BERTopic model is applied as shown in Figure 2, including vector embedding, dimensionality reduction, clustering, tokenization, and topic representation. It begins with embedding extraction using Sentence-BERT (S-BERT) to generate dense -size embeddings that capture semantic meaning. These embeddings include token embeddings, segment embeddings, and position embeddings. To produce a single-size embedding for each sentence, S-BERT applies mean pooling across token embeddings, resulting in 768-dimensional vectors [22].

To optimize the HDBSCAN process, UMAP is employed for dimensionality reduction, which preserves both local and global structures of high-dimensional embeddings in a lower-dimensional space, facilitating efficient clustering [23]. Key hyperparameters, such as the number of neighbours, the number of components, and the distance metric (e.g., cosine similarity), are fine-tuned to maintain semantic relationships and improve clustering performance [24].

The datapoints are then tokenized and vectorized. Tokenization breaks the text into smaller units like words or phrases. CountVectorizer was used to transform these textual units into numerical vectors [25]. Topic representation is then refined using class-TF-IDF, that identifies distinguishing features between clusters. KeyBERT further enhances topic representation by selecting the most relevant keywords based on their cosine similarity to cluster embeddings [25].

Topic quality is evaluated using coherence and diversity metrics. The coherence score (C_V) assesses the semantic relatedness of topic words, with higher scores (e.g., 0.6–1.0) indicating well-defined and interpretable topics [26]. The Coherence score is calculated as follows:

$$C_(T) = 2 / (|T|(|T| - 1)) * \Sigma_\{i=1\}^\{|T|\} \Sigma_\{j \neq i\} sim(Word_i, Word_j) \quad (1)$$

The coherence score (C_V (T)) for a given topic T is calculated based on the number of words in the topic (|T|), the representation of two distinct words (Wordi and Wordj) within that topic, and the similarity measure (sim (Wordi, Wordj)) between these word pairs.

The diversity score measures the uniqueness of topic words across clusters, with values closer to 1 reflecting minimal redundancy. While metrics provide quantitative insights, human evaluation remains essential for validating the interpretability of topics [27].

To enhance topic exploration and reduce outliers, Zero-shot BERTopic uses predefined topics and cosine similarity thresholds to guide clustering. By adjusting the similarity threshold, the model flexibly assigns documents to predefined topics or generates new topics as needed [27]. This iterative process, paired with human judgment, ensures the final topics are actionable.

The model was evaluated against the LDA model, a probabilistic method for uncovering latent topics in text. LDA uses a document-term matrix, treating each document as a mixture of topics and attributing words to these topics based on co-occurrence patterns [28]. TF-IDF was used to enhance feature representation, as it weights terms based on their frequency within documents and importance across the corpus. The resulting TF-IDF matrix serves as input for LDA, enabling it to analyse term significance and distribution to uncover topics.

The models were implemented on Google Colab (CPU runtime), with Key libraries including NLTK and SpaCy for preprocessing, PyTorch, BERTopic, and scikit-learn for topic modelling, and Gensim for evaluation metrics. Core Python packages like NumPy, pandas, Matplotlib, and Seaborn supported data manipulation and visualization.

Figure 2. Methodology to apply BERTopic Model on HAZOP Causes.

4 Case Study and Results

The data utilized in this study comprised node name, causes, and likelihood derived from HAZOP reports focused on oil pump stations, which play a vital role in transporting oil through pipelines between various locations. The dataset was sourced from the thesis of Kilincet al. [29] report of an oil pump station located in Sivas, Turkey, designed to ensure safe and efficient transfer of oil via pipelines. At the station, oil enters from the pipeline and first reaches the pig receiving system. It then passes through the main pump filters before reaching the pumps, where it is energized and sent through the pig launching section back into the pipeline toward its next destination. Additionally, the wax handling system, used to remove wax (solid oil), represents one of the most challenging processes in the operation. The dataset encompasses six nodes and 1,574 data points required for safe oil transfer within the plant.

The BERTopic model was fine-tuned by experimenting with various hyperparameters to optimize topic generation. Key parameters included min_topic_size (20–50) to control the minimum documents per topic, affecting topic granularity; top_n_words (15) to emphasize the most representative terms for interpretability; n_neighbors (10–15) in UMAP for balancing local and global data structures during dimensionality reduction; n_components (3–5) to set the dimensionality of reduced embeddings. These configurations resulted in topics ranging from 6 to 43. Figure **3** illustrates topic coherence and diversity scores across multiple experiments, providing a quantitative assessment of topic quality. Coherence scores peaked at 32 topics, achieved 0.898, while diversity score was highest at 9 topics, with 0.967. Variations in the number of top words had no impact on the scores.

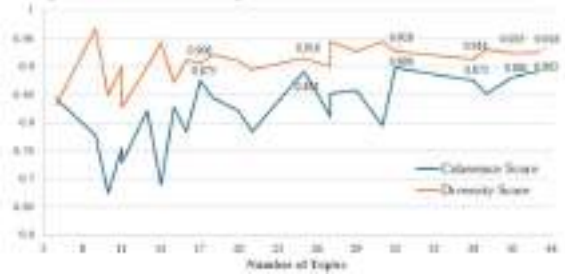

Figure 3. Coherence and Topic Diversity Scores.

As highlighted earlier, the resulting topics should be evaluated through human judgment [30]. Consequently, the topics and their top words were manually reviewed, focusing on experiments with higher coherence and topic diversity scores, such as those with 17, 25, 32, 38, 41, and 43 topics. The evaluation process was guided by the main causes of hazards identified in oil pump stations and pipelines in the literature, including operator error, inadequate pipe management, corrosion, insufficient maintenance, ignored alarms, fire, explosions, and equipment issues [31], [32]. This review assessed whether each cluster contained distinct topics and how well-separated these topics were, or if overlapping top words indicated a lack of distinction among them.

Following this review, 41 topics were initially selected because they exhibited less overlap. However, further analysis revealed several groups of similar topics that required merging. Topics 1, 2, 3, 12, 19, and 21 were found to be closely related and grouped together, as were topics 0, 11, 22, 24, 31, and 33, topics 8, 9, 10, 16, 18, 34, 35, and 36, topics 4, 29, 30, and 39, topics 7, 17, and 27, topics 6, and 14, topics 20, 23, and 28, topics 26, and 38, and topics 13 and 25. These similar topics were merged, and additional experiments were conducted to optimize the coherence and topic diversity scores, resulting in 13 topics, achieving coherence and diversity scores of 80.0% and 92.4%, respectively. Table 1 presents the final topics, including the top frequent words (1-3 grams) associated with each topic and their corresponding suggested labels. Cause topic generation is based on topic words and manual induction. Thus, the topic's formation needs knowledge, experience, and analysis. This approach ensured a robust and interpretable topic modelling outcome while maintaining high performance metrics.

It is worth noting that this model resulted in 71 outliers, stemming from several factors. Some data points contain very short descriptions and general statements, providing insufficient semantic information for clustering. Additionally, the dataset exhibited high variability in text length across data points, further contributing to the outliers. Zero-shot BERTopic was applied to explore potential new topics for documents that did not align with predefined topics. Experiments were conducted with cosine similarity values ranging from 0.5 to 0.95. Values between 0.5 and 0.8 did not yield new topics, while values above 0.8 introduced new topics that closely resembled the predefined ones. Based on these findings, a cosine similarity value of 0.8 was selected, which effectively reduced the number of outliers from 71 to just 32 documents. The frequency of topics is presented in Table 1.

Table 1. The Cause topics and their corresponding labels and Frequency.

Topic	Top Words	Category	Frequency
0	valve, operate valve, motor operate valve, operate, error, close omit, main oil line, completely omit, oil line pump	Omitted or wrong operations	43
1	slop tank, slop tank pump, failure, reinjection, reinjection pump, switch, interlock, flow, block, slop tank block	Pump failure / malfunctions.	200
2	valve, pass, open, valve skid, skid, check valve, check, open pass, valve fail open, safety valve fail, fail open pass	Valve errors or failures.	754

3	maintenance, closure, close maintenance case, blind leave close, maintenance case block, leave close maintenance	Inadequate maintenance	58
4	emergency, emergency shutdown, error false signal, alarm may fail, shutdown valve, error, level, faulty level alarm	Safety system failure	60
5	multiple, multiple simultaneous, multiple drain operation, multiple drain, simultaneous, simultaneous thermal	Simultaneous operations	77
6	roof, complete, complete loss, gauge lead unintended, surge valve gauge, valve gauge, valve gauge lead, valve	Relief devices error/ failure	35
7	insulation, corrosion, corrosion insulation, insulation cui, corrosion insulation cui, cui, cui tank wall, insulation low	Corrosion	87
8	external fire, fire external, external fire external, fire external fire, fire, external	External fire	110
9	underway leak heating, also source, heating coil may, leak heating, leak heating coil, event underway leak,	Leakage	39
10	mode, mistakenly put, put back, put, pump leave manual, tank pump leave, mode mistakenly put, manual mode	Human errors	5
11	pipe, bore, pipe rupture within, pipe rupture, rupture, large bore pipe, large bore, large, bore pipe rupture	Pipe failure or error.	50
12	transmitter fail, transmitter, failure level, failure level transmitter, level transmitter, level transmitter fail	Transmitter failure /error	24

The identified topics were validated against the 11 main causes identified manually by Kilincet al. [29], including omitted operations, fires, inadequate maintenance, operational failures, out-of-range, wrong equipment, incorrect operations, misplaced equipment, equipment failures, safety system failures, and simultaneous operations. The validation confirmed a strong alignment with traditional methods, while the model also provided more granular insights, such as pump malfunctions, pipe rapture, valve failures (the most frequent category), and relief device failures, which align with categories like equipment failure or wrong equipment. Additionally, the model revealed extra causes, such as human errors, leakage, and corrosion, expanding the depth and detail of the traditional HAZOP analysis. Identifying main causes for the entire plant provides valuable insights, but the HAZOP team evaluates nodes individually. Therefore, it is crucial to pinpoint the key causes for each node and determine which risk factors are included, excluded, and prioritized. Figure 4 illustrates the topics and their frequency for each node, highlighting the most critical causes. For instance, in Node 1 (Pig Receiving), the primary causes include valve failures, pipe ruptures, and omitted operations. Notably, Node 1 accounts for 11 out of the 13 identified causes, excluding pump malfunctions and relief device failures.

In addition to those identified main causes for each node, prioritizing them based on likelihood (e.g., 1 to 8, where 1 indicates an event has not yet occurred in the industry and 8 indicates frequent occurrence at the facility) ensures that critical issues are addressed first. High-frequency topics within each likelihood category highlight recurring or critical hazards, guiding the implementation of effective safeguards.

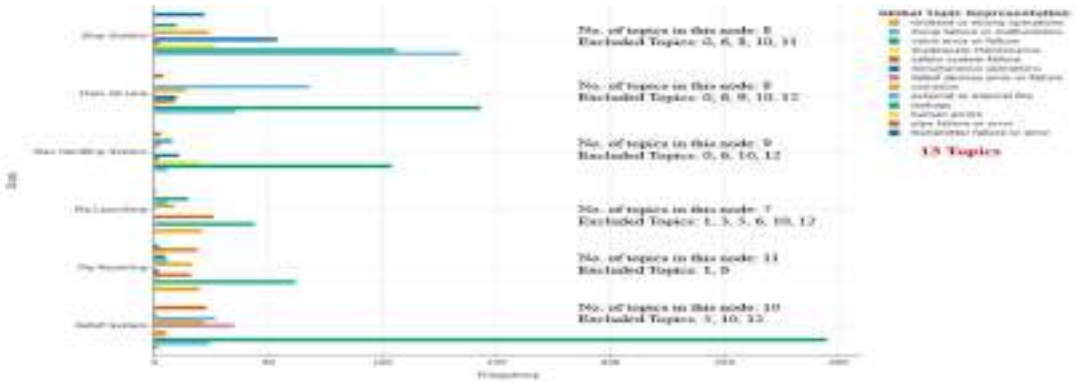

Figure 4. The included and excluded topics associated with each P&ID's node

For instance, in node 2 (Pig Launching), as shown in Figure 5**,** the frequency distribution of topics across probability categories "2," "3," "4," "5," "6," and "7" identifies specific areas requiring mitigation strategies. Topic 9 (leakage) has the highest frequency in category "7," indicating a high probability of occurrence and making it a priority for risk assessment. In contrast, Topic 0 (omitted or wrong operations), Topic 2 (valve errors or failures), and Topic 4 (safety systems failure) are the most frequent topics in categories "4," "3," and "2," respectively. Although these categories represent lower likelihoods, their recurrence across multiple deviations within the same node could cumulatively escalate the overall risk. This emphasizes the need to evaluate whether the frequency of such hazards justifies earlier intervention to prevent escalating if left unaddressed.

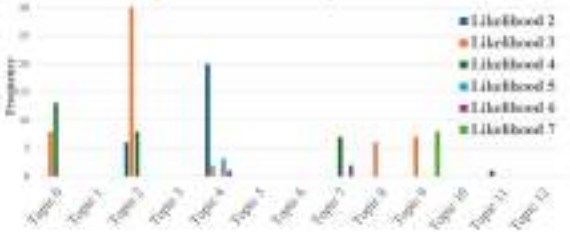

Figure 5. Categorization of topics by likelihood for Node 2 (Pig Launching).

The BERTopic model was compared to the LDA model to evaluate its effectiveness. LDA was selected as it has been extensively applied in HAZOP studies. Since LDA requires a predefined number of topics, a range from 6 to 43 topics (matching BERTopic's output) was tested. Various hyperparameters were explored, including passes (10–100), iterations (1000–5000), and alpha and beta values (0.01). Multiple experiments were conducted to identify the optimal number of topics (K), determined using perplexity and coherence metrics, as smaller perplexity and higher coherence typically indicate better topic recognition [28]. Figure 6 shows perplexity was lowest at 42 topics, while coherence peaked at 12 topics with a score of 45%. However, low and fluctuating coherence scores indicated LDA's challenges in producing stable and interpretable results. Topic diversity was highest (89%) at 8 topics. A detailed review of 42, 12, 8, and 41 topics revealed overlapping clusters, complicating the selection of optimal topics.

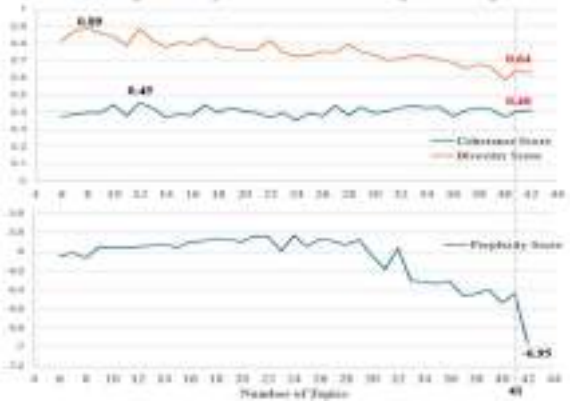

Figure 6. LDA Model Evaluation Metrices.

5 Conclusion

This paper briefly reviewed current developments of intelligent systems in HAZOP studies, emphasizing the potential of utilizing historical HAZOP data to streamline the process. The review reveals several gaps including inadequate incorporation of all HAZOP elements in classification models, prediction of countermeasures based on these interconnected elements, and categorization of causes, consequences, and countermeasures by node, likelihood, severity, and risk levels. This study applied the BERTopic model to categorize causes into 15 risk factors, achieving a coherence score of 80% and a topic diversity score of 92.4%, which outperforms LDA's 45.4% coherence and 88.8% diversity. The model identified key topics by node and likelihood. This approach can be extended to consequences and countermeasures, generating a prepopulated HAZOP table to assist workshop participants in verifying or identifying additional issues.

The main limitation of this study is its focus on oil pump stations, using data from a single HAZOP report, which may affect the model's generalizability. Expanding the dataset is recommended to improve model performance. Moreover, hyperparameter tuning for BERTopic was time-consuming, requiring multiple trials for high coherence and diversity. Optimization techniques are suggested to streamline this process.

A Case Study on Applying Machine Learning on Blockchain (MLOB) for Modular Integrated Construction Inspections

Zhiming Dong[1], Weisheng Lu[1]

[1]Department of Real Estate and Construction, Faculty of Architecture, University of Hong Kong, Hong Kong
zmdong@connect.hku.hk, wilsonlu@hku.hk

Abstract

Modular Integrated Construction (MiC) is an innovative off-site building method that improves productivity, safety, and sustainability by manufacturing standardized modules in factories for on-site assembly. MiC inspections demand high levels of accuracy, efficiency, and security due to the low fault tolerance in factory environments. However, existing approaches fail to comprehensively address these combined requirements. This research explores the application of the Machine Learning on Blockchain (MLOB) framework to real-world MiC inspection tasks, assessing its feasibility and effectiveness. Additionally, a scientific evaluation is conducted to quantitatively measure the performance of MLOB-based MiC inspections. The results demonstrate that MLOB significantly enhances inspection performance by improving decision-making, streamlining processes, and ensuring the integrity of both inspection logic and data. To the best of the authors' knowledge, this is the first study to integrate MLOB into MiC inspections to consider the requirement on both accuracy, efficiency and security, providing a scalable and innovative solution for quality assurance in the construction industry.

Keywords

Machine Learning; Blockchain; Modular Integrated Construction; Inspection

1 Introduction

Modular Integrated Construction (MiC) is an innovative building method that transitions most construction activities from traditional on-site settings to controlled, off-site factories [28]. This method involves the production of standardized, 3D volumetric modules, which are manufactured and preassembled in factories before being transported for on-site assembly [8]. MiC offers numerous advantages, including improved productivity, enhanced safety, reduced waste, and lower carbon emissions. It follows a manufacturing plan that prioritizes precision and standardization, with minimal tolerance for errors in the factory environment [11]. However, any defects or inaccuracies during production can lead to severe complications during on-site assembly, resulting in costly rework and project delays [26]. Consequently, stringent quality control measures are essential to ensure the success of MiC projects.

Recent research underscores the potential of advanced technologies such as machine learning (ML) and blockchain to enhance inspection processes in MiC [22,23]. ML significantly improves inspection accuracy by analyzing large datasets to precisely detect defects, deviations, or anomalies, thereby minimizing errors associated with human oversight. Additionally, ML enhances efficiency by automating repetitive tasks, streamlining the inspection process, and enabling real-time decision-making without continuous human involvement [2]. Meanwhile, blockchain technology bolsters inspection processes by ensuring data integrity, transparency, and security [12]. By creating an immutable record of inspection data, blockchain enhances accountability and fosters trust among stakeholders.

While ML and blockchain independently enhance inspection processes, relying on these technologies in isolation reveals notable limitations. ML lacks robust security and transparency mechanisms, leaving it vulnerable to data tampering and manipulation [16]. Conversely, blockchain ensures data integrity and accountability but does not inherently offer intelligent data analysis or adaptive decision-making capabilities [4]. As a result, current approaches fail to comprehensively address the combined requirements of accuracy, efficiency, and security in MiC inspections.

Machine Learning on Blockchain (MLOB), as a novel computation paradigm, integrates machine learning (ML) with blockchain technology to ensure data and computational security [4]. Unlike conventional ML and blockchain isolated solutions [15,21,29,31], MLOB embeds ML logic directly on-chain, executing computations as smart contracts while preserving execution records on a distributed ledger. This framework offers distinct advantages to the Architecture, Engineering, and Construction industry. From a technical perspective, it mitigates risks associated with external

interference, unauthorized alterations, and adversarial manipulations, ensuring the reliability of critical computations such as project progress monitoring, quality assurance, and risk assessment. Practically, its robust security mechanisms foster greater confidence in adopting advanced ML tools, leading to more precise, efficient, and secure project management.

This research adopts the MLOB paradigm for MiC inspection tasks. The primary objective is to leverage MLOB to significantly enhance the efficiency, accuracy, and security of MiC inspection workflows while assessing the feasibility of its application in real-world construction scenarios. To the best of the authors' knowledge, this study is the first to integrate the MLOB paradigm into MiC inspection tasks.

The structure of the paper is organized as follows: Section 1 introduces the research background and objectives. Section 2 provides a literature review, discussing current research on ML for MiC inspection, blockchain technology for MiC inspection, and the development of the MLOB framework. Section 3 defines the case, offering background and essential details of the MiC project. Section 4 describes the prototype implementation, outlining the four key steps of the MLOB process: ML acquisition, ML conversion, ML safe loading, and consensus-based computing. Section 5 presents the experimental results, while Section 6 discusses the contributions, limitations, and directions for future research. Finally, Section 7 concludes the study.

2 Literature review

2.1 Machine learning for MiC inspection

Liu, et al. [9] evaluates ML object detection algorithms for modular construction, demonstrating faster RCNN's superior accuracy and offering insights into ML's applicability and workflow for improving construction quality and safety. Tusnin, et al. [23] proposes adjustable ML models to efficiently analyze and design modular steel building blocks, achieving accurate stress–strain state predictions with a determination coefficient of 0.88–0.92, overcoming limitations of traditional numerical and engineering methods. Tan, et al. [22] proposes an automated BIM and LiDAR-based inspection method for modular box outer walls and rebars, achieving high accuracy with errors of 2.6 mm for flatness and 2.8 mm for protruding length measurements. Baek, et al. [2] presents an automated framework for monitoring on-site MiC module installation, combining object detection, activity classification, and productivity analysis, achieving 89% accuracy and enabling productivity measurement and improvement across diverse construction sites. Pan, et al. [14] explores future directions for applying artificial intelligence and robotics (AIR) in prefabricated and modular construction through a systematic literature review, proposing five key advancements to enhance interdisciplinary, integrated, and intelligent construction practices. Harichandran, et al. [5] proposes a hierarchical ML framework to enhance activity recognition in Automated Construction Systems (ACS), demonstrating improved precision, robustness, and noise tolerance compared to conventional approaches for monitoring and ensuring safe construction operations.

Moreover, numerous studies have explored the application of ML in inspection-related tasks. [19] applies ML to risk-based inspection (RBI) screening, achieving 92.33% accuracy and 84.58% precision, reducing variability, and improving the reliability and integrity of conventional RBI screening assessments. Ravikumar, et al. [20] explores ML-based visual inspection for defect identification, comparing C4.5 and Naïve Bayes classifiers, with results showing C4.5 achieving superior classification accuracy for automated machine vision system design. Park, et al. [17] proposes a CNN-based method for automated visual inspection of surface defects, demonstrating superior accuracy, efficiency, and cost-effectiveness compared to manual inspection, with applicability to both textured and non-textured surfaces.

The literature demonstrates the versatility and effectiveness of ML in construction and inspection tasks, offering enhanced accuracy, efficiency, and applicability across diverse contexts, from modular construction quality assessments to automated defect detection. However, ML lacks robust security and transparency mechanisms, leaving it vulnerable to data tampering and manipulation.

2.2 Blockchain technology for MiC inspection

Li, et al. [8] proposes a blockchain-enabled IoT-BIM platform (BIBP) for modular construction, achieving decentralized, secure, and efficient supply chain management, validated through a case study demonstrating improved transparency, traceability, and performance in storage, throughput, and latency. Olawumi, et al. [13] critically reviews digital tools and technologies (DTT) in modular integrated construction (MiC), identifying gaps in prefab transportation, highlighting leading countries, and proposing future opportunities for blockchain and integrated DTT adoption in MiC projects. Wu, et al. [26] develops a blockchain-enabled IoT-BIM platform (BIBP) for modular construction, addressing IoT network failures and BIM provenance issues, demonstrating improved reliability, reduced storage costs, and advancing practical applications in off-site production management. Wu, et al. [27] explores blockchain technology to enhance information-sharing accuracy in onsite modular

construction assembly, developing and validating a prototype system that improves information endorsement and synchronization through blockchain's decentralized consensus mechanism.

Likewise, blockchain technology is widely applied in other inspection tasks. Wu, et al. [25] proposes a blockchain-based framework for on-site construction quality inspection (OCQI), integrating IoT and ontology technologies to enhance accountability, automation, and data integrity, validated through a prototype system and analyzed using the TOE theory. Pincheira, et al. [18] presents an end-to-end system for mining asset inspections, integrating IoT devices with blockchain to enhance data integrity, trust, and transparency, validated through a real case study in a mining inspection scenario. Wu, et al. [24] develops a blockchain-enabled framework for tower crane safety inspections, integrating smart contracts and consensus algorithms to ensure automation, transparency, and traceability, validated through a prototype system using Hyperledger Fabric architecture. Ning, et al. [12] proposes a blockchain-enabled secure transmission system (BEST) and improved market matching (IMM) algorithm for remote grid fault inspections, enhancing network performance and ensuring secure, efficient signal transmission using advanced optimization and deep reinforcement learning techniques. Zhang, et al. [30] proposes a blockchain-based performance-security balanced safety inspection framework (PSB-SIF), integrating smart contracts and a novel SIBFT consensus algorithm, ensuring authenticity, security, and efficiency in safety inspections with improved performance over conventional consensus methods.

The literature highlights the significant role of blockchain in MiC and inspection tasks. Blockchain-enabled IoT-BIM platforms improve supply chain transparency, traceability, and reliability, while blockchain-based frameworks enhance accountability, automation, and security in diverse inspection scenarios. However, blockchain ensures data integrity and accountability but does not inherently offer intelligent data analysis or adaptive decision-making capabilities.

2.3 Machine learning on blockchain

There are some existing research has explored the integration of blockchain and ML. Liu, et al. [10] surveys the integration of blockchain and ML for communications and networking systems, highlighting benefits, applications, and challenges, while addressing issues like resource management, data processing, scalability, and security for decentralized and intelligent network operations. Chen, et al. [3] reviews the integration of ML and blockchain, highlighting their collaborative potential for secure and efficient data sharing and analysis, and identifies future directions for deeper integration of these transformative technologies. Kayikci and Khoshgoftaar [7] explores the integration of blockchain and ML, highlighting their transformative potential in finance, medicine, supply chain, and security while addressing challenges like scalability, security, and workflow optimization for broader adoption and impactful applications. Acheampong [1] explores the interplay of big data, ML, and blockchain technology, highlighting big data's impact on ML advancements while proposing blockchain integration to enhance data security, reduce centralization challenges, and encourage further research for improved ML models.

In the context of MiC inspection, ensuring robust data security is imperative because the process involves collecting sensitive sensor and imaging data from multiple sources. Equally, computation security is crucial since the analytical algorithms and ML used for processing this data are vulnerable to adversarial attacks that could distort outputs and lead to erroneous decision-making. Addressing both aspects concurrently ensures that not only is the authenticity of the raw inspection data maintained, but also that the computational processes interpreting this data remain reliable and resistant to cyber threats. This dual security requirement is well demonstrated in the MLOB framework proposed by Dong and Lu [4], which is designed to safeguard both data and computation, thereby providing a comprehensive solution to the unique challenges of MiC inspection.

3 Methodology

3.1 The MLOB framework

The MLOB is a novel computational paradigm that integrates ML with blockchain technology to secure engineering computing processes [4]. The primary aim of MLOB is to safeguard both data and computational security by embedding ML processes entirely within blockchain smart contracts. The workflow of MLOB is shown in Figure 1. Methodologically, the MLOB paradigm encompasses four sequential steps: ML Acquisition, ML Conversion, ML Safe Loading, and Consensus-Based Computing Execution. Each stage systematically migrates traditional ML workflows into a secure blockchain-enabled environment, ensuring that all processes remain tamper-proof, transparent, and accountable.

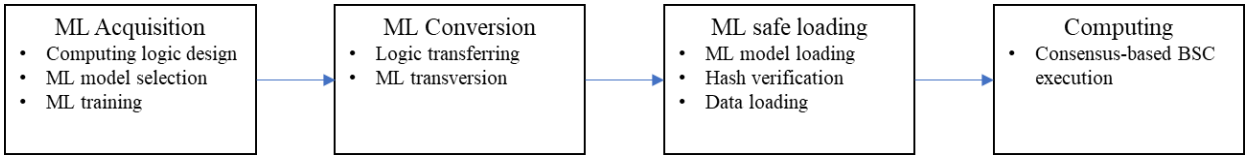

Figure 1. The MLOB framework.

The ML Acquisition phase initiates the methodology by defining and formulating engineering computing logic into ML-compatible tasks, followed by selecting appropriate ML models tailored to specific engineering scenarios and training them with relevant datasets. After acquisition, the trained ML models are converted into blockchain-compatible formats during the ML Conversion phase, ensuring compatibility with blockchain smart contract runtime environments. Subsequently, the ML Safe Loading step securely transfers both the computational models and the required input data onto the blockchain, employing cryptographic hashing to verify integrity and prevent unauthorized modifications during off-chain to on-chain transition.

In the final stage, Consensus-Based Computing Execution, ML computations are executed directly within blockchain smart contracts across multiple decentralized nodes. The transactions—including computational instructions, inputs, and outputs—are collectively validated by consensus algorithms across the blockchain network, significantly enhancing resilience against malicious manipulations. Any inconsistencies or tampering attempts are swiftly identified, preserving computational security. Through these methodological steps, the MLOB paradigm establishes a robust framework for secure ML deployment, effectively addressing both data and computational integrity in engineering applications.

3.2 Case description

The research is set in the empirical context of a MiC

Given the project's advanced and complex nature, it faces challenges such as cross-border transportation, multi-stakeholder collaboration, and stringent quality control. Consequently, the project imposes rigorous demands on inspection processes: accuracy ensures all measurements and installations align precisely with project standards; efficiency focuses on timely and streamlined inspections to prevent delays in prefabrication and on-site assembly; and security safeguards against data tampering and logic corruption. Therefore, adopting MLOB in this research case is essential to enhance the accuracy, efficiency, and security of inspection processes.

Building on insights from previous projects, this research aims to apply the advanced MLOB framework

project in Hong Kong, specifically a student residential development. Selected as one of the Pilot MiC Projects by the Development Bureau of Hong Kong, the project comprises two 17-floor towers, providing 1,224 hostel places, with each room measuring approximately 6.5m². The project involves the assembly of 952 modules across six types. The podium transfer plate and core walls will be constructed using in-situ reinforced concrete, while MiC techniques will be employed for the floors above the transfer plate and the multi-unit bedrooms integrated with core walls. Each room will feature prefabricated polished flooring, anti-mould painted walls, and ceilings, all completed in the factory along with the installation of fixed furniture modules.

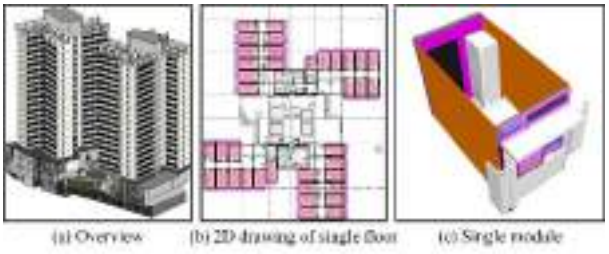

Figure 2. Background information of case study.

Figure 2 highlights the project's design details through both 3D models and 2D drawings. Specifically, Figure 2(a) provides an overview of the 3D model, while Figure 2(b) illustrates a 2D drawing of a single floor. In the 2D drawing, the pink segments indicate the key modules, which serve as focal points for inspection activities (Figure 2(c)).

to enhance construction logistics and supply chain management [11]. A key component of the project management process involves image-based online inspections, which play a crucial role in ensuring quality and compliance. During these inspections, workers are required to upload images of installed structures or facilities, accompanied by a scale bar for dimensional reference. Inspectors then review the submitted images to verify adherence to inspection standards, with particular attention to the presence of the scale bar in the visual documentation to ensure accurate measurements and compliance.

3.3 Evaluation

Qualitative and quantitative methods are used for performance evaluation. The specific evaluation methods for accuracy, efficiency and safety will be introduced in detail below.

The accuracy performance is evaluated using the Accuracy metric. Accuracy is calculated as $Acc = (TP + TN)/(TP + TN + FP + FN)$, where TP, TN, FP, and FN denote true positives, true negatives, false positives, and false negatives, respectively, quantifying the proportion of correct predictions among all outcomes.

Efficiency is evaluated by measuring computing latency—that is, the total execution time required for processing engineering tasks. While the security is evaluated by qualitative discussion. Because this research aims to adopt MLOB into a real-world MiC inspection task rather than modify the MLOB architecture, the security performance remains unchanged and unaffected from the original. Therefore, our analysis primarily focuses on quantifying efficiency and accuracy performance, specifically, without altering the inherent security features, especially on safeguarding data and computational security.

4 Prototype implementation

Based on the MLOB framework, we reengineered the inspection workflow, which is shown in Figure 3. The first step (step 1) is to reengineer the current inspection process into the logic that can be loaded into MLOB framework. Then, the worker collects the image (step 2) and uploads it to the blockchain network (step 3) by a transaction. Then the smart contract is automatically invoked (step 4) to process the image data and call the ML model to output the inspection result (step 5). The inspection result is stored in the blockchain as an immutable record (step 6). After that, the blockchain network sends a response to the worker. The worker can check the inspection result (step 7). The worker also has the opportunity to appeal the result and applies for manual review (step 8). The inspector downloads the record from the blockchain and inspects it manually (step 9). If the result is different, the inspection record in the blockchain will be updated (step 10).

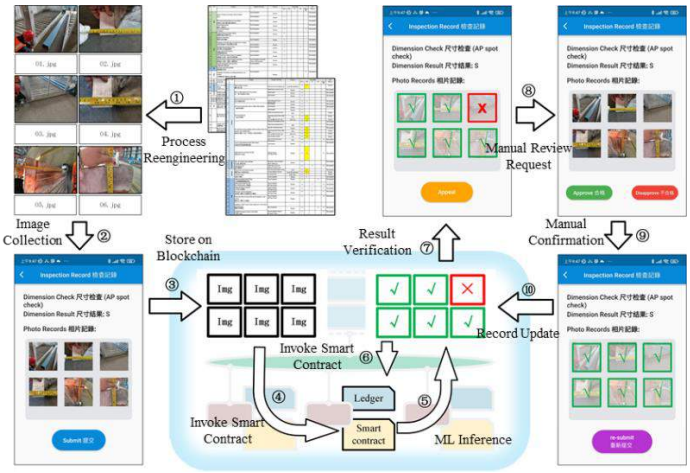

Figure 3. MLOB case study workflow.

4.1 Machine learning acquisition

MobileNet [6] was selected for this ML task, using 312 manually annotated images (qualified/unqualified) for training and 77 for evaluation. Training used sparse categorical cross-entropy loss, RMSprop optimizer, and 1000 epochs on TensorFlow 2.8 (Python 3.8), with accuracy as the metric. The trained model is saved in ".pth" format, storing weights and biases for inference or continued training in off-chain environments.

4.2 Machine learning conversion

The ML model with state dictionary format is used to run on local Python environment and cannot be used directly on blockchain smart contract. Therefore, it need a ML conversion process. As shown in Figure 4, such process needs two steps, firstly the state dictionary is converted to protocol buffer by a customized Python script, then the protocol buffer is converted to layers model by TensorFlow.js converter.

Figure 4. ML conversion workflow.

4.3 Machine learning safe loading

After conversion, an MD5 hash generates a unique

value for the ML model. When uploaded to the blockchain smart contract, this hash is compared against the original to verify integrity. Upon verification, the smart contract loads the necessary vision data for ML-based inspection. This hash comparison effectively detects any tampering or unauthorized modifications, ensuring the model's reliability for inspection tasks.

4.4 Consensus-based computing

After preparation, the ML model executes when inspection images upload to blockchain (Figure 3, Step 4), automatically triggering the smart contract. Hyperledger Fabric manages this process, preventing tampering through its permissioned structure, cryptographic hashing, and consensus mechanisms. The immutable decentralized ledger makes unauthorized changes immediately detectable, maintaining the ML inspection's trustworthiness.

5 Results and evaluation

5.1 Results

We evaluated MobileNet variants' performance and inference times (Figure 5): V1 (blue), V2 (red), and V3 (green), using round markers for local inference and triangular markers for on-chain inference. Newer, larger models like MobileNet V3 (large) and V2 (alpha=1.0) achieved higher accuracy. Notably, models with fewer than 1 million parameters had faster on-chain inference than local inference, demonstrating our ML in BT framework's advantage for small models. This study confirms the framework's feasibility with satisfactory speed and accuracy.

5.2 Evaluation and comparison

Based on our results, we deployed MobileNet V3(large) in the MLOB framework, comparing it against a traditional ML-blockchain isolated solution (baseline 1) [31] and a pure blockchain solution (baseline 2) [11] as shown in Table 1.

Table 1. Comparison with baseline methods

	Accuracy	Efficiency	Data security	Computational security
MLOB	99.52%	106ms	√	√
Baseline1	99.52%	80ms	√	
Baseline2	99.8%	877.6ms		
Baseline2 (HI)	90.2%	1345.6ms	√	

MLOB and Baseline1 both achieve 99.52% accuracy with robust data security, but while Baseline1 is slightly faster (80ms vs 106ms), only MLOB provides computational security. Baseline2's manual inspection achieves 99.8% accuracy but runs slower (877.6ms) and degrades significantly under high interference to 90.2% accuracy and 1345.6ms processing time.

In summary, MLOB delivers the optimal balance of comprehensive security, high accuracy, and competitive efficiency across various operational conditions.

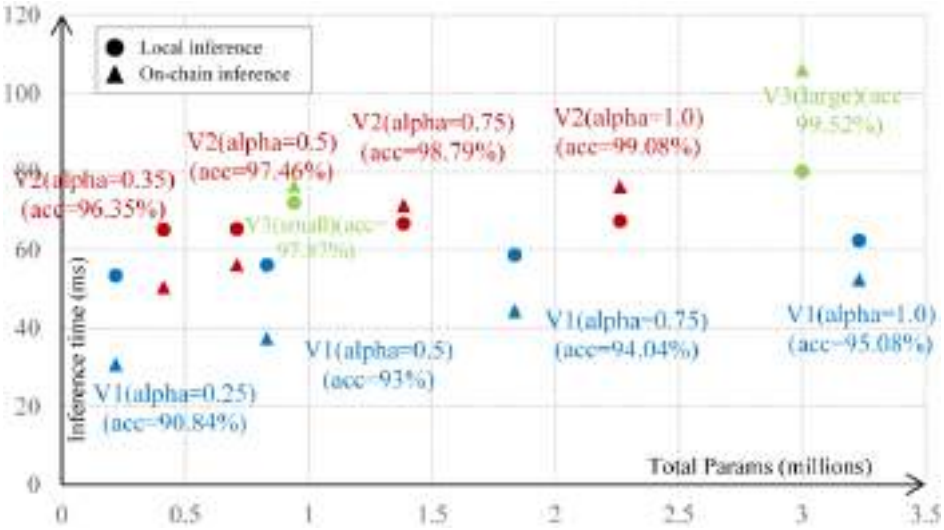

Figure 5. Comparison on different MobileNet variants.

6 Discussion

The contribution of this research lies both on theoretical and practical part. For the practical contribution, this study delivers a working prototype that applies the MLOB framework to reengineer the MiC inspection process. By integrating automated image-based inspections, secure model conversion, and consensus-driven decision-making via smart contracts on a blockchain network, the system achieves enhanced inference speed and robust accuracy while reducing delays and human errors. Its successful implementation in a Hong Kong MiC project demonstrates the approach's feasibility, scalability, and potential to establish new industry benchmarks for quality control and operational efficiency.

For the theorical part, the research offers a contribution by empirically mapping and optimizing the MiC inspection workflow. It identifies critical bottlenecks and validates that the integration of machine learning and blockchain can substantially improve inspection accuracy, efficiency, and security. This systematic re-engineering of traditional processes refines our understanding of how digital innovations can be seamlessly aligned with existing operational practices, setting a new standard for process optimization in construction.

The primary limitation of this research is its narrow focus on specific MiC inspection contexts, with limited real-world testing raising questions about broader applicability. Future research should address this by expanding the MLOB framework to more diverse scenarios and testing it on complex, large-scale projects with varied data characteristics to enhance generalizability. Additionally, collaboration with industry practitioners to integrate MLOB into practical workflows will provide valuable insights, promote real-world adoption, and help address potential implementation feasibility concerns across various construction environments. insights and promote adoption in real-world settings.

7 Conclusion

The MLOB framework integrates ML with blockchain to address accuracy, efficiency, and security challenges in MiC inspections. This approach ensures data integrity while enabling intelligent decision-making. Experimental results demonstrate significant performance improvements, showing potential to transform MiC processes. While proven effective in one real-world scenario, future research should test the framework across diverse construction contexts and optimize its computational resources.

A Critical Review of Supervised and Reduced-Dataset Vision-Based Construction Activity Recognition Methods

Ali Ghelmani[1], Amin Hammad[1]*

[1]Concordia Institute for Information Systems Engineering, Concordia University, Montreal, Canada
ali.ghelmanirashidabad@concordia.ca
amin.hammad@concordia.ca*

Abstract

Tracking and monitoring construction activities (e.g., equipment and workers) is crucial for improving site productivity and safety. Manual monitoring, however, is time-consuming, error-prone, and costly. To address these challenges, computer vision (CV) techniques have emerged for automated detection and classification of construction activities. Traditional supervised CV-based methods often rely on extensive annotated datasets, making it impractical to accommodate the wide range of equipment types and activities. Reduced-dataset methods, such as self-supervised, semi-supervised, and generative approaches, have recently surfaced as promising alternatives. Furthermore, construction digital twins are rapidly gaining traction as an integral component of Construction 4.0. However, their practical implementation requires efficient monitoring systems capable of handling vast data streams and dynamic site conditions using edge devices. Unmanned Aerial Vehicles (UAVs) are an example of such devices that have been increasingly utilized to provide monitoring of dynamic site conditions and consequently, necessitate the development of corresponding activity recognition methods. Previous reviews have primarily focused on supervised methods with stationary cameras, as such, this paper fills a critical gap by examining recent reduced-dataset approaches and also providing a forward-looking review of CV-based activity monitoring on edge devices.

1 Introduction

Monitoring the activities of workers and equipment on construction sites is critical for improving project productivity, safety, and overall efficiency. Traditionally, this monitoring has relied on manual observations by site superintendents, a time-consuming and error-prone approach that struggles to keep pace with the complexity of modern construction projects [1]. As the demand for timely, high-quality project delivery increases, so does the need for automated and accurate continuous monitoring systems [2]. Furthermore, the concept of Construction Digital Twin (CDT) has gained traction as a promising platform for real-time data integration, simulation, and optimization [3]. However, one of the main challenges in CDT implementation, is the availability of accurate, real-time monitoring data, further exacerbating the need for the development of corresponding monitoring methods [3].

Recent prevalence of surveillance cameras in most construction sites has triggered the development of various automated vision-based activity recognition methods for addressing the above challenges [4]. Early vision-based approaches relied heavily on hand-crafted features [4], but the advent of deep learning, particularly Convolutional Neural Networks (CNNs), has shifted the focus towards more robust and scalable solutions [5].

Initial works employed 2D CNNs combined with rule-based logic or recurrent architectures [6, 7] for sequential processing of spatial and temporal information. More recently, 3D CNNs that jointly model spatiotemporal features have emerged to obtain improved performance [8–10]. However, the supervised approach of these methods requires large, annotated datasets for each piece of equipment and activity that is infeasible to collect, hence limiting their scalability [11]. To address these data-related bottlenecks, reduced-dataset methods (e.g., self-supervised [12], semi-supervised [13], and generative techniques [14]) have begun to gain traction. Self-supervised learning involves training models on unlabeled data using labels extracted from the data itself [12] (e.g., predicting rotations or temporal consistency); while semi-supervised learning leverages a small amount of labeled data in conjunction with unlabeled data, typically through techniques such as pseudo-labeling, to enhance learning efficiency [13]. Generative approaches, however, focus on synthesizing additional artificial data that mimic real-world conditions to expand the dataset size and diversity, thereby improving model

generalization [14]. While some studies have explored these approaches for equipment detection [11, 13], few have tackled the more complex problem of activity recognition [12].

Additionally, majority of the state-of-the-art activity recognition methods utilize videos collected from stationary cameras, however, CDT requirement for the availability of real-time data, given the dynamic nature of construction sites, necessitates the development of activity recognition methods employing edge devices such as Unmanned Aerial Vehicles (UAVs). As such, while previous review papers have focused on traditional supervised activity recognition methods (e.g., [4, 15]), there remains a need to thoroughly review these emerging technologies and discuss their potential in construction, particularly for activity recognition. This paper directly addresses these identified gaps by comprehensively reviewing recent advancements in reduced-dataset construction activity recognition methods and exploring the application and potential of Computer Vision (CV)-based monitoring solutions deployed on edge devices. The considered aspects aim to enhance the scalability of current supervised methods and address the challenge of providing dynamic construction site monitoring data essential for the development and implementation of CDTs.

2 Review Method

This study employed a systematic approach to identify and review the existing literature on vision-based construction activity recognition methods. Three main steps were followed: (1) paper collection, (2) initial screening, and (3) in-depth review and synthesis. First, an exhaustive search was conducted using multiple academic databases (e.g., Web of Science, Scopus, Google Scholar) to retrieve publications spanning approximately the last decade. The search keywords were designed to cover three broad categories: (1) terms related to construction (e.g., "construction," "vision-based methods," "automated monitoring," "activity recognition," "productivity analysis,"), (2) terms related to reduced-dataset deep learning methods (e.g., "self-supervised learning," "semi-supervised learning," "few-shot learning", "generative adversarial networks,", "synthetic data"), and (3) terms related to edge devices (e.g., "moving camera activity recognition," "UAV-based monitoring," "aerial construction monitoring").

Following the initial collection, titles and abstracts were screened to remove works focusing solely on non-construction domains or unrelated technologies. However, where gaps existed, particularly for activity recognition using moving edge devices, the search scope was broadened to include highly relevant and applicable methods from the general CV domain. Thus, papers discussing supervised or reduced-dataset approaches for construction activity recognition using stationary cameras, as well as relevant CV methods employing moving edge devices, were selected. Subsequently, a brief content review was then performed to ensure that selected papers substantially contributed to the current review scope. Finally, an in-depth qualitative analysis of the remaining papers was conducted to identify key trends and challenges in the literature.

3 Construction Activity Recognition Using Stationary Cameras

This section reviews supervised and reduced-dataset construction activity recognition methods using stationary cameras. Moreover, Figure 1 presents a categorization of these methods, along with representative publications for each approach.

3.1 Supervised Approaches

In the past decade, many vision-based methods have been proposed for the task of construction activity recognition. With the advent of deep learning, 2D CNNs became central to extracting spatial features from images, while temporal dependencies were increasingly modeled using additional modules such as Hidden Markov Models [16], or Long Short-Term Memory (LSTMs) networks [17]. Such combinations improved performance but often introduced computational overhead by separating spatial and temporal processing into multiple stages [8].

The 3D CNN-based methods alleviated this issue by incorporating the spatiotemporal data extraction into a single architecture. For instance, Chen et al. [1] proposed a three-stage excavator activity recognition method comprising of detection, tracking, and a final activity recognition stage using a 3D CNN network. In another study [5], they used a similar approach to detect excavator and dump truck activities, and to identify reasons for excavator idling by analyzing their interactions. A similar multi-stage approach for worker activity recognition was also proposed by Lou et al. [18]. However, the main limitations of these methods include not being fully optimized and also the propagation of errors from earlier stages to the later ones; thus, degrading the overall performance [19].

To address the abovementioned limitations, Jung et al. [19] proposed a 3D CNN-based single-stage method for simultaneous detection of multiple construction equipment and recognizing their activities. Others have also proposed single-stage methods based on the You Only Watch Once (YOWO) [20] method for joint detection and classification of construction workers' [8] and excavators' [21] activities. Despite improved performance, the main drawback of these methods is the

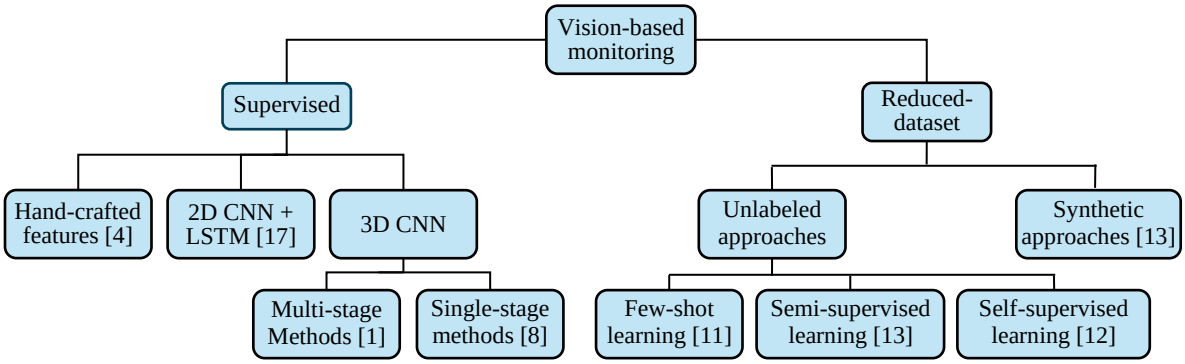

Figure 1. Categories of supervised and reduced-dataset construction activity recognition methods

necessity of post-processing due to their low per-frame activity recognition and localization performance.

Recently, a combination of multiple data modalities for activity recognition has also been suggested by some works. For example, Luo et al. [22] developed a CNN network by integrating RGB, optical flow, and gray-scale images to monitor workers' activities. Yang et al. [23] proposed a two-stream architecture for recognizing workers' unsafe behavior using a transformer model and a 3D CNN network to process RGB and Temporal Gradient (TG) data, respectively. Ghelmani and Hammad [10], also developed a multi-stream method, which leveraged TG data through knowledge distillation to achieve accurate, real-time per-frame activity recognition and localization performance for excavator activities.

Even though the state-of-the-art construction activity recognition methods can achieve high performance, their supervised approach necessitates extensive, annotated datasets for every piece of equipment and each specific activity. Since the types of construction equipment frequently change from one project phase to another [11], generating such comprehensive labeled dataset becomes a significant obstacle for the development of a general activity recognition method.

3.2 Reduced-Dataset Approaches

Researchers in the construction domain have proposed several methods for reducing the time and effort required for dataset collection and annotation. Liu and Golparvar-Fard [24] proposed crowdsourcing the annotation task using Amazon Mechanical Turk. However, such approaches still require human effort for data annotation and for removing the mistakes in the prepared dataset due to crowdsourcing [13]. Generally, reduced-dataset methods can be broadly categorized into methods that utilize a synthetic approach for data generation and methods that utilize unlabeled data for reducing the data annotation cost.

3.2.1 Synthetic Approaches

Calderon et al. [25] employed a virtual and kinematically articulated 3D model of excavators to generate synthetic 2D pose data for excavator activity recognition. Assadzadeh et al. [26] also generated a synthetic dataset for excavator pose estimation using domain randomization. Soltani et al. [27] developed a dataset of synthetically generated images of deformable excavator parts, which were used to estimate the excavator's 3D pose and consequently its kinematic posture. Data augmentation schemes using Generative Adversarial Networks (GANs) were also proposed by some researchers to enhance the variability and size of a collected dataset for construction equipment detection [28], activity recognition [14], and site monitoring [29]. Although synthetic approaches improve model's generalization through generation of challenging scenarios such as viewpoint variation, or partial occlusion, however a major limitation of these methods is the inherent visual differences between synthetic and real data [13], hence limiting their real-world applicability.

3.2.2 Unlabelled-Data Approaches

Few-shot learning. Kim and Chi [11] developed a few-shot learning approach by first training a model on a base dataset with sufficient training images of multiple construction equipment. Afterwards, the trained model was used in a transfer learning scheme to learn to detect new equipment with only a few available labeled images. In another study, Kim et al. [30] proposed a three-stage active learning method in which uncertainty evaluation was used to select an informative subset from the unlabeled data. Then, the selected small subset was labeled manually by the user and used for model training. Recently, Chen et al. [31] developed a multi-stage approach for recognizing excavator activities in a zero-shot learning setting in which the detected non-idling frames were input into a pre-trained CLIP (Contrastive Language-Image Pre-training) model [32] for activity recognition. A similar CLIP-based method for construction safety inspection was also proposed by Tsai et al. [33]. While few-shot and zero-shot learning techniques aim to minimize reliance on large, labeled

datasets, they remain restricted to learning only from the limited number of provided annotated images. Consequently, their final performance can fluctuate greatly depending on the quality and characteristics of the provided data [11].

Semi-supervised learning. Xiao et al. [13] introduced a teacher-student architecture in which a teacher network was first trained on a small, labeled dataset using weak data augmentation (e.g., horizontal translation). The trained teacher then generated pseudo-labels for unlabeled data that underwent stronger augmentations (e.g., cropping) to train the student network (the final output of this method). Such strong augmentations can simulate challenging scenarios, such as occlusions and significant viewpoint variations, potentially enhancing the student network's robustness to these real-world challenges. However, the main drawback of this method is the reliability of the generated pseudo-labels. In other words, Since the teacher network itself is trained in a supervised manner, it requires a sufficiently large, labeled dataset to produce accurate pseudo-labels, which greatly limits the method's applicability for reducing the annotation requirements. Furthermore, pseudo-labeling inherently risks introducing biases into the training data, as incorrect predictions made by the teacher model might be confidently assigned as accurate labels. Such biases could subsequently skew the model toward frequently occurring or easily identifiable examples, potentially diminishing performance on less common, complex, or ambiguous scenarios.

Self-supervised learning. The previous methods leveraged unlabeled data solely for construction equipment detection. However, the collection of an annotated dataset for activity recognition is even more challenging, as they often require frame-level labeling. Thereby increasing the necessity of developing methods that exploit unlabeled data for activity recognition. Nevertheless, only one study has addressed this need: Ghelmani and Hammad [12] proposed a self-supervised, contrastive learning approach for pretraining a 3D CNN network using unlabeled data, followed by fine-tuning using a small amount labeled data for excavator activity recognition. Although this method reduced annotation demands, it only applied self-supervised learning to activity recognition and not localization. No research to date has employed unlabeled data to facilitate the localization of construction equipment, even though this step is among the most annotation-intensive processes. Advancing research in this area could thus pave the way for more general and scalable construction activity recognition methods.

4 CV-based Activity Recognition on Edge Devices

As mentioned in Section 1, an indispensable component for CDT implementation is real-time monitoring using edge devices which include stationary and moving cameras (e.g., on UAVs). Methods developed for stationary cameras were reviewed in Section 3 while this section reviews methods developed for activity recognition using moving edge devices. Moreover, given the lack of activity recognition methods in the construction domain using edge devices, this section also presents a comprehensive review of the corresponding methods developed in the CV domain.

Activity recognition methods using moving edge devices can generally be divided into ground-based and aerial approaches.

4.1 Ground-based Methods

Ground-based methods in the CV domain are mainly concerned with applications related to self-driving cars. For instance, Yu et al. [34] proposed a method for real-time activity recognition in unconstrained video streams by utilizing frame-level foreground segmentation to obtain spatiotemporal proposals for activity recognition. Zhuang et al. [35] proposed a multi-stage road active agent detection and activity classification by initially passing the optical flow and RGB frames through corresponding backbones for object detection, followed by tracking and activity recognition stages. However, the main limitations of ground-based methods include: (1) the need for automated or manual navigations systems, which can be particularly challenging in a construction site; and (2) the limited field of view and ground-level camera angle, which can greatly increase the chance for occlusion and hence, reduce the model performance.

4.2 Aerial Methods

Compared with ground-based methods, a greater volume of research has been conducted on activity recognition using aerial imagery [36, 37]. Unlike traditional stationary cameras, UAVs capture videos from higher altitudes, allowing for a broader field of view. Additionally, UAVs can cover an large surveillance area due to their significant range of movement [36]. However, these factors introduce complex challenges related to detection, tracking, and activity recognition [38]. These challenges include the small resolution of objects of interest due to the high camera altitude. As a result, most of the pixels in a video frame are occupied by the background, with only a small fraction representing the targeted actions. Furthermore, the size and scale of the video can vary dramatically depending on the UAV's flying altitude, making the

extraction of spatiotemporally representative features quite challenging with the possible necessity of a preprocessing stage for scene stabilization [38]. Current activity recognition techniques are computationally demanding and memory-intensive, making it challenging to respect the time constraints in real-world applications. This is particularly true for edge devices with limited computational resources, such as UAVs [39]. To mitigate these constraints, existing methods typically adopt lightweight neural network architectures or hybrid inference schemes, where initial lightweight processing occurs onboard, and computationally intensive processing is delegated to remote servers or cloud-based resources (e.g., [38]). Nonetheless, effectively balancing computational efficiency with high model performance remains an active area of open research.

Dataset collection. The first step in addressing the above challenges using deep learning-based methods is the availability of extensive datasets. To this end, Barekatain et al. [40] proposed one of the first aerial video datasets for activity recognition comprising of 13 different types of human activities. Perera et al. [41] also developed a drone video dataset for activity recognition and pose estimation including 240 video clips recorded at low altitudes and low drone speed to provide high resolution human pose details.

Supervised approaches. Mliki et al. [42] proposed one of the first UAV activity recognition methods comprising of an offline training stage and an inference stage. Their approach utilized a scene stabilization technique for preprocessing followed by a human and non-human detector to filter out moving non-human entities. Finally, the detecting human agents were used for activity recognition. To address the problem of small-scale human targets in high altitude drone videos, Wang et al. [38] proposed the auto zoom and temporal reasoning method, which initially scales and crops human detections. Subsequently, a hybrid approach combining a lightweight 3D CNN network on edge devices and a more powerful 3D CNN network on local devices were employed for activity recognition.

Recently, many approaches have suggested a combination of feature-based and deep learning methods for aerial video activity recognition. For instance, Gundu and Syed [43] utilized Histogram of Oriented Gradients features for pattern extraction followed by a combination of CNN and LSTM networks for human activity recognition. Peng and Razi [44] used speeded up robust features (SURF) and Lucas-Kanade method for motion stabilization of the UAV captured videos, followed by detection and activity recognition stages. Kothandaraman et al. [45] employed Fourier analysis to separate out the human agent from the background in the frequency domain. Afterwards, a novel Fourier space-time attention module was utilized for activity recognition. Despite their improved performance, these methods still depend on manually engineered feature extractors, which introduce biases and constrain the representational capacity of the subsequent deep learning networks. The prevalence of such hybrid approaches can be attributed, in part, to the scarcity of large, high-quality aerial video datasets as reviewed earlier. As such, further development in this domain warrants the availability of large, annotated datasets.

Reduced-dataset approaches. As stated in Section 3.2, another possible approach for addressing the abovementioned limitations can be to utilize reduced-dataset approaches. To this end, Sultani and Shah [46] introduced a multi-task learning approach for activity recognition using aerial images, which leveraged a GAN network to synthetically transform ground activity video features into their aerial counterparts. To further improve performance, a small number of real aerial activity videos were also incorporated alongside the synthetic data. Choi et al. [47] proposed unsupervised and semi-supervised domain adaptation approaches to leverage the existing action recognition datasets in combination with unannotated or only few annotated drone videos for activity recognition. Although these approaches lessen the need for annotated aerial data, they mostly focus on domain adaptation from ground videos to aerial counterparts, a process that inevitably introduces errors and restricts the final model's accuracy. As such, there is a need in this area for new methods that can directly exploit unlabeled aerial videos to facilitate both activity recognition and localization, without relying solely on cross-domain transformations.

Aerial approaches in construction. Several studies have addressed the task of detecting construction entities from aerial images. For example, D. Kim et al. [48] proposed a UAV-assisted monitoring method as a proactive safety measure against struck-by hazards by utilizing a YOLOv3 [49] network for object localization and an image rectification method to measure actual distance from collected images. Guo et al. [50] proposed a method for detecting construction equipment from UAV-captured images. The proposed method combined orientation-aware feature fusion with a 2D CNN network for detecting equipment with arbitrary orientations. Comparison between different object detection methods were also carried out by Mutis et al. [51] for construction resource detection and by Pi et al. [52] to detect various construction site entities using aerial top-view images. A few studies have also developed UAV-based methods to improve construction site safety by detecting small and medium objects to avoid struck-by accidents [53–55] and for monitoring worker safety compliance [56].

To address dataset requirements for training deep learning methods Ersoz et al. [57] developed an aerial image dataset for construction machinery detection.

Others have developed methods to reduce annotated data requirements for aerial construction entity detection. For example, Bang et al. [58] proposed a variety of data augmentation techniques including moving-and-inpainting, cut-and-paste, and image-variation to improve the performance of a Faster R-CNN [59] network for detecting construction resources from UAV-captured images. Wang et al. [60] employed a 3D reconstruction technique using a UAV and photogrammetry to synthetically generate an image dataset for the analysis of crane productivity. Specifically, they reconstructed a crane bucket and used this synthetic data to conduct their study. However, as discussed in Section 4, all current aerial approaches in construction have focused solely on equipment or resource detection. To enable accurate, real-time monitoring that supports CDT implementation, methods must also address activity recognition, an area that remains unexplored for aerial-based methods.

5 Summary and Contributions

This paper provided a critical review of the state-of-the-art in vision-based construction activity recognition, examining both traditional supervised methods and the emerging reduced-dataset methods that leverage self-supervised, semi-supervised, and generative approaches. The data annotation barriers in current supervised methods were identified, followed by highlighting promising reduced-dataset strategies that mitigate these challenges. Moreover, given the growing demand of emerging CDT systems for the availability of accurate, real-time monitoring data, this review addressed a previously underexplored area: activity recognition using moving cameras (e.g., on UAVs) on edge devices, which is essential for capturing dynamic site conditions. Finally, the existing research gaps were identified, especially in reduced-dataset activity localization and aerial-based applications, hence proposing future directions for development.

Abstract –

This paper presents an automated workflow for weekly construction progress reporting, streamlining data integration and analysis. The proposed approach focuses on three key areas: planned activities, weekly performance, and projected progress. Inputs include an updated baseline schedule and weekly inspection data, such as images. Outputs, generated autonomously, provide project status and performance metrics, including Earned Value and Planned Value. Leveraging multimodal large language models (MLLMs), the system processes text and images, enabling seamless data integration. Key contributions include a simplified, reliable reporting process that reflects actual construction execution and planning while reducing time and resource demands. The paper also addresses implementation challenges, AI-driven solutions, and scalability for broader construction reporting applications.

Keywords –

Construction Progress Reporting, Automation Workflow, Multimodal Large Language Models, Project Management, EVM

1 Introduction

Progress reporting is a cornerstone of effective construction management, offering stakeholders insights into the current status, challenges, and future directions of a project. Weekly reports serve as a critical tool for tracking planned versus actual progress, identifying delays, and updating schedules. However, generating these reports remains a labor-intensive process, often requiring manual consolidation of diverse data sources, including project plans, contracts, on-site observations, and multimedia documentation. Not to mention that such reports are very subjective and based on multiple human-relying factors, such as the quality and completeness of the collected data, the analysis made on said data, and the completion of the actual report.

This paper addresses the challenge of automating construction site progress reporting by designing and implementing a streamlined semi-automated workflow. The proposed system focuses on three core sections of the weekly report:

- Automatically identifying what has been planned for the reporting week;
- Evaluate and determine the activity performance of the reporting week using sight inspection data inputs.
- Update and generate feasible activity plans for the following week.

These sections were selected due to their recurring importance for tracking progress and generating reliable weekly construction status reports.

2 Background

In the construction industry, weekly reports are essential tools for monitoring project progress and ensuring effective communication among stakeholders [1]. A critical component of these reports is the assessment of progress made by construction activity. This evaluation typically involves referencing data from previous reports or updated schedules, while the actual progress for the current reporting week is manually estimated or measured on-site and manually entered into the report. This manual process demands significant time from the engineering team for data synthesis and evaluation, potentially diverting attention from other vital tasks [2].

The quality and accuracy of weekly progress reports heavily depend on the competencies of the individuals preparing them, which can lead to inconsistencies, subjectivity, and biases [3]. The quality of weekly reports is directly linked to the successful coordination between stakeholders and the completion of construction projects. High-quality reports provide early warnings of potential

risks and constraints, enabling timely corrective actions.

Automating the generation of construction reports could enhance their quality and accuracy, minimizing subjectivity. By reducing time spent on less productive activities, such as inspection of the collected data and writing the report, automation aligns with lean construction principles, which emphasize waste reduction and value maximization [4]. Within the Last Planner® System (LPS), accurate weekly reports are vital for improving communication and collaboration among all stakeholders involved in the construction process [5]. Weekly plans and reports play a crucial role in identifying and managing construction constraints. They structure constraint information and facilitate the development of data-informed lookahead plans, detailing upcoming work and potential obstacles. This process incorporates actual construction progress into the master schedule, ensuring preparedness for potential issues and adherence to plans [6].

Incorporating automation into report generation not only improves efficiency but also supports the continuous improvement ethos central to lean construction. By streamlining information flow and reducing manual errors, automated reporting systems contribute to more predictable and successful project delivery [7].

2.1 Automated Construction Reporting

As stated above, automated construction reporting have multiple benefits of handling overwhelming data influx from multiple sources and improving productivities. Various studies have proposed workflows aimed at automating the whole construction progress monitoring and reporting system, which consists of four main processes: data collection, data analysis, progress estimation, and visualization [8]. El-Omari and Moselhi [9] implemented automated data acquisition technologies within an IT platform for construction project reporting. Shrestha et al. [10] developed computational algorithms to generate as-built schedules, both during and post-construction, updating progress dynamically. Jafari et al. [11] leveraged Natural Language Processing (NLP) and Machine Learning (ML) for automated reporting extraction, coupled with stochastic simulations to predict time and cost. Xiao et al. [12] integrated computer vision-based data acquisition with ChatGPT to automatically generate construction reports. Shamsollahi et al. [13] created a complete workflow for automated progress monitoring, incorporating object recognition, objectives tracking, and automated report generation. Ekanayake [14] explored computer vision-based progress monitoring, focusing on automated data collection, analysis, and progress report generation.

These advancements underscore the potential of automation in improving the efficiency and accuracy of construction reporting. However, many of them focus on only one or two sub-processes while overlooking manual efforts and the challenges of developing automation tools, which hinders the implementation of a fully integrated workflow.

2.2 Vision-Based Construction Progress Recognition

One of the challenging parts of automated construction reporting is the automated construction progress recognition. The use of images in construction progress monitoring has grown significantly, facilitated by advances in ML [15]. Martinez et al. [16] used an R-CNN model and CCTV footage to track the progress of floor paneling workstations. Wei et al. [17] employed a Mask R-CNN model to track construction activities such as wall construction progress on a single floor. They also used an improved PointRend model to monitor the progress of prefabricated components across an entire building [18]. While these models have demonstrated high accuracy in task-specific scenarios, their effectiveness hinges on high-quality annotated datasets and specialized training. Extensive validation is necessary to ensure these models perform reliably across diverse construction contexts.

In recent days, MLLMs and Vision Language Models (VLMs) have shown tremendous ability to handle text and image information simultaneously in zero-shot tasks transferred to many real-world scenarios [19]. A VLM developed by Tsai [20] for construction safety reporting demonstrated its ability to generate textual descriptions for safety inspectors. Similarly, GPT models, which support few-shot and zero-shot learning can quickly analyze data, adapt to tasks with minimal training, and improve reporting, progress monitoring, and communication, have shown great potential for the construction industry [21]. Pu et al. [22] explored the capabilities of MiniGPT4-7B and GPT-4o in generating automated construction reports, combining automated data collection with LLMs. Despite the aforementioned efforts, the integration of the advanced construction progress recognition methods with the whole automated construction reporting remains underexplored.

In summary, automated construction reporting involves multiple processes, including data acquisition, data extraction, data analysis (e.g., progress description, delay identification, and forecasting), and visualization. While existing research has showcased advancements in automating multi-source data integration and generating construction reports to support decision-making, these efforts often rely on code-intensive workflows and substantial manual input in each sub-process. Vision-based data analysis remains heavily dependent on task-specific datasets and exclusive access to long-term computational resources.

The proposed approach in this paper uses an open-source and expandable workflow automation platform, focusing on seamless and easy integration in current practices and processes. By utilizing a low-code environment and integrating various data processing algorithms, the proposed approach aims to:

1. Simplify and automate progress reporting processes, reducing potential time waste.
2. Eliminate the need for specialized expertise in data collection, processing, and interpretation, by leveraging existing widely used tools for data generation and integration.
3. Minimize bias, reduce manual operations, and enhance workflow efficiency through automation.

3 Methodology

The methodology employed in this study is explained through process flowcharts using the BPMN notation [23]. The overall process is divided into two main sections: (1) manual process (Figure 1) and (2) automated process (Figure 2). BPMN uses "pools" to show the processes of different entities and "lanes" within these pools to present different sub-entities. In this paper, automated and manual processes are presented in separate pools, and different roles involved in the manual process flow are shown in different lanes.

The overall process involves using a developed chatbot to upload site images, and further request weekly progress reports from the chatbot conversation. Telegram was chosen to create the chatbot due to its seamless integration with automation tools. As shown in Figure 1 and Figure 2, a Common Data Environment (CDE) is employed for storing images and schedule files, which serve as the process inputs. While the process reduces manual effort by automating progress reporting, the actual schedule updating remains a separate task and is outside the scope of this paper. This study used Google Drive as the CDE because of its convenience. Overviews of manual and automated parts of the process are presented in the following subsections.

3.1 Manual Process

The manual process involves three roles: (1) site employee, (2) project scheduler, and (3) management/client (Figure 1). The details of each role and related tasks are as follows:

1. **Site employee:** This role is responsible for taking site inspection photos to capture and document the progress. It can be anyone who works on-site and has access to the developed chatbot. The only tasks related to this role are taking site photos and uploading them to the chatbot.
2. **Project scheduler:** This role is responsible for converting the most recently updated MS Project schedule file into the comma-separated values (CSV) format and uploading it to the CDE. CSV was chosen in this study for its structured format, which facilitates data extraction. These tasks and the site employee's tasks are performed in parallel since they are not dependent on each other (Figure 2).
3. **Management/client:** This role represents the stakeholders requesting the report from the automated process flow. Some examples of this role are the site manager, the project manager, and the client. Due to the unbiased nature of the workflow, the generated report provides transparency regarding the project progress and improves the information flow among the stakeholders. The "request report through chatbot" task is dependent on the previous tasks related to photo and schedule uploads performed by the site employee and scheduler.

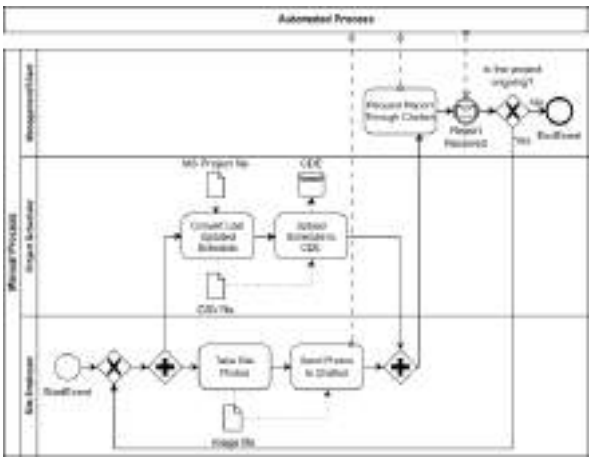

Figure 1. Manual part of the overall process flow

3.2 Automated Process

The automated part of the overall process flow was developed on the low-code workflow automation platform, n8n [24]. This platform was used due to its advanced graphical user interface, which allows visual programming without requiring extensive coding knowledge. However, other low-code development platforms or traditional programming can serve the same purpose.

The automated part of the process flow has two message start events, "photo received" and "report request received", triggered by the tasks from the manual process. Once the site inspection photos are uploaded to the chatbot in the manual process, the "photo received" event is triggered, and the photos are automatically uploaded to the CDE. The connection between the chatbot and the automation process was made using the Telegram node in n8n.

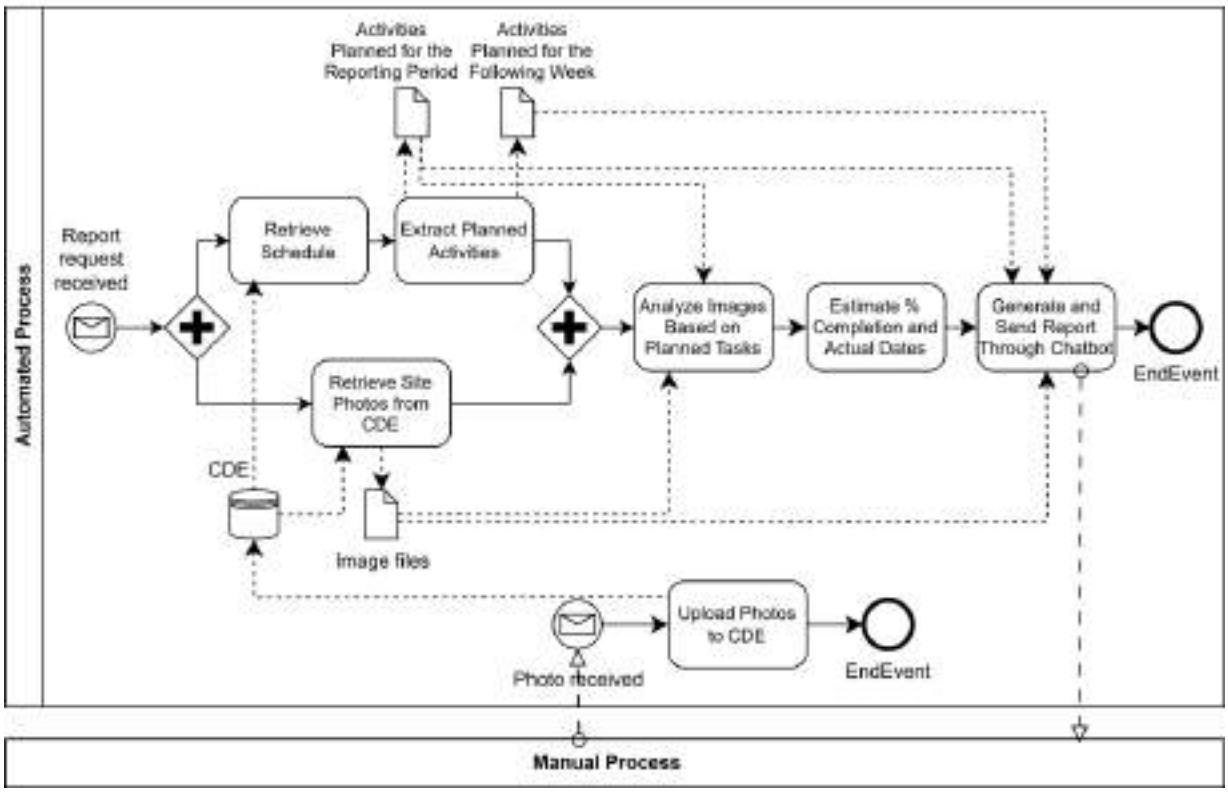

Figure 2. Automated part of the overall process flow

Once the report request is received from the project management or the client, the retrieval of the schedule and photos is performed. These are facilitated through the Google Drive integration of the n8n platform in this study. The activities planned for the reporting period and the upcoming week are extracted from the schedule file using custom JavaScript code and integrated into the n8n workflow via the Code node. The images retrieved from the CDE are analyzed based on the planned tasks using a MLLM. GPT-4o was used in this study due to its powerful capabilities and the built-in OpenAI nodes in n8n. However, an open-source model could be utilized for the same purpose if data privacy or cost were to be prioritized. GPT-4o was used to generate the prompts for its own tasks. This approach ensures structured and efficient prompts for each task.

The MLLM is asked to analyze the construction site images and determine the percent completion of each planned activity, having the rest of the provided information as context for said analysis. The result from this analysis is passed into another LLM instance to compare it with the percent complete values from the last updated schedule, and then output the highest percentages based on this comparison. These percent complete values are then used to calculate the estimated actual start dates for the activities started during the reporting period and the estimated actual finish dates for the activities completed during the reporting period.

Finally, the planned tasks for the reporting period, their percent complete values, the activities planned for the following week, and the site inspection photos are included in the weekly progress report generated as the last step of the automated workflow. The generated report is sent to the user who requested the report through the chatbot.

4 Case-study

This case study presents the automated generation of a weekly construction progress report for a fit-out construction project conducted on a university campus. The project involves the conversion of a meeting venue into an auditorium, incorporating several specialized upgrades to meet the functional and aesthetic requirements of the new space. These upgrades include structural modifications for tiered seating arrangements, enhanced audio-visual systems tailored for auditorium use, and upgrading the heating, ventilation, and air conditioning (HVAC) systems to accommodate the revised space usage. Additionally, the project involves aesthetic and functional enhancements such as floor carpeting and the integration of electrical systems,

particularly beneath the stepped seating, to support the operational needs of the auditorium.

The specific week in the timeline used for this case study was selected due to the significant activity observed on-site during that week and the availability of comprehensive data, making it an ideal timeframe for detailed analysis. The focus on this time period captures substantial progress while providing a reliable snapshot of the construction activities. For consistency and accuracy in assessment, the schedule is assumed to be up to date as of the last day of the previous reporting date, reflecting all completed activities up to that point. This assumption ensures a clear baseline for evaluating the progress during this time.

4.1 Data inputs

One of the data inputs necessary for the process was the updated schedule. As of the last day of the previous reporting week, the overall project progress was 54%, with significant milestones achieved. Partition work was 83% complete, with closure and wall finishing still pending. The ceiling installation had reached 37%, with ceiling panel installation not fully completed. Floor preparation tasks were fully completed at 100%. MEP work stands at 38%, with ductwork and data conduit installations finished, wiring and cable installation at 60%, and initial stages of HVAC air diffuser installation underway. The seating area framework and concreting were 63% complete, with framework installation fully finished and rebar installation nearing completion at 90%. The updated list of tasks with their percentage completion is shown in Figure 3. It highlights the project's progress, with several activities scheduled for completion in the target week. The second critical input to the process was raw data from the site inspection. In this case, the site inspection was conducted on the 5th day of the reporting week, and 360 images, such as the one shown in Figure 4, were collected.

4.2 Report generation process

The report generation process is initiated by sending the image taken from the construction site during the inspection directly to the Telegram bot. The Telegram bot initiates the image renaming and uploading process to the cloud data storage space, where the image is renamed to carry the data collection date and stored in the Google Drive folder that is prepared for this purpose.

Custom-made plugins in the scheduling software, Microsoft Projects in this particular case study, were employed to convert the existing schedule to a structured, easily readable data format such as CSV and uploaded to the cloud storage that the workflow can access. As mentioned previously, this case-study experiment employs n8n as the low-code workflow automation platform to connect all the different processes. Hence, a command "/report" in the Telegram bot initiates the relevant information generation process, using the available data inputs that are pre-uploaded in the cloud storage, following the process shown in Figure 1 and Figure 2.

Task Name	% Complete
A6 Room 2 (3B) construction	**54%**
Partition Work	**83%**
Gypsum Board Installation	100%
Closure, finishing wall surfaces	0%
Ceiling Installation	**37%**
Ceiling Frame Installation	100%
Ceiling Panel Installation	10%
Floor preparation	**100%**
Layout and mark the floor for precise positioning of partitions, conduits, seating framework, and other installations.	100%
MEP work	**38%**
Installation of MEP Ductwork and fixture installation	100%
Installation of MEP and Data Conduits	100%
Wiring and Cable Installation	60%
Installation of Wall Fixtures (MEP and Data)	0%
Installation of Floor Boxes (MEP and Data)	0%
Installation of HVAC Air Diffusers and Grilles	7%
Conduct final checks and installation of any remaining electrical components	0%
Seating area framework and concreting	**63%**
Seating Steps Framework Installation	100%
Seating Area Floor Rebar Installation	90%
Concrete casting and covering it with wet curing blanket for seating area	0%

Figure 3. Extract of the Baseline tasks list and percentage completion updated as of the last day of the previous reporting week.

Figure 4. 360 image taken during the site inspection on the 5th day of the reporting week

5 Results

The generated report is composed of five sections, including (1) basic project information, (2) a high-level description of the current weekly site work progress, (3) a summary of weekly project status, (4) a list of tasks planned for next week, and finally (5) a list and descriptions of the inspection photos.

The basic project information section carries the static project information such as Project ID, and designation of the specific zone in the project where the current report is targeted to. This section also provides information regarding the specific reporting week.

The weekly report is meant to be delivered to

nontechnical stakeholders, such as clients with limited understanding of the detailed project status metrics. Therefore, the second section provides the list of tasks planned for the current week, dividing these tasks into three different categories: (1) *complete*, mainly for the set of tasks that are finalized during the week; (2) *in progress*, for tasks that are still active but not complete; and the last category (3) *planned but not started yet*, mainly for those tasks that the schedule indicates that they need to be started during the week but have not actually been started in the construction site yet.

For the project used in this case study, even though all of the tasks except ceiling panel installation were planned to be completed by the end of the studied week, the process generated a report showing that none of the tasks were actually completed. Moreover, three of the six planned tasks (i.e., installation of wall fixtures, installation of floor boxes, and concrete work for the seating area) are classified as planned but not started yet in the generated report.

This report offers (Table 1) even more expanded information on the planned vs actual performance of the project showing the Work Breakdown Structure (WBS) ID, Task Name, Status, % Completion to Date (EV), % Planned Completion (PV), and Actual Completion of the work at the end of the reporting week (AC).

Table 1: Output summary of the project status

WBS	Task Name	Status	EV*	PV	AC
1.2.2	Ceiling Panel Installation**	In progress	60%	85%	21%
1.4.3	Wiring and Cable Installation**	In progress	70%	100%	80%
1.4.4	Installation of Wall Fixtures (MEP and Data)**	Not started	0%	100%	0%
1.4.5	Installation of Floor Boxes (MEP and Data)**	Not started	0%	100%	0%
1.4.6	Installation of HVAC Air Diffusers and Grilles**	In progress	50%	100%	90%
1.5.2	Concrete Work for Seating Area**	Not started	0%	100%	100%

* The information was generated from site inspection photos using VLM; hence, verification from the site crew would be required.

** Shows tasks that are potentially delayed according to their SPI value.

Based on the performance of the current week, the automated workflow also presents a section in the report suggesting the list of planned tasks for the next week. This computation considers the SPI of the EVM. Given this case study does not involve the cost calculation, the SPI calculation is summarized as EV/PV, where EV is taken as equivalent to the percentage completion and PV is computed as the ratio of the number of actual activity days related to a planned task with the number of planned days of the task-related activity.

Based on the SPI, the baseline finish date and the revised task duration, the new list of tasks planned for the following week is reported. The last segment of the report presents the raw image data involved in the generation of the report with systematically defined captions that relate the site status and active tasks with the actual image collected. Readers interested in the specific details of the report generated and the data used for the generation of the report are encouraged to contact the authors to request a copy.

6 Discussion

This study successfully demonstrates the potential of automated processes for generating construction weekly progress reports, effectively addressing the three key objectives stated at the beginning of the paper: reducing potential time waste, eliminating the need for specialized expertise in data collection, processing, and interpretation, and lastly minimizing bias in the report results.

The automation demonstrated in this case study reduces potential time waste by streamlining the data collection and reporting processes. Traditionally, generating progress reports involves multiple manual steps, including data collection, image labeling, information synthesizing and processing into a coherent report format. The workflow presented in this study minimizes these repetitive tasks by automating image renaming, cloud storage, data integration, structuring the information into the report, and finally, updating the schedule as per the actual site findings. As a result, site personnel can allocate more time to critical construction activities rather than administrative tasks. This efficiency is particularly valuable in time-sensitive projects where delays in reporting can lead to cascading schedule disruptions.

A significant strength of the approach is its ability to eliminate the dependency on specialized expertise for data collection, processing, and interpretation. By leveraging widely used tools, such as Microsoft Project and Google Drive, the system simplifies complex workflows. The integration of a Telegram bot for streamlined image data uploading and a low-code workflow automation platform like n8n ensures accessibility for non-specialist stakeholders. This supports broader adoption in the construction industry, aligning with recent findings emphasizing the role of digital technologies in minimizing manual operations and enhancing workflow efficiency.

The automated generation of reports succeeded in capturing nuanced aspects of project progress. For instance, the system provided detailed insights into the planned versus actual status of tasks, identifying discrepancies such as the non-initiation of key activities (e.g., wall fixture installations and HVAC diffusers).

Such insights are critical for stakeholders, enabling proactive decision-making and improving a deeper understanding of site progress without requiring technical expertise. This aligns with previous studies advocating for automated reporting systems to enhance decision-making efficiency.

The case study highlights the ability of the proposed automation system to reduce bias, a major challenge in manual reporting processes. By relying on data inputs directly from site inspections and schedule updates, the developed workflow fully eliminates potential subjective interpretations often introduced by human intermediaries. For example, the categorization of tasks as "not started" or "in progress" is derived from structured data rather than personal judgment, ensuring consistency in reporting. This objectivity is further enhanced by visual evidence from 360-degree images, which provide a verifiable basis for evaluating site conditions. Such an approach aligns with findings that emphasize the role of the proposed automation workflow in enhancing transparency and objectivity in construction management.

7 Limitations and Future Work

Despite these strengths, the study identifies some limitations. First, the reliance on scheduled updates and inspection photos as primary data inputs introduces vulnerabilities to inaccuracies. For instance, the discrepancy between planned and actual progress, particularly the underreporting of completed tasks (i.e., in the case study, task “Concrete work for seating area”), underscores the need for site verification. While automation streamlines data integration, human oversight remains essential to validate outputs.

Second, the scope of the study focuses on construction progress reporting without considering cost metrics. While the SPI computation in the study provides a functional basis for assessing schedule adherence, the lack of cost-related indices limits its applicability in budget-critical projects. Future work should integrate cost parameters to provide a more comprehensive project performance evaluation. Additionally, the use of static image data and dependency on a basic interpretation of the image content introduces challenges in capturing dynamic site conditions, such as real-time adjustments to workflows or unforeseen disruptions. Moreover, without performing evaluations of the work volume, and purely relying on the evaluations performed by the MLLM, understanding the accurate extent of work from the existing information could be challenging. To address these limitations, future work should incorporate advancements in real-time data acquisition methods (e.g., automated LiDAR data acquisition), considering more information as data input (e.g., an audio voice note from the worker collecting the images clarifying details about the extent of completed work) as well as automated work volume measurement mechanisms in the workflow.

8 Conclusions

This study introduces an innovative and practical approach to automating construction progress reporting, demonstrating benefits in minimizing manual effort, reducing reporting bias, and improving workflow efficiency. A case study conducted at a university campus highlights the system’s ability to generate detailed, accurate, and accessible reports that cater to both technical and non-technical stakeholders. By integrating schedule data with image-based site inspections and leveraging MLLMs for data processing and analysis, the proposed approach effectively bridges the gap between traditional reporting methods and the evolving demands of modern construction management. This integration ensures seamless data processing, enhances reporting accuracy, and supports more informed decision-making throughout the project lifecycle.

Acknowledgments

This research was partially supported by different Centers at NYUAD. In particular, the Center for Sand Hazards and Opportunities for Resilience, Energy, and Sustainability (SHORES) funded by Tamkeen under the NYUAD Research Institute Award CG013, the Center for Interacting Urban Networks (CITIES), funded by Tamkeen under the NYUAD Research Institute Award CG001, and the Center for Artificial Intelligence and Robotics (CAIR), funded by Tamkeen under the NYUAD Research Institute Award CG010. The authors would like to thank William Fulton and Mohamed Rasheed from the Campus Planning and Projects Office at NYUAD for their support and for allowing access to ongoing projects on campus to be used for our research.

Abstract – The construction industry persistently underperforms in hazard recognition, often leading to severe workplace injuries due to unrecognized hazards. With the recent advancements in Artificial Intelligence (AI) and the emergence of Large Language Models (LLM), the construction sector has begun exploring these technologies for various applications. However, a systematic comparison of popular LLMs to evaluate their effectiveness in identifying construction hazards remains unexplored. Additionally, previous studies have primarily focused on assessing LLMs using textual input and output, leaving their performance with visual inputs underexplored. This study addresses this gap by systematically assessing and comparing the hazard recognition performance of five widely used LLMs using construction case images. The findings establish a baseline standard for LLMs in construction hazard identification through zero-shot learning and reveal that LLMs do not perform significantly well in this context. Additionally, the study provides valuable insights into the reliability and potential applications of LLMs for enhancing hazard recognition in the construction industry.

Keywords – LLM, Hazard Recognition, Construction Safety, Image Analysis

1 Introduction

The construction industry plays a pivotal role in developing and maintaining the infrastructure, thereby shaping broader society [1]. Despite its importance, the construction industry reports a disproportionate number of safety incidents around the world [2]. These incidents often result in fatal and non-fatal injuries to the workers. In the United States alone, approximately 1,000 fatal injuries take place every year and the number go well beyond 200,000 for non-fatal injuries [3]. In addition to the fatal and non-fatal injuries, these incidents also cause a significant amount of economic damage [4].

Over the years, researchers and industry professionals have put much effort into investigating the reasons behind these safety incidents. Evidence suggests that one of the main reasons for these incidents is the failure to identify construction hazards [5, 6]. Studies show that the construction industry performs poorly in recognizing workplace hazards, with over 70% of work-related incidents attributed to poor hazard recognition [7].

Several tools have been developed over the years to improve the hazards recognition efforts in the construction industry. For example, job hazard analysis (JHA) tool is used to catalog hazards that are associated with specific construction tasks. However, this method assumes that workers possess a level of proficiency in identifying hazards, which in reality is not the case [8, 9]. On the other hand, tools such as safety checklists fail to contribute due to their limitation of identifying a limited number of hazards [10]. A number of studies have demonstrated that, despite the usage of such safety tools, over 40% of construction hazards remain unrecognized in the construction workplaces and they in turn cause these fatal and non-fatal incidents [11, 12].

On the technological front, several other tools have been developed to aid hazard recognition over the years. For example, usage of Building Information Modeling (BIM) has been popular among researchers and industry professionals [13]. BIM enables collaboration, visualization, and enhances the hazard identification process. Other efforts have focused on technologies such as eye tracking, augmented reality (AR), and virtual reality (VR) environments [14, 15]. While these technological solutions aid the hazard recognition process, they have their own limitations. For instance, these technology-driven tools require significant expertise, development time, resources, and financial investments. These barriers often hinder widespread

adoption of these technological solutions.

In recent years with the development and uprising of Artificial Intelligence (AI) and Large Language Models (LLM), the construction industry has also leaned towards adopting these solutions to improve the safety situation of construction workplaces. Different studies have demonstrated how some popular LLMs, such as ChatGPT, can be beneficial in improving construction safety [16-19]. In light of recent advancements, this study focuses on evaluating the capabilities of five different LLMs in identifying construction hazards using zero-shot learning. This evaluation aims to establish a baseline standard for LLM performance with no prior training, additional knowledge base, or guidelines, and offer insights on the reliability of LLMs in recognizing construction hazards.

2 Use of LLM in Construction Safety

In recent years, Large Language Models (LLM) have gained significant popularity across different industries and domains. Construction industry is no different from others. Although the industry is in its very early stages of adopting LLMs on a full scale for diverse applications, several studies have explored the opportunities these LLMs present. For example, a number of studies explored the possibility of integrating LLM and BIM to support information retrieval from the building models [19-21]. Other studies have focused on leveraging different LLMs for project management tasks such as automated sequence planning [22], generating construction schedules [23], automated classification of contractual risk clauses [24], automatic matching of look ahead planning tasks [25] etc. Additionally, some studies focused on how to effectively use LLMs to improve the construction education outcomes [16, 26, 27].

On the safety front, several studies have examined the usability of LLMs to improve the health and safety condition of construction workplaces. For example, Uddin et al. [18] conducted a controlled experiment with 42 construction engineering students. Their effort demonstrated that LLMs can be particularly effective in aiding hazard recognition efforts. They also suggest that LLMs can be integrated as part of safety education for construction students albeit with caution. Another study by Uddin et al. [17] explored the usability of LLM in aiding construction hazard prevention through design efforts. The study demonstrated that LLM can improve the hazard recognition efforts during the design phase by approximately 40%. Wang et al. [28] evaluated LLM's ability to extract causal factors from construction accident reports. The study found that LLM can perform well as an assisting tool, offering clear and reliable insights, but it still requires further development for professional applications like crane safety. The research highlights the potential of LLMs in construction while emphasizing the need for refinement to enhance their practical utility.

Smetana et al. [29] leveraged an LLM model to analyze textual data from OSHA's Severe Injury Reports (SIR) for highway construction accidents. Using advanced NLP techniques, clustering, and LLM prompting, they identified major accident types, including heat-related and struck-by injuries, while uncovering commonalities between incidents. The findings demonstrate the potential of AI and LLMs to enhance data-driven safety analysis and support the development of more effective prevention strategies in the highway construction industry. Hussain et al. [30] developed a virtual reality-based safety training system incorporating LLM as a live AI instructor to address communication barriers and trainer limitations, particularly for migrant workers. Testing across five countries showed a 23% improvement in knowledge scores, demonstrating the system's effectiveness. The research highlights the system's potential to improve safety training globally, reduce construction site accidents, and advance immersive and AI-driven training methodologies.

While the existing studies have demonstrated the potential of LLMs in various aspects of construction including workers' health and safety, they predominantly focused on evaluating a single LLM and relied exclusively on textual inputs and outputs. None of these efforts explored a comparative analysis of multiple LLMs to assess their relative effectiveness in achieving safety outcomes. Additionally, the studies did not investigate the use of image-based inputs for hazard recognition, despite the growing capabilities of modern LLMs to process and interpret visual data.

With recent advancements in LLMs enabling them to analyze multimodal inputs, including images, it becomes crucial to evaluate whether these models can effectively extract safety-critical information from construction images and identify hazards. Such an investigation would address a significant gap in the literature and provide insights into the broader applicability of LLMs for improving construction safety practices.

Hence, this study focuses on assessing five different LLMs' capability of identifying potential hazards from construction case images and then conducting a comparative analysis to demonstrate if all the LLMs are reliable and if they perform equally in identifying potential hazards from construction case images.

3 Methodology

To achieve the goals of this study, it was necessary to establish a ground truth for evaluating the hazard recognition capabilities of the LLMs. This was

accomplished by using a dataset of 16 different images of construction activities captured as part of a previous study [31]. These images depict a wide variety of construction activities such as welding, cutting, drilling, crane rigging among others.

Once gathered, these images were then analyzed by a panel of 17 construction industry safety experts. The collective experience of this panel was over 300 years at the time of this assessment. The expert panel was tasked with analyzing the images and identifying all the potential safety hazards for each image. One example image with annotated safety hazards is shown in Figure 1. The expert panel identified a total of 120 construction hazards from these 16 case images. These pre-identified hazards are going to serve as ground truth for our LLM assessment experiment.

Figure 1. Example image of construction activity with pre-identified hazards.

Next, we chose five LLMS, i.e., ChatGPT 4, GPT 4o, GPT o1, Gemini 2.0, and Claude for this experiment. The selection of these five LLMs was based on their industry adoption [17, 32, 33], multimodal capabilities [34, 35], architectural diversity [36], and expected performance variation. These models are widely used and include multimodal processing which is crucial for hazard recognition from construction case images. The study specifically leveraged the zero-shot learning capabilities of these models, allowing them to identify hazards without requiring domain-specific training or environment customization. This approach was deemed particularly relevant to assess the baseline performance of these LLMs without any training or additional knowledge input.

To ensure consistency and standardization, a systematic approach was developed to input all the images into these LLMs for hazard identification. First, the following prompt was provided:

"You're a construction safety expert. You will be provided with 16 different construction images. You will have to analyze these images and identify the potential safety hazards for each image."

Then each image was fed into to LLM chat prompt along with the following instruction:

"Identify all potential safety hazards for the construction activity in this image."

No additional contextual or domain-specific prompts were provided, ensuring the zero-shot learning approach remained intact. This standardized methodology facilitated comparability of outputs across all the models.

Once the LLMs returned their results for each image, the hazards were then recorded carefully by the research team ensuring traceability and consistency for subsequent analysis. The process was conducted under controlled experimental conditions, ensuring that all models were evaluated using identical inputs and queries.

The output generated by the LLMs were then compared against the ground truth dataset to evaluate their hazard recognition performance. Three different metrics were used to evaluate the performance of these LLMs, i.e., Precision, Recall, and F1-score [37, 38]. Precision score denotes the proportion of correctly identified hazards relative to the total hazards identified by the model. Recall is the proportion of correctly identified hazards relative to the total hazards present in the ground truth dataset. And F1-score is the harmonic mean of precision and recall, providing a balanced measure of accuracy and completeness of the models.

4 Data Analysis and Results

In order to measure the Precision, Recall, and F1-Score of each LLM, we used equations 1, 2, and 3 respectively for each image.

$$Precision_i = \frac{TP_i}{TP_i + FP_i} \quad (1)$$

$$Recall_i = \frac{TP_i}{TP_i + FN_i} \quad (2)$$

$$F1 - Score_i = 2 \times \frac{Precision_i \times Recall_i}{Precision_i + Recall_i} \quad (3)$$

Where:

TP_i = Hazards correctly identified by each LLM
FP_i = Hazards incorrectly identified by each LLM
FN_i = Hazards that exist in the ground truth but were missed by each LLM

Once the Precision, Recall, and F1-Score for all 16 images were gathered, then they were averaged to get the mean Precision, Recall, and F1-Score using equations 4, 5, and 6 where n is equal to 16.

$$Avg.Precision = \frac{1}{n}\sum_{i=1}^{n} Precision_i \quad (4)$$

$$Avg.Recall = \frac{1}{n}\sum_{i=1}^{n} Recall_i \quad (5)$$

$$Avg.F1-Score = \frac{1}{n}\sum_{i=1}^{n} F1-Score_i \quad (6)$$

Table 1 below shows the summarized results for the five LLM models that were assessed.

Table 1 Summary of LLM Performance

Models	Precision	Recall	F1-Score
ChatGPT-4	0.30	0.29	0.30
GPT4o	0.25	0.30	0.27
GPTo1	0.27	0.30	0.27
Gemini 2.0	0.31	0.33	0.31
Claude	0.42	0.29	0.34
Overall	0.31	0.30	0.30

4.1 ChatGPT-4

As can be seen in Table 1, ChatGPT-4 achieved 0.30, 0.29, and 0.30 scores in Precision, Recall, and F1-Score metrics respectively. A precision score of 0.30 indicates that only 30% of the hazards identified by the model were accurate, which also highlights a significant proportion of false positives. This indicates that ChatGPT-4's level of precision in recognizing construction hazards as a standalone tool may not be very reliable. Similarly, the recall score of 0.29 demonstrates the model's inability to detect the majority of the hazards present in the actual scenarios. The F1-score of 0.30 shows that the model struggles to achieve both accuracy and completeness in construction hazard identification from images.

4.2 GPT4o

GPT4o's performance in construction hazard recognition from the images is similar to GPT4's. GPT4o's precision score of 0.25 indicates that only 25% of the identified hazards were accurate, reflecting a higher rate of false positives. Additionally, the recall score of 0.30 shows that the model was able to identify only 30% of the actual hazards in the test scenario. The F1-score of 0.27 indicates that this model also struggles to identify construction hazards on its own from the construction images.

4.3 GPTo1

GPTo1 model performed rather poorly in construction hazard identification in this study. GPTo1 achieved 0.27 in precision which demonstrates a poor performance in recognizing hazards accurately, with a higher level of false positives. The recall score of 0.30, which is consistent with GPT4 and GPT4o, shows that the model was able to identify 30% of the actual hazards present in the test scenarios. This underscores that a significant proportion of hazards went unrecognized. The F1-score of 0.27, which is similar to GPT4o, highlights the model's limitations in recognizing construction hazards successfully.

4.4 Gemini 2.0

Gemini 2.0 with precision score of 0.31, recall score of 0.33, and F1-score of 0.31 demonstrated a slight improvement over the other three LLMs. The precision score indicates that 31% of the hazards were identified accurately. While the recall score of 0.33 demonstrates a higher percentage of correctly identified hazards from the hazards present in the ground truth dataset. The F1-score of 0.33 shows the balanced performance between precision and recall for this model.

4.5 Claude

Claude's performance in construction hazard recognition with a precision score of 0.42 demonstrates its ability to identify hazards with relatively higher accuracy, which is the highest among other models tested in this study. This score also highlights a significantly lower rate of false positives. However, a lower recall score of 0.29 indicates that Claude identified only 29% of the actual hazards from the ground truth dataset. While its precision ensures that the hazards identified are likely correct, the lower recall suggests that many actual hazards remain unrecognized, which could be a concern in environments requiring exhaustive risk identification.

4.6 Trend of Hazard Identification

Along with assessing different LLMs' hazard recognition performance, it is also important to examine if there's a common trend demonstrated in construction hazard recognition. To achieve this, we aggregated all the hazards that were correctly identified by the LLMs, referred to as True Positives (TP), to gain insight into which hazards were most successfully recognized. We also summed up all the False Negatives (FN) to identify the hazards that were least frequently recognized by the LLMs. Figure 2 and figure 3 below show the top five and bottom five hazards identified by the LLMs.

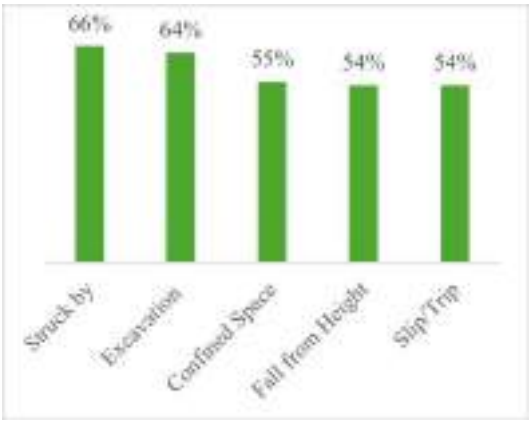

Figure 2. Top five hazards identified by the LLMs.

As can be seen in figure 2, the LLMs overall performed better in identifying more common hazards such as struck by, excavation, confined space, and fall hazards.

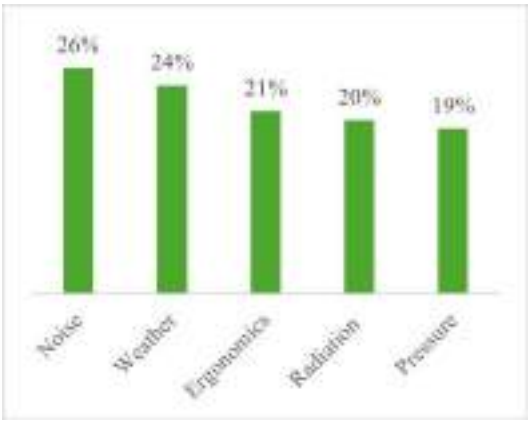

Figure 3. Least five hazards identified by LLMs.

On the other hand, figure 3 demonstrates that the LLMs performed rather poorly in identifying hazards such as noise, weather, ergonomics, radiation, and pressure. This finding is consistent with previous research efforts where the studies evaluated the hazard recognition trend of the construction workforce [12, 39].

5 Discussion

The performance of the evaluated LLMs in construction hazard recognition from images under zero-shot learning conditions reveals a varied outcome across all the measured metrics. Among the five tested models, Claude showed the highest precision level in identifying construction hazards. This suggests that Claude minimizes false positives better than the other models, making it particularly suitable for applications where avoiding unnecessary interventions is critical. However, the lower recall value of Claude indicates the failure to identify all the hazards present in the ground truth dataset. On the other hand, Gemini 2.0 achieved the highest recall score and maintained a balanced F1-score. Compared to Claude, Gemini 2.0 sacrifices some precision but compensates with better recall, making it a more reliable choice for scenarios requiring broader hazard identification.

The superior performance of Claude in precision may be attributed to its underlying architecture, which possibly favors conservative predictions by avoiding overgeneralizations. Meanwhile, Gemini 2.0's balanced performance could stem from a more robust generalization capability, enabling it to identify a larger proportion of hazards without excessively sacrificing precision.

The remaining three models, ChatGPT-4, GPT4o, and GPT-o1 exhibited comparable performance, with precision ranging from 0.25 to 0.30 and recall clustering around 0.30. These models struggled to achieve a balance between precision and recall, with their F1 scores hovering at 0.27 to 0.30. Notably, ChatGPT-4 demonstrated the highest F1 score among this group at 0.30, indicating a slightly better overall performance in balancing accuracy and coverage. The relatively lower precision of GPT4o (0.25) suggests a greater tendency toward false positives, while GPT-o1 showed a slight improvement in reducing these errors.

The overall average metrics across all models, precision of 0.31, recall of 0.30, and F1 score of 0.30, highlight a consistent challenge for LLMs in performing hazard recognition tasks as standalone tools under zero-shot learning conditions. However, it is worth noting that the hazard recognition performance of LLMs using zero-shot learning is comparable to that of human participants with no prior intervention or training, as observed in previous studies [12, 31, 40].

The variation in precision, recall, and F1-score across LLMs can be attributed to differences in model architecture, training data, and inference strategies. For example, Claude exhibits high precision but low recall as it applies conservative thresholds, flagging only high-confidence hazards to minimize false positives. In contrast, Gemini 2.0, designed as a multimodal AI, prioritizes higher recall over precision, leading to more hazard detections but also increased false positives. The GPT models from OpenAI are balanced models that achieve moderate precision and recall, making them consistent but not specialized in hazard detection.

The results obtained from this experiment indicate that LLMs face significant challenges in construction hazard recognition from images when they are used without domain specific knowledge, fine tuning, or specific guidance. The findings contrast with previous studies that showed LLMs perform exceedingly well when they are integrated into safety training or education contexts for construction professionals. Previous studies

used LLMs to support humans by generating insights or suggesting hazards, leveraging human reasoning to fill gaps in understanding [17, 18]. While on the other hand, the current zero-shot learning setup relied entirely on the models' ability to independently interpret the construction images and identify hazards. This exposes the limitations of the LLMs' specific knowledge base.

These findings of this study demonstrate that, while LLMs perform remarkably well with structured prompts, and additional knowledge base, without these interventions and without human assistance, LLM's can perform rather poorly in construction hazard recognition.

6 Conclusion

Construction hazard recognition is one of the pivotal steps in order to ensure a safer construction environment. Previous studies have demonstrated that construction hazards often remain unrecognized in the workplace which translates to both fatal and non-fatal accidents. In order to tackle this issue, numerous studies have focused on developing and adopting various tools to help with hazard recognition.

With the advancement of modern technology, Artificial Intelligence (AI), and Large Language Models (LLM), researchers and practitioners have started to utilize these technological solutions to improve construction hazard recognition. However, since there are multiple different LLM platforms available, it was necessary to conduct a comparative analysis to see if they are reliable and which model performs better than others. Additionally, it was also important to assess these models' performance with zero-shot learning, in other words, with no enforced knowledge.

This study was designed carefully to evaluate five different LLMs performance in construction hazard recognition from construction case images. The findings of this study reveal that LLMs perform rather poorly in identifying construction hazards with zero-shot learning as standalone tool. However, the hazard recognition trend demonstrates that the LLMs' performances are not too different from the human subjects from construction industry. LLMs show a similar trend in identifying common hazards and missing out uncommon hazards, similar to previous other studies [12, 39, 41].

The study highlights that although LLMs show a promise in identifying construction hazards, they may require some input, training, additional knowledge base, interventions, and human assistance to perform better as previous studies have demonstrated an improved hazard recognition performance by human subjects with assistance from different LLMs [17, 18].

In future work, we plan to explore the impact of fine-tuning LLMs using larger construction-specific datasets to assess their potential for improved hazard recognition. While our current study leveraged zero-shot learning to establish baseline performance, real-world applications would likely require models that have been trained on domain-specific data. We plan to expand our analysis to include a detailed examination of false positives and false negatives for each model, providing deeper insight into the specific types of hazards that LLMs fail to recognize or misclassify. This will help identify recurring patterns in model errors and guide improvements in hazard recognition accuracy through targeted fine-tuning and dataset enhancements.

Additionally, building on our analysis of hazard identification trends in Section 4.6, future work will incorporate qualitative insights from construction safety experts to better understand the nature of LLM errors. While our study quantitatively identified the types of hazards frequently missed by LLMs, expert consultation will provide deeper context on why certain hazards are overlooked and how models can be improved. Specifically, we will work with industry professionals, site safety managers, and researchers to identify common misclassifications, potential biases in AI hazard detection, and effective strategies for model training.

Abstract –

As the construction industry adopts digital technologies, cybersecurity risks are rising. However, the absence of a standardized incident reporting framework has resulted in limited disclosure of cybersecurity incidents and a lack of a centralized database. This prevents construction companies from learning from past events and developing effective cyber risk management strategies. To address this issue, this study applies the Cybersecurity Incident Severity Scale (CISS) model to assess the severity of cyber incidents within the construction sector. The CISS model uses a structured, semi-quantifiable approach to generate an integrated score, evaluating dimensions such as safety and financial impacts to provide a comprehensive understanding of an incident's consequences. A real-world construction cyber incident serves as a case study to demonstrate the model's applicability. By promoting standardized reporting, the CISS model can improve data collection, ensure consistent reporting across organizations, and enable meaningful comparisons over time and across regions.

Keywords –

Cyber Incidents; Severity Score; Construction 4.0; Construction Projects; Cyber Attacks

1 Introduction

The Construction 4.0 integrates the Internet of Things (IoT), Building Information Modeling (BIM), artificial intelligence (AI), and other digital technologies. These have transformed the industry by improving efficiency and collaboration. Although phishing, ransomware, and other cyber risks are prevalent in every sector involving digitalization, the construction industry faces unique cybersecurity challenges. Construction projects often involve many stakeholders, such as owners, contractors, and suppliers, who rely on BIM and IoT to exchange data in real time. This high level of coordination enlarges the cyberattack surface because each partner or device might be an attack entry point. The supply chain's fragmentation, the tight project schedule, and the limited budget make it hard to implement unified cybersecurity standards and regulations for different parties. Cyberattacks not only lead to data loss but interrupt physical site operations, delay the project, and may cause physical and financial harm. Through IoT equipment and smart machines, increased connectivity exacerbates these vulnerabilities, impacting time, cost, and safety. As for the cloud-based BIM platform and collaborative tools based on sensitive data analysis, strong security is necessary. AI-driven analytics must be protected to avoid tampering. Furthermore, ongoing digitalization needs updates to protect emerging techniques and processes. Multiple stakeholders with different cybersecurity awareness, expertise, and standards make it complicated to maintain a unified defense [1].

To effectively manage these cyber incident risks, the construction sector must implement comprehensive, effective, and robust cybersecurity strategies informed by lessons from past incidents. However, such progress is limited, and one primary reason is the absence of a standardized incident reporting framework. Without such a framework, the disclosure and documentation of cyber incidents remain fragmented and inconsistent across various projects and organizations, leading to a lack of a centralized database. This also hinders the analysis of trends, the identification of recurring vulnerabilities, and the design of effective preventive measures. Consequently, the industry misses out on critical insights essential for developing cybersecurity practices to address existing and emerging threats [1].

Global cybersecurity incident reporting frameworks vary significantly, offering lessons for the construction sector. The EU's NIS2 Directive [2] mandates rapid notifications and uniform reporting across member states, while Singapore's Cybersecurity Act [3] imposes a two-hour window for incident reporting. China's draft measures emphasize quick initial and follow-up reports [4] and Australia and India also enforce stringent

timelines to safeguard critical infrastructure [5]. In the United States, the Cyber Incident Reporting for Critical Infrastructure Act [6] aims to unify reporting across sectors. Despite the push for standardization, current frameworks rely on qualitative evaluations that overlook the complex threat landscape in construction. Without standardized quantitative metrics, comparing data across projects remains difficult. This limits thorough data collection and obscures key vulnerabilities. A comprehensive, quantitative approach could enhance security status and strengthen cross-sector collaboration.

To address this challenge, Conard (2024) proposed the Cybersecurity Incident Severity Scale (CISS) [7] to provide a semi-quantifiable and standardized metric for evaluating cybersecurity incident severity. We apply this approach to construction projects by utilizing it to assess and score the severity of cybersecurity incidents that uniquely impact this sector. By incorporating data related to the cybersecurity incident of the project as the inputs, this model derives a single severity score, making the assessment more evidence-based and objective. With a standardized severity score derived from uniform data inputs, stakeholders can quickly assess and learn from cybersecurity incidents, facilitating the sharing of materials and lessons across groups and organizations. This, in turn, enhances the overall efficiency of cybersecurity incident data preservation and collection.

2 Related Works

2.1 Industrial Cybersecurity Solutions

Cybersecurity is a rapidly evolving field, where practical knowledge and insights often originate from industry solutions. For instance, Willis Towers Watson's (WTW) "Cyber Quantified" platform [8] helps organizations model and quantify cyber risk exposures using insurance analytics and real-world benchmarks, while Marsh & McLennan's "Cyber Risk Analytics Center" [9] utilizes proprietary datasets to evaluate potential losses and guide mitigation strategies. Widely recognized annual reports such as Verizon's Data Breach Investigations Report (DBIR) [10] highlight patterns in attack vectors, adversary tactics, and breach trends. CrowdStrike's Global Threat Report [11] similarly maps the evolving threat landscape across diverse sectors. The Threat Landscape publications [12] of an EU commercial agency called ENISA offer industry-driven insights that complement academic literature. From a broader industrial perspective, frameworks such as the IAEA's guidance on "Computer Security for Nuclear Security" [13] demonstrate how other critical infrastructure sectors assess and manage risk severity. Collectively, these sources demonstrate the prevalence of real-world cyber threats and the necessity for practical assessment mechanisms. However, when it comes to the construction industry, research on cybersecurity, particularly the systematic scoring and comparison of incident severity, remains sparse. This indicates a clear need for deeper investigation within this sector.

2.2 Lack of Incident Severity Scoring Studies Within the Construction Industry

Awareness of cybersecurity within the construction industry, though increasing, remains relatively underdeveloped compared to other sectors. This is evidenced by the limited body of research dedicated to the topic. A 2023 scoping review by Pargoo and Ilbeigi [14] identified only 45 studies focused on cybersecurity within the construction industry, which can be broadly categorized into: discussions, reviews and solutions.

Among specific solutions, several studies focus on risk assessment of the entities (software, hardware, stakeholders, etc.) in construction projects. Mantha and García de Soto [15], for example, utilized agent-based models to examine how vulnerabilities spread among stakeholders in a construction network of projects. However, this remains at a very preliminary stage, lacking real-world case study validation, and the score assignment process is relatively subjective. In another study [16], they applied the CVSS to score stakeholders' vulnerabilities in construction networks based on the Confidentiality, Integrity, and Availability (CIA) Triad. Nevertheless, its manual and subjective score assignment process limits swift adaptability across different project contexts. Subsequently, Mantha et al. [17] enhanced their agent-based model from [15] by introducing seven more detailed steps to assess vulnerability spread among entities in construction projects, but the quantitative aspect has not significantly improved, and a large portion of the vulnerability score assignments remains non-data-driven. More recently, Yao and García de Soto [18] proposed a machine-learning-centric approach to assess the probability of cyber risks across project phases but lacked extensive case studies for validation.

Besides each study's limitations, they all focus on the vulnerability of entities and the probability of cybersecurity incidents to these entities within projects, failing to address the potential impact of incidents on the projects themselves. This gap highlights the need for comprehensive research on assessing the impact of cybersecurity incidents within construction projects.

2.3 Scoring Methods in Other Industries

Scoring methods have been widely adopted across diverse fields to quantify and communicate the severity of incidents, offering insights for robust cybersecurity scoring in construction. In the financial sector, the Data Envelopment Analysis (DEA)-based system [19]

synthesizes financial ratios into a "credibility score," helping institutions gauge credit risk and streamline decisions. Similarly, the IHS Markit Banking Risk Rating System (RRS) [20] employs a 0-100 scale to evaluate structural risk factors, detecting critical vulnerabilities early on. While quantitative, these approaches may overlook nuanced qualitative elements crucial for a holistic risk perspective. In public health, the NIH Stroke Scale [21] exemplifies a more granular clinical tool by assessing neurological function in stroke patients, but its specialized application underscores the challenges of designing universally applicable scoring systems. Transportation also illustrates how scoring or categorization frameworks must remain flexible. For example, the SAE Levels of Driving Automation [22] provide standardized automation categories but require ongoing adjustments as technology rapidly evolves.

In cybersecurity, the Common Vulnerability Scoring System (CVSS) [23] ranks software vulnerabilities on a 0–10 scale, guiding remediation priorities but potentially missing broader organizational effects. Insurance approaches like Willis Towers Watson's "Cyber Quantified" [8] translate threats into financial impacts using proprietary analytics, focusing on underwriting yet illustrating how data-driven methods can be adapted elsewhere, including construction. Across critical infrastructure, the U.S. National Cyber Incident Scoring System (NCISS) [24] developed by CISA is recognized as a best-practice for evaluating and prioritizing cyber incidents. It assigns severity ratings based on threat actor capabilities, potential critical infrastructure impacts, and disruption scale, offering a structured approach to triage. These scoring methods each contribute valuable methodologies for assessing various types of risks and incidents. However, their applicability to the construction sector, particularly for capturing the multi-stakeholder, project-based nature of construction projects, remains an open question, emphasizing the need for tailored or adapted scoring systems.

2.4 The CISS Model by Conard

In 2024, Conard [7] proposed the Cybersecurity Incident Severity Scale (CISS) model, drawing from established frameworks with potential applications in the construction sector for severity assessment. It aims to foster a uniform incident reporting scheme for cybersecurity incidents across various industries. The model integrates elements from scoring systems in other industries, focusing on standardized, detailed, and practical assessments. It evaluates factors such as data type, system criticality, individual harms, and organizational impacts, providing a comprehensive understanding of cybersecurity incidents. Additionally, the model must be adaptable to evolving risks and offer granular classifications for precision. International standardization, like those in transportation and public health, is crucial to support global collaboration and consistent cybersecurity threat mitigation. CISS is especially relevant for construction, where cybersecurity breaches can cause financial losses, operational disruptions, and stakeholder repercussions. Its holistic, semi-quantitative approach captures the sector's multi-dimensional nature, ensuring precise severity evaluations. Applying the CISS model would help address gaps in consistent incident reporting and severity assessment.

3 The CISS Model

For a more standardized cybersecurity incident severity assessment model in the construction industry, we considered Conard [7]'s CISS framework as a starting point because it provides a structured calculation methodology and includes critical factors such as financial repercussions, operational disruptions, and harm to individuals. Regarding the calculation method, the CISS model quantifies an incident's impact using a structured assessment pathway incorporating severity and criticality assessments. This is also useful for construction, where cybersecurity incidents may not only disrupt IT systems but also affect physical safety, project schedules, and contractual obligations. Regarding the factors, these align well with the key cybersecurity risks in construction, where incidents often impact supply chains, project timelines, collaborative digital platforms (e.g., BIM), and IoT-enabled smart construction sites. As a preliminary study, we apply the proven CISS framework to assess cyber incidents in construction. This helps ensure that our model is compatible with other sectors while demonstrating its practicality for the construction industry. However, we also recognize the need for future adaptations, such as integrating more granular construction-specific considerations due to the complexity of multi-stakeholder networks, supply chain vulnerabilities, and regulatory requirements.

3.1 Overview of the CISS Score

The overview of the scoring mechanism is shown in Figure 1. The CISS score (Y) is calculated using a weighted approach based on severity score(S), criticality score (C), and their weights β_1, β_2 using Equation 1.

$$Y = \beta_1 S + \beta_2 C \quad (1)$$

S is computed based on the financial score, individual score, and operational score, whereas C is measured based on the National Critical Function (NCF) score and National Security Impact (NSI) score. More information about each score is provided below. However, as the purpose of this paper is to implement and apply this scoring system within the context of construction, only a brief overview is included. The reader is encouraged to

refer to [7] for a more detailed description.

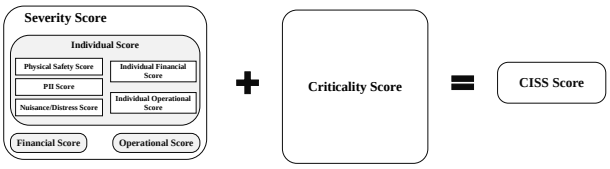

Figure 1. Overview of the CISS Scoring methodology adopted from [7]

Using the current estimation process, which incorporates a weighted approach and proposed scales, the overall CISS scores range from 0 to 10, where 0 indicates no impact, and 10 represents a very high impact. Table 1 outlines the various impact levels, corresponding score ranges, and their descriptions.

Table 1. Overview of different impact levels, corresponding score ranges, and description for CISS

Impact Level	Score Range	Description
No Impact	0	No observable impact or disruption to information and/or operations
Minor Impact	1-2	Minimal impact with no significant consequences; minor disruptions or inconveniences that do not affect core information and/or operations
Low Impact	3-4	Noticeable disruptions with limited consequences to information and/or operations
Medium Impact	5-6	Significant disruptions affecting critical information and/or operations
High Impact	7-8	Severe disruptions with major impacts on critical information and/or operations, potentially hindering recovery efforts
Very High Impact	9-10	Catastrophic disruptions causing long downtime, substantial losses, or permanent damage to information and/or operations

3.2 CISS Score Calculations

3.2.1 Severity Score (*S*)

According to [7], the Severity score evaluates the impact of an incident by combining three components, namely individual score, financial score, and operational score. This comprehensive metric provides insight into the scale and intensity of the incident. These are aggregated by considering an average, ensuring a balanced representation of the harm caused to individuals, financial systems, and organizational operations.

Individual Score: It evaluates the harm to affected individuals across five subcategories: physical safety, personally identifiable information (PII) breaches, nuisance/distress, financial harm, and operational harm. Each subcategory is scored on a scale from 0 (no impact) to 10 (extreme impact) and combined with population scores that account for the number of people affected. For example, physical safety measures range from minor injuries requiring first aid to fatalities, while PII breaches evaluate the sensitivity of compromised data, from basic contact information (low impact) to highly sensitive records like health data or legal information (high impact). Nuisance/distress measures emotional or psychological harm, while financial harm reflects direct monetary losses to individuals. Operational harm assesses disruptions to daily tasks, such as accessing essential services or managing personal responsibilities. These are also aggregated using the average of all the subcategories, reflecting both the severity of harm and the scale of those affected. This ensures a nuanced understanding of the incident's impact on individuals.

Financial Score: It quantifies monetary repercussions stemming from a security incident, using a scale from 0 (losses under $100K) to 10 (losses over $1B). These levels are informed by empirical breach reports, insurance data, and industry benchmarks, which ensures incremental levels of financial severity. Assessors factor in direct expenses such as investigation, legal actions, and response measures, as well as indirect costs tied to reputational damage or diminished customer trust. Because incidents can grow in scope as hidden liabilities appear, the Financial Score is recalculated whenever new data emerges. This dynamic nature allows stakeholders to grasp evolving fiscal burdens, guiding decisions on resource allocation and risk mitigation strategies. Ultimately, this score provides a consistent metric for comparing economic impacts.

Operational Score: It measures the extent to which an incident disrupts an organization's core functions on a scale of 0 to 10. It accounts for both the breadth (how many processes or systems are affected) and the duration (how long these disruptions persist). Minor issues such as short outages in non-critical applications receive lower scores, while incidents that halt production lines, obstruct customer services, or compromise safety protocols could reach the highest. Recovery progress influences the score, which may shift as incident response teams implement fixes or uncover new complications. By examining factors like system interdependencies, infrastructure resilience, and contingency procedures, the score provides a structured view of how deeply an incident impacts essential operations.

3.2.2 Criticality Score (*C*)

The criticality score, according to [7], evaluates the systemic importance of the affected systems by combining two dimensions, National Critical Function (NCF) and National Security Impact (NSI), into a single metric. Each dimension is scored on a 0–10 scale, with 0 indicating no impact and 10 representing a severe, prolonged effect on core national assets. The final

criticality score is an average of these two components.

The NCF evaluates the disruption to essential services, such as power grids, telecommunications, water supply, or financial transactions. The scoring scale ranges from short, localized interruptions, such as a brief internet outage scoring near 0–2, to multi-day failures across multiple interdependent services, such as energy, transportation, and emergency response, scoring 8–10. The framework often references established guidelines, such as the U.S. Cybersecurity and Infrastructure Security Agency (CISA)'s NCF pillars (Connect, Distribute, Manage, Supply) [25], but it is adaptable to country-specific classifications. The cascading effects of a single disruption can create ripple effects in other sectors, particularly if critical infrastructure is shared, thereby amplifying the overall severity.

The NSI assesses the sensitivity of any exposed or compromised data from unclassified but sensitive information to highly classified documents that, if leaked, could threaten national security. The scoring scale assigns higher values as data classification levels escalate. For example, a score of 0 signifies that no classified data was involved, a score of 4 might reflect unauthorized access to need-to-know information, and a score of 8–10 indicates a breach of Secret or Top Secret materials. The global adaptability of this scale allows organizations to align scoring with their own national standards, as classification systems vary by country. For instance, organizations may categorize data as "Confidential," "Secret," "Top Secret," or use equivalent local labels.

4 Implementation

To illustrate the applicability of the CISS model, we analyzed a real incident from a leading engineering and contracting firm in the UAE. During the 24-month construction phase of a $5 million commercial building project, phishing attempts occurred approximately every two months. One incident highlighted the effectiveness of the company's proactive cybersecurity measures. The attack was detected by the company's spam filtering system and promptly reported to the IT team, allowing for swift containment with only minor impacts. Thanks to robust defenses, including employee awareness training and immediate response protocols, the company ensured no data was compromised, and there were no significant operational, financial, or reputational damages. This incident underscores the critical role of structured cybersecurity practices in managing threats, maintaining operational continuity, and safeguarding stakeholder trust with minimal disruption.

4.1 Severity Score (S)

Individual Score. The phishing incident's individual impact was assessed across multiple dimensions to determine its severity. For physical safety, no harm occurred and thus no one was affected. In the Personally Identifiable Information (PII) category, PII with moderate sensitivity (e.g., contact details, employment information) was breached, affecting 10 employees. For nuisance/distress, about 100 employees (mostly IT staff, managers, and those who reported phishing attempts) were affected. Personal communication data (e.g., personal emails and messages) was stolen, causing inconveniences and disrupting daily routines. No financial losses were reported, so no one was financially impacted. For operational harm, about 150 employees (mainly IT and operational staff) experienced disruptions while managing phishing emails, delaying tasks like accessing online communication services. Table 2 shows a detailed breakdown of these dimensions. The integrated individual score, the average of all dimensions, is 1.5.

Table 2. Breakdown of Individual Score

Dimension	Impact Score	# of People Impacted	People Score	Ave. Score	Indv. Score
Physical Safety	0	0	0	0	1.5
PII Impact	2	10	2	2	
Nuisance/ Distress	3	100	2	2.5	
Financial Harm	0	0	0	0	
Operational Harm	4	150	2	3	

Financial Score. Although the phishing attacks led to some minor incidental costs (e.g., investigation and staff time), the overall financial impact remained below the $100k threshold set by [7]. As such, the Financial Score for this incident was 0, largely due to the company's proactive defenses (e.g., spam filtering) that effectively mitigated the threat.

Operational Score. In contrast, the Operational Score is 5, indicating significant disruptions to the firm's operations. The phishing incident required operational adjustments, such as workarounds and managing delays, underscoring its major impact on day-to-day processes even if it did not result in substantial financial losses.

The severity score can be computed by taking the average (as suggested in [7]) of the individually estimated scores as follows. However, it is worth noting that several other methods can be used, more of which are detailed in the discussion section.

$$Severity\ Score = \left(\frac{Individual\ Score + Financial\ Score + Operational\ Score}{3}\right) = \left(\frac{1.5 + 0 + 5}{3}\right) = 2.17$$

4.2 Criticality Score (C)

The incident occurred in a normal commercial

building project, which had no direct impact on critical infrastructure or cascading effects on national operations. Therefore, the NCF score is 0. Similarly, no sensitive or classified information was exposed, so the NSI score is 0, so the incident posed no risk to national security.

$$Criticality\ Score = \frac{NCF\ Score + NSI\ Score}{2} = \frac{0+0}{2} = 0$$

4.3 Overall CISS Score

The overall CISS score is derived from the Severity Score and Criticality Score with a weighted combination of 0.9 and 0.1, respectively, as suggested by [7]. Although several other weights can be considered, extensive set of correlative experiments conducted showed the significance of these weights and hence the usage for this implementation.

$$CISS\ Score = 0.9 * Severity\ Score + 0.1 * Criticality\ Score$$
$$= (0.9 * 2.17) + (0.1 * 0.0) = 1.95$$

The final CISS score is 1.95, indicating the incident had a small impact without significant consequences. It only caused minor disruptions or inconveniences without affecting core information or operations.

5 Discussion

5.1 Model Efficacy

The CISS score of 1.95 indicates that the phishing attack on the company only caused a minor impact. This score closely aligns with the reality of the case study, reflecting the effectiveness of proactive mitigation measures such as spam filtering systems and employee awareness. These measures successfully prevented any significant financial, operational, or security consequences. The score's consistency with the facts of the case demonstrates the efficacy of the proposed model in accurately assessing the impact of the phishing incident. By quantifying the relatively low severity and negligible criticality of the incident, the model effectively underscores its ability to provide a realistic and data-driven evaluation of cybersecurity risks. This correlation between the calculated score and the actual case outcomes further validates the model's robustness and utility in real-world scenarios.

5.2 Suggestions for Model Adaptation

Scoring Granularity. The severity score should be derived through systematic analysis of evidence across multiple hierarchical layers, each corresponding to specific causative factors or events, inspired by frameworks like the IHS Markit RRS [20] and the NIH Stroke Scale [21]. For example, the scoring can incorporate metrics such as individual repercussions and assessing the impact on personnel. It can be quantified by evaluating both the number of affected individuals and the severity of harm incurred. This multi-dimensional approach ensures a highly granular assessment, enabling the identification and consideration of nuanced factors that might otherwise be overlooked.

Adaptive Evolution. The model must prioritize adaptability to address the evolving cyber risks in construction. Inspired by frameworks like the SAE Levels of Driving Automation [22], which are updated to reflect technological advancements, the scoring model should also evolve in terms of its structure, dimensions, and inputs. This ensures responsiveness to emerging technologies, such as AI-powered design tools, and to evolving threats targeting interconnected systems. By maintaining this flexibility, the model can integrate new threat vectors and technologies, providing an up-to-date framework for assessing cybersecurity incidents in construction projects. This adaptability enhances resilience and promotes industry-wide collaboration.

Threshold Customization. Our study used predefined thresholds as illustrative baselines to reflect typical financial, operational, and stakeholder impacts. While these cutoffs effectively demonstrate how the model can be applied in practice, they should not be viewed as universally applicable. Different regions, project scales, and regulatory environments may require notably different threshold values to capture the true impact of cybersecurity incidents. We therefore recommend that future applications of this model begin with a calibration phase, during which these thresholds are adjusted based on local conditions, expert judgments, and available incident data. This can ensure that the model retains its relevance and accuracy as it is extended to broader contexts or more diverse construction project scenarios.

5.3 Insights and Implications

The CISS provides a standardized framework for reporting and assessing cybersecurity incidents. Using structured inputs, it ensures consistent data collection, produces a unified severity score, and facilitates reliable documentation across different organizations. The resulting quantitative metric helps prioritize and triage incidents, enabling meaningful comparisons of severity over time and across regions. By analyzing these scores, stakeholders can learn from the past, promote best practices, and respond to evolving cyber threats. CISS can also align cybersecurity efforts across public and private sectors, helping policymakers develop targeted regulations and allocate resources effectively. Through its common framework for assessment and reporting, CISS fosters transparency and accountability among clients, partners, and regulators. This standardized approach enhances industry resilience, promotes global

coordination, and protects critical infrastructure, making it valuable for the construction industry and beyond.

Many modern construction contracts, such as those using standard forms like FIDIC or NEC, now include clauses requiring specific cybersecurity standards and rigorous protocols for data protection. They may mandate compliance with recognized frameworks or set requirements for incident reporting. By integrating the CISS model into these contractual clauses, contractors can standardize severity assessments, ensuring compliance and fostering transparency. This alignment clarifies responsibilities and promotes uniformity across projects, facilitating more robust monitoring, response, and documentation of cyber incidents. Furthermore, embedding the CISS score into contractual deliverables encourages proactive adoption of best practices, reinforcing project security and stakeholder trust. Future work can investigate additional ways to link CISS metrics with emerging contractual obligations.

5.4 Limitations and Future Work

While the CISS model's applicability to construction has been demonstrated, several limitations exist, and further improvements are needed.

(1) The model's broad applicability can sometimes overlook industry-specific nuances due to the lack of context-specific factors in the model. In the construction sector, critical factors such as project delays, supply chain disruptions, and stakeholder confidence play a significant role but are not directly accounted for within the model's current dimensions. Addressing these industry-specific aspects would make the model more effective in reflecting the unique risks and impacts of construction-related cybersecurity incidents, enhancing its accuracy and relevance in this context.

(2) Another limitation of the CISS implementation is its reliance on weighted averaging, which can oversimplify the cybersecurity incidents. By converting impact dimensions into a single score through weighted averaging, granular interactions and cascading effects may be overlooked, hiding critical insights. However, this approach serves as a starting point to demonstrate how the CISS model can be applied in construction. In the future, more sophisticated weighting schemes or multi-criteria decision-making approaches could be integrated into the model to capture the complexity of cyber incidents more accurately in construction.

(3) Another technical limitation is the model's inability for real-time updates, a key aspect given fast-paced IT developments and evolving cyber threats. Although the current CISS model relies on static or post-incident data, construction environments shift quickly. By enabling real-time data inputs like IoT sensor feeds and continuous project updates, the model could provide near-instantaneous threat detection and adaptive scoring, aligning more closely with proactive cybersecurity strategies. As IT technology advances and threats grow more sophisticated, real-time adaptability will be crucial to safeguarding construction projects by enhancing situational awareness and rapid response capabilities.

(4) Using a single case study may limit the model's generalization, which may overlook the diversity of potential incident types, project scales, and organizational contexts. Consequently, certain scoring factors and contextual details within the model may not fully capture all conditions, which necessitates more extensive data and multiple examples to validate and refine the scoring model. Further research with a range of real-world incidents would help ensure that the scoring methodology is robust and reflective of the complex realities faced by different construction projects.

6 Conclusion

This study addresses the research gap regarding the lack of cybersecurity incident severity assessments and the absence of standardized measurement and reporting within the construction industry. By applying the CISS model, this study provides an integrated score for evaluating the severity of cyber incidents in construction projects. The model assesses severity based on financial, operational, and individual impacts, while criticality considers NCFs and the potential exposure of classified information. These dimensions collectively provide a comprehensive evaluation of a cybersecurity incident's impact and significance. Through a case study involving a real-world phishing incident at a construction company, the model demonstrates its applicability in assessing cybersecurity incidents within the construction context. The implications of this research include promoting the adoption of an existing structured framework for consistent and standardized incident reporting, enabling uniform data collection, supporting meaningful incident comparisons over time and across diverse contexts, fostering collaboration across organizations and regions, and ultimately contributing to industry-wide efforts to enhance cybersecurity resilience and coordination.

Development of a Construction-Information System by Measuring, Processing, and Utilizing 3D Data Toward Creating a Digital Twin

Satoshi Kubota[1] and Aika Yamaguchi[1]

[1]Faculty of Environmental and Urban Engineering, Kansai University Graduate School, Japan
skubota@kansai-u.ac.jp

Abstract

Because the scale and conditions of construction sites vary widely and it can be difficult to use a one-size-fits-all method to acquire data, a method for transferring and utilizing three-dimensional (3D) data from one stage to another in construction projects is urgently needed. In this study, we developed a construction-information system based on 3D point cloud data, taking into consideration the characteristics and conditions of construction sites and the definition of information systems in order to efficiently distribute and utilize 3D data. The use cases of the system were applied to the digital twin of a construction site. 3D point cloud data constructed using UAVs and camera-based photogrammetry were used to visualize the progress at the construction site and to understand the transition of earthworks. The results suggested the necessity of changing the measurement and processing methods according to the conditions of the construction site and the intended use of the data, as well as devising ways to reduce the impact on the current workflow.

Keywords –

digital twin, three-dimensional point cloud data, information system, construction practice

1 Introduction

The Ministry of Land, Infrastructure, Transport and Tourism (MLIT) of Japan is promoting "i-Construction," in which information and communication technology (ICT) is fully introduced in construction projects. However, construction sites are diverse and it can be difficult to use a one-size-fits-all method for acquiring three-dimensional (3D) data and 3D point cloud data to understand the site conditions. In urban spaces, digital twins are being promoted to collect data related to civil infrastructure and urban activities and visualize them in a three-dimensional space. An evolution has been transition from using each digital tools to the more integrated framework of digital twins [1][2]. However, in the construction field, there have been few initiatives to collect and manage information on construction sites with the aim of creating digital twins that reproduce information from construction sites in a virtual space, and it remains unclear which types of data can be acquired on construction sites. It is expected that the collection and visualization of data will advance i-Construction; eliminate interference with electric power, gas, and sewage systems in underground buried structures; and assist the engineer's decision-making process in inspection and diagnosis. However, no methods for transferring data between the planning, surveying, design, construction, inspection, maintenance, and renewal stages of civil infrastructure have been established.

In this study, a construction-information system is proposed in which 3D data and 3D point cloud data are distributed and utilized at small and medium-sized construction sites. The construction information that can be obtained at construction sites is considered and defined, a construction-site digital twin based on 3D point cloud data is considered, and use cases for utilizing construction information are discussed. Furthermore, the issues related to the acquisition, processing, management, and utilization of construction information at each stage of the use case are clarified.

2 Issues of Construction Information

2.1 Current Status and Issues Related to Construction Information

MLIT has published a public survey manual and management guidelines, which include surveying standards for 3D data at construction sites, but detailed information on shooting conditions, survey methods, and survey equipment for different site characteristics are not provided, making it difficult to measure and maintain data in a uniform manner at all sites.

Small and medium-sized construction companies

face the problem that the use of 3D data and i-Construction equipment has not progressed. Suzuki et al. proposed a measurement method with the aim of addressing coverage and cost issues [3]. However, a simple 3D data–surveying method and a 3D data–construction method involving inexpensive unmanned aerial vehicles (UAVs) and cameras are necessary to enable small and medium-sized construction companies to introduce ICT and carry out construction projects efficiently. Tanaka et al. [4] and Takahashi et al. [5] proposed and validated a measurement method involving a UAV-mounted camera or laser scanner. However, when determining the target structure and performing measurements, it is necessary to follow a survey method that is appropriate to the scale of the site and the surrounding conditions.

Kanzaki demonstrated how to utilize 3D models in the planning, construction, and maintenance stages and discussed the effects of their introduction but did not describe the data transfer from planning to construction and from construction to maintenance, nor the effects of this [6]. Fujita et al. proposed a method for assigning attributes to point cloud data but did not consider the data volume and format of point cloud data in consideration of operation [7]. Therefore, it is necessary to demonstrate how data can be transferred from the construction stage to the maintenance management stage as well as how data can be utilized between stages.

Building information modeling was used from the design process to the construction process as research for displaying various information in 3D space and using it for decision-making. Methods for utilizing 4D models by linking 3D models with scheduling information and for developing a 4D integrated construction-site planning system have been proposed [8][9]. A digital twin used in a bridge inspection has also been discussed [10].

2.2 Problem solving in this research

To address the issue of surveying according to the scale and conditions of the site, this study considers methods that are appropriate to the characteristics of the site, where construction equipment and people are present and data-feature points are few, when measuring the construction site with a terrestrial laser scanner (TLS) or camera. To construct 3D data using inexpensive equipment, we propose the acquisition of 3D point cloud data using cameras shooting from high locations in addition to UAVs, so that the data can be used even at construction sites where there are limitations on the equipment used. A construction-information system is conceived to solve the problem of passing data from the construction stage to maintenance management stage. The points to be considered in the measurement, processing, management, and utilization of data at each stage of pre-construction, construction, post-construction and maintenance are clarified.

3 Concept of a Construction-Information System Using 3D Data

3.1 Construction-Site Digital Twin

In this study, a digital twin is the visualization of a construction site in a digital space that is created by processing data collected at the construction site. The digital twin collects and accumulates daily progress and construction records as data from the start to the completion of construction. It is also assumed that a 3D construction site based on 3D point cloud data will be constructed, and the daily accumulated data will be displayed and used for construction planning and other purposes. Here, the digital twin has three roles: to provide “past records” as a data storage base that can be referred to when data are needed in later processes, by accumulating work records and changes in site data up to the present; “understanding the present” by reproducing the three-dimensional construction space digitally and reflecting the situation in the real world; and “predicting construction progress from the data accumulated thus far.”

In order to use ICT technology to advance construction management and realize a digital twin, it is important to save the data generated at the construction site as a log from the day-to-day construction. However, there is no research on the construction of a digital twin by accumulating data acquired at the construction site from the planning stage to the completion of construction. The 3D data related to the social infrastructure of the digital twin has issues such as surveying methods and 3D data construction according to the site conditions, and verification of accuracy due to differences in objects and surveying methods. Images related to urban activities, the action history of workers and logs of construction equipment are important information that should be acquired and retained at construction sites for use in safety management and health management. However, it is difficult to introduce these systems to all construction sites due to the need to store large amounts of data, the lack of data standardization to accumulate and utilize the data generated on a daily basis, and the high costs involved.

There are no current government initiatives to realize a digital twin of construction sites, where the data acquired from the planning stage to the completion of construction are accumulated. The reasons for this are as follows: the type of data to be acquired and stored at construction sites has not be specified; the work of artificially acquiring data without automatically obtaining logs from i-Construction equipment and wearable devices places a burden on workers; and the use cases for storing data are not clear. The use case for

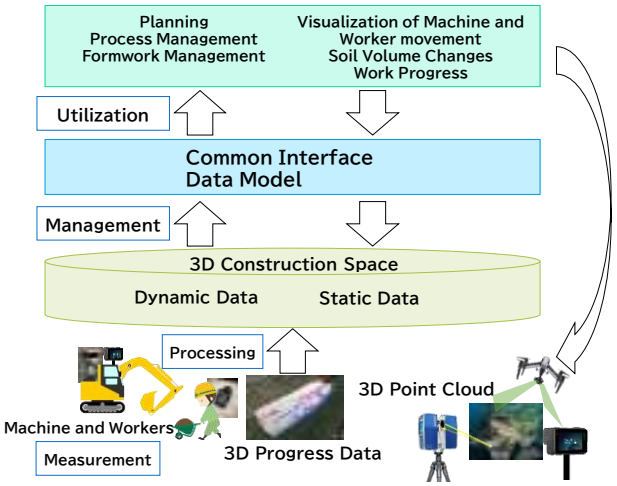

Figure 1. Concept of construction information system

storing data is not clear.

The construction site digital twin collects and accumulates data in accordance with data definitions based on the idea of digital threads that accumulate data transitions. The digital thread is a concept that accumulates data attributes and their transitions, analyses useful data from the accumulated data, and uses the results to realize construction sophistication through data utilization. An image of the construction site digital twin is shown in Figure 1. In the construction site digital twin, daily progress and construction records are collected and stored as data during the entire construction period of a civil engineering structure, from the start of construction to construction and completion. The accumulated data is used to construct a three-dimensional construction site based on 3D point cloud data, and as feedback to the site, the daily accumulated camera images and action logs are displayed and used for construction planning.

3.2 Use Cases

The use cases of the construction-site digital twin are process management, quality management, and safety management. In process management, 3D point cloud data of the site topography are acquired on a daily basis by measuring equipment such as TLS and UAVs and then superimposed on past data, enabling each day's progress to be monitored. Because daily records are accumulated, they can be checked regularly and corrected at the construction stage before construction defects are discovered after completion. In quality control, when a construction defect or deficiency occurs, the data collected on the digital twin can be used to reconstruct the situation at the time and identify the cause of the construction error. Furthermore, information from

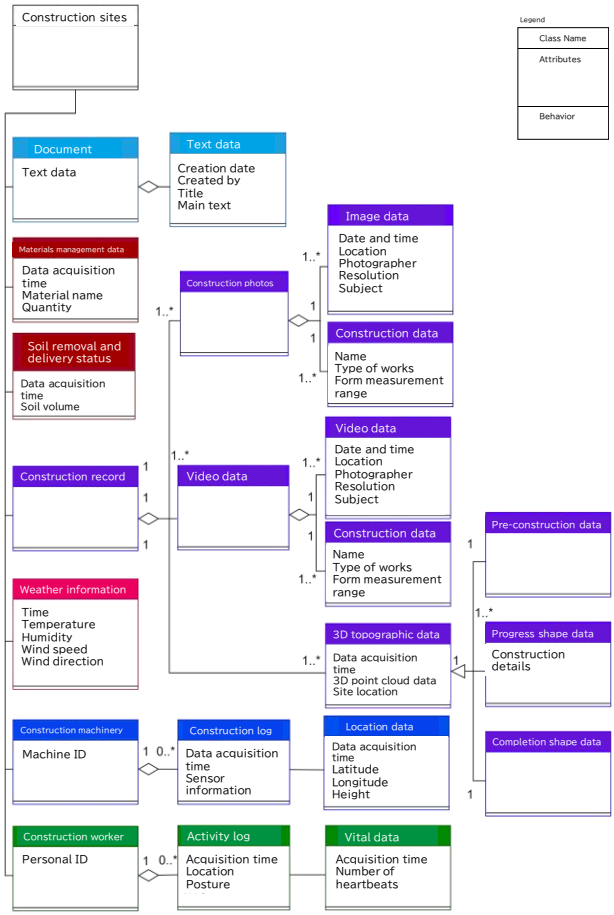

Figure 2. Class diagram of data acquiring at the construction site

the construction site is aggregated in the digital twin, enabling a remote presence in the digital space. In safety management, the physical condition of workers is managed by quantitatively evaluating changes in their physical condition based on vital data acquired using smart devices. For this purpose, movement history and changes in heart rate are recorded using Global Navigation Satellite System (GNSS) information. The location information of construction machinery and workers is used to analyze situations where contact accidents are likely to occur.

3.3 Proposal for a Construction-Information System

In this section, a digital twin-oriented construction-information system (Figure 1) is proposed to manage data generated at construction sites. It was utilized in the use cases described above. At the construction site, the shape and changes of the structure are acquired by TLS and UAVs, and by cameras and wearable terminals to reduce the workload of artificially acquiring the behavior of

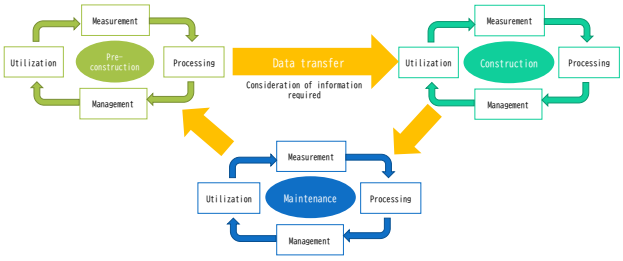

Figure 3. The information-systems cycle in construction projects

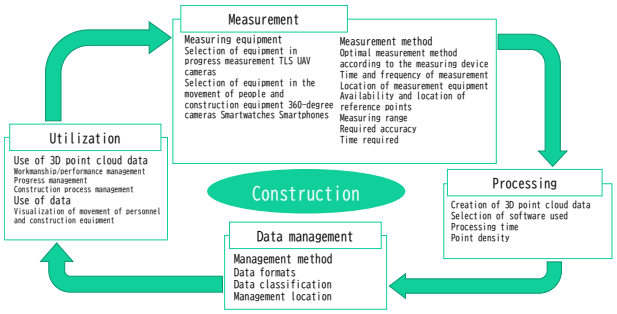

Figure 4. Collection, processing, communication, and use of information during and after construction

construction equipment and workers. The data to be acquired and accumulated at the construction site are classified with reference to the data hierarchy in the local dynamic map [9] in automatic operation, based on the characteristics of the construction site where the situation is constantly changing. In other words, the data are classified as “dynamic information” or “static information” according to the speed of change in the acquired data, while the acquisition frequency is defined so that the data acquired at the construction site are always the latest. The data to be managed were examined based on the MLIT guidelines, as shown in the class diagram in Figure 2. Figure 2 was described using UML (Unified Modeling Language). Construction photographs and 3D point cloud data are classified as “construction records.” The 3D point cloud data for the ground survey, which are acquired before construction, and the 3D point cloud data used for the formwork inspection at the time of completion are each acquired once. In contrast, the topographic data acquired to record the daily progress during construction are managed on a daily basis together with the details of the construction work, thereby serving as a construction record. By classifying these data, it becomes easier for the user to distinguish the data by purpose. In addition, the metadata that summarize the measurement and processing methods of the data are also managed together, providing a reference when proceeding to the next step in the process.

As shown in Figure 3, the construction-information system implements the process of collecting information by measuring the construction site or structure, processing the collected data, communicating by managing the data and utilizing the data at each stage of pre-construction, construction, and post-construction as well as maintenance management. This cycle is repeated for each stage of construction and maintenance management, and information is accumulated accordingly. When the pre-construction, construction, post-construction, and maintenance management processes are completed and the next stage is reached, the necessary information is reviewed and the data are passed on. The data acquired in the maintenance management stage are used as part of the completion drawings and construction plans before repair work is carried out.

Figure 4 shows the items to be considered at each stage of measurement, processing, management, and utilization of information in the construction-information system during and after construction. In the “collection of information” stage, the measurement range and equipment locations are set according to the measurement target, the existence and location of reference points, and the timing and number of measurements in order to meet the required accuracy, specified in the workmanship management guidelines, workmanship management supervision and inspection guidelines, and the work piece calculation guidelines. In the case of 3D point cloud data, the TLS point cloud data measured at multiple locations are combined and 3D point cloud data are constructed based on videos and photographs. Software is selected that is appropriate for the equipment used, and the density of the 3D point cloud data is taken into account. In the “information transfer” stage, data are passed from the construction stage to maintenance management stage in accordance with the data specification (Figure 2). In the “use of information” section, the constructed 3D point cloud data and visualized soil volume data are used for daily progress management, construction-process management, and formwork management. It is also possible to visualize changes in soil volume from two 3D point cloud data measured at different times and to visualize the movements of people and construction equipment from 3D point cloud data and GNSS information. In the maintenance management stage, the 3D point cloud data of structures captured when construction was completed can be used to visualize damage as well as for periodic inspections.

4 Implementation of Construction Information Systems

4.1 Experimental Overview

In this section, the cycle of measurement, processing, management, and utilization of the construction-information system is verified at the construction site, and the points to be considered in each process toward the construction of a digital twin are clarified. Figure 5 and 6 show the experiment. Assuming a small to medium-sized construction site, measurements were taken before and after construction with different embankment shapes. An Inspire2 UAV (DJI) was used when human access was restricted, and an action camera mounted on a monopod was used for photogrammetry from a height in areas where UAV flight was restricted or where the area was too narrow. From these, 3D point cloud data were generated using structure from motion/multi-view stereo processing. In aerial photogrammetry, the measurement time, 3D point cloud data construction time, and TLS 3D point cloud data are compared with the accuracy of the data as the most accurate values by changing the measurement equipment and altitude.

4.2 Experiment

4.2.1 Measurement of Construction Sites

To verify the accuracy of photogrammetry and visualize progress using the UAV-mounted camera and a camera mounted on a monopod, four black-and-white markers were used as feature points on the photographs: two wooden stakes were used as marking points and two wooden stakes as verification points. The positions of the fixed points and verification points were not changed before and after the construction, and the same values were used: the UAV flew one round-trip at 30 m and two round-trips at 20 m, depending on the angle of view of the camera. Photogrammetry by UAV and camera was carried out twice, once before and once after construction, in order to visualize the construction progress, using 3D point cloud data.

4.2.2 Data Processing

The data measured by the camera were given the absolute coordinate values of the six fixed points, so that the actual dimensions of the site could be measured. The accuracy and quality of the data during processing were considered to be the highest. In the public survey manual, the standard is 80% overlap and 60% sidelap, but in this study, the number of photographs was reduced by changing the shooting altitude, considering that the measurement and processing time for constructing the 3D point cloud data from camera images is proportional to the number of photographs used, given that the construction progress is the subject of this study. In the constructed 3D point cloud data, the UAV photogrammetry was carried out in the vertical direction, so depending on the flight route and altitude, the vegetation became a barrier and data on the ground surface were lost. When constructing the 3D point cloud

Table 1 Accuracy assessment by comparison of photogrammetric results with TLS point cloud data.

	Percentage of points within the required accuracy of ±200 mm (%)			Measurement Time	Processing Time	Data (GB)
	Land 1	Land 2	Land 3			
UAV (Height 20 m)	92.9	95.9	99.9	3 m19 s	24 m	2.45

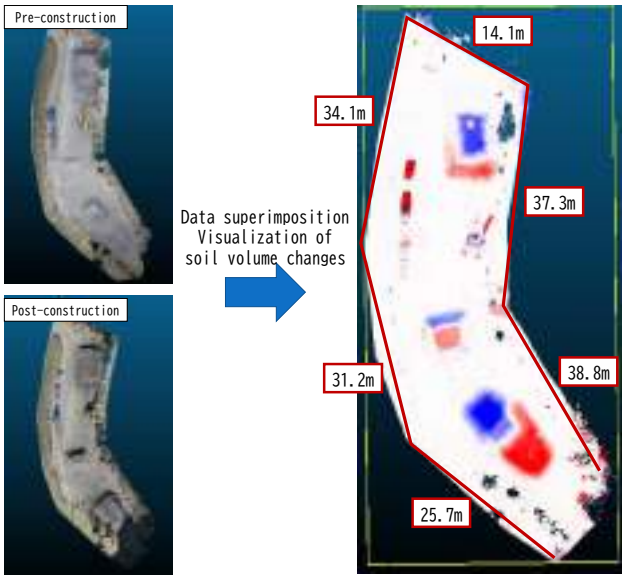

Figure 7. Visualization of construction progress with color display

data, any people, vehicles, and building materials reflected in the data were manually clipped out, thereby reducing noise.

4.2.3 Data Management

The processed data were classified according to the class diagram: the 3D point cloud data were classified as 3D topographic data in the construction record. The 3D point cloud data before construction were classified as pre-construction topographic data and the post-construction data as progress topographic data, and the acquisition time, measurement location, and construction implementation details of each data point were recorded.

4.2.4 Utilization of Data

To quantitatively monitor the daily progress at the construction site, the accuracy for this study was set according to the MLIT's Draft Guideline for the Calculation of Earthworks Completion Using Stereo Photogrammetry (Ground Moving Object) and Draft Guideline for the Calculation of Earthworks Completion Using Ground Photogrammetry (Moving Image Type), using 3D point cloud data captured by the TLS as the most accurate value. The horizontal and elevation range were within ±200 mm.

As a verification method, the difference between the 3D point cloud data captured by the TLS and the 3D point cloud data captured by aerial photogrammetry was calculated using the 3D point cloud data-processing software CloudCompare. The accuracy evaluation results are shown in Table 1. UAV aerial photogrammetry and high-altitude camera photogrammetry surveys conducted in this study, more than 92% of the 3D point cloud data points satisfied the required accuracy of ±200 mm. This indicates that the overlap and sidelap in the photogrammetric surveys were adequate. Noise and deficiencies due to vegetation and photogrammetric errors resulted in some points failing to meet the required accuracy, so it is necessary to cut out unnecessary data and change the number and location of the fixed points.

The distance between the points of the 3D point cloud data before and after construction is calculated as the construction progress at the site, and the change in soil volume is visualized by a color display. As shown in Figure 7, red indicates a positive change in height after construction compared with before construction, blue indicates a negative change, and white indicates no change. The color becomes darker if the change in soil volume is large, and lighter if it is small. If 3D measurements are taken at each stage of the construction progress, they can also be used for construction-progress management.

The third use case is to understand the construction status by tracing back the time period from the data recorded throughout the construction. The camera images were positioned and oriented on top of the 3D point cloud data, which are topographic data. In addition to the data acquired before and after the construction, the topographic data visualizing the progress of the slide shown earlier are also displayed, and the acquisition time (shooting time) for each data point was set. As shown in Figure 8, by moving the time axis, the site conditions and the data acquired at that time can be displayed.

Figure 8. Construction-information system

5 Considerations

5.1 Considerations on the Construction Information System

For photogrammetry using the UAV-mounted camera, the flight altitudes were 20 m and 30 m. In this study, to compare 3D point cloud data at different flight altitudes, two round-trips were made over the site at an altitude of 20 m, where the angle of view is narrower, and one-round trip was made at an altitude of 30 m, with the same lap rate. At an altitude of 30 m, the flight time and the construction time of 3D point cloud data were shorter than at an altitude of 20 m. Increasing the altitude increases the area that can be photographed, reduces the number of images, and shortens the time for photographing and constructing the 3D point cloud data. Although the accuracy of the 3D point cloud data decreases as the altitude increases, the topographic data measured on a daily or weekly basis is not required to have high accuracy for the purpose of understanding the daily progress. In the photogrammetric measurement at an altitude of 3 m using a camera mounted on a monopod, the construction site was photographed in two rounds, with the camera facing forward in the direction of travel in the first round and facing sideways in the second round, in order to reduce the loss of 3D point cloud data. Depending on the site conditions, it is necessary to devise ways to extract feature points, such as setting the walking route and image cropping intervals when taking photographs. By mounting the camera on a monopod, it is possible to take photographs from high altitudes, even in areas where UAVs have flight restrictions or weather conditions are not met.

5.2 Considerations on the Feasibility of Use Cases

In this chapter, use cases of process control, quality control, and safety control are examined to clarify the feasibility and issues. In the process control, 3D point cloud data and workers' vital data were used to determine the quantity of work, work progress, and workload of embankment construction. The results suggest that the UAV can be utilized for workmanship control. Therefore, the front wrap rate of 60% and sidelap rate of 40% set for the measurement using the UAV-mounted camera and the walking route for the measurement using the elevated camera were appropriate. On the other hand, 7.1% of the points did not meet the required accuracy at an altitude of 20 m for the UAV and 4.3% at an altitude of 8 m for the camera. It is necessary to walk around the measurement target multiple times and change the camera angle to avoid blind spots caused by structures and construction equipment. For the soil volume, the coordinates of the cross section were evaluated using the coordinates of the cross section of the 3D point cloud data from the UAV flight altitude of 30 m in the embankment area and the TS coordinates.) In this study, errors were also found at the top and bottom corners of the embankment by TS surveying. This difference may have affected the construction progress, volume and volume.

The volume of soil was calculated because the volume of soil is used to calculate the progress of construction in earthwork. Since each embankment was deformed, the volume of soil did not change significantly, but the volume of soil before and after deformation differed due to the use of heavy machinery to shape and compact the soil. This difference in soil volume can be used to calculate the compaction ratio, which is one of the criteria for earthwork.

In this study, the accuracy is low because 3D point cloud data by SfM/MVS processing was used, but if the measurement accuracy is high, a more accurate evaluation is possible. To visualize the progress of construction, two sets of data, one before and the other after construction, were superimposed and displayed in color to grasp the transition of earthwork. The 3D point cloud data before and after construction were given absolute coordinates, which eliminated the need to superimpose the data. In this study, two sets of data were used for construction progress, but daily progress can be visualized with three or more sets of data. In the experiment, the distance between two selected data points was calculated, so that the worker can select two data points at worker discretion and grasp the daily progress of construction and the progress since the start of construction. In this study, the 3D point cloud data by TLS was used as the most accurate value, but it can be used for visualization of construction progress in the same way as photogrammetric data by camera.

In quality control, time synchronization of the acquired images was performed to reproduce the on-site conditions. This allows us to confirm the site conditions at that time from multiple viewpoints. Video data was replayed on 3D point cloud data using TerraExplorer. We set the shooting position, orientation, and height, and we believe that we were able to reproduce the construction site digitally. However, the data acquired at the construction site must be brought back to the office for processing, and it takes time for the data to be reflected. A system is needed to upload the data acquired at the construction site to the cloud and display detailed information on the site status in real time.

For safety management, 3D point cloud data created based on worker positions and heart rate data were superimposed on the underlying 3D point cloud data. The color of the points changes according to the heart rate value, enabling quantitative judgment of changes in the worker's physical condition. The superimposition of the position of the construction machinery on these data can be used to prevent accidents involving contact between the construction machinery and the worker. Vital data can be visualized as 3D point cloud data, and it is effective to change the display method depending on the application. However, there are issues such as setting threshold values to capture changes in workload and physical condition, and managing the time axis to display the worker's position in real time.

In Japan, local governments have released 3D point cloud data on the Web. However, these data are available only at the operational stage or after construction, and there are no examples of releasing 3D point cloud data during construction. If the data measured in this study during construction and 3D point cloud data, along with metadata, are made publicly available on the Web, it is expected to promote the use of 3D data and new applications at many construction sites. Therefore, it is necessary to consider how to manage and store the enormous amount of data acquired at construction sites.

6 Conclusion

In this study, a construction-information system was proposed with the aim of distributing and utilizing 3D data and 3D point cloud data at small and medium-sized construction sites where ICT-assisted construction may be challenging. The system enables the construction of a digital twin and specifies the data to be acquired. In verifying the use case, the measurement method and required accuracy of the UAV-mounted camera and an elevation camera to monitor the construction progress were clarified. In addition, soil volume changes were visualized by data superimposition and measuring differences in distance, using 3D point cloud data.

In the future, the usefulness of the construction-information system will be evaluated through practical application at several sites. Furthermore, to manage the enormous amount of data acquired daily at construction sites, a system for sharing weekly 3D point cloud data and images extracted from videos among construction workers as well as a method for visualizing the site situation by using mesh data generated from 3D point cloud data will be studied.

Abstract –
In the construction industry, critical safety information is often scattered across numerous documents, standards, and regulations, making it challenging for practitioners to access and comprehend safety knowledge in their daily operations efficiently. To address this challenge, we propose an intelligent and reliable question-answering system for information retrieval and response generation on the construction health, safety, and environment documents via retrieval-augmented generation. Specifically, our system combines a fine-tuned LLaMA-3-8B base model with a vector database constructed using embedding models, enabling accurate information retrieval and enhancing the generated responses' reliability. Initial validation using cosine similarity analysis demonstrates promising results, with our system achieving a cosine similarity score of 0.936, outperforming the LLAMA3-8B base model's score of 0.884 in processing construction safety documentation. The preliminary findings show that: 1) our RAG-enhanced system provides safety information access, and 2) our specialized preprocessing techniques effectively synthesize and retrieve safety information, reducing fragmentation and access time.

Construction Safety; Information Retrieval; Large Language Model (LLM); Retrieval-Augmented Generation (RAG); Question Answering System; Vector Database

1 Introduction

Construction remains one of the most hazardous industries globally, with persistent workplace accidents and injuries despite technological advancements [1]. A significant challenge in ensuring construction safety lies in the scattered nature of safety information across numerous documents, standards, and regulations, making it difficult for practitioners to efficiently access and utilize comprehensive safety information in their daily operations.

Current approaches to construction safety documentation typically rely on traditional documentation systems and manual searches, which have proven inefficient and time-consuming for construction practitioners [2]. These conventional methods often require workers to navigate through extensive documentation to find specific safety information, a process that can be particularly challenging given the dynamic and transient nature of construction operations [3]. The construction industry would benefit from an intelligent and reliable system that can quickly retrieve relevant safety information from various sources and present it in a user-friendly format through natural language interaction.

Traditional construction safety information management relies heavily on manual document searching and interpretation, which is time-consuming and prone to human error. Current approaches lack the capability to efficiently integrate multiple safety information sources while providing natural language interaction. To bridge this gap, this study leveraged large language model (LLM), a type of artificial intelligence system trained on vast amounts of text data, and retrieval-augmented generation (RAG) technology to enable precise information retrieval from various safety document sources. By integrating LLM with RAG, our system provides automated, accurate responses to safety-related queries using construction safety documentation as its knowledge base.

The key contributions of this research included: (1)

proposal and development of a novel RAG-based system that enhanced construction safety information accessibility through automated retrieval and natural language generation, and (2) empirical validation of the system's accuracy and effectiveness in a controlled construction safety management environment.

The remainder of this paper is organized as follows: Section 2 reviews relevant literature, Section 3 presents the prototype development, Section 4 details system validation and evaluation, with conclusions and future directions discussed in Sections 5 and 6.

2 Literature Review

This section reviews the development and limitations of safety information retrieval systems in construction, focusing on the progression from traditional keyword-based approaches to advanced language models. We examine how different technological solutions have attempted to address the challenges of efficient information retrieval, particularly highlighting the persistent limitations in query processing and response generation that impact the practical utility of these systems in construction safety applications.

Many natural language processing (NLP) applications have been developed to retrieve construction safety information, each with limitations. Early research focused primarily on discrete tasks such as incident report classification and safety information extraction from unstructured text [4,5]. These traditional NLP approaches have typically treated natural language understanding (NLU) and natural language generation (NLG) as separate components, resulting in fragmented solutions. In 2023, Ricketts et al. highlighted that fully automating safety processes through NLP could be problematic without a strong underlying system [6], particularly when handling complex safety queries that require both accurate understanding and contextual response generation.

The emergence of LLMs has introduced new possibilities for addressing these limitations. Unlike conventional NLP methods, LLMs leverage pre-training on vast, diverse corpora, enabling generalization across various tasks without task-specific data preparation [7,8]. However, while LLMs have demonstrated superior capabilities in analyzing safety incidents [9], commercially available solutions remain too general-purpose for specialized construction safety applications and raise significant data security concerns.

Current construction safety information retrieval primarily relies on manual searches and keyword-based retrieval, which have shown significant limitations in practice. Studies have demonstrated that these document-centric systems require users to navigate through multiple sources and extensive text documents to find specific safety information, thus failing to meet construction workers' diverse needs [10,11]. For example, when workers need to access relevant safety protocols during on-site operations, they often need to search through various safety manuals, regulatory documents, and incident reports separately, making the process time-consuming and risking incomplete information retrieval.

Recent research has demonstrated how RAG technology can enhance model reliability by incorporating accurate, context-specific information during the generation process in healthcare, education, and materials science domains [12–14]. In healthcare, RAG has improved clinical decision-making, pharmacogenomics interpretation, and disease-specific information delivery through specialized applications like GastroBot [12]. In education, RAG has enhanced intelligent tutoring systems and domain-specific knowledge delivery, particularly in technical fields like geotechnical engineering [13]. In materials science, RAG has supported engineering analysis and design processes by enabling access to comprehensive materials databases and enhancing knowledge graph integration [14]. Despite these promising applications across various fields, no study has implemented RAG to enhance construction safety information retrieval, according to our knowledge.

To summarize, research gaps exist in the following two critical aspects: 1) current approaches lack the ability to integrate accurate information retrieval with natural language interaction seamlessly, and 2) existing systems are unable to effectively synthesize and retrieve safety information from multiple sources, leading to fragmented and time-consuming information access processes.

3 System Development

Our proposed system was built upon the LLaMA-3-8B foundation model and integrated the BGE-large embedding model for semantic search capabilities, as shown in Figure 1.

The system architecture comprises three main components: (1) a vector database powered by the BGE-Large embedding model for semantic search functionality, (2) a fine-tuned LLaMA3-8B language model for natural language understanding and response generation, and (3) a context integration module that combines retrieved information with query processing.

The system processes user queries through these components in a streamlined workflow. When a user submits a query, it simultaneously triggers a semantic search in the vector database to retrieve relevant safety documentation while being processed by the language model. The context integration module then combines these elements to generate accurate, contextually grounded responses based on the safety documentation. This architecture ensures reliable safety information

delivery while maintaining natural language interaction capabilities.

The development of our system followed two essential steps to ensure its effectiveness. First, we established a comprehensive data processing pipeline to prepare construction safety documentation for the system, as detailed in subsection 3.1. Second, we conducted careful model selection and fine-tuning to optimize the system's performance in the construction safety domain, as detailed in subsection 3.2.

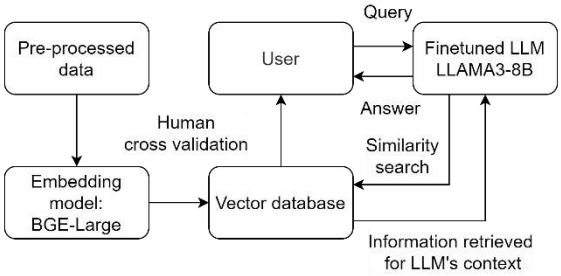

Figure 1 System Design

3.1 Data Processing Pipeline

The data processing pipeline has three key components: data collection, document pre-processing, and information organization and retrieval. First, we established a comprehensive health safety and environment (HSE) information data source as our foundation, as detailed in subsection 3.1.1. Next, a document pre-processing layer converted these diverse document formats into standardized JSON representations while preserving critical safety information, as detailed in subsection 3.1.2. Finally, we implemented an information organization and retrieval system that enabled efficient access to safety information through vector-based search and maintained traceability to original documents, as detailed in subsection 3.1.3.

3.1.1 Data Collection

We obtained a comprehensive collection of health safety and environmental (HSE) documentation from a leading construction company for our information retrieval system. The dataset comprised 1,299 pages and 327,336 words of safety protocols, guidelines, and procedures, as shown in Table 1. This extensive documentation set served as the source material for our information retrieval system. According to industry experts, our documentation set represents standard industry HSE protocols and procedures.

Table 1 HSE Data Source

Document Type	Count
Core HSE Manuals	3
Operational Forms	23
PPE Specifications	11

3.1.2 Document Pre-processing

Our document pre-processing transformed raw safety documents into structured data, as shown in Figure 2. The process consisted of two main steps: content extraction and visual processing.

In the content extraction step, we leveraged the Unstructured library to systematically parse PDF documents [15]. This library enabled precise extraction of three types of content while maintaining the structural relationships between different document elements: tables, images, including diagrams and illustrations, and text.

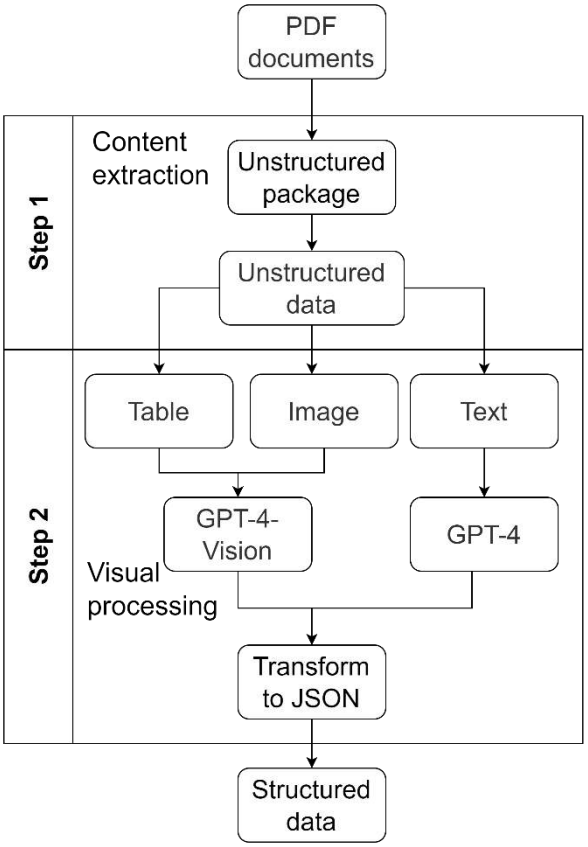

Figure 2 Document Pre-processing Layer

The extracted tables and images presented unique challenges. We addressed these through the implementation of GPT-4-Vision [16], which generated detailed textual representations of the visual content. This approach ensured that critical safety information contained in visual formats was preserved and made accessible for subsequent processing.

All processed content was then consolidated into a

standardized JavaScript Object Notation (JSON) structure. This transformation was crucial for construction safety documentation, where the relationships between different content types (e.g., textual instructions, diagrams, and tables) often had significant safety implications. The resulting structured data served as the foundation for generating the fine-tuning dataset and constructing the vector database.

3.1.3 Information Retrieval

The information retrieval process is the key component of our system, implementing similarity search and traceability mechanisms to effectively process and access construction safety documentation.

Our information retrieval system utilizes the BGE-large-en-V1.5 embedding model to convert HSE document into high-dimensional vectors [17,18], enabling similarity search capabilities. We selected this model for its superior performance in capturing technical and domain-specific relationships in construction safety content.

To effectively manage and trace information and their reference source, we developed a traceability framework with multi-vector retrieval capabilities. We designed and implemented a custom JSON mapping system that preserves structural relationships while facilitating efficient retrieval. Our system pre-processes documents, extracts nodes, and preserves comprehensive metadata to maintain bidirectional traceability between processed content and source documents.

3.2 Model selection and Fine-tuning

Model selection and fine-tuning enhances our system's capability from general knowledge to domain-specific expertise in construction safety information retrieval. Fine-tuning complements our RAG framework by enabling the model to better interpret construction safety terminology, recognize domain-specific relationships, and effectively integrate retrieved content into coherent responses. This synergy between fine-tuning and RAG is essential, as neither component alone would achieve the accuracy and relevance needed for construction safety applications. This process consisted of two main stages: base model selection and model fine-tuning, as detailed in subsections 3.2.1 and 3.2.2.

3.2.1 Base Model Selection

Our base models were selected considering the following reasons: 1) less than 8 billion parameters due to GPU memory limitation of our training hardware (RTX A6000), and 2) open source for data privacy protection and security when processing construction safety documents. Based on the context window and massive multitask language understanding (MMLU) score as listed in Table 2, we selected Llama-3-8B. MMLU score is a comprehensive benchmark that evaluates models across 57 subjects, including science, engineering, and professional knowledge.

Table 2 Model Selection Criteria and Performance

Model	Context Window	MMLU
LLaMA-3-8B	**8K**	**66.6**

3.2.2 Model Fine-tuning

Our model's fine-tuning consists of two main steps: (1) Q-A pairs generation from structured dataset using Langchain Tuna, and (2) model fine-tuning through LLAMA Factory. Figure 3 illustrates this fine-tuning pipeline.

First, we utilized Langchain Tuna to generate high-quality training data from our structured construction safety dataset. This tool created 11,837 structured question-answer (Q-A) pairs that comprehensively cover various aspects of construction safety protocols [19]. These Q-A pairs are designed to maintain technical accuracy and contextual relevance for safety documentation. Figure 4 presents an example of these generated Q-A pairs.

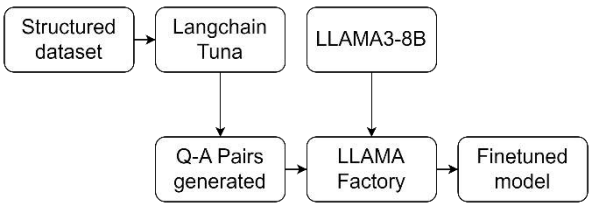

Figure 3 Fine-tuning steps

As our second step, our model's fine-tuning leverages the LLAMA Factory framework [20] to enhance the LLaMA-3-8B model's understanding of construction safety protocols. We chose Low-Rank Adaptation (LoRA) technology [21] for the fine-tuning, as it enables efficient domain adaptation while preserving the model's fundamental capabilities. We used LLAMA Factory using GPUs with CUDA v12 (RTX A6000), with carefully selected hyperparameters shown in Table 3 based on empirical experiments and model characteristics:

Table 3 Fine-tuning Parameters

Parameter	Value
Batch Size	2
Learning Rate	5.00E-05
Training Epochs	3
LoRA+ Ratio	16

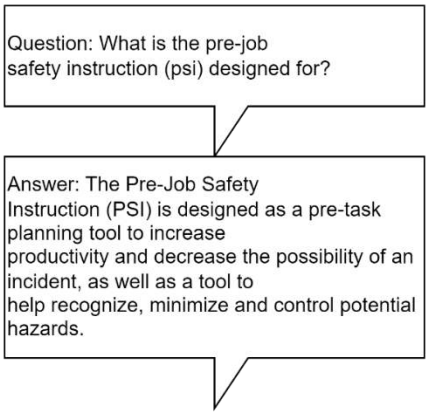

Figure 4 An example of Q-A Pairs generated by Langchain Tuna

While our system architecture incorporates both RAG and fine-tuning, it is important to clarify their distinct yet complementary roles in enhancing construction safety information retrieval. RAG primarily addresses the challenge of information access by retrieving relevant context from the vector database, while fine-tuning addresses the challenge of domain understanding by adapting the model to construction-specific terminology and concepts. Fine-tuning is essential in our approach because construction safety documentation contains specialized terminology, regulatory references, and technical concepts that general-purpose models may not adequately understand. Without domain adaptation through fine-tuning, even a model with perfect retrieval capabilities would struggle to correctly interpret construction-specific queries or synthesize retrieved information into coherent, domain-appropriate responses.

4 Validation and Evaluation

We compared our model with the base LLaMA-3-8B model to evaluate its performance. Our validation and evaluation followed three steps: test case selection, quantitative analysis, and qualitative analysis, as detailed in subsections 4.1, 4.2, and 4.3.

4.1 Test Case Selection

For test case selection in our validation and evaluation, we identified a representative scenario focusing on crisis response protocols from a safety operational manual. We used one specific test question ("What are the steps for Crisis Response?") as our validation case. This case was specifically selected to evaluate our system's ability to handle complex procedural information—a seven-step protocol with sequential dependencies and decision points. Such protocols represent a particularly challenging test case for safety information systems as they require both accurate retrieval of each procedural step and correct preservation of the sequential relationships between steps. This type of complex procedural information is abundant in construction safety documentation and essential for proper safety management. By successfully processing this challenging protocol, our system demonstrates its reliability for handling the diverse information needs in construction safety applications. This case was chosen to evaluate our model's comprehensive understanding capabilities in two key aspects: (1) the ability to process and interpret complex textual information in safety procedures, and (2) the capability to accurately comprehend and convert visual flowchart representations into structured data. The source information was originally presented as a visual flowchart (Figure 5), which was pre-processed using GPT-4V for text conversion and subsequently stored in our vector database.

We designed the test case query as "What are the steps for Crisis Response?" This query was selected to assess the model's capabilities in: comprehending and articulating complete protocol sequences, handling interconnected steps in safety procedures, and maintaining accuracy in complex information retrieval scenarios.

The selection of this test case is based on the real-world case, as protocol-based information represents a substantial portion of construction safety documentation. The ability to accurately retrieve complete step sequences is crucial for maintaining safety compliance in real-world applications.

We present the comparative responses from the LLaMA-3-8B model and our model in Figure 6 and Figure 7, respectively, demonstrating their performance differences in handling this complex query.

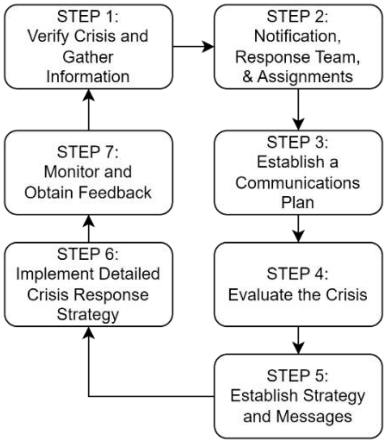

Figure 5 An example adapted from the graph information in the PDF document

4.2 Quantitative Analysis

To evaluate our model's performance quantitatively, we employed two complementary approaches: ROUGE (Recall-Oriented Understudy for Gisting Evaluation) for assessing text generation quality [22], and cosine similarity for measuring semantic relevance between responses and reference documents [23].

The ROUGE metrics we adopted provide a comprehensive evaluation framework that includes precision (accuracy of generated content), recall (coverage of reference content), and F1 score (harmonic mean of precision and recall). This multidimensional analysis through ROUGE metrics offers a complete view of the system's performance beyond simple text overlap. Our evaluation examined three ROUGE variants: ROUGE-1 calculates unigram overlap to assess content coverage, ROUGE-2 measures bigram overlap to evaluate fluency, and ROUGE-L employs the longest common subsequence algorithm to evaluate structural similarity. Additionally, cosine similarity provides a direct measure of semantic alignment between the model's outputs and the source safety documentation.

Following standard practice in NLP evaluation [24], we pre-processed all texts for consistent tokenization and normalization. As shown in Table 4, the experimental results demonstrate substantial improvements across all metrics, indicating that our model better captures both content accuracy and structural coherence in construction safety responses.

As shown in Table 4, our model demonstrates substantial improvements across all evaluation metrics. It is important to note that each ROUGE score reported represents the F1 measure, which balances precision (the percentage of generated content that is accurate) and recall (the percentage of reference content successfully captured). The significant improvements in ROUGE scores (44.9%-60.4%) indicate that our model not only produces more accurate content but also achieves superior coverage of the essential safety information. These comprehensive metrics collectively validate our system's effectiveness for construction safety information retrieval and response generation tasks.

The cosine similarity improvement from 0.884 to 0.936, while appearing modest in absolute terms, is particularly meaningful considering the high baseline. As visualized in Figure 6 and Figure 7, this enhancement manifests in the model's responses being more focused and domain aware. The base model's responses (Figure 6) tend to be more generic, while our model (Figure 7) provides more precise, construction safety-specific responses with clear source references.

Table 4 Model Selection Criteria and Performance

Metric	Our Model	Base Model	Improvement
ROUGE-1	70.8%	10.4%	60.4%
ROUGE-2	47.6%	2.7%	44.9%
ROUGE-L	67.7%	7.3%	60.4%
Cosine Similarity	93.6%	88.4%	5.2%

4.3 Qualitative Analysis

From a qualitative perspective, the comparison between model responses (Figure 6 and

Figure 7) clearly demonstrates the superiority of our model. When processing the crisis response flowchart, our model accurately captured and reproduced the exact procedural steps and decision points from the source documentation. As shown in Figure 7, our model provides direct references to the original safety documentation, with each reference corresponding to specific sections in the source HSE manuals. These references enable users to verify information and access additional context from the original documents, thereby enhancing the traceability and reliability of the provided information.

For instance, when asked about emergency response procedures, our model correctly identified the sequence "Initial Assessment → Hazard Evaluation → Response Selection" without introducing additional, unsourced steps or procedures. In contrast, the base model tended to supplement the flowchart information with general safety protocols do not present in the original documentation, demonstrating hallucination tendencies. The base model's responses often included generic safety knowledge and theoretical frameworks that, while potentially valid, were not part of the source material. Our model's ability to strictly adhere to the source content while maintaining the logical flow of the cyclic graph structure showcases its enhanced reliability for safety-

critical information retrieval tasks.

```
>>> What are the steps for Crisis Response
Crisis response is a structured approach to managing
 unexpected events or crises that threaten an organi
zation,
its reputation, or its stakeholders. The following s
teps outline a comprehensive crisis response plan:

1. **Detection and Initial Response**:
        * Identify the crisis situation quickly.
        * Activate the crisis management team (CMT)
or incident response team.
        * Establish communication channels with affe
cted parties (e.g., employees, customers, media).
        * Provide initial guidance and reassurance t
o stakeholders.
2. **Assessment and Situation Analysis**:
        * Gather facts about the crisis situation.
        * Assess the severity of the crisis and its
potential impact on the organization.
        * Identify key stakeholders affected by the
crisis (e.g., employees, customers, regulatory agenc
ies).
3. **Communication Strategy**:
        * Develop a clear and consistent communicati
on strategy to address stakeholder concerns.
        * Designate a single point of contact for me
dia inquiries and other external communications.
        * Establish protocols for internal communica
```

5 Discussion and Conclusion

This study addressed the critical challenge of efficiently retrieving and processing construction safety information, traditionally hindered by complex documentation structures and technical terminology barriers. We proposed an RAG architecture that combines fine-tuned LLaMA-3-8B with specialized document preprocessing capabilities. Our system demonstrated superior performance in handling construction safety queries through a natural language interface while maintaining high accuracy in information retrieval.

Unlike previous studies that rely on commercial LLMs with data privacy concerns, our approach leverages a locally deployable, smaller model (LLaMA-3-8B) enhanced through domain-specific fine-tuning and RAG architecture. Our approach provides enhanced security for sensitive safety information and greater customizability through construction-specific adaptation.

The reliability of our system was systematically validated through multiple complementary approaches. The quantitative evaluation showed substantial improvements across all metrics, with our model achieving significantly higher ROUGE scores than the base model and improved cosine similarity from 88.4% to 93.6%. These technical improvements manifested in more precise, construction safety-specific responses with better source reference integration, as evidenced in our system's outputs (Figure 7). Particularly noteworthy was our system's ability to correctly process and present the seven-step crisis response protocol, demonstrating its capability to handle complex procedural information with high fidelity. This performance validates both the retrieval capabilities of our RAG architecture and the domain understanding provided by fine-tuning.

This research addresses critical gaps in construction safety information management through two key contributions: (1) the development of a RAG architecture that seamlessly integrates accurate information retrieval with natural language interaction, enabling intuitive access to safety information, and (2) the implementation of specialized document preprocessing techniques that effectively synthesize and retrieve safety information from multiple sources, significantly reducing information fragmentation and access time.

This research has the following limitations. First, while the system excelled at information retrieval, it did not address broader information management challenges such as information creation, organization, and updating. Additionally, its performance varied across different types of construction safety documentation, and its effectiveness in actual construction site conditions needed further validation. Second, the system's capabilities were confined to English-language documentation, restricting its utility in international construction contexts. These limitations suggested opportunities for future research in developing more comprehensive and multilingual implementations.

Abstract

It is crucial in complex production environments, such as precast concrete manufacturing, to have efficient data management. Construction enterprises must navigate and organize vast amounts of data as part of their critical decision-making functions. The research described in this paper uses a case study to examine the implementation of a custom database solution for data management in a precast concrete manufacturing facility. The database is developed to address existing organizational issues and production inefficiencies stemming from the absence of a centralized data management system. By automating and organizing data retrieval, the database streamlines data flow and enhances the accessibility and integrity of critical information. Moreover, a dashboard is developed to display essential performance indicators, such as project tracking, estimates of future revenue, and production schedules. The system manages various types of data, from management to production information. The case study highlights the importance of integrated data management systems in improving productivity, quality control, and overall performance in the construction industry.

Keywords

Data Management, Precast Concrete, Modular Construction, Database

1 Introduction

The application of data-driven approaches in construction projects has increased significantly in recent years, reflecting a growing recognition of the crucial role these approaches can play in project lifecycle management [1]. This expansion of data-driven applications within the construction industry is primarily attributable to the emergence and maturation of knowledge-based management [2], which facilitates innovation, ensures effective quality control [3], and can be used to manage large, complex datasets in an efficient manner [4]. Construction projects typically operate in complex environments, necessitating precise coordination among stakeholders, materials, and production processes. Consequently, the use of integrated database systems has become increasingly critical as a means of handling the substantial volumes of data generated throughout a facility's lifecycle [5].

In today's construction industry, efficient management of data, which is extensive and sourced from multiple stages and stakeholders, remains a challenge [6]. Traditionally, data management and information exchange in construction have been performed manually [7], resulting in wasted time, increased costs, and frequent data loss and inconsistencies stemming from human error [8]. Therefore, there is a critical need to transition from manual methods to robust technologies that ensure consistency and quality, as well as automated database management solutions that minimize these risks and support precise, informed decision-making.

Precast concrete manufacturers face unique industry-specific challenges, such as the need for optimized resource allocation, streamlined production workflows, and enhanced project monitoring, and this further emphasizes the importance of database solutions explicitly tailored to the needs of this subsector [9]. Data-centric structures have been demonstrated to be particularly effective in safeguarding data quality, maintaining security, and ensuring that critical information is accurate and readily accessible [10]. Moreover, the diversity and complexity of the data sources associated with construction necessitate comprehensive, versatile databases populated with data from real-life projects [11].

The studies outlined above provide a foundation for understanding the benefits of database integration in construction project management. In this context, this paper presents a data management framework that provides a solution to the industry's need for historical data tracking and a centralized data system. The main objective and contribution of the paper is the development of a structured database tailored to enterprises producing ribbed-structure precast concrete panels. The developed database enhances data integrity,

ensures consistent quality control, and enables efficient data storage while supporting informed decision-making.

The database was developed using data collected through a case study conducted at a precast concrete manufacturing facility in Edmonton, Canada. The database encompasses records of various aspects of management, production, geometric information of the panels, installation, material tracking, project tracking, and quality control.

2 Background

2.1 Literature review

Knowledge management plays a crucial role in project-based industries such as construction. However, the distinctive characteristics of construction projects often pose challenges with respect to the effective capture and utilization of information [3]. Dawood and Marasini [9] emphasized the significance of tailored database solutions in addressing specific challenges faced by precast concrete manufacturers, highlighting advantages such as optimized resource allocation, streamlined production workflow, and improved project monitoring. Similarly, Mathew Zachariah et al. [10] underscored the capability of data-centric structures in preserving data quality and security, ensuring that critical information remains accurate and accessible.

Christensen et al. [11] noted that the diversity of data significantly influences a database's overall quality. Supporting this perspective, Batselier and Vanhoucke [12] emphasized that comprehensive and versatile databases incorporating data from real-life projects are essential for integrated project management. Such databases facilitate real-time project tracking and reporting, thus enabling informed decision-making and proactive problem-solving [13, 14].

Recent studies have highlighted the value of dashboards in visually representing real-time data. Nimbarte et al. [15] emphasized the critical role dashboards play in improving user engagement and clarity in decision-making. They noted that dashboards effectively enhance communication among team members and offer a centralized platform for monitoring project progress, financial metrics, and key performance indicators (KPIs).

The Entity Relationship (ER) diagram has also been widely recognized as an essential component of database design. ER diagrams graphically illustrate relationships among entities such as people, objects, locations, or events, providing the foundational structure for relational databases [16]. ER diagrams are especially useful for clearly depicting data structures and relationships [17].

In summary, the literature underscores the utility of customized database solutions in addressing the specific challenges associated with precast concrete manufacturing, emphasizes the role of knowledge management in enhancing data quality and security, and highlights the advantages of dashboards and ER diagrams in improving data visualization and system design. Collectively, these insights establish the foundation for the structured database solution presented herein.

2.2 Case company's concrete panel system

The case company produces a wide range of precast concrete products and custom-built solutions for the residential and commercial markets. Its unique reinforced ribbed concrete panel system features vertical and horizontal ribs. The panel's structure includes layers of plywood, rebar, Styrofoam, wire mesh, and concrete. The panels are designed to provide structural and thermal strength, enhance durability, and reduce concrete usage. Figure 1 shows the layers of the panel's ribbed structure.

Figure 1: Breakdown of the case company's concrete panel system

2.3 Case company's project lifecycle

The case company's projects typically follow the lifecycle shown in Figure 2. The cycle begins with consultative meetings between management and the client to clarify the project's scope of work and to specify design criteria. The project management team then issues a quote to the client. If the client accepts the quote, a contract is negotiated and executed, and the project proceeds to the engineering stage. At this point, the

Figure 2: Project lifecycle

permit and production drawings are issued for production. The project then advances to production, at which stage precast panels are formed and poured. The project then proceeds to the final stage, installation.

2.4 Problem statement

Variations in product specifications, as well as the different attributes linked with each project, underscore the need for a system that combines work orders and organizes data flow within the enterprise while also serving as a resource for data reference. Such a system must support the following functions:

- Store client information (e.g., contact information).
- Input new project information into the system as projects are received from clients.
- Update the status of projects during each phase of their lifecycle.
- Generate production orders once a project is approved.
- Store panel information and bills of materials.
- Track concrete orders and the compressive strength testing results for the concrete panels manufactured.
- Store material and supplier information to support procurement and issue purchase orders.
- Provide reports to track sales and provide overall performance insights.

3 Methodology

The primary objective of the research presented in this paper was to create a comprehensive database solution that addresses the need to have a system that protects data integrity, tracks performance, forecasts production schedules, and generates reports as needed. MS Access was used to structure the database due to its user-friendly interface, cost-effectiveness, and ability to create tables, queries, forms, and reports. Another reason for choosing MS Access is that the case company is relatively small, such that having a single employee manage the database is sufficient. Its cost-effectiveness makes it an ideal fit for the case company's needs, offering robust functionality without the need for extensive IT resources. Moreover, given that there are plans to link the database to a simulation model that will be created using the Simphony.NET in the future, the interoperability between MS Access and the Simphony.NET simulation environment is another notable advantage.

Tables were built to contain critical information related to clients and projects, and they were connected using the appropriate relationship types. Additionally, the database was designed to facilitate tracking of project status and to generate reports of relevant project information. Each table is crucial in organizing and managing specific aspects of projects, clients, and resources. A structured database design ensures data integrity, efficient data retrieval, and comprehensive reporting for various stakeholders within the organization. In order to appropriately structure the database, the case company's workflow was studied. The flowchart shown in Figure 3 was built to represent the company's production process.

The process begins with gathering information about the project as the basis for establishing a scope of work. The project management team prepares a quote and issues it to the client. Upon the client's approval, the project will proceed to the engineering phase, which involves preparation of production drawings of the panels and a bill of materials. Purchase orders are issued based on materials' suppliers and prices, the bill of materials, and the project information. Following this phase, concrete is ordered. Following forming and pouring in the off-site production facility, quality control testing is conducted, marking the completion of the production phase. The final stage is the installation of precast components at the site.

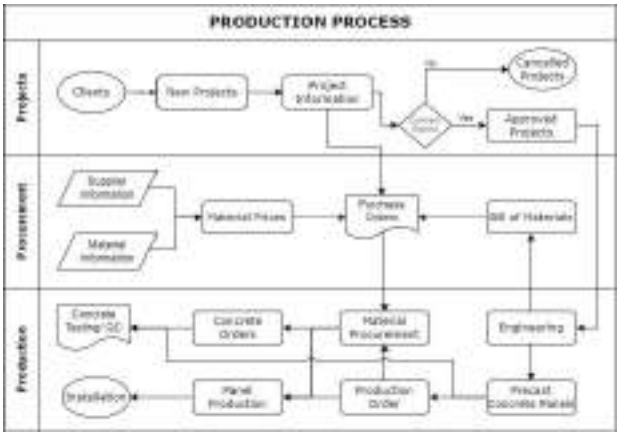

Figure 3: Production flowchart

4 Database development

4.1 Entity-Relationship diagram

An ER diagram was created to support the development of a database skeleton, complete with relationships between the various entities across different tables. The ER diagram served as a crucial blueprint for creating the database, visually representing the database's structure and the relationships among various entities. This diagram not only aided in understanding the intricacies of the data model, but also formed the foundation for effective database design. The ER diagram guided the decision-making process by outlining entities, relationships, and attributes, ensuring a coherent and organized database. Figures 4 and 5 illustrate the different entities, their attributes, and the relationships among them.

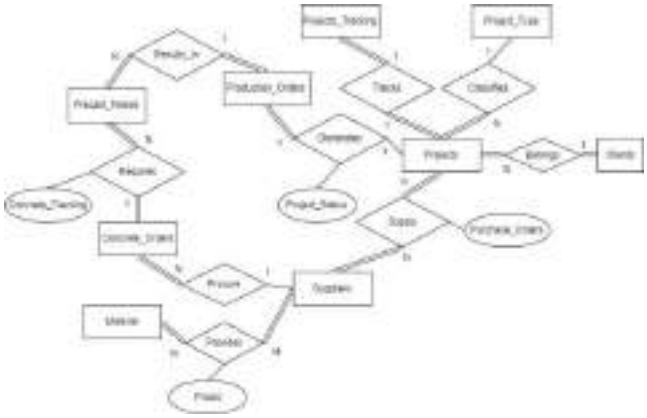

Figure 4: ER Diagram

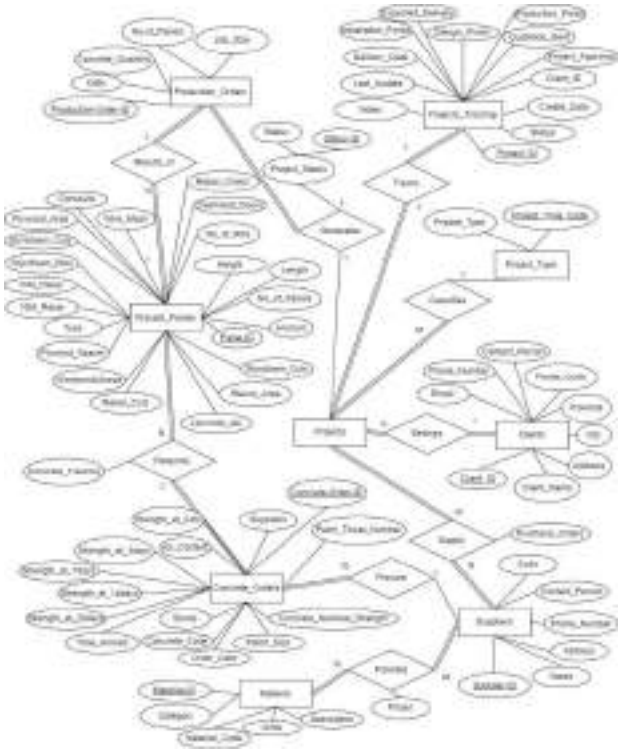

Figure 5: High-level ER Diagram

4.2 Database tables

The database tables (designed in MS Access) and their assigned attributes closely follow the proposed ER diagram. What follows is a summary of the tables and their use:

- *Clients*: This table is crucial for maintaining client information, including contact details. It provides centralized client data storage, facilitating access for various departments.
- *Project_type*: This table defines various project types, serving as a point of reference for categorizing and searching projects. It also ensures consistency in project-type definitions across the database.
- *Projects_info*: This table stores detailed project information, including cost estimates and scopes of work. It centralizes project-specific details for efficient project management and facilitates easy tracking and reporting on project-related metrics.
- *Project_tracking*: This table provides a comprehensive overview of project progress by tracking project status and key dates. It enables real-time monitoring of project timelines and milestones and facilitates communication among team members by documenting important project events.
- *Production_orders*: This table manages production orders and tracks concrete quantities. It organizes orders and links them to projects, streamlining the production process. Additionally, it provides insights into resource allocation and project-specific production requirements.
- *Precast_panels*: This table details the design specifications of precast panels. It offers a comprehensive view of panel characteristics, aids in quality control, and supports the accurate estimation of material and resource requirements.
- *Concrete_orders*: This table manages concrete orders, recording details such as supplier information and concrete specifications (e.g., strength). It tracks concrete usage across projects for resource planning purposes and facilitates quality control by recording concrete strength at various stages.
- *Panels_concrete_tracking*: This table tracks concrete usage for precast panels. It provides a detailed account of concrete application on panels and aids in troubleshooting and quality assurance for panel-related concrete work.
- *Project_status*: This table defines various project statuses, standardizes project status definitions for consistent reporting, and enhances communication by providing a common language for tracking project progress.
- *Materials*: This table centralizes information about materials used in projects. It tracks material details to support efficient inventory management and facilitate project cost analysis and budgeting.
- *Suppliers*: This table stores details about suppliers, including contact information and rates. It enables quick access to supplier information for procurement activities and supports the establishment of relationships via purchase orders and prices.
- *Prices*: This table records prices of materials from

different suppliers. It facilitates cost estimation and budgeting for projects and streamlines the process of selecting suppliers based on pricing information.

- *Purchase_orders*: This table manages purchase orders, including details such as quantity, price, and delivery information. It tracks procurement activities, ensuring timely and accurate order fulfillment. Additionally, the table provides transparency in financial transactions related to project expenses.

4.3 Entity relationships

The relationships between tables in the database help to connect the data and facilitate a cohesive project and client management system. The Clients table is a foundational element, establishing connections with multiple other tables. The Projects_info table is linked to the Clients table through the "Client_Code," connecting each project to a specific client. The Project_type table provides a reference point for categorizing projects, which in turn determines the "project_type_code" in the Projects_info table.

The Project_tracking table is connected to the Projects_info table through the "Project-ID," enabling seamless tracking of project statuses and key dates. The Production_orders table is linked to both the Projects_info and Clients tables, providing a bridge between production activities and the specific projects and clients they pertain to. The Precast_panels table also establishes connections with the Production_orders and Projects_info tables, ensuring that details about precast panels are associated with the corresponding projects and production orders.

The Concrete_orders and Panels_concrete_tracking tables connect to the Projects_info and Production_orders tables, recording information about concrete supply and usage in relation to specific projects and production orders. Additionally, the Prices and Purchase_orders tables are linked to the Suppliers table, forming relationships that aid in tracking material costs, procurement details, and supplier information. These interconnected relationships create a comprehensive network, allowing for efficient information retrieval, accurate project progress tracking, and seamless coordination among the various elements of the company's operations.

4.4 Database dashboard

A dashboard for this database was developed to showcase the results by enhancing the user experience and providing valuable insights into the company's projects and financial status. The dashboard consists of twelve forms for entering information into the database and twelve reports for information retrieval.

Figure 6 provides an overview of the developed dashboard.

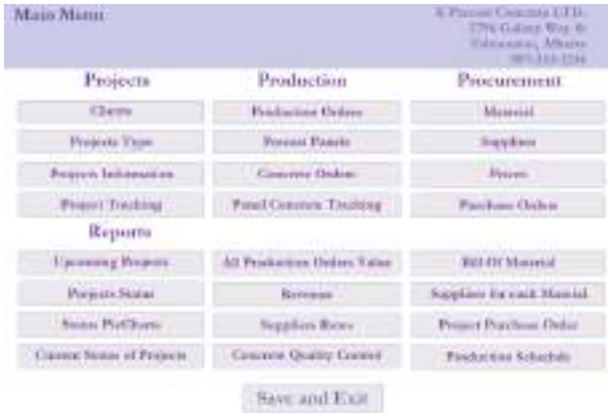

Figure 6: Developed dashboard

Below is a brief description of the reports generated by the developed dashboard:

- *Upcoming Projects*: Displays a list of approved future projects, providing details such as the project's name, client, and expected completion date.
- *Project Status*: Utilizes a bar chart and table to categorize projects based on their status (e.g., in progress, completed, or pending approval).
- *Status Pie Chart*: Incorporates a pie chart reflecting the distribution of projects across different statuses, providing both the project count and their cumulative value.
- *Current Status of Projects*: Allows users to input a specific project status, generating a report that details the projects in that particular status, including all relevant information.
- *Production Value*: Presents a comprehensive report listing the details of projects progressing to production orders, along with their associated values.
- *Revenue Report*: Generates a report showcasing completed projects and their values, enabling quick assessment of the revenue generated.
- *Suppliers Rates*: Includes a table summarizing the prices of materials from different suppliers, facilitating comparisons and procurement decisions.
- *Concrete Quality Control*: A detailed report linking concrete orders to the panels they were used for, including testing results for quality control purposes.
- *Bill of Materials*: Offers a breakdown of materials required for each project by panel, with a summary of total materials for efficient project planning and resource allocation.
- *Suppliers for Each Material*: Enables users to input a material type, generating a list of suppliers to aid in procurement decisions.

- *Project Purchase Order*: Lists all purchase orders related to the queried project, aiding in tracking of procurement activities.
- *Production Schedule*: Displays projects scheduled for production within a given date range, aiding in resource planning and scheduling.

The developed reports and dashboard provide a user-friendly interface for efficient project and client management, informed decision-making, and comprehensive data analysis.

5 Results

The developed database was implemented at the case company and was found to greatly improve project performance by streamlining processes such as purchase order management, reducing material waste, and providing more accurate production forecasts. Tailored reports, such as the "Upcoming Projects" and "Project Status" reports, were found to offer valuable insights into project progress and financial implications. The database, integrated with a dynamic dashboard, enabled real-time monitoring of KPIs and visual representations (e.g., "Status PieChart") that aided in identifying trends and bottlenecks in the project lifecycle. Figures 7, 8, 9, and 10 display some of the key outputs from the generated reports, including the exported concrete quantity report, project status percentage and value charts, and summary of upcoming projects.

It should be noted that the database is specifically designed to handle the unique requirements of precast concrete panel production. The database was found to improve communication and is now in use by the case company as an essential decision support tool. The developed database with user-friendly dashboard offers several benefits:

- Efficient monitoring: Tracks project status and performance metrics to support timely interventions.
- Enhanced productivity: Provides quick access to information for streamlined decision-making.
- Strategic planning: Offers a clear view of KPIs, helping management to identify areas for improvement.

While the use of a database for information storage and retrieval in construction management is not novel, the database developed in this study is structured to accommodate the unique design specifications and geometric information associated with ribbed precast concrete components. This approach ensures optimal performance and addresses the distinct needs of this construction subsector. Future work will involve creating a simulation model representing the case company's production process and integrating it with the developed database for estimation purposes.

Enhancing Circular Construction Through Structural Steel Reuse: Case Study of Champlain Bridge

Dina Abouhelal[1] and Amin Hammad[1]

[1]Gina Cody School of Engineering and Computer Science, Concordia University, Canada

dina.abouhelal@mail.concordia.ca , amin.hammad@concordia.ca

Abstract – The construction industry plays a critical role in tackling the challenges of climate change, carbon emissions, and resource consumption. Current practices predominantly adhere to a linear supply chain model that gives insufficient attention to the End-of-Life (EOL) phase of structures. Transitioning to Circular Construction (CC) is essential for minimizing waste and mitigating negative environmental impacts. While recycling structural steel is widely utilized at the EOL, it is energy-intensive and may degrade material quality. In contrast, steel component reuse presents a more sustainable option, requiring minimal alterations and significantly reducing embodied energy and Greenhouse Gas emissions. The main aim of this study is to advance CC by developing a framework for the catalyzing factors that can enhance the efficacy of the deconstruction process and structural steel component reuse. These factors were gathered through a comprehensive literature review. The identified factors were then mapped to a high-profile deconstruction project, the original Champlain Bridge deconstruction, to assess the challenges and initiatives involved in improving deconstruction efficiency and optimizing the reuse of structural steel components. The data of the deconstruction process and structural steel reuse were obtained through series of meetings with the Jacques Cartier and Champlain Bridges Incorporated (JCCBI) team. The numerical data regarding quantities and weights of structural steel was analyzed to assess the types of reusable steel components. Finally, the paper highlights future research areas for improving the efficiency of the value chain processes, maximizing the steel component reuse, improving the decision-making at the EOL.

Keywords –

Deconstruction; Circular Construction; Infrastructure Sustainability; Structural Steel Reuse; Adaptive Reuse; End-of-Life Management; Champlain Bridge.

1 Introduction

Effective construction waste management has gained paramount importance in recent years due to increasingly stringent regulations focusing on material recycling and reuse [1]. The construction industry is responsible for about 40% of the global natural resource exploitation [2, 3]. The current practices in the construction industry follow a linear supply chain model (take-make-dispose) with minimum consideration of the End-of-Life (EOL) phase of the structures [4]. There is a need to change this model to a circular model that aims to keep resources in use for as long as possible, which will minimize waste and reduce the negative environmental impact [5, 6]. Adopting Circular Construction (CC) is highly dependent on the way of handling the structure's components at the EOL phase, where two main options are available: demolition or deconstruction [7].

Demolition involves dismantling the structure, with most steel being recycled, although some steel end up in landfills due to contamination or recycling limitations. Deconstruction is a more methodical approach that focuses on carefully disassembling the structure to maximize the recovery of valuable components [8]. Following deconstruction, recovered materials can be managed through two main pathways: reuse or recycling. In practice, a combination of reuse and recycling often occurs. Recycling is a common approach for handling materials at the EOL, but it entails energy-intensive processes, such as steel melting and fabrication, which can elevate energy consumption. Additionally, these processes may compromise material quality, potentially leading to increased demand for new materials in future applications [9]. Alternatively, reuse often presents a more sustainable approach, as it involves minimal physical alterations [10]. Furthermore, the embodied energy and Greenhouse Gas emissions of the structures made of reused components are 63% and 56% lower, respectively, than those of the new components [11]. However, implementing deconstruction and reuse practices necessitates radical changes in the construction industry, moving away from the traditional approach of fixed-lifespan structures to a more flexible approach that

facilitates deconstruction and component reuse [12]. This will require the adoption of new business models and technologies that prioritize deconstruction and support CC [13].

While several studies have recognized the importance of the EOL phase of existing steel structures, and the opportunity of their component reuse, there is a significant gap in the development of a comprehensive methodology that integrates the catalyzing factors necessary to facilitate the reuse of structural steel after deconstruction [14 – 16]. Accordingly, this paper aims to promote CC by developing a framework that enhances deconstruction efficiency and facilitates the reuse of structural components, incorporating key factors and actionable insights to support sustainable deconstruction strategies. The study is structured into two main stages. The first stage involves identifying the catalyzing factors that promote the efficient reuse of structural components, encompassing technological, regulatory, and economic influences, which were sourced from various scholarly references. The second stage involves mapping these factors within a high-profile deconstruction project, the original Champlain Bridge deconstruction project in Montreal, Canada, to identify successes and challenges associated with the deconstruction process and the reuse of structural steel components. Finally, the research highlights future directions for enhancing value chain processes, promoting component reuse, and improving decision-making through the integration of advanced technologies.

2 Catalyzing Factors for Enhancing Structural Component Reuse

This section focuses on catalyzing factors aimed at enhancing the efficiency of the deconstruction process and maximizing the reusability of structural components. These factors were determined through a comprehensive review of recent research papers, conference proceedings, books, and review articles.

2.1 Structure Attributes

(1) Structural Design: The design of structures plays a crucial role in determining both the efficiency of the deconstruction process and the potential reusability of their components. Steel structures are not only highly recyclable, but also easy to dismantle and store [17]. The modular design of structural components is a potential approach for designing structures that can easily adapt, be moved, dismantled, and reused [18]. Mechanical connections such as bolts and fasteners can facilitate easier disassembly during the deconstruction process. Properly designed connections that allow for straightforward removal without damage to the components or surrounding materials simplify the extraction of reusable parts [19].

(2) Component Condition: The condition of the components and desired reuse application influence the level of refurbishment required. The examination of several key subfactors related to a structure's condition, including structural integrity, historical value, and cost-effectiveness informs decisions and strategies in managing deconstruction, emphasizing practicality and sustainable outcomes [20].

(3) Location: The strategic location provided easy access for heavy machinery and transportation, enabling efficient removal and transport of salvaged materials. Efficiently matching of supply and demand for reused components reduces logistics costs in deconstruction projects [21].

2.2 Business Attributes

(1) Willingness to Reuse: Finding a client willing to take a risk and pay a premium for CC or reuse solutions decreases the cost risks for value chain actors [22].

(2) Organization Competences and Circular Readiness: The project team’s compatible skills, and innovative approach facilitate creative solutions for implementing structural component reuse, resulting in high reuse rates and reduced transition costs and time for efficient circular processes [23].

2.3 Value Chain Activities

(1) Deconstruction Planning: Effective deconstruction planning is crucial to minimize the risks of deconstruction processes and ensure the maximization of reusable structural components [24]. Digital technologies enhance the efficiency in inventorying and tracking components. Also, visualizing the deconstruction process over time using 4D simulation aids in efficient resource allocation, minimizes disruptions, and improves cost efficiency through identifying and eliminating non-value-added activities [25]. Quality management ensures that salvaged components meet standards for reuse. The use of heavy machinery enables the safe dismantling of structures. Implementing a reusing and recycling program promotes sustainability by diverting materials from landfills and integrating them into new construction projects [19]. For certifying reused steel or quality control procedures in the steel industry, both ISO [26] and ASTM [27] standards provide essential frameworks. These standards involve evaluations such as material non-destructive testing and inspections of structural integrity to ensure the steel's reliability and safety in new applications. Environmental monitoring ensures compliance with regulations and minimizes environmental impacts [21].

(2) Safety Planning: Safety planning in the

deconstruction process is critical for mitigating risks and protecting both workers and the environment. This involves conducting risk assessments, training programs, regular site safety audits, and an emergency response plan [20, 21].

(3) Logistics Optimization: Careful logistics planning minimizes environmental and economic costs associated with component transportation, preserving the value potential of reusable components and reducing transportation expenses [28]. Value chain actors can efficiently access information on available reusable components and their locations. Moreover, verifying the environmental benefits of refurbished components in Environmental Product Declarations enhances demand for building component reuse. Furthermore, establishing metrics for tracking progress, component recovery rates, and types of components salvaged, enables real-time adjustments and reporting on reuse success for future projects [19].

(4) Storage Conditions: Good-quality storage enables the value of salvaged components to be preserved and minimizes risk of additional costs [21].

(5) Lean Processes: Lean processes could meticulously identify each step involved in deconstruction, allowing for the elimination of unnecessary tasks, optimization of workflows, and minimization of wastes [19]. Quality control measures, such as regular inspections and evaluations, enforce rigorous standards for reusable materials and minimize defects. Moreover, training programs provide workers with the necessary skills and knowledge in best refurbishment practices, reducing errors and enhancing safety [29].

2.4 Project Management

(1) Public Consultation and Stakeholders' Involvement: An effective advertising campaign for sustainable deconstruction educates the public and promotes awareness and support. Collaboration among stakeholders streamlines processes and maximizes resource reuse. Working with nearby city administrations aligns regulations and enhances regional planning. Pilot projects provide experiential learning, helping refine best practices. Influencing industry attitudes encourages broader adoption of sustainable practices, driving long-term resource conservation in the built environment [30].

(2) Performing Feasibility Study: The feasibility study can improve deconstruction efficiency by evaluating methods that align with sustainability goals, focusing on minimizing environmental impact and maximizing component recovery [3].

2.5 Legislations

Regulatory support is crucial with policies that streamline permitting processes for projects incorporating salvaged components, thereby facilitating the efficient reuse and promoting environmental sustainability in the construction sector. Sustainability programs initiated by governments prioritize sustainable construction practices, incentivizing the reuse of components from deconstruction projects. Legislative financial incentives encourage the usage of reused components in construction, increasing profitability and accelerating the construction sector's transition to circular practices [31].

Several initiatives are being actively implemented to enhance the reuse of steel components, focusing on reducing waste and advancing sustainability within the construction sector. For example, the Toronto Green Standard (TGS) sets environmental performance standards to accelerate GHG reduction, aiming for near-zero emissions by 2030. Higher tiers mandate embodied carbon assessments (e.g., LCA) to measure material and construction emissions. Compliance is enforced through the Site Planning Approval process [32].

3 Champlain Bridge Deconstruction and Steel Component Reuse

The original Champlain Bridge is one of the largest infrastructure projects in North America. It was built in 1962 by Jacques Cartier and Champlain Bridges Incorporated (JCCBI). It has a total length of 3.4 km, with six lanes for vehicular traffic, three in each direction. The original Champlain Bridge faced several significant structural problems that contributed to its eventual deconstruction. The primary issue was severe corrosion, exacerbated by de-icing salts and an inadequate drainage system in its original design. The absence of a proper drainage system in the bridge's design led to the accumulation of water and salt on critical structural elements, worsening corrosion and compromising the integrity of the bridge. Throughout its service life, the bridge required frequent and significant maintenance activities, including repainting the steel structure, repairing piers, replacing the concrete deck with a steel deck, and reinforcing girders. Despite these efforts, the bridge's deterioration continued to worsen, compromising its performance and reliability [33]. In 2013, the need to replace the original Champlain Bridge was further confirmed when sensors detected unusual deformations in the edge girders. In response, the bridge was closed, and a 75 tonne, 56-meter steel "super beam" was installed to reinforce a cracked girder, reducing traffic capacity by one lane. Five months later, the super beam was replaced with 50 tonnes of steel modular trusses. Despite these measures, the aging bridge's condition continued to deteriorate, highlighting the need for a full replacement [34].

The planning of the original Champlain Bridge's

deconstruction began in 2017. The planned deconstruction cost was around Can$225 million, while the overall investment cost was Can$400 million. Design-build of the deconstruction was chosen as the project delivery method, and work on-site began in July 2020. The deconstruction process finished in November 2023.

3.1 Mapping the Catalyzing Factors to the Case of Champlain Bridge Project

The data were derived from the JCCBI website [34], the steel components catalogue [35], consultation reports [36], the competition report [37], alongside meetings with the JCCBI team.

(1) Structure Attributes: The main part of the original Champlain Bridge was steel truss cantilever with approach viaducts constructed of prestressed concrete beams supporting a prestressed concrete deck paved with asphalt. A total of 413 standardized steel components, with a total weight of 401 tonnes, were identified for potential reuse in other steel construction projects. Mechanical connections enable easier component separation during deconstruction, using techniques like heat cutting for large elements, unbolting, and removing rivets.

For the component condition, the bridge's deconstruction produces approximately 25,000 tonnes of steel, with structurally viable components for salvaging and repurposing. Moreover, some components were used for non-residential structures (e.g., car canopy) which were not subject to high structural requirements, reducing bureaucracy and enabling the simplification or avoidance of cost-intensive steps related to element recovery, inspections, repairs, and certification.

Pertaining to the bridge location, the proximity of the bridge to the surrounding infrastructures facilitates the deconstruction process and the reuse of components by providing easy access for logistics, as well as enabling efficient removal and transport of salvaged materials. Also, the bridge's legacy and historical significance added intrinsic value to its components, making them appealing for preservation and reuse in heritage projects. The urban setting increased demand for reused components, promoting interest from local builders and developers in acquiring salvaged components. Moreover, due to the environmental considerations, the contractor has to propose a greenhouse gas compensation strategy for ensuring a carbon-neutral project.

(2) Business Attributes: JCCBI set sustainability targets for handling and transportation, emphasizing the innovative reuse of components rather than traditional recycling. They also implemented continuous performance monitoring to improve the project's profitability. Furthermore, a sustainability decision support tool was created, incorporating environmental, economic, social, and technical factors. The tool was utilized to evaluate different scenarios and compare all the available deconstruction methods, possible ways for the reuse/recycling of the components, and transportation methods.

(3) Value Chain Activities: JCCBI enhanced logistics by devising a phased deconstruction strategy that prioritizes the safe removal of components while minimizing disruption to surrounding areas. A comprehensive assessment was conducted to evaluate the bridge's structural integrity and determine which components were suitable for reuse. Also, they developed a 4D model for the bridge's deconstruction to facilitate comprehensive planning, scheduling, and coordination. Visualizing the deconstruction process over time aids in efficient resource allocation, minimizes disruptions, and improves cost efficiency through identifying and eliminating unnecessary activities. Moreover, non-destructive tests were performed to evaluate the quality of the bridge components. The structural steel components were dismantled using specialized equipment, including cranes, barges, and excavators. Additionally, JCCBI implemented a reusing and recycling program as they directed the contractor to meet specific reuse and recycling targets, including 100% steel reuse or recycling and a 90% overall component recovery from the bridge, with penalties for non-compliance. The contractor was bound by the design-build requirements to recycle the components within a 150 km radius from the project site.

Moving to safety planning, the deconstruction process involved 200 specialists and laborers with specialized training in safe deconstruction practices, machinery operation, and emergency response protocols. Regular safety audits and inspections were carried out to ensure compliance with safety regulations and to address any emerging risks. An emergency response plan was established, detailing procedures dealing with accidents, injuries, or other unforeseen incidents.

For logistics optimization, a phased deconstruction strategy was developed to prioritize the safe removal of components while minimizing disruption. To facilitate data access and flows, a data labeling system was implemented for each reusable component. Additionally, a traceability protocol using QR codes was established to monitor the materials, enabling precise georeferencing of each component from its origin to its destination. Reusable components were systematically stored on-site in designated areas specifically allocated for sorting and inventory management. These storage areas were equipped with protective measures to shield components from adverse weather conditions and potential damage.

To mitigate deconstruction waste, JCCBI integrated specific clauses into the design-build contract of the deconstruction to establish a comprehensive

sustainability program. This program prioritizes the reuse of components wherever feasible, thereby reducing waste and advancing sustainable practices throughout the project. For quality control, they conducted regular inspections and evaluations of reusable steel components. Also, they provided training for employees on best practices for refurbishment.

(4) Project Management: The community was engaged through an extensive multiplatform advertising campaign to gather innovative ideas regarding sustainable development, environmental protection, and component reuse. The consultation involved 4,186 participants via various channels. An advisory committee was established consisting of representatives from different environmental and cultural organizations to provide strategic guidance and expertise throughout the project. Moreover, JCCBI searched similar projects and identified the Bay Bridge deconstruction project in San Francisco as a relevant example [33]. The California Department of Transportation initiated a program to repurpose components of the bridge but reused less than 1% of the bridge's steel. In contrast, JCCBI developed its reuse program earlier in the project, aiming to achieve a significantly higher percentage of component reuse.

In 2017, JCCBI commissioned the PTA Consortium (Parsons/Tetra Tech/Amec Foster Wheeler) to conduct a feasibility study and targeted environmental analysis for the Champlain Bridge deconstruction, assessing different options for deconstruction methods, transportation of components, and component recovery. The study evaluated various scenarios based on sustainable development criteria, focusing on technical feasibility, economic viability, environmental impacts, and social acceptability.

(5) Legislations: The Government of Canada has shown a robust commitment to sustainability, requiring all ministries and agencies to contribute to the "United Nations Sustainable Development Goals" and align with Canada's national sustainability strategy [38]. Consequently, the deconstruction of the original Champlain Bridge is designed to promote environmental performance for future projects, reflecting both national and international sustainability objectives. The deconstruction of the original Champlain Bridge and the reuse of its components have been supported by various financial incentives, including public funding sources such as local tax revenues, federal funds, fares, and bonds.

3.2 Data Analysis

The authors conducted an analysis of the data provided in the catalogue to gain insights into the quantities and weights of different types of reusable steel components of the Champlain Bridge [35]. The methodology involved classifying the reusable steel components based on their location, followed by calculating the amount of reused steel components and the weight percentage for each category. Figure 1 shows the histogram of the reusable steel components in terms of their quantity. The horizontal axis categorizes the different types of structural components in the Champlain Bridge, including Diagonal, Bracing, Vertical, Top chord, Lower chord, and Deck beam. The vertical axis represents the number of reusable steel components, showing how many structural elements of each type were identified for reuse. This histogram visually compares the distribution of reusable components across these categories.

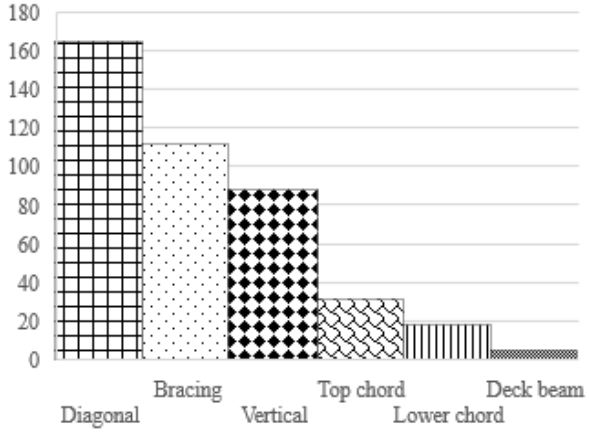

Figure 1. Quantity histogram of reusable steel components

The histogram shows that diagonal components are the most abundant, totaling 165 units. Bracing and vertical components follow with significant quantities of 112 and 88 units, respectively. Top and lower chord components have moderate quantities, at 31 and 18 units, while deck beams are the least numerous with only four units. Figure 2 shows the percentage of reusable steel components classified by their weight. The analysis of steel component weights reveals that the top chord components have the highest proportion by weight (23.7%). Lower chord components are significant in both quantity and weight, suggesting they are moderately heavy. Vertical components reflect a balance between their quantity and weight. While diagonal components are numerous, they are relatively lighter compared to components in other locations, indicating these components are heavier per unit. Deck beam components have low quantities but higher weight percentages (8.9%), suggesting they are dense despite their limited numbers.

The analysis indicates a varied distribution of steel in terms of quantity and weight, reflecting their different applications and structural roles. Understanding these distributions aids in planning the reuse of these components in future projects.

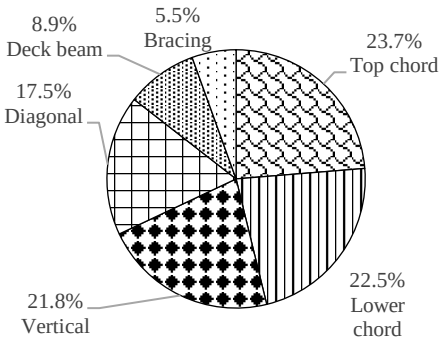

Figure 2. The weight percentage of reusable steel components

4 Future Research Areas

For improving the efficiency of the processes related to value chain activities, maximizing the reuse of components, and supporting the decision-making, the following future research areas can be considered:

(1) Automation in Deconstruction Planning and Optimization: AI algorithms can be applied for identifying the optimal sequence of steel components deconstruction based on their structural importance and condition. Also, it helps to simulate potential problems during the deconstruction process and automate the decision-making [39]. Furthermore, automated systems can classify components by category to facilitate repurposing [40].

(2) 3D Scanning and Digital Twin Technologies: Adopting 3D scanning and developing digital twin of the structure can assist in the efficient deconstruction processes and the precise planning for maximum reuse of steel components. It provides a highly accurate, real-time representation of the structure's condition, including the identification of critical components and potential structural weaknesses [41].

(3) Material Passport System: Material Passport is a digital record that details the composition, origin, lifespan, and condition of each component used in the structure. It has the potential to maximize the reuse of structure components, reducing costs, and environmental impact through matching deconstructed components to future construction projects. Radio Frequency Identification could be used to track the component throughout its lifecycle, facilitating the efficient identification and recovery of valuable components during deconstruction [42].

(4) Advanced Robotics: The use of autonomous robots or drones in the process of scanning, dismantling and sorting of bridge components can improve accuracy and reduce the associated risks. For instance, robots can be designed to safely remove steel components while conserving their integrity for reuse [43].

(5) Enhanced Workers Training with Virtual Reality (VR) and Augmented Reality (AR): VR and AR can ensure that workers are adequately trained for the deconstruction process. These technologies allow workers to simulate deconstruction scenarios and understand the best practices for handling components, improving safety, and maintaining the integrity of reusable components [44].

5 Conclusions

The transition toward CC is increasingly vital as the construction industry confronts pressing challenges related to climate change, carbon emissions, and resource depletion. Adopting a circular approach offers a sustainable solution by minimizing waste, conserving resources, and lowering embodied energy, making it a key strategy for addressing these critical issues. This study emphasizes the need for a shift towards CC, particularly through the reuse of structural steel components. It begins by identifying the key factors that could catalyze the deconstruction process and enhance the reuse of components. The factors include the structure attributes, business attributes, value chain activities, project management, and legislations. These factors were applied to the Champlain Bridge deconstruction project to evaluate process effectiveness, identify challenges, and define the potential for optimizing the reuse of structural steel components.

The analysis revealed several success criteria, including the development of a phased deconstruction strategy, comprehensive audits of structural integrity, and the integration of digital technologies for effective planning and coordination, thereby enhancing overall project efficiency. Additionally, incorporating specific sustainability clauses into the deconstruction contract significantly increases the potential for steel reuse. Furthermore, presenting a sustainability decision support tool to evaluate various deconstruction methods can facilitate informed decision-making. Engaging the community and collaborating with environmental organizations, along with organizing competitions for innovative reuse ideas, further fosters a culture of sustainability within the construction industry. Finally, the research provides future research areas for supporting the processes of the value chain activities, increasing the potential of reusing components, and enhancing the decision-making. The future research areas emphasize the integration of advanced technologies such as artificial intelligence for deconstruction planning, robotics for precision dismantling, 3D scanning for accurate modeling, and material passport systems for enhanced traceability. However, while this study provides valuable insights for enhancing deconstruction processes and the structural steel reuse, it lacks detailed quantitative

analysis for the environmental and economic benefits in comparison with the traditional steel recycling. Future research could focus on conducting scenario analysis for the EOL of structural steel utilizing sustainable life cycle approach. This would include a detailed comparison of the environmental and economic benefits of reuse relative to traditional recycling.

The research results could improve the decision-making process for EOL phase of structures by adding comprehensive qualitative analysis towards sustainable management and conservation of resources. These results align with Canada's international commitments to sustainable development, including the United Nations Sustainable Development Goals, particularly Goal 12 (Responsible Consumption and Production). Furthermore, this study provides numerical data and actionable insights that will support the Canadian government's objectives related to sustainability, economic efficiency, and environmental responsibility, contributing to a more sustainable construction industry.

Acknowledgement

The authors sincerely thank Mr. Moctar Sidibe, Senior Engineer at JCCBI, for his willingness to engage in meetings with our team, which significantly deepened our understanding of the deconstruction process and the reuse of structural steel components. We also extend our gratitude to other students in our research group (Hosna Ghorab and Golnaz Mirzaei) for their initiative in launching this collaborative effort.

Reducing Carbon Emissions in 3D Printed RCC Slabs

Abhishek Patel1 and Benny Raphael1

1Indian Institute of Technology, Madras, India
abhi300894shek@gmail.com, benny@civil.iitm.ac.in

Abstract

Concrete 3D printing offers significant potential to revolutionize construction through improved efficiency and cost-effectiveness. However, high cement content in 3D printable mixes raises questions about the environmental sustainability of this technology. This study proposes an automated methodology for 3D printing Reinforced Cement Concrete (RCC) filler slabs using compressed polyethylene (PE) waste to reduce the carbon footprint. A gantry-style 3D printer with integrated pick-and-place functionality is designed to position recycled plastic fillers, reducing raw material consumption and emissions. A cradle-to-gate life cycle assessment is employed to compare three scenarios: conventional slabs, filler slabs with clay pots, and filler slabs with PE waste. The results show that the proposed method significantly reduce material use and carbon emissions, while mitigating the environmental impact of polyethylene waste mismanagement. This study demonstrates the potential of integrating 3D printing and automation to advance sustainable construction practices and lower the carbon footprint of RCC slabs.

Keywords – Concrete 3D printing, filler slabs, carbon footprint, carbon emission, automation, sustainable construction, recycling, polyethylene waste.

1 Introduction

Concrete 3D printing has potential to transform the construction industry in terms of productivity, cost effectiveness and environmental sustainability. 3D printing can help construction industry by improving productivity, overcoming skilled labor shortages [1–3], and increasing safety at off-site plants and on-site construction. 3D printing also eliminates the need for formwork, offering geometric flexibility and enabling significant material savings through structural optimization [4, 5]. Though Concrete 3D printing has various potential benefits, challenges like limited automation and dependency on manual labour, insufficient research on structural elements like slabs, and high cement content in 3D printable mixes persist.

The construction industry accounts for around 39% of global energy-related CO2 emissions, a figure expected to rise with urbanization [6]. Concrete, the second most used material worldwide due to its affordability and compressive strength [7], significantly contributes to this footprint, with cement production alone responsible for 5-8% of global CO2 emissions [8]. While concrete 3D printing reduces material waste and eliminates formwork, its high binder content elevates the carbon footprint, leaving its sustainability performance inconclusive. [9–11] have conducted studies to establish the sustainability performance of Concrete printing but they are limited to the non-structural components. The calculations for environmental impact in these studies lack consideration of electricity consumption and transportation of the materials. Inclusion of these aspects would give a clearer aspect on the sustainability performance of Concrete 3D printing process.

In flexural members like slabs and beams concrete tension zone has only one function to connect the concrete in the compression zone to the rebars in the tension zone, thereby facilitating shear transfer. This provides an opportunity to reduce the consumption of concrete in this region. Filler slabs reduce concrete usage in the tension zone by incorporating elements like clay pots and tiles between rebars, decreasing concrete consumption by 25-30%. While this lowers carbon emissions, the benefits are offset by the significant emissions from manufacturing these fillers [12]. Additionally, filler placement is time-intensive and requires meticulous supervision, inadequate oversight or poor workmanship can cause reinforcement bars to contact fillers, increasing the risk of corrosion. The world produces around 2.01 billion tons of solid waste, with 33% poorly managed and 11% incinerated, resulting in significant carbon emissions [13]. Waste management contributes 5% of global GHG emissions [14]. Using mechanically compressed plastic waste as fillers can mitigate emissions from clay pot and tile production while reducing those from incineration and mismanagement of polyethylene waste.

Most reported applications of concrete 3D printing

focus on architectural elements or compression members [15]. To maximize its benefits, efforts are now directed toward printing structural elements capable of resisting tension and flexure [16]. While concrete 3D printing can reduce labour and enhance productivity, reliance on manual tasks such as reinforcement placement and curing may undermine efficiency and compromise the benefits of automation. As structural slab casting is labour-intensive process, concrete 3D printing integrated with automation for ancillary works can help reduce the requirement for manual labour and improve efficiency of the process.

This study proposes a methodology to leverage the benefits of concrete 3D printing, automation and filler slabs to reduce the carbon footprint of the RCC slab. A gantry-type 3D printer integrated with a robotic gripper is proposed to automate the precise placement of filler elements and reinforcement cages and casting of filler slabs. The system's environmental performance is assessed through cradle-to-gate life cycle carbon emission assessment of a case study comparing embodied carbon emissions for different scenarios of a 6 m × 4 m RCC slab. Mechanically compressed polyethylene (PE) waste is proposed as a filler material to overcome the limitations of clay pots.

2 Materials and Methods

2.1 Slab Design & Mix Design

As an illustrative case study, an RCC slab of width 4 m and length 6 m is designed. The design follows the Indian Standard Code for Plain and Reinforced Concrete [14]. Assumptions made for the design are mentioned in Table 1.

Table 1 Assumptions for the design of RCC Slab

Design Parameters	Unit	Value
Grade of Concrete	N/mm^2	35
Reinforcement Grade	N/mm^2	415
Live Load	kN/m^2	2
Floor Finish	kN/m^2	1.5
Exposure Conditions	N/A	Mild
Support Condition	N/A	Simply Supported

The design summary is presented in Table 2.

Table 2 Design Summary

Design Parameters	Unit	Value
Thickness of the Slab	mm	250
Rebar Diameter	mm	10
Main Rebar Spacing	mm c/c	150
Distribution Rebar Spacing	mm c/c	180
Cover Provided at the Bottom of the Slab	mm	20
Neutral Axis Location considered from the bottom of the slab	mm	130

The mix design [17] and the material usage detail are presented in Table 3 and Table 4 respectively.

Table 3 Mix proportion for OPC + 30% LC2 concrete design.

Material	Quantity (kg/m^3)
Quartz Sand	1206
Cement	575
LC2 (Limestone Calcined Clay)	246
Water	288

Table 4 Detail of material usage in conventional and filler slab

Material	Unit	Filler	Conventional
Total Volume	m^3	4.37	6
Printable Concrete (tension zone and boundary of compression zone)	m^3	1.63	3.26
Conventional M35 Concrete (used in compression zone)	m^3	2.74	2.74
Volume of Voids	m^3	1.64	-

2.2 Proposed Concrete 3D Printing Setup

A gantry 3D printer with a robotic gripper is proposed for slab printing, comprising three main components: a

printing head with dual nozzles a pneumatic gripper for pick-and-place operations, and a motion control system. Concrete is pumped from the mixer to the printing head, where an auger mechanism ensures controlled extrusion. The dual nozzles handle 3D printable mix and regular concrete, respectively. The gantry operates in the x-y-z plane, facilitating rebar cage and filler element placement, with a workspace of 8 m × 8 m in the x-y plane and 1 m in the z direction. Workspace and the 3D
printer is shown in Figure 1 and Figure 2 respectively. An early prototype of the design integrating 3D printing with robotic pick and place features is shown in Figure 3.

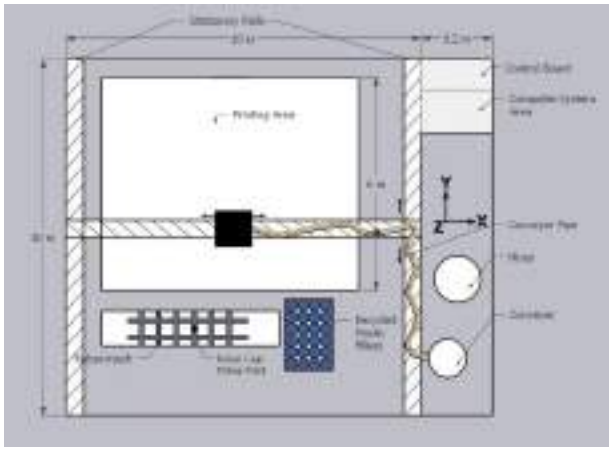

Figure 1 Plan view of the 3D printing system integrated with automated pick and place function.

The process flow is illustrated in Figure 4.

2.3 Filler Slab Printing Process

The slab is assumed to be printed as 6 panels, each 5m long and 1m wide. The printing has been carried out in three parts: cover layers, compression zone, and tension zone printing Figure 5.

The filler and rebar placement settings are shown in Figure 6. “2w” and “2b” are the main and distribution bar spacings, “G+a” indicates the distance between filler pickup point and the first void. The movement in the z-direction is assumed to be 100 mm per pick and place operation.

2.4 Life Cycle Assessment

The LCA used in the study is based on ISO 14040/44 [18, 19] guidelines. The consequential LCA (CLCA) approach is used to show the change in carbon emissions by adopting the proposed concept.

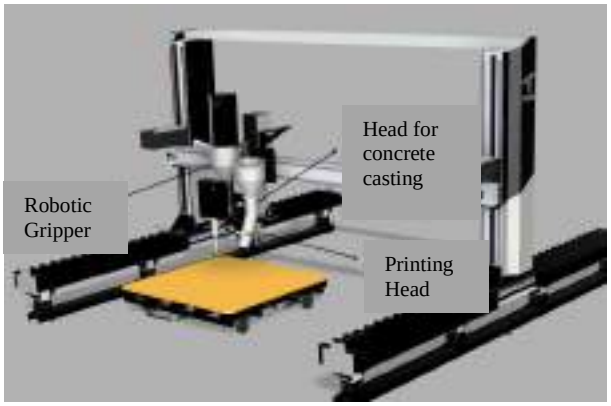

Figure 2 Plan view of the 3D printing system integrated with automated pick and place function.

Figure 3 An early prototype of the design integrating 3D printing with robotic pick and place features

2.4.1 Goal, Scope and System Boundary

This study aims to quantify the reduction in carbon emissions by adapting the proposed method of printing filler RCC slabs using recycled PE as fillers, compared to conventional slab printing. The results provide new insights for the industry and research community, promoting the integration of robotics, concrete 3D printing, and waste recycling to develop sustainable construction alternatives. The recyclable waste used is polyethylene (LDPE or HDPE), the most consumed plastic, with a gantry-type concrete 3D printer integrated with a gripper for pick-and-place operations employed in the process.

The functional unit in this study is the concrete 3D printing 1 m^3 volume of a 250 mm thick structural slab spanning 6 m X 4 m to allow comparisons between different printing scenarios.

Case-1: 3D printing of 6 panels of 4 m length and 1m width for a 6 m X 4 m RCC slab without any fillers.

Case-2: 3D printing of 6 panels of 4 m length and 1m width for a 6 m X 4 m RCC slab with clay pots as fillers.

Case-3: 3D printing of 6 panels of 4 m length and 1m width for a 6 m X 4 m RCC slab with Recycled PE waste as fillers.

Case-1 is considered the base case for the comparing the carbon emissions. The system boundary used for conducting LCA in this study is shown in Figure 7.
.

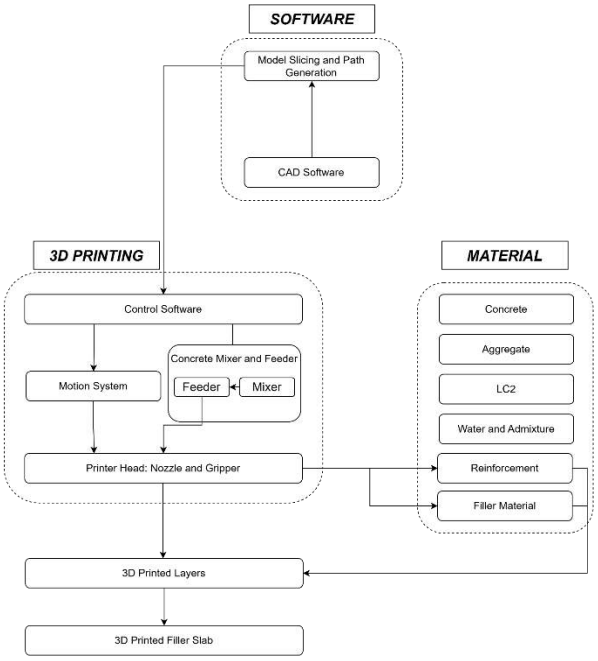

Figure 4 Process flow for 3D printing of filler slab

2.4.2 Life Cycle Inventory

Concrete production emissions are based on design mix [17] and carbon emission study of concrete printed mix [9]. Plastic waste recycling involves motors for washing, drying, and compressing PE waste, with emissions calculated from electricity use (Ecoinvent v3.9), the power calculation for washing and drying has been done based on study by [20], a 5 HP motor is assumed to compress 1 ton of waste in 10 seconds.

Clay pot production emissions is taken from [12] market data is used for volume to weight calculation, assuming 1 litre. pot weighs 1kg. Transportation emissions are calculated for a 10 km local distance using a 3-ton vehicle with 6 km/L mileage and Ecoinvent v3.9.

3D printing emissions account for electricity consumption, while avoided emissions are based on the incineration of PE waste which is calculated using data from Ecoinvent v3.9. Only 11% of the waste used as filler is assumed to be incinerated.

This study employs CML v4.8 2016 to assess life cycle carbon emissions, focusing on the reduction of cement and concrete content and related carbon emissions, as required by the baseline impact category.

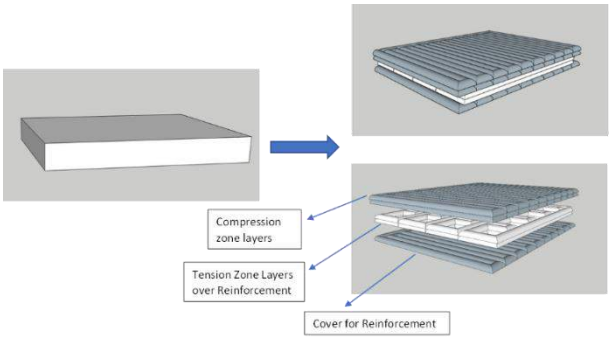

Figure 5 Representation of a Conventional Slab (Left). 3D printed slab (Right Top). Different layers of 3D printed slab (Right Bottom)

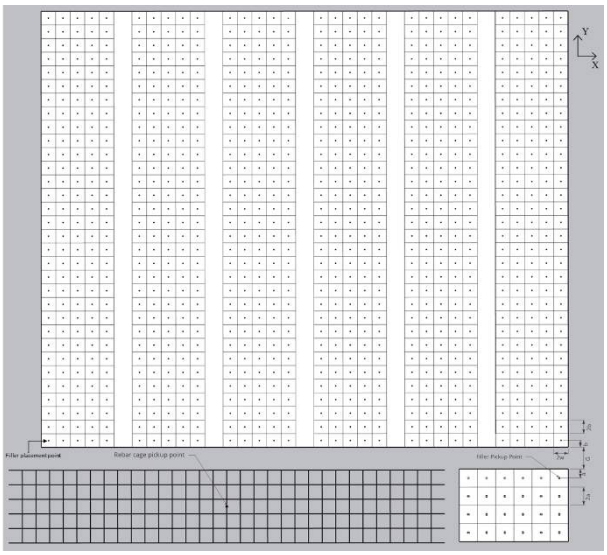

Figure 6 Plan for placement of fillers and rebar cage

3 Results and Discussions

3.1 Concrete 3D Printed Slab Output

The printing path and the placement of the filler are shown in Figure 8. The size of filler material for one void is 140 mm by 110 mm cross-section and 110 mm deep. Figure 9 shows a cross-section view of the 3D printed elements for the case of conventional printing and printing with fillers.

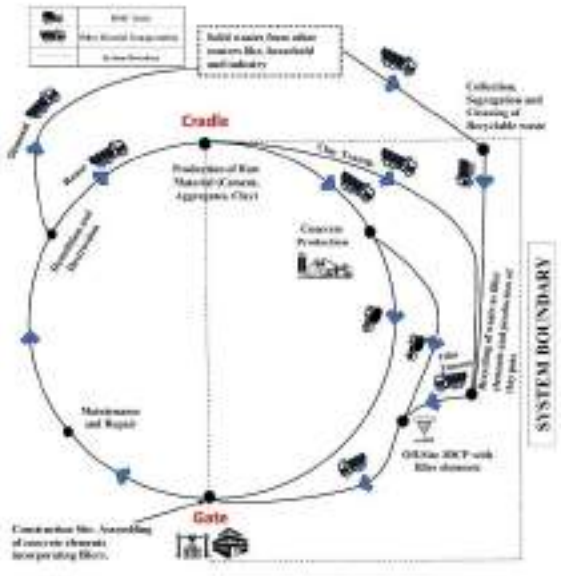

Figure 7 Schematic for life cycle assessment of concrete filler slab

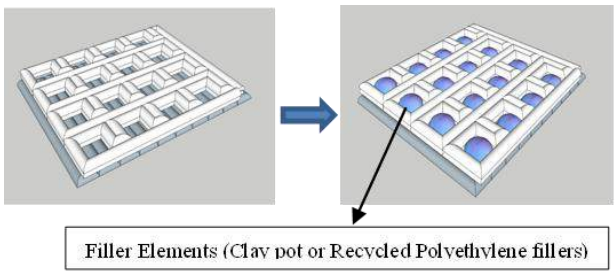

Figure 8 Printing path over rebars in tension zone (left), placement of fillers in voids (right)

3.2 Carbon Emission Assessment

3.2.1 Filler Production

As per the assumptions stated in section 2.4.2 the carbon emission assessment for clay and recycled PE filler production is mentioned in Table 5 and Table 6.

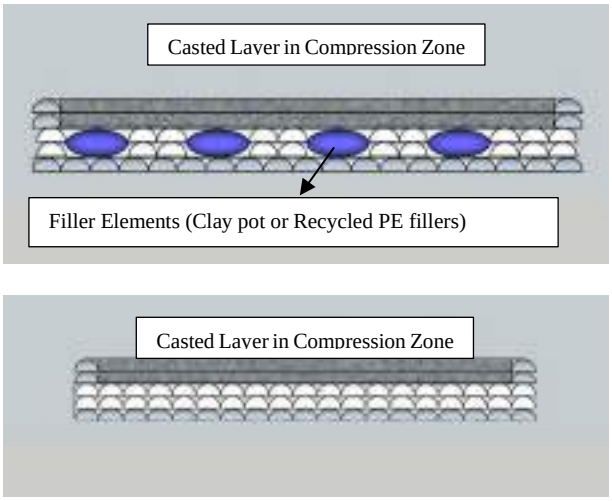

Figure 9 (a) Cross Sectional View of Slab in Scenario Case-1 and Case-3 (b) Cross Sectional View of Slab in Scenario Case-1

Table 5 Emissions generated due to the production of clay pot fillers.

Description	Unit	Value
Weight of the Clay Pots Required	kg	1636.4
Carbon emissions per kg of unit produced	$kgCO_2$ eq.	1.91
Total Carbon emissions for clay pots required	$kgCO_2$ eq.	3125.53

Table 6 Emissions generated due to the production of recycled plastic fillers.

Process	$kgCO_2$ eq. emissions
Transportation from scrap dealer to MRF	12.20
Washing of waste PE	4.07
Transportation to the 3D printing facility	12.20
Compaction using Automatic Baler	16.24
TOTAL	44.70

Using recycled polyethylene fillers reduces emissions by 98%. Additionally, the weight of the recycled polyethylene filler slab (total weight of PE fillers used is 2.08 tonnes) is 6% lower than the clay pot filler slab and 60% lower than the conventional slab, reducing the slab's dead load. This reduction helps minimize material consumption in the substructure.

3.2.2 Electricity Consumption in Printing the slab

The printer head operates at an assumed speed of 80 mm/s in both the x and y directions. For movement in the z-direction, rather than calculating the total distance, the number of layers is considered, with each layer transition taking approximately 1 second. The gantry system employs 1 kW, three-phase motors for the x, y, and z axes. The electricity consumption is determined by multiplying the power rating of the motors by the total operational time. The pump used for extruding concrete has a power rating of 5.5 kW.

The total electricity consumption for printing the filler slabs is presented in Table 7.

Table 7 Total Electricity Consumption for printing slab

Description	Filler Slab	Conventional Slab
Printing Process	36.62	57.48
Filler Placement	37.30	-
Rebar cage placement	0.28	0.28
Pumping Concrete	183.08	287.40
Total Electricity Consumption in kWh	257.28	345.16

3.2.3 Embodied Life Cycle Carbon Emission

Two concrete mixes were used to produce printed slabs. An M35 mix [21] with 30% Class F Fly Ash replacement, emitting 289 kg CO_2/m^3, was used for casting the compression zone, while an OPC-LC2 mix [17] was used for printing the cover, tension and boundary zones, with emissions data sourced from [9]. CO_2 emissions from plastic waste incineration and electricity consumption were derived from Ecoinvent v3.9 [22]. The emission assessment results are summarized in Table 8.

The table reveals that using recycled plastic waste as filler elements reduces carbon emissions by 37%. Conversely, clay pot filler slabs increase emissions by 55% due to the high carbon footprint of clay pot production (3125 kg CO_2 eq.), despite reduced material usage. Case 3 demonstrates the lowest emissions, attributed to avoided emissions from repurposing waste plastic. This highlights that filler material selection is crucial, as the production emissions can offset the benefits of reduced raw material consumption, as seen in Case 2.

Table 8 Life cycle carbon emission comparison for the three scenarios

Description	Case-1 (kgCO2 eq.)	Case-2 (kgCO2 eq.)	Case-3 (kgCO2 eq.)
Concrete Production for compression zone (M 35-35% fly ash replacement)	790.76	790.76	790.76
Concrete Production for tension zone (OPC+30% LC2)	2153.5	694.74	694.74
Production of Filler Element	-	4221.5	49.7
Electricity Consumption in 3D Printing	531.54	396.21	396.21
Avoided Emissions	-	-	-120.48
NET EMISSIONS	3475.78	5385.95	2189.64
NET EMISSIONS PER m^3	579.29	897.65	364.94

4 Conclusion

Concrete 3D printing has significant potential to transform the construction industry, but its full realization is hindered by challenges such as limited automation, minimal application in printing structural elements like slabs and beams, and the high cement content of 3D printable mixes. Hence, developing techniques to reduce raw material consumption is essential to minimizing the carbon emissions associated with production of concrete 3D printed elements. This study proposes an automated methodology for 3D printing RCC filler slabs using compressed polyethylene (PE) waste as an alternative to clay pots. A case study of

a 250 mm thick slab spanning 6 x 4 m is analyzed to evaluate the carbon footprint of 3D printing a RCC slab.

Following are the major findings of the case study:

- The findings suggest that the proposed 3D printing methodology can effectively reduce material usage and carbon emissions, offering a cleaner and more sustainable construction alternative. In the case study, utilizing polyethylene waste as a filler material decreased concrete consumption by 27% and carbon emissions by 37% compared to the baseline scenario of 3D printing slabs without filler elements.
- The lower carbon emissions in filler slabs with recycled PE waste, compared to those with clay fillers, are primarily due to the significantly reduced emissions from producing recycled PE fillers, which are 98% lower.
- Also, Recycling PE waste into slab fillers prevents the emissions that would have resulted from the incineration of plastic if the waste had not been recycled.
- Slabs with recycled PE waste as fillers have a lower dead load compared to those with clay pot fillers or no fillers, further contributing to material and carbon emission savings in substructure construction.

The study has assumed various transportation distances which may not be the real scenario. The equipment production related emissions were ignored in the calculation of carbon footprints because the equipment being used in all the three scenarios mentioned is same. Also, a cradle to gate approach for carbon emission assessment was used, because the main objective of the study was to compare the scenario in production phase. In future other phases like operational and demolition phases can also be studied. Also, the study demonstrates the potential using a single slab case, in future the results will be generalized using different cases and structures.

Nevertheless, these findings offer a path toward utilizing the advantages of concrete 3D printing and automation for sustainable construction. Automating tasks such as placing rebars and fillers reduces the risk of human error, addressing one of the key drawbacks of the conventional filler slab technique.

Abstract –

The construction sector faces significant challenges in reducing emissions, with extending the lifespans of architectural products emerging as a key strategy. As stakeholders of the built environment focus on decarbonization, the concentration of efforts diverges towards either sustainable development of future products or sustainable preservation of the existing built environment. Critical intersections between development and preservation are the reuse, repurpose, repair, and refurbishment stages within a circular economy. This research investigates the integration of Design for Disassembly (DfD) principles into the lifecycle of high-performance facade systems, as complex architectural systems frequently utilize materials and methods that hinder circularity, such as fixed connections. Designing and advocating for future uses is challenging without explicit disassembly standards or supporting infrastructure. By analysing existing disassembly methodologies, a tailored approach was developed for high-performance façade design, leveraging Schüco KG's existing digital infrastructure to optimize disassembly workflows. This methodology focuses on the generation of practical disassembly outputs, for use cases across designing, manufacturing, and constructing façade systems. Coordinating with fabricators, a proof-of-concept for a Disassembly Application is developed to integrate with existing digital infrastructure. The case study on the AWS 75.SI+ window system highlights the feasibility and benefits of incorporating disassembly planning from the early design stage. This framework provides a scalable model for reducing construction waste, improving material reuse, and supporting circular economy goals for high-performance façade systems and across complex building systems.

Design for Disassembly; Life Cycle Analysis; Built Environment; Building Façade System; Case Study

1 Introduction

There is a substantial amount of embodied energy in existing buildings. Demolishing obsolete buildings in favor of higher-performing new construction is a popular path, but the energy cost of demolition and disposal must be addressed. Standard Architecture, Engineering, and Construction (AEC) education and practice center buildings with lifecycles of 30-50 years, programmed for demolition rather than renovation [1]. Frequent technological advancements increase the rate of technical obsolescence of façade systems. Instead of considering future technological upgrades as a design criterion, many façade systems are replaced in their entirety in favor of higher-performing systems. High-performance façade systems often contain aluminum and other critical materials in the Critical Raw Materials Act (CRMA) [2]. Smart façade systems with integrated technology contain critical raw materials such as cobalt, coltan, and lithium. The technology sector and transportation sector account for critical material recovery, but the building sector does not have a comprehensive recovery strategy. Demolition involves all materials going to landfill, with no planned recovery. Deconstruction, however, is the systematic recovery of materials with circular intention. Disassembly refers to the capacity for deconstruction in a system, meaning systems intended for deconstruction must be designed with easy part disassembly [3]. Design for Disassembly (DfD) is a research field and design practice developed within the manufacturing and construction industries, geared towards expanding material circularity. DfD considers the various parameters including material composition, component connection, data accessibility, material flow, stakeholder incentives, and local options. Developing infrastructure to facilitate DfD across construction would allow valuable materials to re-enter the Material Bank [4] and outline opportunities for future designs, reducing both resource extraction and construction waste.

Disassembly for architecture has decades of existing research and methods, with many digital solutions and case studies; however, there is a gap in disassembly

research pertaining to high-performance facade systems and associated components and processes. While façade systems often use critical and high-value materials such as aluminum and steel, high-performance systems rely on polymers and adhesives, that reach technical obsolescence sooner, to meet structural, thermal, and acoustic criteria. Although high thermal performance significantly lowers operational carbon, current practice uses fixed connections, permanently sealing non-circular materials to systems. Thus, although facade assemblies are historically among the most demountable, reconfigurable, and reusable building systems, the only End-of-Life options for these high-performance systems are recycling, incineration, and landfill.

This research begins with a brief review of published disassembly methodologies, identifying applicable modeling for high-performance facades. A methodology is developed to integrate into existing digital design and manufacturing infrastructure. The product catalog provides a wide range of façade systems with varying degrees of performance and disassembly. Various electronically operated systems assist with ventilation, solar shading, security, operability, and comfort. As with other technology devices, these smart components contain cobalt, lithium, and coltan. The documentation of disassembly data serves three main purposes: it improves the efficiency and effectiveness of deinstallation during fabrication, construction, maintenance, and at End-of-Life; it improves circularity and circularity documentation; and lastly, it assists with product design, improvement, and development related to product circularity. Next, the methodology and case study portions follow Schüco system AWS 75.SI+ to develop a disassembly application. The research aims to bridge existing construction disassembly theories and studies with AEC workflows.

2 Review of Published Methodologies

For this research, multiple published disassembly and work estimation methodologies were reviewed and assessed for applicability. The review included Durmisevic's Knowledge Model [5], BIM-DAS [6], Selective Disassembly Planning for Buildings (SDPB) [7], Disassembly Network Analysis (DNA) [8], Method Time Measurement (MTM) [9], Maynard Operation Sequence Technique (MOST®) [10], Adaptive Reuse Model (ARP) [11], AdaptSTAR [12], and the Parent Action Child (PAC) model [13]. With considerations of users, inputs, outputs, and level of automation, four main methodologies were selected. Durmisevic's Knowledge Model is one of the older and most referenced disassembly methodologies. Outputs include disassembly sequences, connection-type knowledge, and an independence and exchangeability aggregated score. While it considers small-scale connection information applicable for facade systems, the manual process cannot be easily integrated into existing workflows [5]. The BIM-DAS method is a Building Information Modeling (BIM) based Deconstructability Assessment Score, developed to assess and minimize construction waste from the design stage. Outputs include the Deconstruction Score, the Reuse Score, and finally, the Deconstructability Assessment Score (0% being the lowest, 100% being the highest). The scores are not appropriately weighted, and the focus is on larger scale building connections than facade systems [6]. Consideration of component end-of-life conditions is necessary for disassembly effort assessment. The PAC model divides products into assemblies and subassemblies, further categorized into parents, actions, and children. Considering disassembly failures (DFs), the PAC model outcomes include the Disassembly Effort Index (DEI) and the circularity index (CI). The DEI represents the time required to perform an action and disassemble a component, and the CI represents the circularity of the components after disassembly [13]. Disassembly failures are categorized into three types: Type One occurs during product use and are related to the children in the PAC model, Type Two is associated with actions in the PAC model, and Type Three affects the parents, meaning both the action and one or more children are impacted. MOST® is a predefined motion time system used in industrial settings to establish the standard time required for a worker to perform a task. Tasks are broken down into individual motion elements and assigned Time Measurement Units (TMUs), where 100,000 TMUs equal one hour [10]. This information can be integrated into the PAC model to assess the DEI, providing a comprehensive understanding of the disassembly process and identifying areas for efficiency improvements [13].

3 Methodology

The existing disassembly methodologies described in the methodology review portion were assessed for criteria related to facade system product lifecycles: intended user groups, required inputs, outputs, and transparency. Existing methodologies were also selected based on the availability of case studies. A methodology was defined by analysing the physical components and life cycles of facade products, as well as the existing product documentation and company-wide digital infrastructure. Existing information necessary to disassembly was mapped, and remaining information was identified.

Building Façade Systems (BFS) are composed of elements and components. Façade elements are the functional assemblies: external walls, doors and windows.

Façade systems are combinations of multiple elements. Components are the parts that make up the elements, such as the frame, handle, or reinforcement profile. The functions of components are structural support, thermal and acoustic control, aesthetic and resilient finish, and integration to other components through connection [3]. The disassembly of façade systems is dependent upon the separation and removal of components for replacement and reuse. Components can serve multiple functions, which constitutes a closed façade system. If the functions of components are separate, they are considered functionally independent. A component can be removed from the element if it is functionally independent, and a system comprised of functionally independent components is considered an open façade system [5].

As shown in Figure 1, there is currently no selective disassembly and recovery integrated into the standard facade system product life cycle. All façade building materials are either sent to recycling or landfill. Highlighted in green is the "closed loop" of material circularity, stages A3 - D. Life cycle stages aligned according to ISO 14040 [14].

Figure 1. The typical product life cycle of a facade system product.

Figure 2 shows how building materials gain the opportunity to be diverted from the two previous End-of-Life pathways, to be refurbished and reused in new products without shredding. Existing products have many reusable components that do not need the additional energy use of recycling. Additionally, this analysis can be used by product designers to develop future products that have higher disassembly potential.

Figure 2. Integrating Design for Disassembly (DfD) into the facade system product life cycle.

Product ordering, fabrication, and assembly are often well-documented across facade systems. However, there is a large gap in documentation of deconstruction and deinstallation of products. From lifecycle stages A1-A5, extensive product information is accessible through internal digital infrastructure, BIM tools, and product documentation such as EPDs and BOMs. This methodology limits the necessary input from fabricators, manufacturers, and designers by utilizing available data. Fabrication processes vary, even across facilities at the same company. Necessary inputs for disassembly calculation are thus split into two lists: existing company data and data to collect from users (see Table 1). User input is necessary to map a disassembly process to a product system once. Then, it can be stored for future applications using the same products.

Table 1. Data Sourcing

Existing Internal Data	User-Input Needed
System Type	Connection Type
Element Type	Disassembly Sequence
Component Type	Disassembly Action
Material	Disassembly Equipment
Weight	Component Recoverability
Assembly Action	

One of the key outputs of the application is the breakdown of materials based on their End-of-Life potential. All components in a BOM are sorted into three categories: reusable, recyclable (but not reusable), and waste. This breakdown is shown in item count as well as item weight. An additional valuable materials End-of-Life breakdown documents materials that must be recovered in the material flow; ideally none which go to landfill/incineration. Unaltered and slightly altered reusable components can be salvaged and reused with minimal alteration. For example, un-crimped cleats cannot be re-crimped but can be screwed on a second configuration. The list of unrecoverable elements guides product designers to identify weak points of design in relation to disassembly. The disassembly sequence output is the written list of directions to dismantle the configuration. First, the objects in the BOM are sorted into element groups, such as an operable vent, fixed light, door, or framing. Within each element group, each item is placed in descending order based on Sequence ID. Lastly, all identical items within each field group are

grouped to condense the disassembly sequence. In the case of complex façade systems, this is necessary to avoid tediously lengthy lists that spell out the directions for every individual screw and other small components, where there may be dozens, if not hundreds. The disassembly sequence thus lists the number of components in each element to dismantle for each step, with the time estimate. For components that cannot be disassembled, that is reflected instead of an instruction and time estimate. The total number of steps and the total time estimate are provided along with the sequence. An output for sustainability experts includes the Material Circularity Indicator (MCI), developed by the Ellen McArthur Foundation; quantifies the minimization of linear material flow and maximization of restorative flow for all component materials in a product [15]. A score of 100% implies total repurposing upon completing a lifecycle. Typically, the MCI of a facade product is calculated using an EPD generated for life cycle stages A1-A3; in this methodology, the MCI is calculated considering the realistic end-of-life of the product, including potential disassembly failures. Similarly, The Water Circularity Indicator (WCI) is measured as the ratio, in cubic meters, of circularly sourced water over the total amount of water used. The Energy Circularity Indicator (ECI) is measured as the ratio of renewable energy used over the total energy used [16]. An output geared towards product designers involves a summary of all limitations to disassembly identified in the product. This includes conditions such as rolled thermal breaks, permanently sealed joints, structural sealant, and petroleum-derived materials. This section explains the reasons these decisions are typically made and provides suggestions for improvement. In the Case Study section, this methodology is implemented on a specific façade product, Schüco's AWS 75.SI+.

4 Integration and Operability

Building Information Modeling (BIM) facilitates collaboration across all project stakeholders. Disassembly information affects design, engineering, LCA, and construction means and methods; therefore, it should be accessible to all stakeholders. Single platform hosting all performance metrics allows for easy comparison and assessment, weighing the trade-offs of disassembly capacity with structural, thermal, or acoustic performance and cost. As the disassembly information may change across the supply chain, having a single source of truth for reference is essential.

Users of a disassembly application must be able to add all related data points for their model. Product designers can initially specify the BIM content of an architectural component, documenting this initial disassembly data in a standardized "Information Delivery Specification" (IDS) format. Developed by buildingSMART, IDS is a standard for specifying alphanumeric information following the Industry Foundation Classes (IFC) schema [17]. This format is appropriate for applying the outlined disassembly specifications and can be supplemented with additional specifications, such as recommended assessment criteria in ISO 20887(EN) [18]. This documentation can then be shared with engineers for simulation and calculation, shared with sales and other contributors, and collaboratively finalized in an interoperable format such as IFC. For the disassembly information to be open source and publicly accessible, this IFC compliance is critical [19].

Once the product model is complete, all complex system logic and disassembly documentation are available for the project architects, engineers, and contractors. These models can be used in all IFC-compliant BIM tools, such as Autodesk Revit® and Tekla Structures®. In addition, disassembly outputs can be generated and accessed in addition to existing outputs within the BIM tools. As the project develops, these stakeholders can also update the architectural component. For disassembly, this is necessary when, for example, a component is designed as fully deconstructable, but the structural engineer makes a call to use a permanent connection for a site-specific wind load; this disassembly information would be updated in the BIM model to reflect the change for the deconstruction team's disassembly instructions.

5 Case Study

The case study implementing the methodology outlined in this research uses Schüco's AWS 75.SI+ window system (see Figure 3), which shares many manufacturing and fabrication processes with similar window and facade systems, within Schüco and across the facade industry. The disassembly planning was mapped for an inoperable fixed light as well as for an operable turn-tilt window, both with the standard dimensions of 1480 x 1230 mm. A simplified overview of Schüco's workflow begins with product designers and engineers creating profiles and systems; next, manufacturers extrude, cut, and assemble composite profiles; next, fabricators assemble configurations based on project specifications. Many locations provide maintenance services during the products' use phase, and several locations and product types provide recovery services for materials after use. All Schüco profiles and accessories have unique identification numbers that contain profile data, including material, weight, price, description, and more, and are accessible through various internal portals. The digital infrastructure contains documentation platforms, ordering, planning, modeling,

and calculation software, and a material passport system. Although the profile data is comprehensive for many applications, disassembly data is not included. The case study interfaces with configuration tool SchüCal, which is utilized across the value chain. Order, fabrication, and physics data can be exported, including BOMs and EPDs. These two exports are mapped to additional disassembly data, used to derive disassembly metrics in a disassembly application.

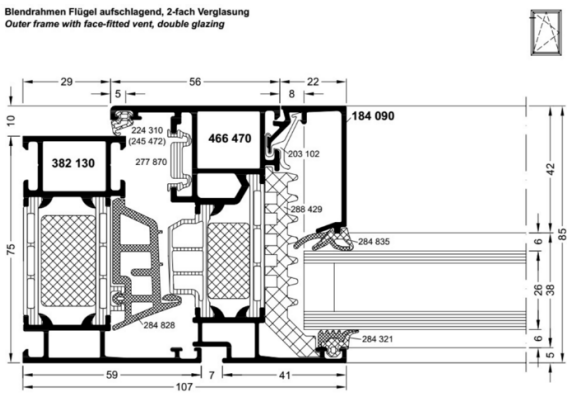

Figure 3. AWS 75.SI+ outer frame with face-fitted vent

The system contains aluminum profiles that are thermally broken with polyamide (PA) or proprietary material Polythermid (PT) isolators, which are permanently rolled into the aluminum profiles with insulation in between each thermal break component. Gaskets are made of EPDM and PE foam is used for insulation. Corners and profile joints are fixed with aluminum cleats and sealed with epoxy in addition to steel screws. Locking bars are a combination of plastic and metal, and most fittings are metal and fully removable.

5.1 Network Analysis

Integrating disassembly to each system type starts with system network analysis. Following the process mapped in Durmisevic's Knowledge Model, all system components are plotted as nodes and all components and connections are labeled. This mapping highlights the hierarchies and dependencies and the order in which they can safely be separated from the total configuration. Network analysis also highlights which components are inaccessible for removal due to sequencing and permanent connections. This process establishes a disassembly sequence for each system type and provides the necessary framework for disassembly metrics via a component database. This mapping requires coordination with fabricators familiar with the products' assembly processes. Fabricators are familiar with the physical limitations of product components and the adjustments necessary during imperfect assembly, knowledge that is not documented in Schüco internal resources, making disassembly mapping, product design, and onboarding incoming fabricators more challenging. For the case study of Schüco's AWS 75.SI+ window system, there was coordination with fabricators. AWS 75.SI+ is a high-performance window system with a depth of 75 mm. Increased thermal insulation for efficiency and performance is included in the center gasket and glazing rebate insulation in addition to standard gaskets and insulation foams [20].

In Figure 4, the left image shows an exploded axonometric view of a corner condition of an AWS 75.SI+ frame, and the top right image shows the frame cross-section. The bottom right diagram shows the network of these components.

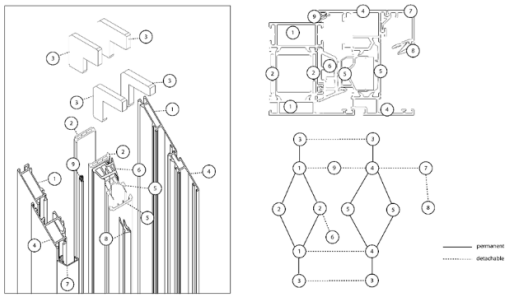

Figure 4. AWS 75.SI+ Network Analysis

Maintaining the connection network, Figure 5 details all names, materials, and article numbers. Connections are distinguished between permanent, detachable, and easily detachable, with connection-type descriptions, and arranged from left to right in order of assembly steps. The aluminum profiles are first rolled with thermal breaks in a permanent connection. After cutting and processing the profiles with end cuts, holes, notches, and slots, the corner cleats are nailed, screwed, or crimped into position, and then sealed with epoxy to secure mitered frame corners. In coordination with fabricators, these two permanent connections were highlighted as assembly challenges, as mistakes during these steps cannot be reversed. Finally, glazing and gaskets are snapped into place, starting with the bottom glazing gasket, after which the aluminum glazing bead is snapped in, followed by the other gaskets. In configurations with operable vents, all fittings are attached after the gaskets and glazing. Schüco's proprietary fitting kits are designed to be easily attached and removed in no specific order.

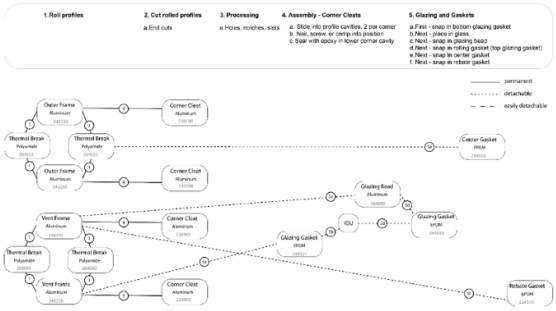

Figure 5. Assembly Sequence Mapping

Using the assembly sequence mapping as a reference and relying more on fabricator knowledge, the disassembly sequence is mapped in Figure 6, showing the components in the order in which they are removed. The remaining components are shaded to indicate that disassembly is no longer possible at these stages.

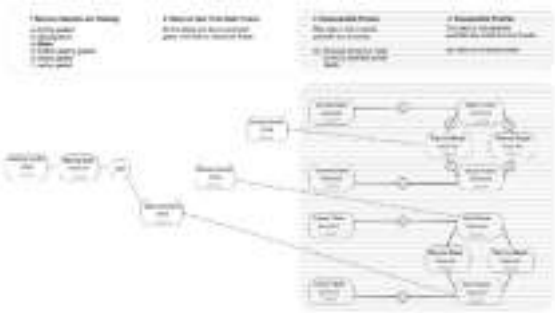

Figure 6. Disassembly Sequence Mapping

5.2 Disassembly Mapping

With system analysis and sequencing complete, disassembly mapping is expanded following portions of the BIMDAS, PAC and MOST® methods. Each separate component from the network analysis is assigned a unique identifier from e^1 to e^n, and each associated connection is assigned a unique identifier from c^1 to c^n. A table is created using these unique identifiers, placing all disconnection actions sequentially, assigning a Sequence ID for every element. Following the principles documented in the BIMDAS method, each component type is assigned several necessary attributions for calculating the Deconstruction Score, the Recovery Score, and DAS. This process establishes a disassembly database for the system. This documentation stage is flexible to adjust for workflow and output goals. Several data points can be mapped from SchüCal, while the rest are mapped from a disassembly database developed for this application to fill the gaps of disassembly documentation. Existing system information taken from SchüCal is the BOM, EPD, system type, and glazing information. Component-specific information from SchüCal is article number, material, secondary finishing, weight, and field number.

Table 2 contains all mapped data of the disassembly database. Column T refers to the component type (ex., frame, gasket, etc.). These tags can be set as defaults for each element type in a system, assuming they are the same for each type. Weight is kilograms, and Material is the material description or associated material code. Fixed (Cf), Bolted (Cb), Nailed (Cn), Prefab (P), Reusable (Ru), Recyclable (Rc), Secondary Finishing (Sf), and Nontoxic (N) are all filled as either true or false. Here, several additions and alterations are made to the table framework detailed in the BIM-DAS method to incorporate inputs for the PAC and MOST methods as well Schüco practices: fitted connections (Cft), demount-ability (D), the disassembly action (DA) as a description of how to remove the component, the sequence ID (SID) integer placing the component along the disassembly sequence, and disassembly time (DT) as the measure of time it takes for that action based on the MOST methodology, measured in TMUs, converted into minutes at later stages.

Table 2. Mapping Data

T	Cf	Cb	Cn	Cft	P	Ru	Rc	Sf	N	D	DA	SID	DT

Database rows are mapped to each component in the BOM fetched by API from SchüCal. A separate API fetches the system's EPDs to calculate circularity indicators following the MCI [15, 17]. In the case study, this database is used to generate disassembly outputs via an external application, but it can also be used for material passport data in Internet of Facades (IoF), the material passport system. Connection-types for each component can be found in the Fabrication Manuals of Schüco products; this is not a guarantee for other companies' workflows. The case study application is designed as a desktop application. With SchüCal open, a user may select any configured project. The application fetches available configuration data and maps disassembly data to each component in the BOM. Figure 7 shows the application workflow with two input streams, internal software SchüCal (for BOM and EPD) and disassembly database (compiled per component, developed with fabricators), and the four disassembly output categories: disassembly instructions, recovery material lists, disassembly and circularity metrics, and design improvement recommendations.

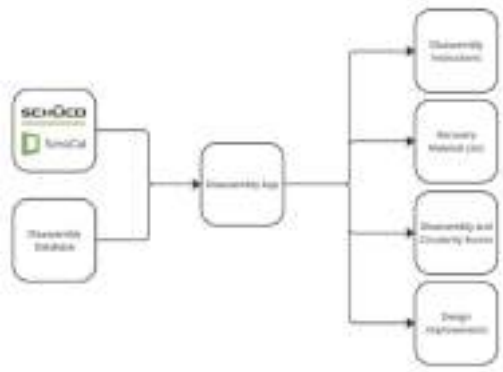

Figure 7. Application Workflow Diagram

The application consists of multiple services, each containing equations and processes relevant for their outputs. The main service maps BOM components to that system's disassembly database and calls calculation engines. One service calculates all ratios necessary for the Deconstruction Score, Recovery Score, and aggregated Deconstructability Assessment Score, and sorts components for material breakdowns and recovery lists. A second service groups and sequences components for the disassembly sequence, calculating time and noting the limitations. The total disassembly time is estimated using the MOST® process. A third service calculates the Material Circularity Indicator, Water Circularity Indicator, and Energy Circularity Indicator. Lastly, a Document Service synthesizes the results from each service into PDF output. Although not included in the case study, this information can also be entered into a material passport to provide stakeholders with up-to-date data.

6 Results

The disassembly sequence for AWS 75.SI+ is an almost direct reversal of the assembly sequence. For configurations with operable vents, disassembly begins with the removal of all fittings. After gaskets and glazing components are removed, the corner cleats and thermal breaks cannot be separated from the aluminum profiles, leaving the outer and vent frame assemblies without any more recoverable components, as thermal breaks and corner cleats cannot be removed without damaging the elements around them. Some assumptions were made to calculate the time required for the complete window disassembly, including that only one skilled worker is required to disassemble the window, and the second assumption is that only one workstation is required. The AWS 75.SI+ fixed light contains 25 components and 6 materials. 5 items are reusable with a total weight of 1.32 kg, 14 items are recyclable at 11.40kg, and 6 items totaling 0.12 kg are designated for waste, none of which contain valuable materials. It has an MCI of 45%, a Deconstruction Score of 79%, a Recovery Score of 57% and an aggregated score of 68%. It has a realistic disassembly time of 42 minutes, with 9 total steps, 3 of which are not possible. Limitations identified are rolled thermal breaks, permanent sealants, and petroleum-derived materials. The AWS 75.SI+ with a Turn-Tilt vent contains 50 components and 7 materials. 11 items are reusable with a total weight of 3.43kg, 32 items are recyclable at 23.48kg, and 7 items totaling 0.21kg are designated for waste, none of which contain valuable materials. It has an MCI of 43%, a Deconstruction Score of 80%, a Recovery Score of 55% and an aggregated score of 67%. It has a realistic disassembly time of 57.85 minutes, with 23 total steps, 6 of which are not possible. There are no additional limitations identified. The most time-intensive process is removing all the hardware from the frames.

7 Conclusion

Design for Disassembly (DfD) for high-performance façade systems is critical to minimizing the extraction of raw materials, lowering recycling energy demands through material reuse, and lowering emissions in the construction sector. Standardization of disassembly modeling and documentation is currently lacking across AEC. As the objectives of circularity regulations and certifications solidify, comprehensive and accessible disassembly documentation future-proofs the framework. In this research, existing disassembly methodologies are compared for relevance to façade system application; components of BIMDAS, Durmisevic's Knowledge Model, PAC, and MOST® are utilized, with network analysis, sequencing, instruction, time estimation, and end-of-life modeling identified as critical to a comprehensive framework. The proposed framework is not exceedingly complex and can integrate with existing digital workflows seamlessly. Interdisciplinary coordination and data collection are front-loaded in the process, consolidating the inputs necessary for multiple disassembly methodologies. Thus, disassembly calculation and presentation processes remain highly modifiable, depending on the use case, generating outputs for various user groups. Fabricator-specific outputs include material recovery lists and disassembly sequencing and time estimation. Designer-specific outputs include disassembly metrics and design limitations and improvement suggestions. Sustainability expert-specific outputs include circularity metrics, recovery lists, and Global Warming Potential. Accessible internal databases are supplemented with input from experienced fabricators. A proof of concept for a

disassembly application was developed to interface with Schüco's existing digital platform SchüCal, documenting the disassembly of the AWS 75.SI+ system for a case study.

In future development, this research's integration of disassembly documentation with BIM tools has the potential to be incorporated directly into the modeling workflow, with a library of parametric components available for connections in new products. Similarly, disassembly modelling can lead to a more dynamic design workflow and results. Digital twin systems can be utilized in combination with BIM and enable real-time monitoring, predictive analysis, and automated decision-making. After construction, BIM data to be continuously updated with sensor feedback and IoT data, ensuring designers and engineers can assess structural conditions, material degradation and disassembly feasibility over time. This research can expand towards the creation of a library of generic and manufacturer-specific products, publicly accessible for utilization in BIM tools.

The methodology outlined in this research and demonstrated in the case study can be adapted to a range of complex building systems, applicable to existing building stock, existing system designs, and future design development. It is particularly pertinent to modular, prefabricated, and high-rise construction. This research demonstrates how disassembly modeling can be integrated into the existing digital workflows of AEC and implemented to map selective deconstruction and Design for Disassembly across lifecycles of building systems.

Abstract -

Given the significant impact of the construction industry on climate change, efforts must focus on reducing energy consumption, emissions, and raw material extraction. Through improved planning and continuous design optimization, building sustainability and circularity can be enhanced. Significant progress has been made in the fields of Building Information Modeling (BIM) and Life Cycle Assessment (LCA). However, it is still necessary to meet the diverse BIM model requirements defined by LCA software vendors, whose proprietary Property Sets (PSets) must be enriched with information in the BIM model for accurate assessments. However, there are also open developments that have agreed on a common information requirement for sustainability assessment and circularity assessment available as datasets in the buildingSMART Data Dictionary (bSDD). This paper presents the development of an Information Delivery Specification (IDS) that combines the information requirements of two LCA software and two bSDDs. The IDS is successfully validated on two BIM models and will be further developed in an ongoing research project.

Keywords -

Circularity, Construction domain, LCA, BIM, IDS, bSDD

1 Introduction

The construction industry is crucial for efficient energy and resource use, because it accounts for an estimated 37 % of global operational energy and process-related CO_2 emissions [1]. The circular economy paradigm emphasizes the importance of reuse over recycling, advocating for the reuse of complete elements as a more sustainable approach than simply recycling materials. To achieve circularity in the construction domain, it is crucial to have a detailed knowledge of the installed elements.

Building Information Modeling (BIM) is a digital planning method that captures extensive planning information, but its application in terms of circular value creation and energy optimization is still limited [2]. To strengthen the connection between sustainable and digital engineering, it is necessary to ensure a consistent data flow between design and assessment, including the circularity potential of elements. Currently, the circularity assessment is based on proprietary information requirements that are custom-tailored for certain vendors.

To facilitate the annotation of BIM models in early design phases with information about reusability and allow for optimizing the design, it is important that this information can be defined in vendor-neutral schemes with open standards.

This paper explores the potential of the Information Delivery Specification (IDS) standard for enhancing information requirement management in circularity assessments. To this end, current requirements from software vendors and publicly available specifications from the buildingSMART Data Dictionary (bSDD) are analyzed and integrated into a unified IDS for validating models in the Industry Foundation Classes (IFC).

Given that various software solutions for Life Cycle Assesment (LCA) are already available, it must be ensured in construction planning that the BIM models used are also suitable for use as input files. The software manufacturers agree on the established IFC standard. For purely geometric and technical planning, the model does not need to be enriched with all the information required for a sustainability and circularity assessment. In particular, the reuse of components is becoming increasingly important. Thus, it must be stored in the data if components originate from reuse or are designed for reuse. Incomplete input data would lead to an incorrect LCA. Assuming that the respective software manufacturers have drawn up modeling guidelines and have either used IFC Property Sets (PSets) for all the required information or have developed their own custom PSets, the following research questions arise:

1. *How can it be ensured that all required information is available in order to carry out an accurate life cycle assessment for buildings?*
2. *How can different proprietary PSets be unified for a vendor-neutral LCA using open standards?*

Answering these research questions, a resulting unified IDS demonstrates how an open standard for LCA can be established and existing approaches harmonized. Its applicability is validated using two IFC models, with further

refinements planned as part of an ongoing research project.

This general objective is addressed in the 'CLUE' research project by the procedure described. This research project aims to develop digital tools that provide feedback on resource-efficient, energy-efficient and circular construction during the planning phase. These tools will evaluate building designs based on energy and resource efficiency and the potential for implementing a circular economy. CLUE is an acronym for the project title '**C**ircu**L**ar b**U**ilding d**E**sign'. The project involves stakeholders from all phases of a building's life cycle, ensuring comprehensive analysis and optimization [3].

2 Background and Related Work

2.1 BIM-based LCA and Circularity Assessment

Life Cycle Assessment (LCA) is pivotal for achieving more sustainable construction practices. Through life cycle analysis, it is possible to evaluate the environmental impacts of an entire building as well as individual components and construction materials, providing guidelines on how planning can be modified to achieve greater sustainability.

According to Feng et al. [4], the adaptive reuse of precast concrete and timber can significantly reduce carbon emissions and concludes that secondary materials should replace virgin materials wherever possible. Reuse of materials leads to a greater reduction in carbon emissions than recycling. Minunno et al. [5] have demonstrated that the positive environmental impacts of reuse far exceed those of recycling, as evidenced by a modular building designed for dismantling and reuse. Specifically, a reduction in greenhouse gas emissions of 88% was achieved with reuse compared to recycling. Prefabricated elements have a higher reuse potential than in-situ and ready-mixed concrete [4]. The comparison shows that wood and metals have high recyclability because they can be easily recycled or reused, unlike concrete which usually has to be crushed. According to Feng et al. [4], maximizing the reuse of materials should be a key strategy for planners when selecting material resources.

Based on the growing demand for sustainable buildings, Azhar et al. [6] reviewed three building performance software solutions in 2009 and described how they work when embedded in BIM. However, the topic of BIM lacks any reference to the IFC standard that has been developed in recent years and this study is concerned with the operation of buildings. Nevertheless, it is found that the greatest influence on the subsequent environmental impact of a building takes place in the early planning phases. Therefore, the environmental impact of the construction project can be analyzed as early as possible during the planning stage. Backes and Traverso [7] include the social and economic impact of buildings in addition to their ecological impact and make a proposal for such an evaluation system. These two aspects should also not be neglected during construction, but it is questionable to what extent they can be analyzed using BIM data or whether it makes more sense to consider them outside of BIM planning. This aspect is, therefore, not considered in this paper. Carvalho et al. [8] have developed a workflow of BIM-based LCA for the portuguese market. They further parameters that are based on the portuguese SBTool^{PT}-H method and could be used in Revit to optimize building sustainability assessment [9]. Based on the fact that circularity research has identified decisive parameters for the LCA of buildings, these must be annotated in the BIM model. Fenz et al. [10] show how PSets can be developed for the sustainability context, compare them with third-party sources and integrate the results into an ontology. This shows how the sustainability parameters can be processed in the BIM context. In addition to the question of how the information required for the LCA gets into the BIM model, it is also crucial that the information in the BIM model is correctly compared with the material databases in order to determine the environmental impact. There is already research in this area, for example, by Forth et al. [11].

There are several software solutions on the market for implementing an LCA (see overview by [12]): The Madaster platform is a well-known LCA software that uses IFC data to analyze the circularity of a building and is also used in scientific publications (see Rieke et al. [13] and Theißen et al. [14]). Madaster can also be used to compare variants of different construction methods. Concular has already been successfully used by Gordon et al. [15] in the field of stocktaking for circularity assessment.

The concept of reuse is inherently connected to urban mining, which emphasizes the importance of establishing a comprehensive knowledge base on potential sources of reusable components and building materials. Additionally, considerations such as minimizing transportation distances and optimizing interim storage durations are critical. Akbarieh et al. [16] present relevant approaches addressing these aspects.

2.2 Open BIM Standards

BIM as a central planning method is established in the construction sector. Open BIM has an open orientation that enables various manufacturers to use the IFC data standard to foster interoperability.

IFC enables the exchange of construction data between different software in the planning process. IFC4 is the current standard of the IFC format as an 'open international standard'[17] and offers, among other things, broader support for infrastructure projects. Version 4 is registered as an ISO standard [18] and has existed since 2014 [19].

In the current IFC4x3 format, geometric, semantic, and alphanumeric information about buildings can be stored. For instance, this can be data that is used for a sustainability assessment. However, the IFC standard only contains the types of information that are industry standard. Other data used by specific software manufacturers can be stored in additional custom property sets (custom PSets). These can be developed and made available by the manufacturers so that full compatibility of the manufacturer's software with a file in IFC format is achieved.

Furthermore, IDS (Information Delivery Specification) defines information requirements in a machine-readable XML format closely related to the IFC format. It is a newly introduced buildingSMART standard that enables the automatic checking of IFC models to verify that all requirements are met [20]. Thus, the IDS file can be transmitted to any stakeholder, that prepares an IFC model for any following purposes. In this context, IDS thus also replaces Model View Definitions (MVDs), which were previously used in part to define information requirements, although the filtering of information is their actual benefit. The IDS format is now recommended by buildingSMART for the definition of information exchange requirements [21].The complete documentation of the IDS schema and the user manual can be found in the buildingSMART Github repository [1].

To facilitate the sharing of standardized definitions for describing the built environment in IFC models, the buildingSMART Data Dictionary (bSDD) is a service provided by buildingSMART [22]. This service aims to ensure the use of consistent and agreed-upon terminology across various software solutions. bSDD comprises a collection of interconnected data dictionaries, each containing definitions of classes and properties relevant to the built environment. These dictionaries are published by independent organizations and researchers and encompass international classifications, national standards, and company-specific agreements. Additionally, bSDD can store relationships between definitions, map between classifications, and provide translations, so that different interpretations of terms by different actors or software are prevented. bSDD focuses on the metadata-definitions of terms used to describe products and projects. This makes bSDD a valuable vendor-neutral reference library for shared definitions in IFC and IDS. The content within bSDD is organized into classes, properties, and their interrelations, adhering to the bSDD data model based on international standards. In the bSDD, the properties listed are divided into groups of properties. However, these groups of properties do not necessarily represent a property set as defined in ISO 16739-1 [23]. The prefix 'PSet_' is reserved for the official IFC and not the bSDDs [23].

3 Methodology and Framework

In order to force more sustainable construction methods and increased circularity, the approach shown in Figure 1 is pursued. First, the information requirements for BIM models are investigated and a modeling guideline is developed on this basis. This incorporates the existing requirements of LCA software manufacturers as well as open approaches. This is the aim of this work. With the help of these modeling requirements, BIM models can be enriched with the necessary information. The result is a collection of existing planning alternatives that can be stored as expert knowledge. If this expert knowledge is incorporated into building planning in the form of a software tool, greater sustainability and circularity can be achieved by considering suitable planning alternatives.

The proposed solution is the creation of an IDS with which the information requirements for the IFC model for an LCA can be checked at any point in the planning process. This is a rule-based approach. The proposed workflow with the IDS is shown in Figure 2:

The IFC model can be checked at any time during planning using the IDS to ensure that it contains all the information required by the LCA software (1). The IFC model is then transferred to the LCA software (2). This could also use the IDS to check whether all the required information has been transferred (3). However, the LCA software analysed already has its own functions for checking whether all the required information is available. Depending on the

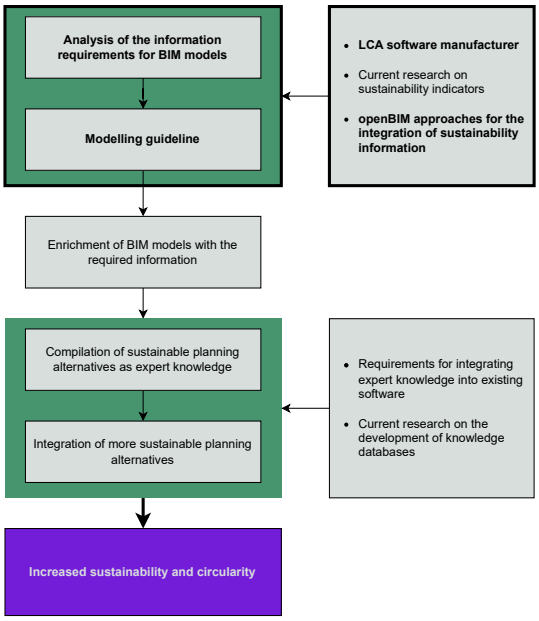

Figure 1. Schematic representation of the overarching research method

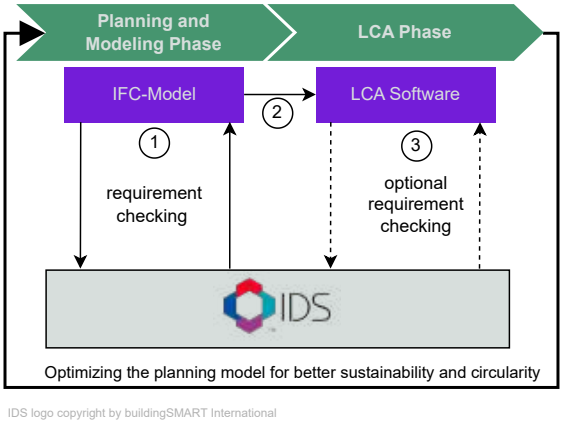

Figure 2. Schematic representation of the proposed workflow for sustainable building planning

assessment by the LCA tool, the design can then be improved in terms of sustainability and circularity. Although Concular and Madaster support both IFC2x3 and IFC4, the IDS created was designed for the current IFC4x3 version, as the different versions each have alternative requirements and no redundant IDS should be set up.

4 Implementation

We implemented a generalized IDS, which combines two proprietary solutions (custom PSets) with open approaches (bSDDs). As described in the methodology and related work above, there are various approaches to carrying out LCA. This paper analyzes the requirements of two distinct software solutions which, according to the DGNB's assessment [12], offer a wide range of functions compared to alternatives. However, despite functioning proprietary solutions, the aim is to map all functions using an open solution.

In Figure 3, the idea of the standardization procedure is shown: The two software solutions of Madaster and Concular and two open bSDDs are combined in an IDS. The bSDD dataset *Decommissioning and Reuse (DOR)* by Akbarieh [24] and the dataset *Circularity* by Al-Qazzaz [25] were used as open solutions. It should be noted that the latter is currently a preview version (as of March 2025).

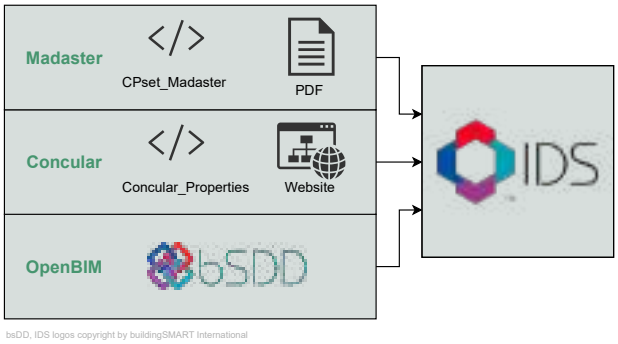

Figure 3. Schematic representation of merging the custom PSets with the *DOR* and the *Circularity* bSDD

Madaster offers a modeling guide in PDF format for preparing IFC models for their LCA platform [26]. The modeling guide contains detailed tables of all property names of their custom PSet. The main disadvantage of a formatted PDF modeling guideline to an IDS is that it is not machine-readable, so there could be some typos included, for example, a false space or a line break. Concular offers their modeling guide on their website [27]. There could be mistakes caused to display errors in the browser or similar. Therefore, all of the property names must be reviewed before transferring them to the IDS.

The respective PSets are also available for download for various BIM software, such as Revit and ArchiCAD [28, 29]. However, the verification of the model to ensure that all information required for the LCA, depending on the specific LCA solution used, is present, takes place within the respective LCA software. Using IDS, this verification can occur without access to the LCA software, allowing it to be integrated into the workflow during the modeling phase and supporting the open BIM approach. This ensures that the planning model being transferred directly meets all requirements, eliminating the need for multiple iterative model adjustments due to missing information.

4.1 Implemented Properties and PSets

For this IDS, parameters of different origins were initially selected to illustrate the standardization approach. The custom PSets of the LCA solutions from Concular and Madaster were selected as well as the mentioned two bSDDs. From these PSets and the bSDDs, parameters were selected that are suitable for describing the reuse case of solid building elements. It is clear from Table 1 that the four approaches partly describe similar element properties, although the property names differ.

4.2 Procedure for Creating the IDS

The IDS was implemented using the IDS web editor by LastBIM [30] as shown in Figure 4.

The main problem in the formulation of a generally valid IDS, in which several approaches are harmonized and which is to check whether the necessary information is available at all elements, is the 'applicability' of the IDS. This must be defined for each requirement. The first significant issue is that only one entity can be employed as applicability (see IDS standard according to buildingSMART [31]). As a result, alternative elements

Figure 4. Setting up the IDS with the LastBIM IDS editor [30]

cannot be evaluated, and it must be explicitly clear which elements are present in the IFC model under examination to ensure that the requirement rules are applied precisely to these elements. Another challenge is that abstract IFC classes, which do not have instances themselves but only contain other classes, cannot be checked by the current IDS standard v1.0. This limitation makes it difficult to design the IDS to be as universally applicable as possible.

Therefore, the following approach is used, as shown in Figure 5: First, the IDS was created as shown in Figure 4. The requirements were formulated in general terms and no applicabilities were defined yet. The rules should be applied to all components. The entities for which these rules are to be applied were taken from the IFC documentation as a list [18]. A Python script was then used to manipulate the IDS document in XML format in order to duplicate the requirements, which were only available in one specification and only applied to the placeholder entity, into several new specifications and assign an entity from the list of instantiable entities in the IFC schema to each specification. The newly created IDS is, therefore, the basis for the model check and contains the properties shown in Table 1, which originate from Concular, Madaster, and the bSDDs.

5 Validation

Two existing IFC building models were used to validate the developed IDS. One is a residential building provided by the Institute for Automation and Applied Informatics (IAI) at Karlsruhe Institute of Technology (KIT) [32] as an IFC4 test file, and the other is an office building belonging to the Ruhr University Bochum (RUB). The IDS is validated in the open-source software Blender with these two models, as shown in Figure 6. Blender [33] is known as a 3D-modeling software with roots in video production and special effects. In Blender, the BIM-add-on Bonsai [34]

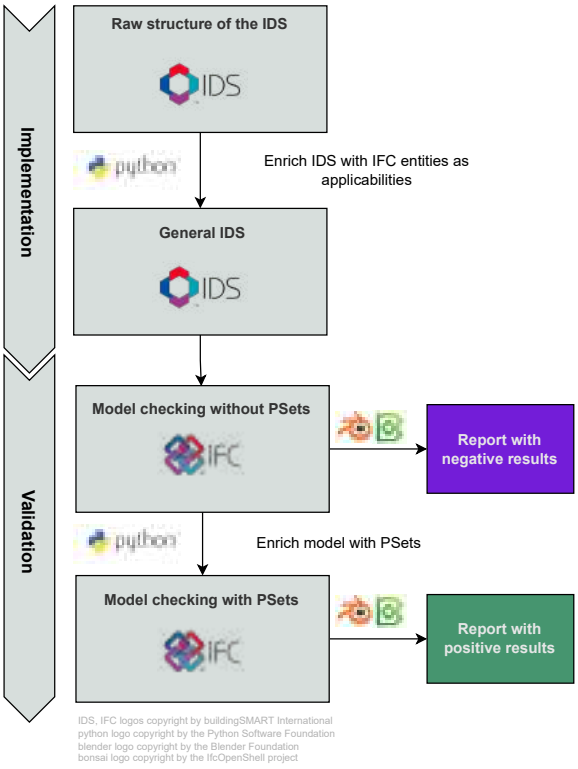

Figure 5. IDS creation and validation workflow

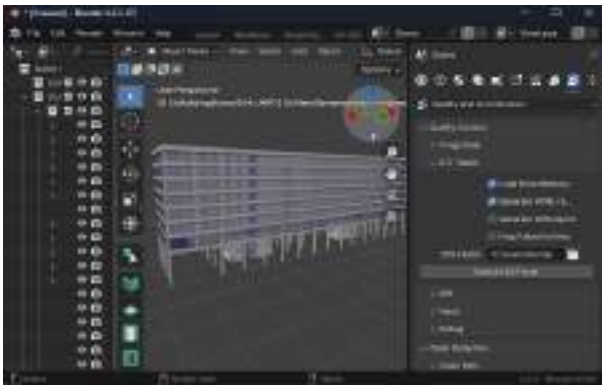

Figure 6. Validation of the IFC model of the RUB office building via Blender and the add-on Bonsai; screenshot of [33], [34]

is used to ensure the open BIM approach and check IDS requirements. An advantage of Bonsai is, that it is based on IfcOpenShell, so it works with native IFC and does not convert it to a proprietary format. The software generates a report after validation, which outlines which requirements are met or violated. This makes it possible to validate that the IDS is working properly. First, the models are checked in which the required PSets and bSDDs are not annotated. This control check, therefore, only resulted in unfulfilled requirements and thus in a negative report (see Figure 5).

Second, both IFC models were edited, and the properties were filled in accordingly with IfcOpenShell [35]. The focus was not on plausible values from an engineering perspective but only on ensuring that all properties were assigned a value. During the audit of the model enriched with sustainability information, the IDS audit rules were fulfilled, and positive results were reported by the IDS checker in Blender. This indicates that the PSets entered were accurately reported as present by the IDS. The IDS model checker displays the results in the program window and generates an HTML report, as well as a detailed ODS report. Based on the entities employed as applicabilities and the selection of PSets implemented (see Table 1), the IDS generated 889 specifications in which a total of 4,318 requirements were checked. Subsequent to this, 2,788 checks were conducted for the IAI building and 497,896 checks for the RUB office building due to the higher number of applicable building elements.

Overall, the IDS standard, as a recently developed standard, necessitates further refinement to ensure its more robust establishment. In this paper, the absence of reference from abstract classes to subordinate classes was of particular significance, as numerous component properties pertaining to reuse must be queried for nearly all solid components. Fischer et al. [36] have previously identified the absence of a reference to related elements, and Kremer and Beetz [37] have demonstrated the integration of geometric and topological checks with semantic information checks, for example, in the simulation of building energy models. The solution provided by the Python script for generalizing the information requirements in this paper could be replaced by a more advanced IDS standard in the long term.

6 Conclusion and Outlook

This paper has reviewed current practices in information requirements management for LCA and circularity assessment and proposed a unified method using IDS. A prototype IDS has been developed and demonstrated to meet the specified requirements for an accurate life cycle assessment for buildings. The proposed method can be utilized in an open BIM environment to ascertain the presence of the requisite LCA data within the IFC model.

The proposed workflow, which involves the implementation of an IDS to verify the requirements stemming from LCA for an IFC model, is thus proven to be a rational approach. However, the current IDS standard v1.0 has applicability limitations that required the use of the Python script to create it. Given the highly diverse requirements and the varying designations of the same model properties across different software, the creation of a universal IDS for LCA necessitates either the standardization of the LCA software solutions to function with the same PSets or an extensive compilation of all prevalent PSets. The latter option is less practical in application, as software manufacturers can continuously evolve their PSets, resulting in the IDS becoming obsolete rapidly. In this regard, software manufacturers could consider the option of automated creation or updating of an IDS. Achieving the greatest conformity with the open BIM working method could be achieved by several participants agreeing on a common bSDD, which is further developed and could be based, among other things, on the four originating sources analyzed. A potential avenue for advancement could be the generalization of the requirements, accompanied by the incorporation of informative reuse data, which could be a by-product in the form of an updated IDS of the CLUE research project. For further validation, a larger study with additional IFC models would be necessary so that all IFC entities used as applicability are validated. The next step is to develop a design-for-reuse, that can be validated using the IDS and assessed for optimizing the reusability potential of a structure.

Abstract –
In recent years, there has been an increasing focus on adopting circular approaches within the construction sector, particularly reusing building components in new projects. Facilitating design for reuse can significantly expand the scope of deconstruction and reuse efforts. Unlike conventional structural design, which assumes an unlimited supply of standardized components and follows a straightforward process of geometric design, structural analysis, and member sizing, reusing structural components introduces unique challenges. With limited component availability, conventional design methods often fall short, leading to time-consuming trial-and-error processes or non-viable solutions. Despite growing interest, research in this area remains limited, focusing primarily on isolated criteria like minimizing material waste or embodied energy, without offering a comprehensive framework that balances environmental and economic considerations. Additionally, conventional approaches rely on traditional mathematical optimization methods, restricting the exploration of complex design spaces. To address these challenges, this research proposes a novel optimization framework that leverages generative design using genetic algorithms to streamline the design of steel structures with reused components. The framework uses the Non-Dominated Sorting Genetic Algorithm II to refine the geometry and topology of steel structures, minimizing environmental impacts and costs. A case study on optimizing a steel truss design using reused components demonstrates the framework's effectiveness.

Keywords –
Optimization; Steel Structures; Reuse; Generative Design; Circular Construction

1 Introduction

In recent decades, global population growth, urbanization, and industrialization have triggered significant environmental challenges, including global warming, resource depletion, and pollution in air, water, and soil. The construction, renovation, and demolition sector has emerged as a major contributor to these issues. This sector is a major energy consumer and greenhouse gas emitter, contributing nearly 30% to global energy usage and one-third of greenhouse gas emissions [1]. Consequently, construction industry has become a focal point in global sustainability initiatives, pivoting towards innovative approaches grounded in the principles of the circular economy.

Circular construction aims to minimize environmental impacts through the principles of reducing, reusing, recycling, and recovering building components throughout the entire lifecycle [2]. The focus is on strategies that keep materials in use, reducing the need for new resource extraction, energy consumption, and CO_2 emissions [3, 4]. This can occur either through extending the service life of a building, or the reuse and recycling of building components at the end of their service life. Reuse is a more valuable option than recycling because it preserves existing components, giving them a new life and adding value. Reusing building components also reduces energy and embodied carbon more effectively than recycling, as reuse typically requires only minor modifications for the components to be incorporated into new structures. This approach aligns with circular economy practices in construction by emphasizing the importance of retaining and repurposing components to minimize waste and maximize resource efficiency [5–7]. In contrast, recycling typically involves breaking down the product or component into secondary materials, resulting in a loss of quality, value, and energy [3, 8].

Among the four stages of the building life cycle—production, construction process, use, and end of life—the first stage (i.e., production), which includes raw

material supply, transport, and manufacturing, can account for up to 50% of total embodied impacts [9]. Therefore, structural engineers can make the most significant reductions in embodied impacts by focusing on designing with reclaimed components [10]. Also, according to Webster [11], load-bearing structures contribute 20-70% of a building's embodied impacts, depending on factors like building type, size, and used components. By incorporating reused primary components into the design of load-bearing structures, structural designers can further reduce embodied impacts [10, 12]. This is particularly important for steel components, where reuse significantly lowers embodied carbon by avoiding the energy-intensive production of steel components made of virgin or recycled steel. Brütting et al. [13] demonstrated the efficacy of this approach in a real-world application, designing the truss for the main station roof in Lausanne using reclaimed components from electric pylons, resulting in a 63% reduction in embodied energy compared to newly fabricated components.

However, reuse is not yet widely considered in the architecture, engineering and construction field. For instance, stakeholders in construction projects often avoid reuse due to economic uncertainties [14, 15]. Designers are also concerned that the use of reusable components, which are often limited in shape and quantity, could complicate the design process [14, 16]. Additionally, the lack of accessible information on available reusable components poses a significant challenge [14, 15, 17]. The primary goal of this research is to develop a comprehensive optimization framework that uses advanced computational methods to streamline the design of steel structures with reused components. By utilizing generative design, the framework will address challenges related to designing with components with limited availability while minimizing cost and environmental impacts.

2 Literature Review

2.1 Optimization of Structures Made from Reused Components

Brütting et al. [13] introduced a novel framework for designing truss systems using reused components. Their approach formulates the problem as a mixed-integer linear programming (MILP) model to minimize mass and cut-off waste, while meeting structural safety and serviceability requirements. The framework begins by defining a stock of reusable components characterized by their material properties, geometric attributes, lengths, and available quantities. Through discrete structural optimization, the proposed framework iteratively optimizes the topology and geometry of the truss to align with the available stock. Structural constraints, such as equilibrium, stress, and serviceability, are integrated to ensure compliance with performance standards. A two-step process is employed, first solving the assignment problem to allocate stock components optimally and then adjusting the geometry to reduce cut-off waste. Brütting et al. [13] expanded their work to propose a *kit-of-parts* approach, enabling the reuse of components across multiple structural configurations. This method integrates two optimization problems: one for assigning stock components to predefined layouts and another for designing a shared stock inventory. The iterative process optimizes both individual structures and the shared inventory to reduce waste and minimize unique component requirements. De Boer [10] further advanced the optimization of reusable structures by incorporating connection design into the process. Recognizing the importance of connections for enabling reuse, the study developed a parametric design tool using Grasshopper for Rhino to automate the design process. By integrating connection length as a variable, the methodology optimizes both structural layouts and bolted steel connections.

2.2 Using Generative Design for Structural Design and Reuse

The complexity of optimizing structures for reuse, especially when dealing with diverse components, has made traditional design and optimization methods impractical. In other words, if the types of reusable components vary or large quantities of components are needed, the large number of alternatives will make it impossible to find the optimal solution using traditional design methods. Therefore, a metaheuristic approach is necessary to tackle such complex problems [18]. One effective metaheuristic approach is generative design, which generates, evaluates, and selects multiple potential solutions based on their effectiveness. This approach often relies on genetic algorithms (GAs) for optimization. GAs are powerful tools that have gained attention in structural design and other engineering domains due to their ability to solve complex optimization problems [18]. As defined by Koza [19], a GA is a sequence of mathematical operations that transforms individual objects within a population into a new population by selecting a subset based on fitness criteria. This process mimics natural selection, where the fittest individuals are chosen to pass on their traits to the next generation. GAs are particularly effective in solving problems with discrete variables, such as the selection of structural components, and are valuable for exploring optimal combinations of structural components under specific constraints in vast solution spaces [20].

Building on the capabilities of generative design and GAs, Kim & Kim [18] explored the structural reuse in modular

construction with a novel method that leverages GAs to minimize both CO_2 emissions and costs. Their study focuses on noise barrier tunnel (NBT) construction. NBTs are modular structures installed along highways or railways to reduce noise pollution. The research integrates Building Information Modelling (BIM) with a multi-objective optimization framework using Non-Dominated Sorting Genetic Algorithm II (NSGA-II). The process begins with a BIM model providing detailed attributes of reusable components, such as shape, length, cross-sectional properties, curvature, and remaining life. This data forms the foundation for optimization, aligning the reuse strategy with structural and environmental constraints. Also, Van Marcke et al. [21] introduced a framework that leverages GAs to optimize the reuse of partially disassembled triangular components from steel trusses. Unlike previous approaches, which emphasized full disassembly and reuse at the component level, this method minimizes the labour-intensive and costly aspects of complete disassembly by leveraging partially intact structural components. The methodology consists of two main components: an aggregation engine for generating initial truss designs and a GA for optimizing these designs. The aggregation engine arranges reclaimed triangular subassemblies row by row to fit the desired truss geometry, allowing for cutting or the addition of new components when necessary. Once an initial design is created, the GA optimizes it by minimizing the total length of new components and reducing the amount of cutting required for reclaimed components.

2.3 Research Gaps

Existing research on structural design optimization with reused components has made valuable contributions but remains limited in scope. Most studies focus on specific criteria, such as minimizing material waste, reducing embodied energy, or optimizing connections, without providing a comprehensive framework that integrates environmental sustainability, economic efficiency, and the maximization of reused components. Moreover, many approaches rely on traditional optimization methods, which restrict the exploration of complex design spaces.

To address these gaps, this research introduces a framework that leverages generative design to explore a broader range of criteria. By considering material waste, energy consumption, CO_2 emission, and cost as a weighted multi-objective optimization problem, the framework achieves a balance between environmental and economic considerations.

3 Proposed Framework

As shown in Figure 1, the proposed framework employs a seven-step computational approach to optimize the geometry and topology of steel structures by reusing predefined stock components, with a focus on minimizing cut-off waste, cost, energy and CO_2 emission. This framework systematically integrates reusable components while ensuring structural integrity and economic feasibility. The process begins with designing an initial structure (topology and geometry) using new components to ensure feasibility, followed by an iterative process of replacing them with suitable reusable components. Each design alternative is generated and evaluated using GA. The key steps are outlined as follows:

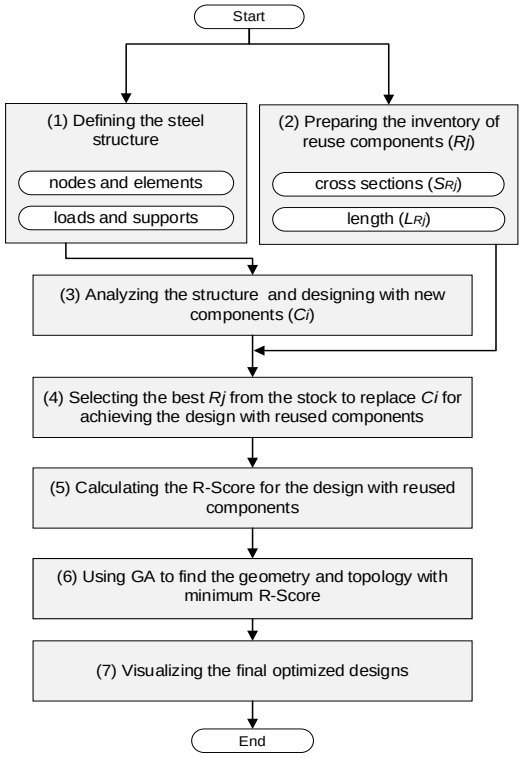

Figure 1. Proposed Framework

(1) Defining the steel structure by specifying its geometry and topology, including nodes and components, along with boundary conditions such as supports and applied loads, to ensure the design accounts for all relevant factors. This step provides a clear starting point for the optimization process.

(2) Preparing an inventory of reusable components ($\boldsymbol{R_j}$) based on their dimensions and properties, including lengths L_{R_j} and cross-sections S_{R_j}, which provides the required data to match components

(3) Analysing the structure to evaluate its performance under specified conditions from Step 1 and **designing the**

initial structure by assigning new components (C_i), which provides a baseline for comparison when incorporating reused components.

(4) Selecting the best match from reused components. This step involves replacing each initial design component C_i with a reusable component R_j from the inventory. The process compares the initial assigned components C_i with inventory components based on two key properties: length and cross section. For R_j to be suitable for C_i, it must meet the following conditions:

$$Match\,(C_i,\,R_j) = \begin{cases} 1 \;\; if\; L_{R_j} \geq L_{C_i}\; and\; S_{R_j} \geq S_{C_i} \\ 0 \;\; otherwise \end{cases} \quad (1)$$

where L_{R_j} and L_{C_i} are the lengths of the inventory component R_j and the design component C_i, respectively; S_{R_j} and S_{C_i} are the cross-sections of the inventory component R_j and the design component C_i, respectively.

After identifying all suitable matches, each initial design component C_i is replaced with the best match from the inventory. The best match, R_j, is the component that is closest in length (L_{R_j}) and cross-section (S_{R_j}) to C_i. If no suitable R_j is available in the inventory, a new component N_i is used to fulfil the requirements of the initial design component C_i.

This approach ensures that the final design uses the lightest and most appropriate reusable components, maximizing material efficiency, while ensuring feasibility and structural performance are not compromised.

(5) Evaluating each design by calculating a Reuse Score (R-Score), which integrates energy consumption (E), CO_2 emissions (G), cost (C), and material waste (W). This provides a quantitative method for comparing different designs, not only minimizing the cost but also environmental impact indicators.

Each parameter is derived from the specific characteristics of *n* new and *m* reused components within the design. As part of this process, a Life Cycle Assessment (LCA) is conducted to evaluate CO_2 emissions and energy consumption. The LCA focuses on a part of the lifecycle of components, beginning with their supply and ending with their transport to the site. Construction-related energy consumptions, CO_2 emissions, and costs are excluded, as they are identical for all reuse-based designs. The detailed steps for these calculations are outlined below:

- **Energy Consumption (E):** The energy consumption for *n* new components (E_N) includes production and transportation:

$$E_N = \sum_{i=1}^{n} \left(E_{product(N_i)} + E_{transport(N_i)} \right) \quad (2)$$

The energy consumption for *m* reused components (E_R) includes deconstruction, modification, and transportation:

$$E_R = \sum_{j=1}^{m} \left(E_{decon.(R_j)} + E_{modify(R_j)} + E_{transport(R_j)} \right) \quad (3)$$

The total energy consumption (E_T) for the design is:

$$E_T = E_N + E_R \quad (4)$$

- **CO_2 Emissions (G):** The total CO_2 emissions are calculated similarly to energy consumption:

$$G_N = \sum_{i=1}^{n} \left(G_{product(N_i)} + G_{transport(N_i)} \right) \quad (5)$$

$$G_R = \sum_{j=1}^{m} \left(G_{decon.(R_j)} + G_{modify(R_j)} + G_{transport(R_j)} \right)$$

$$G_T = G_N + G_R \quad (7)$$

- **Cost (C):** The total cost is calculated by summing the production and transportation costs of new components, as well as the deconstruction, modification, and transportation costs of reused components.

$$C_N = \sum_{i=1}^{n} \left(C_{product(N_i)} + C_{transport(N_i)} \right) \quad (8)$$

$$C_R = \sum_{j=1}^{m} \left(C_{decon.(R_j)} + C_{modify(R_j)} + C_{transport(R_j)} \right) \quad (9)$$

$$C_T = C_N + C_R \quad (10)$$

- **Waste (W):** Material cut-off waste is calculated as the total mass (M) of excess material removed from reused components:

$$W = \sum_{j=1}^{m} \left(M_{R_j} - M_{C_j} \right) \quad (11)$$

- **R-Score:** The R-Score is computed as a weighted sum of these four parameters:

$$RS = \alpha \times E_T + \beta \times G_T + \gamma \times C_T + \delta \times W \quad (12)$$

where $\alpha, \beta, \gamma, \delta$ are weights assigned based on project priorities, satisfying:

$$\alpha + \beta + \gamma + \delta = 1 \quad (13)$$

(6) Implementing GA for minimizing the R-Score, balancing components cut-off waste, environmental impact and cost by exploring a wide range of design possibilities. The optimization process utilizes NSGA-II to explore various design alternatives, applying genetic operators such as crossover and mutation to iteratively refine solutions. The key steps include **(a) Generating initial designs** to form the population of alternatives; **(b) Calculating fitness value** by evaluating the R-Score, where designs with lower waste, energy use, CO_2

emissions, and cost achieve a higher fitness value; **(c) Applying genetic operations**, such as crossover and mutation, to create new design alternatives; and **(d) Iteratively refining the geometry and topology** to minimize environmental impact and cost.

For each design alternative, steps 1, 3, 4, and 5 of the proposed framework are repeated to ensure that the optimization process considers all relevant factors and continuously improves the design until the most efficient and sustainable solution is identified.

(7) Visualizing the final optimized design with the highest fitness value, which allows designers to better understand the structural configurations, as well as their cost and environmental impact, leading to better decision-making.

4 Implementation and Case Study

To demonstrate the practical application of the proposed framework, a case study was conducted using Grasshopper [23] and Rhinoceros [24] to optimize the topology and geometry of a 10-meter-long two-dimensional Warren steel truss.

Grasshopper, a visual programming tool within Rhinoceros3D CAD, was selected for its parametric modelling and generative design capabilities. This tool is widely used by architects and engineers for algorithm-driven design through graphical elements. Additionally, the study integrates plugins such as Karamba [25] for structural analysis and Galapagos [26] for GA optimization. The implementation process consists of the following steps of the proposed framework:

(1) Defining the steel structure: The first step involved modelling the truss geometry and topology (Figure 2) in Grasshopper by defining its nodes, elements, and structural boundary conditions, including loads and supports. A Warren truss configuration with verticals was selected, with a fixed overall span of 10 meters and three bays, with a 5 kN load applied along the lower chord nodes. To explore design flexibility, the allowable movement of the upper chord nodes (0, 2, 4, 6) was constrained to ±0.80 meters in both horizontal and vertical directions as shown in Figure 2. Additionally, to ensure the generated design alternatives remain practical, symmetry constraints were applied to upper nodes so that nodes 0 and 6, as well as nodes 2 and 4, move together. The truss height was set at 2 meters, adjustable within a range of 1.2 meters to a maximum of 2.8 meters. Furthermore, the horizontal positions of nodes 0 and 6 were further restricted to +0.8 meters and -0.8 meters, respectively, so that the length of the upper cord will not exceed 10 meters. In addition to geometry, six different topology configurations, defining how nodes are connected, were incorporated to explore alternative structural layouts. These constraints were integrated as adjustable sliders to explore different design alternatives.

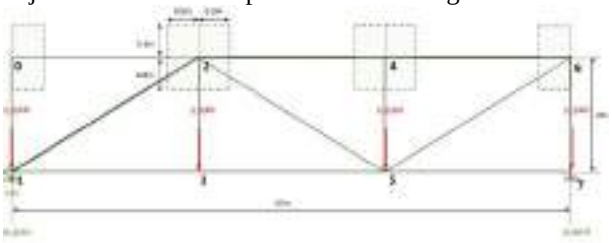

Figure 2. Modelling the geometry of the truss

(2) Preparing the inventory of reusable components: An inventory of reusable steel components (Figure 3) was prepared, consisting of circular hollow sections (CHS) selected from the EN 10219 standards. The cross-sections and lengths of the inventory components were chosen to ensure they are not too large, which would waste material without structural benefits, or too small, which would not properly replace the initial design components. All steel bars are assumed to have a yield strength of 235 MPa, a Young's modulus of 210 GPa, and a density of 7,850 kg/m³. The inventory specifies the types, quantities, and lengths of the available components, ensuring compatibility with the design optimization process.

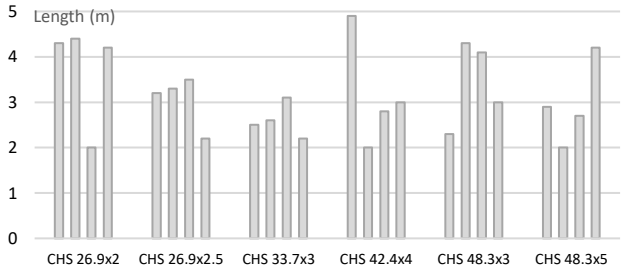

Figure 3. Inventory of reusable components

(3) Analysing the structure and designing with new components: The *Assemble Model* component in the *Karamba* plugin was used to prepare the truss model for structural analysis. This process included defining the cross-section library, loads, joints, and supports. The structural performance of the initial design was then assessed to ensure it met the criteria for stress, displacement, and buckling constraints in accordance with Eurocode 3 (EN 1993-1-1). To achieve this, the *Karamba CroSec Optimizer* was used to determine the lightest cross-sections that satisfied the structural performance requirements while considering stress limits, displacement constraints, and local buckling checks. Specifically, the maximum axial stress in any truss element was limited to 0.9 × yield strength (235 MPa) to maintain a safety margin, while the maximum vertical deflection of any upper chord node was restricted to $L/250$ (e.g., 40 mm for a 10 m span) to comply with serviceability criteria. Additionally, local buckling

checks were incorporated to prevent instability in slender elements.

(4) Selecting the best match from inventory: To incorporate reusable components into the design, each truss components of the design were compared to the available inventory based on two key properties: length and cross-section area. For a component from the inventory to be a suitable replacement, its length had to be equal to or greater than the required length of the design component, and its cross-section area had to meet or exceed the design requirements. Among the suitable options, the component closest in length and cross-section was chosen. If no matching component was found in the inventory, a new steel component was introduced to meet the design specifications.

(5) Calculating the R-Score for the design with reused components: The evaluation of each truss design alternative is conducted by calculating the R-Score, as described in Section 3.

To simplify the analysis, the environmental impacts from modifications are considered negligible. Only components incorporated into the final structure contribute to environmental impacts, as leftover materials are assumed to be reused elsewhere. For new components, it is assumed that they are produced to exact lengths, resulting in no additional waste.

The energy consumption in MJ/Kg and CO_2 emissions in $kgCO2\ eq/Kg$ for a new component, with a transport distance of 70 km are:

$$E_N = 13.227\ M_{N_i} \quad (16)$$

$$G_N = 0.925\ M_{N_i} \quad (17)$$

where M_{N_i} is the mass of the new component. The energy consumption and CO_2 emissions of a reused component are calculated using the following equations, based on transport distances of 200 km [12]:

$$E_R = 3.245\ M_{R_j} + 3.235\ \Delta M_{R_j} \quad (14)$$

$$G_R = 0.277\ M_{R_j} + 0.276\ \Delta M_{R_j} \quad (15)$$

where M_{R_j} and ΔM_{R_j} are the masses of the reused component and the material waste from cutting it, respectively.

The cost estimation for a new component of the truss is calculated by multiplying the unit costs, as shown in Table 1, by its mass (Eq. 18). The cost estimation for the reused components is calculated in a similar way, but it considers both the mass of the uncut component and the cut-off part, as shown in Eq. 19. It is assumed that components are transported between locations at a speed of 40 km/h using a 25-ton truck. The unit cost for purchasing new CHS components is assumed to be 1.25 USD/kg [27], and for this study, the unit cost of reused components is assumed to be half that of new components (i.e., 0.625 USD/kg), and the cut-off waste is assumed to be sold as scrap steel. Consequently, the total costs for new and reused components are estimated using the following equations:

$$C_N = 1.256\ M_{N_i} \quad (18)$$

$$C_R = 1.313\ (M_{R_j} + \Delta M_{R_j}) - 0.325\ \Delta M_{R_j} \quad (19)$$

Table 1. Cost estimation assumptions [18, 22, 27]

Component type	Work	Unit price (US$/kg)
Reuse	Deconstruction	0.383
	Purchase	0.625
	Modification	0.289
	Transportation (200 km)	0.016
	Scrap steel sales	0.325
New	Purchase	1.250
	Transportation (70 km)	0.006

Also, material waste for each design alternative in the case study is calculated based on the material cut-off during the modification process, as mention in Section 3.

For calculating the R-Score, since all factors in this case study are considered equally important, a uniform weighting of 0.25 is applied to each factor (i.e. $\alpha = \beta = \gamma = \delta = 0.25$).

(6) Using GA to find the geometry with minimum R-Score: The Galapagos solver in Grasshopper was then used for generative design to optimize the truss's geometry and topology. Galapagos iteratively refined the design by exploring different configurations of variables (nodes' position and connection) to minimize the R-Score while ensuring structural performance. The GA was tested with two different population sizes of 20 and 50 individuals, both using an elitism ratio of 5%, where the top-performing individuals were carried forward to the next generation. The search space consisted of both discrete and continuous variables, including continuous adjustments in node positions, six discrete topological configurations, and discrete inventory component replacements using a combination of new and reused components. The termination criterion was set to stop the optimization when the improvement in the R-Score is below 1% over 5 consecutive generations. As shown in Figure 4, the GA with a population size of 50 (P50) achieved a lower final R-Score compared to the population size of 20 (P20). The process for the P50 case stopped after 32 generations and took a total of 68 minutes and 17 seconds, including 5 minutes and 28 seconds for the initial design phase.

(7) Visualizing the final optimized truss and results: The final optimized design was visualized in Rhinoceros3D, with detailed structural analysis performed using *Karamba*. Figure 5 shows the final optimized design, which includes 13 reused and 0 new

components. Table 2 compares the criteria considered in this design with those of the initial design, which has the same geometry but uses only new components. The final design reduced energy consumption and CO_2 emissions by approximately 64% and 56%, respectively, while increasing the cost by about 47%. These results show that incorporating reused components in the design can have significant positive environmental impacts that could justify the increase in the cost.

Table 2. Comparing the initial and final designs

Criteria	Initial design	Final design	Change (%)
Energy (MJ)	958.61	589.31	63.73 ↓
CO_2 ($kgCO2\ eq$)	66.78	45.08	55.56 ↓
Cost ($US\$$)	90.68	128.99	-47.24 ↑
Weight (kg)	55.03	62.93	-14.35↑

5 Conclusions and Future Work

This paper proposed a framework using generative design to streamline the design process of steel structures with reused components. It introduces a systematic seven-step framework, leveraging the NSGA-II to iteratively refine structural geometry and topology, enabling efficient matching of limited sets of stock components to the desired design. This framework is able to minimize cut-off waste, energy consumption, and CO2 emissions, highlighting its potential for sustainable design practices aligned with circular economy principles and evolving sustainability regulations. Additionally, it enhances the financial viability of structural reuse by reducing costs in two key areas: (1) material procurement by utilizing existing components instead of new ones and (2) waste management by lowering disposal and handling costs. By demonstrating that reuse can be both environmentally responsible and economically feasible, this study contributes to the broader adoption of sustainable structural design practices.

While the proposed framework offers significant advancements, the case study introduced several simplified assumptions when calculating the R-Score. Future research should aim to improve the framework to enhance the R-Score by incorporating additional criteria and utilizing Pareto optimization. Furthermore, future work would benefit from integrating material passports and Environmental Product Declarations (EPDs) to provide more comprehensive data on the sustainability and lifecycle impacts of reuse. To further validate the framework's robustness, future research will also extend its application to seismic and wind load considerations, ensuring its suitability for a broader range of structural conditions. Additionally, the framework will be applied to three-dimensional space trusses, allowing for a more complex and realistic evaluation of its effectiveness in optimizing material reuse.

Abstract –

The construction industry (CI) is widely recognized for its inherent reluctance to adopt new digital tools, largely due to less than optimum user interface and user-centered functionalities compared to other sectors. Poorly designed software tools that fail to consider users' needs, such as ease of use, adaptability, and intuitive learning experiences face limited acceptance. Despite this understanding, few studies have reviewed user-oriented capabilities in software tools for the construction industry, particularly those designed for circular economy applications, resulting in tools with fragmented functionalities. This qualitative study addresses this gap by identifying key user-centered requirements for circular economy (CE) software tools (STs), focusing on tools for material inventorying. A literature-based review is performed to develop an evaluation framework adapting the framework of life-cycle assessment (LCA) tools for early-design stages four themes: Input, Analysis, Output, and User Interface (UI) or User Experience (UX). Using this framework, four commercially available STs for material inventorying of built facilities were evaluated to understand their relevance to support CE practices. Results indicate that essential user requirements such as integration, decision-making support, adaptability, and interoperability with other CE technologies are largely unmet. Additionally, no comprehensive tool currently addresses performing financial analyses of various deconstruction techniques, and disposal choices. The proposed framework with user-centered criteria provides a valuable roadmap for developing user-friendly software tools, to advance circular economy practices. While the user-centered needs are defined based on literature, there is a necessity to assign an order of importance to these criteria from the perspective of industry stakeholders.

Keywords –

Deconstruction, Circular Economy, User-Centered Design, Evaluation Framework, Tool Review

1 Introduction

The construction industry significantly contributes to global solid waste. In Canada, the construction, renovation, and demolition (CRD) waste accounts for 12% (4 million tonnes) of Canada's total solid waste, with only about 16% diverted from landfills in 2010 [1]. Circular economy (CE) offers an effective solution to manage CRD waste by eliminating the end-of-life (EOL) phase of materials. CE aims to extend the materials and components lifespan in the built environment, maximizing their economic, environmental, and social value [2]. This is achieved through the direct reuse of materials and components from old structures as secondary resources in new construction [3].

Maximizing recovery of secondary resources requires understanding of material and component stock (MCS) composition of built facilities nearing EOL. This knowledge guides the selection of deconstruction techniques and their sequence, and in turn, influences the type of resources generated and second-life use decisions [4]. However, in legacy buildings, this data in the format of as-built documentation is often unavailable or incomplete [5], necessitating labour-intensive and non-scalable manual pre-demolition audits.

Demonstrating the potential secondary resources is necessary to shift stakeholders' perception from conventional demolition to selective demolition, if not deconstruction. However, most of the current research to simplify estimation of MCS composition and reduce manual efforts focuses on urban-scale and above, helping governments assess potential and formulate regulations for urban mining. They fall short in supporting other industry stakeholders, especially contractors and developers, who require MCS information at smaller spatial scales, preferably building level or lower [6].

With increasing recognition of the value of inventorying existing facilities [7], there is a need for

reliable, quick, accurate, and affordable software tools (STs) that estimates MCS of built facilities, effectively transferring frameworks devised in research to industry. Despite this pressing need, few STs exist and most lack practical functionalities, limiting their use to inform decision making.

Yet, a tool that only estimates the material and component stock may not be able to provide enough value to advance the idea of circular economy practices or get widely adopted by the industry users. If a tool does not follow needs-driven development or imposes labor-intensive workflows, adoption is unlikely [7]. For instance, a Dutch social housing organization generating material passports (MPs) for its building stock as a pilot project preferred a service provider that automated MP creation via artificial intelligence (AI) vision techniques over a provider's tool that made use of building information modelling (BIM) data and required manual input. The users in the latter case perceived MPs as just another task, rather than recognizing its underlying value [8]. This user perception reflects that even with identical outputs, tools that address user needs and minimize workload are favored.

Evaluating how well existing STs are designed to meet the needs of stakeholders is crucial, considering the wide recognition of the construction industry's (CI) inherent reluctance to adopt new digital tools [8]. This reluctance is often paired by less than optimum user interface (UI) and user-centered functionalities in CI compared to other sectors [9]. This understanding is essential for developing STs for fast quantity take-off (QTO) of built facilities, which are still in their infancy, that go beyond material stock estimation and account for other user-centered needs.

What are these user-centered design requirements that must be incorporated into software tools for fast QTO of built facilities to advance CE? This paper seeks to evaluate the technical features, and user-centered design requirements for such a tool by addressing the following specific objectives:

1. Understand user-centered requirements to increase a software tool's acceptance; and
2. Identify the capabilities and limitations of commercially available software that support automated QTO by assessing their alignment with the defined user-centered requirements.

2 Methods

This paper achieves its objectives in two steps. In first step, the criteria from existing studies on Life Cycle Assessment (LCA) tools for early design stages are utilised to establish user-centered design requirements of STs for automated QTO in the CE space. In second step, commercial software tools are identified and evaluated based on their features, shortcomings, and alignment with the defined criteria, providing insights for future ST development. The two steps are discussed in detail below.

To define user-centered requirements, criteria formulated by [10] -[12] to assess LCA tools for early design stages were taken as a starting point, see Figure 1. This is because these tools share the similar context: limited data availability on building geometry and materials during early design stages, and they aid users in decision-making of design choices. This parallels the requirements for STs for fast QTO of built facilities.

These criteria were refined and adapted to fit the specific nature of fast QTO for built facilities, through a review of articles on digital technologies for the circular economy, resulting in a revised framework with four themes: Input, Analysis, Output, and User Interface (UI) or User Experience (UX).

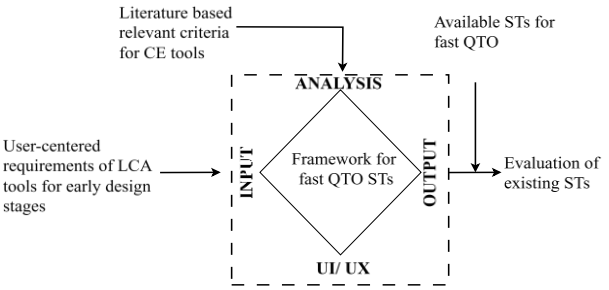

Figure 1. Methodology for framework development

The list of STs for automated QTO was compiled through a review of published and grey literature as well as an informal Google search. A keyword search using ("Software Tools" OR "Digital Tools") AND ("existing buildings" OR "building stock" OR "legacy buildings" OR "built environment") was conducted in "Scopus" and "Google Scholar" yielding many results. The search identified tools that are either proposed in research, existed as proprietary software, or function primarily as material inventory management software for recovered materials at a building's EoL. While these STs come under the broader CE context, they are either underdeveloped as research projects or unavailable for purchase or subscription, or lack core CE functionalities, making them unsuitable for this study's scope. To ensure relevance, the STs presented in this study are selected based on the following criteria:

- focus on built facilities (as opposed to new construction);
- generate material composition as a primary function or as part of other functionality, such as LCA;
- provide granularity at the building level or lower (i.e., building assemblies and subsystems);
- do not require detailed as-built drawings or 3D

digital models; and
- are not BIM software plugins or addons.

The selected STs were evaluated based on their software characteristics, purpose, data requirements, analysis mechanisms, output generation, and limitations, gathered from software websites, documentation, and literature. Subsequently, their alignment with the user-centered requirements was analysed.

3 Framework Development

Few studies analysed the essential functionalities required for software tools to promote a circular economy but have done so in a fragmented way. Rexfelt and Selvefors [7] provided a comprehensive review of circular design tools and their characteristics. Çetin et al. [8] and Yu et al. [9] identified barriers to adopting digital technologies for circularity in the built environment. Akinade et al. [13] outlined the essential technical functionalities for a BIM-based deconstruction tool to ensure wider acceptance. Relevant recommendations from these studies were used to revise and adapt original framework, LCA tools for early design stages, to suit the context of STs for fast quantity take-off of built facilities. These user-centered requirements are categorized into four key themes: Input, Analysis, Output, and UI/UX, and are summarized in Figure 2, with each theme represented by a distinct colour. These criteria are discussed in detail in the following subsections.

3.1 Input theme

In terms of inputs, the primary requirement is the integration of software tools into existing systems of users' organizations, with minimal need for new infrastructure or adjustments, and the ability to read information from existing databases. Additional requirements include limited data input, indicating the use of easy-to-access building characteristics or properties, and support for scalability.

3.2 Analysis theme

In the analysis theme, users favour transparency concerning the assumptions, equations, and thumb rules used to derive the material quantities [12], for a better understanding of a software tool's performance. Another key requirement is fast calculation, which in the current context implies minimal run time to generate results through reduced computational complexity and resource intensity. The tool's acceptance is also affected by its ability to support decision-making through the evaluation of alternative disposal choices, respective financial costs and returns [8], making the potential profits tangible.

Apart from the above, Kobylinska et al. [14] suggested that STs using machine learning to predict material quantities should include a pipeline in the system architecture for continuous training of machine learning (ML) models on the expanded dataset when certain preset criteria are met.

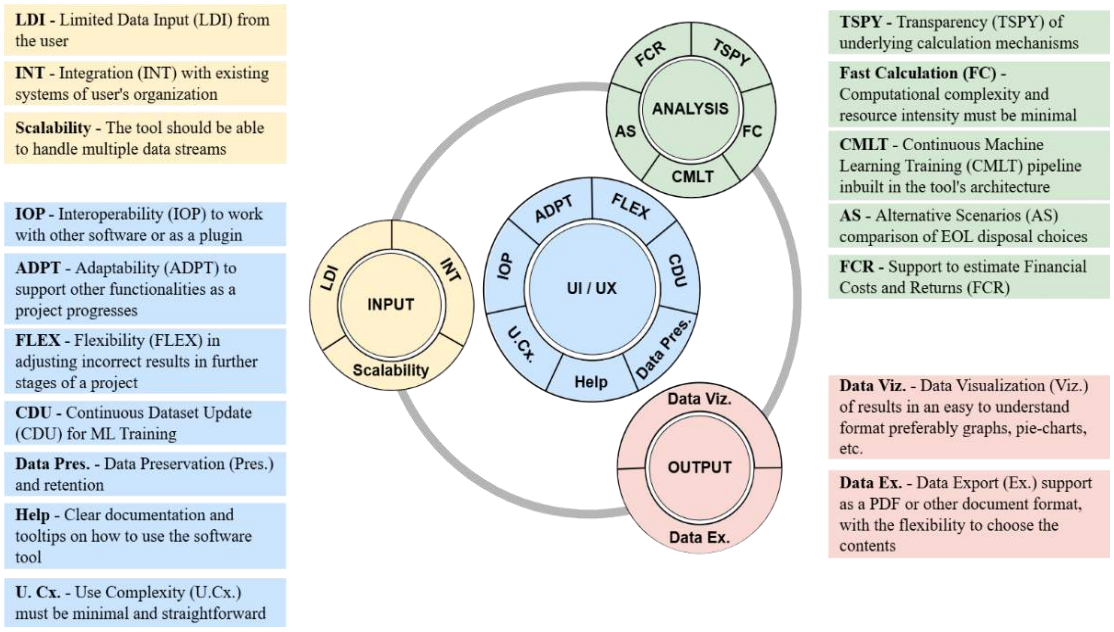

Figure 2. User-centered requirements for software tools

3.3 Output theme

The qualities favoured in the output theme include results presentation in visually appealing formats such as bar charts, pie-charts, etc., and the ability to generate reports in commonly used file formats for data sharing among stakeholders [12]. The tool should also allow users to query material quantities aggregated at the whole building level as well as by building systems and assemblies. Additionally, it should enable exporting the results in an open file format for use in other circular digital tools.

3.4 UI/ UX theme

Under this theme user-centered requirements, which are general, include ease of use and intuitive learning, floating tooltips, data preservation to prevent loss, and documentation for tool use and troubleshooting. Other characteristics preferred include interoperability, representing communicability with other software such as geographical information systems (GIS) to query geometrical information of a building, circularity indices, LCA, MPs, and digital marketplaces for secondary resources. These tools are being increasingly used in the construction industry to drive CE initiatives. The adaptability of a tool as the project advances into the next stages is another important requirement, which for the circular economy means support for deconstruction scheduling, in-built material passport generation, end-of-life LCA, etc. Since the material quantities generated by the STs are not always accurate, the tools should be flexible enough to allow users to modify quantities and specifications when inaccuracies are identified in later project stages.

4 Evaluation of Commercially Available Software Tools

To assess the extent to which the user-centered criteria were incorporated into commercial software, STs were identified and evaluated for alignment, with results provided below.

4.1 Existing Software Tools

Four software tools, with an overview provided in Table 1, were identified and selected after performing the search outlined in section 2: Demolition Waste Generation (DWG) Calculator for Metro Vancouver, EVALMETAB, Carbon Designer 3D add-on for One Click LCA, and the LCAbyg tool. Of the four tools, two tools focus on demolition waste, and the other two are designed for the whole building LCA.

DWG Calculator, Metro Vancouver is a web-based developed for the Vancouver Metropolitan Area, British Columbia to allow denizens to estimate the waste generated from residential demolitions [15]. The tool estimates the quantities of five materials, in kg (or) lb, using MICs based on gross floor area (GFA) and the municipality where the house is located.

EVALMETAB is a web-based tool, specific to France, that quantifies fourteen materials, in tons, based on GFA and covers 14 typologies of existing buildings and 12 typologies of new buildings. The tool allows users to visualize the materials generated from the demolition of old buildings and those required for new construction. It also supports the evaluation of various recycling scenarios, transportation cost estimation for waste disposal, and the associated greenhouse gas emissions [16], [17].

Carbon Designer 3D is a web-based add-on for the One Click LCA tool, originally designed for early design stages, generates predefined assemblies and corresponding material quantities of existing buildings to perform whole building LCA. The areas of predefined assemblies and material quantities are calculated based on parametric equations and thumb rules. Users start by selecting country-specific representative buildings from predefined types and input information regarding building characteristics to estimate the areas of assemblies aggregated by building systems [18], [19]. The tool allows users to modify the estimated quantities, assembly types, and material composition of the assemblies, and inventory is presented to the user in tabular format and carbon footprint as a heatmap on a 3D model of the building.

LCAbyg is a desktop-based building LCA tool for Danish buildings and features an automated material inventory functionality [20], [21]. The tool requires users to input information for eight variables, which are then used to calculate the quantities of predefined component layers of assemblies using predefined geometrical constants and parametric equations. At present, the tool provides automated inventorying of only one typology, masonry apartment – 1850 to 1920, and has the flexibility of allowing users to modify the generated results.

4.2 Discussion

The few software tools available in the market are not comprehensive and focus on demolition waste prediction at the whole building level for limited typologies or support whole building LCA rather than building material inventorying, falling short in supporting the circular economy for built facilities. Apart from technical functionalities, the available STs fall short in their lack of alignment with user-centered requirements.

Key user requirements, as outlined in Figure 3, missing from available tools include integration, decision-making support, adaptability, interoperability with other CE technologies, and enhanced data output

Table 1. Overview of software tools for automated inventorying of built facilities

	Tool name	DWGR Calculator	EVALMETAB	Carbon Designer 3D	LCAbyg
CHARACTERISTICS	Type	WebApp	WebApp	WebApp – add-on for OneClick LCA	Desktop Application
	Country	Canada	France	Europe, USA, Canada, and International	Denmark
	Release Date	July 2018[1]	June 2021	May 2022	October 2020
	Access	Open-Access	Open-Access	Paid	Open-Access
	Purpose	Demolition Waste	Material Flows and Demolition Waste	WBLCA	WBLCA
	Calculation Algorithm	MIC*	N.S. *	Geometrical and parametric equations, average ratios, and thumb rules	Geometrical and parametric equations
CAPABILITIES	Number of Typologies	1	14 - Existing and 12 - New	15	1
	Number of Building Systems	0	0	6	7
	Lifecycle Phase	End-of-Life	End-of-Life and Early-Design	Early-Design and Renovation	Renovation and End-of-Life
	Unit of Measurement	kg (or) lb	Tons	m^2 or m	m^2 or m
	Level of Granularity	Whole Building	Whole Building	Assemblies	Assemblies
	Level of Recovery	Materials	Materials	N.A. [2]	N.A. [2]
	Calculable Materials	5	12	N.A. [2]	N.A. [2]
INPUT	Input Features (Total/ Categorical/ Numerical)	2 / 1 / 1	1 / 0 / 1	17 / 3 / 14	8 / 5 / 3
OUTPUTS	Special Features	None	Recycling Costs	3D building model with carbon heatmap	None
	Data Export	None	Excel	PDF, Excel, CSV, XML	PDF, Excel, JSON
	Data Visualization	None	Bar charts	Predefined charts, Sankey, Spidergrams	Predefined charts

* MIC – Material Intensity Coefficient (material weight in kg/ m2 of floor area), WBLCA – Whole Building LCA,
N.S. – Not Specified, N.A. – Not Applicable
1. Reflects the first known reference to the tool. However, exact release date remains unavailable
2. The software tools provide a detailed material composition of each assembly; however, material quantities must be added manually if required.

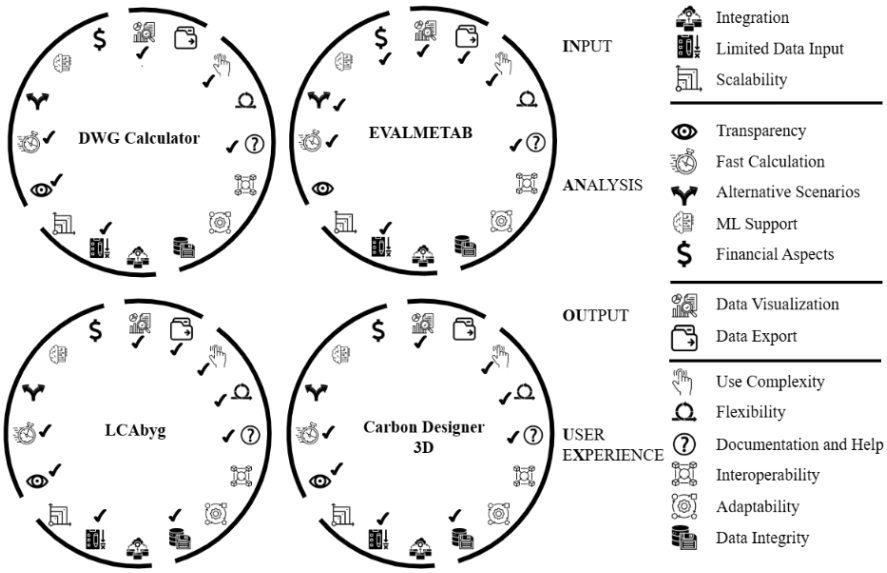

Figure 3. Alignment of identified software tools with user-centered requirements

capabilities. Although the reviewed tools provided some knowledge of the underlying calculation mechanisms, the information is neither comprehensive nor complete. This lack of transparency hinders user acceptance, as potential users may not fully understand the results [22]. The reviewed tools also have limited capabilities for performing financial analyses of alternative demolition techniques and disposal choices, and the absence of these affects their usefulness in decision-making. The lack of these functionalities in Carbon Designer 3D and LCAbyg tools is understandable as they are not primarily designed for material inventorying.

Currently, the STs for circular economy possess stand-alone functionalities requiring the use of several tools to accomplish diverse tasks as a project advances. As the data requirements for circularity applications are not yet standardized [8], the variety of digital technologies used by stakeholders can result in interoperability challenges. Accommodating different functionalities under the umbrella of a single tool or establishing data standards for data sharing among different tools can solve adaptability and interoperability challenges.

Most digital tools in the CE environment such as OneClick LCA and GaBi Circularity Toolkit, focus on LCA component during the early design stages, as the decision-making strategy [18],[23]. The research on software tools for CE has focused on developing digital marketplaces (DMP), data management, and material passport generation tools such as Madaster [24], Cirdax [25], and Loopfront **Error! Reference source not found.** require material information to be entered manually and are useful only once the material inventorying is completed.

As an industry known for the slow adoption and the workforce's inherent resistance to modern technologies, the shift to circularity is further complicated by high implementation costs, lack of trained personnel, and difficulty in identifying available tools [27]. To address these issues STs should be robust, effective, comprehensive, and meet the actual needs of CE stakeholders. Future tools developed for the circular economy should consider these requirements and aim to bridge the gaps in the existing STs to improve their quality.

5 Conclusion

The results indicate a consensus among the industry stakeholders on the potential of mining buildings for secondary resources and the vital role of digital technologies in driving circularity. However, a gap remains in the availability of STs for rapid, accurate, and affordable material inventorying of existing buildings.

This paper derived a literature-based framework on user-centered design requirements to guide the development of software tool that performs fast quantity take-off of built facilities to support a circular economy. Based on this review, an evaluation framework with criteria for user-friendly software tools in circular economy applications was developed and used to determine the adequacy of four identified commercial tools for automated inventorying. The development of this key-criteria is a valuable step toward designing new STs for CE in built environment.

This study is limited to the user-centered requirements derived from published literature, and the software tools were evaluated based on these criteria,

highlighting only theoretical requirements. Consequently, further research will focus on identifying user-centered design requirements and technical functionalities considered critical and feasible by industry stakeholders, through surveys and interviews. Based on these insights, the feasibility of implementing the prioritized criteria in a software tool for fast QTO of built facilities will be investigated.

Abstract -

The prevalence of prefabrication in the modern construction industry has highlighted the importance of sustainable management of these new construction materials. Despite reduced emissions through minimizing construction time and production waste, at the end of the building's life, the amount of construction waste produced remains constant. This paper aims to investigate the environmental and economical sustainability impacts from reusing prefabricated concrete and cross laminated timber panels sourced from buildings reaching the end of its service life. The main framework used focuses on applying a lifecycle assessment in terms of embodied energy to a unit of the selected prefabricated material. The results from this analysis are then further expanded to include varying distances between the donor and host building, allowing for a comparison between the embodied energy saved and additional energy consumption from transporting the construction materials. Furthermore, the economic sustainability of this construction practice are calculated. A case study was conducted using a 3D BIM model of a residential structure whereby the materials are quantified and paired with data obtained from the LCA. The results have shown that there are energy savings of 36,628.6 MJ/m^3 and 66.6 MJ/m^3 for concrete and cross laminated timber panels, respectively. Additionally, a trendline showing the correlation between distance and embodied energy savings for both materials were observed. The research contributes to providing alternatives for sustainable waste management and material selection policy in the construction industry.

1 Introduction

As climate change becomes a more significant challenge, it is in the best interest of humanity to combat this phenomenon to minimize the impact of climate change on the global ecosystem. The World Commission on Environment and Development (WCED) defines sustainability as the preservation of the current world for future generations [1]. The construction industry is named one of the major contributors to climate change because of its large greenhouse gas emissions. This is largely caused by an increase in demand for infrastructure, housing and resources as the human population continues to grow and modernize, which ultimately results in the expansion of the construction industry. One of the construction methods that has been implemented to keep up with demand for infrastructure is through prefabrication, which has been proven to be faster to build and more environmentally friendly [2].

A building's lifecycle starts in the pre-building stage where the building is planned and designed, this is the best stage to include any sustainable design principles into the project as nothing physical has been built and can be easily altered as needed. This stage is then followed by the construction stage, where the building is constructed and consequently by the operational stage where the building is used for its intended purpose. Once the building has reached the end of its service life, the building will be demolished or deconstructed to make way for a new building to better suit the needs of society at the time [3]. A major issue of this linear lifecycle is that there will be a large amount of waste produced. Improper demolition waste management reduces reuse potential as the waste will head straight to landfill. Reusing and recycling waste obtained from all the stages of a building's lifecycle ensures the minimization of waste that goes to landfill and thus reduces the harvest of new raw material.

Studies on prefabrication have shown that with prefabricated products, construction waste and time can both be reduced, leading to more sustainable practices [2,4]. Despite these established benefits, there seems to be limited knowledge of methods in which the prefabricated products can be harvested and reused as part of a new building's structure. A major downside to

current industrial practices is that significant additional processing energy will be needed, such as when steel is melted and reused [5]. However, reusing already made prefabricated products circumnavigates this problem as these products are relatively ready to use. It appears that a gap in the research exists in finding the benefits of reusing prefabricated materials salvaged from a building's end-of-life stages. Surveys have shown that despite poor public perception of second-hand structural products, this reusing technique may be necessary to ensure responsible use of the Earth's finite resources and promote a sustainable construction industry moving forward.

This paper aims to investigate the environmental and economic feasibility of reusing prefabricated concrete and cross laminated timber panels sourced from buildings reaching the end of its service life. The paper focuses on the comparison of the embodied energy and cost savings from reusing these materials against common transportation methods. In this research, the benefits as well as the limitations of reusing prefabricated concrete and CLT panels were quantified. The benefits to be analyzed will revolve around the two of the three pillars of sustainability, namely environmental, and economic sustainability.

2 Literature Review

Sustainable development is "a development that meets the needs of the present generation without compromising the ability of future generations to meet their own needs" [1]. This concept is commonly separated into three main categories namely, economic, environmental, and social sustainability [6]. When all three sustainability categories are achieved, then total sustainability has been attained.

There are three basic principles that can serve as a basis for sustainable construction such as resource management, life-cycle design, and human design [7]. Resource management involves the efficient use of the Earth's finite resources. This can be done by implementing renewable energy sources, reducing construction wastes, etc. For example, the design of a building's façade can be optimized to reduce its operational energy consumption [8]. Additionally, human design involves both biophysical and social part of the project in which the requirements of the building does not exceed the capacity of the environment to fulfil those needs [7]. This design is usually implemented in the design stage of the building's lifecycle [9]. In life-cycle design, all aspects from the design up to the demolition is to be considered in the planning stage [3].

The promotion of sustainability in the construction industry can also be achieved through optimal material selection. Being one of the most used materials in the construction industry, concrete plays a key role which greatly affects the sustainability of the industry. Another method in which sustainability of concrete can be improved is through the incorporation of waste in less demanding work [10]. For example, an Egyptian case study employed rice stalks can be used as cement fillers for low-cost housing [11]. Another approach in material selection is with the use timber in the form of Cross Laminated Timber (CLT) as a renewable source of material, which has been growing in popularity. The structure of CLTs involves planks which are sawn, glued, and layered wood where the layers are placed perpendicular to one another [12]. The main advantage of CLT is that it is made from timber, a renewable source of material, unlike concrete and steel which are both non-renewable [13].

Prefabrication has also been closely linked to a more sustainable construction practice. In general, there are two types of prefabrication namely 2D and 3D prefabrication [14]. There are both advantages and drawbacks of prefabrication in the construction industry. Advantages of prefabrication includes a reduction in construction time leading to cost savings, lower margin of error and that the modules can be reused or altered as needed [2,4]. When compared to conventional construction, prefabrication has also been shown to reduce the amount of waste by 81.3% and 83.2% for small and large structures, respectively [15]. A case study conducted in Hong Kong has shown that prefabrication can reduce construction waste by 65%, labour requirements by 16%, and construction time by 15% [16]. However, there are also drawbacks such as the need for specialized skill and equipment during assembly, the lack of product variety, etc. Another key drawback is that when an error occurs either during production or assembly, there may be major delays to the project [2,4].

Despite of these advantages during construction, prefabricated buildings are still being decommissioned in a linear manner. Identifying and prioritising the end-of-life solutions for prefabricated buildings are essential to reduce carbon footprint and promote circularity in construction [17]. Research has shown that prefabricated buildings have higher recyclability rates compared to traditional buildings, which drives the possibility of reusing these components in future projects with minimal processing [18]. With regards to these recycled components, BIM has been shown to aid in the deconstruction process by analysing existing conditions, labelling reusable elements and simulating the deconstruction process [19].

The concept of reusing prefabricated components has been applied to multiple projects across the world. One of the concepts is the Pilot Houses in Berlin developed by TU Berlin. In this project, prestressed concrete slabs of type WBS70 were modified by sawing them into the

required sizes and then connected to form the external walls of the houses [20]. The façade is then covered with an External Thermal Insulation Composite (ETIC) system. A case study house in Schidlow, Berlin has achieved 245m^3 of concrete saved with a significant reduction in construction time, which has been shown to reduce greenhouse gas emissions such as CO_2, N_2O and CH_4 [20,21]. Other examples can be seen in the BedZED development in London and the UN17 Village in Copenhagen where it successfully implements the basic principles of sustainability. These projects also adopted the practice of reusing second-hand materials as part of an efficient resource management policy and design for human strategy.

As the use of prefabricated components become more widely accepted, steps should be taken to consider the end-of-life stage of these parts [17]. Improper disposal strategies may lead to unsustainable construction techniques which may accelerate the deplet ion of natural resources. Reusing these components may be one of the ways for the industry to process and control the amount of waste being produced. Additionally, it may lower construction costs and preserve finite resources.

3 Research Methodology

In this research, a method known as Life Cycle Assessment (LCA) will be used to measure the benefits brought on by reusing prefabricated concrete and CLT panels to construct new buildings. There are three different methods for LCA. The first of these methods is called Process Analysis where a product is identified and the inputs that go into production of the product is analysed. The second method is called the Input-Output (I/O) analysis where the energy usage of a particular industry in a country is obtained from national survey data. These two methods can be combined to form a "hybrid" LCA to have the simplicity of I/O analysis and the accuracy of process analysis.

A detailed framework of the method used in this paper can be seen in Figure 1. It highlights the major components starting from the LCA, then followed by both environmental and economical sustainability studies. Finally, to show how this method can be applied, a case study involving a 3D BIM model will be conducted. The framework aims to provide a generic plan in which all materials can be analysed and then applied to various case studies.

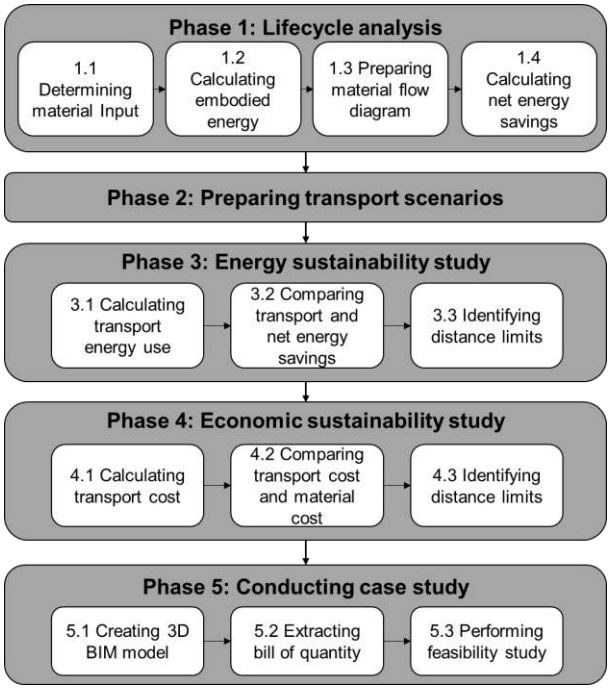

Figure 1. Research framework to quantify feasibility of reusing imported prefabricated components

Firstly, the unit of system processes will be obtained from sources such as research papers, industry examples, databases, etc. The data collection process is followed by the data calculation stage. In this stage, the data obtained is calculated according to the amount of material used. Then, these values are arranged according to the appropriate flow of processes when reusing prefabricated components. The flow will then be based on the law of conservation of energy where the sum of the energy entering a process must be equal to the sum of the energy leaving the process. This stage in the LCA allows for the verification of data energy used throughout the process. This iterative process ensures that the inputs and outputs can be maximally captured to ensure a high-quality and accurate assessment.

In this LCA assessment, data such as the materials being used and their respective processes are first gathered. The respective processes such as transport, assembly and panel cutting will be added onto the analysis. The framework used in this LCA will begin from the material harvesting up to the assembly of the model houses. The maintenance and operation as well as the end-of-life stage of the buildings will not be included in the analysis as it is assumed that the digital model will have similar operational conditions as its real-life counterpart if it is built using new raw materials.

In order to evaluate the framework, a sensitivity analysis is conducted. The aim of the sensitivity analysis is to establish which processes will impart the largest effect on the overall LCA flow diagram. This is done by

altering parts of the processes and assessing which of these changes results in a large effect on the overall embodied energy. Sensitivity analysis can then be used to determine which processes to include and exclude from the system boundary. In this study, the sensitivity analysis will revolve around the transportation aspect of the reuse process. This is done by changing the location of the donor building and changing the method of transport accordingly. These scenarios can help determine the limit in which the proposed construction technique is no longer sustainable. By changing the location of the donor building, changes in the feasibility of the project can be seen. Using these changes, trends can be inferred and thus provide a quantitative value to measure the sustainability of reusing these prefabricated panels. This value allows for this technique to be applied to real-life projects and have their sustainability measured.

In Phase 5, a real-life building will be modelled using Revit and then a bill of quantities for the materials used in the house is gathered. The building being modelled draws inspiration from the house mentioned in [20], where the external wall of the house is made from reused concrete panels. In addition to the external walls, the internal walls will also be considered. In this study, it will be assumed that the internal walls will be made from CLT panels. Then, the energy and cost savings value obtained in the LCA can be used to determine the sustainability of the project. This section of the paper is used to verify the framework set out in Figure 1. It shows how the framework can be applied to other projects as the data produced from the LCA is per unit volume.

Finally, an interpretation of the LCA results will be conducted, which includes the verification of the results. This section will highlight the potential limitations of this study and ways in which these limitations can be overcome. It will also show paths in which future research can take to further develop this construction concept and provide a better understanding of material and resource sustainability in the construction industry.

4 Reusing Concrete and CLT Panels

The LCA conducted in this study involves 1 m^3 of reused concrete and CLT panels, where both the donor and host buildings are both located in Sydney. This will include processes starting from the harvesting of these materials up to the assembly of the materials. In this lifecycle analysis, several assumptions will be made. For example, panels harvested from the donor building will be in the exact measurements required by the host building and thus no additional processing of the panels is required. Next, as materials are being reused, the embodied energy of the material itself will no longer be included in the LCA as it has already been included in the LCA of the donor building. Finally, the energy used to assemble 1 m^3 of each material is sourced from [24], where the total energy used for onsite construction is divided by the total volume of material used during construction. This results in the energy consumed for assembly of 294.2 MJ/m^3.

The LCA results suggests that reusing concrete panels requires an additional 1,032.8 MJ/m^3. It is also worth noting that 71.3% of the energy consumed arises from transport which is followed by the energy consumed when assembling of the panels (28.5%). When factoring in the embodied energy of the raw material itself, energy will still be saved. This is because no new material will be required and thus there will be no energy expenditure from the material aspect. The embodied energy of 1 m^3 of tilt up concrete panel which constitutes 95% concrete and 5% steel has an embodied energy of 37,661.4 MJ. Therefore, it can be concluded that the net energy savings for reusing concrete panels is 36,628.6 MJ/m^3.

On the other hand, reusing CLT panels requires an additional energy consumption of 433.4 MJ. In the case of CLT panels, most of the energy consumed comes from the assembly process. It constitutes 67.9% of the additional energy required and then it is followed by transport which contributes to 31.8% of the energy consumed. The embodied energy of 1 m^3 of CLT panels is 5,000 MJ [17]. As there is no new CLT panels being used, the embodied energy of CLT can be considered as energy saved. Thus, it can be inferred that the net energy savings for reusing 1m^3 of CLT panels is 4,566.6 MJ/m^3.

The next section of the journal paper revolves around a cost-benefit analysis of this construction method to fulfil the economical sustainability aspect of this construction technique. The analysis adds eight scenarios in addition to the base scenario previously mentioned. The additional scenarios alter the location of the donor building, leading to increased transportation cost and its environmental impact while keeping the host building in Sydney. The location of the donor building is comprised of cities in Asia, Europe, and North America. The list of scenarios and their respective travel distances can be seen in Table 1. The total distance travelled is the sum of the travel distances of all modes of transport namely, truck, rail, and ships, used during the panel's transportation process. Truck, rail, and ships were selected as the preferred mode of transportation as they are representative of how most construction materials are transported from the factories to the construction site.

Table 1. Scenarios and their respective travel distances

Source	Distance (km)			
	Truck	Rail	Ship	Total
Sydney	120	0	0	120
Perth	182	3,290	0	3,472
Jakarta	170	0	7,119	7,289
Tokyo	150	0	8,043	8,193
Shanghai	270	0	8,579	8,849
San Francisco	70	0	11,957	12,027
London	105	0	21,352	21,457
Stockholm	110	0	23,230	23,340
Moscow	90	631	23,728	24,449

In Table 1, the scenario where Perth is the location of the donor building, Rail is mainly used to transport these panels over the Australian component as it is deemed more efficient than trucks. For the Moscow case, Rail was used to transport the panels from landlocked Moscow to St. Petersburg to be loaded onto ships. This material transfer is assumed to be done by rail. The distances for ships are calculated using distances of typical shipping routes between the locations.

The first part of the result analysis involves comparing the energy consumed during transport of the materials and the energy saved from reusing the material itself. The energy consumption for trucks, rail and ships are 4.6 MJ, 0.9 MJ and 0.4 MJ per ntkm (net-tonne kilometre), respectively [23]. This is done for all scenarios and both concrete and CLT panels and the results are shown in Figure 2. The threshold whereby the transport energy exceeds the saved embodied energy is also included in this figure.

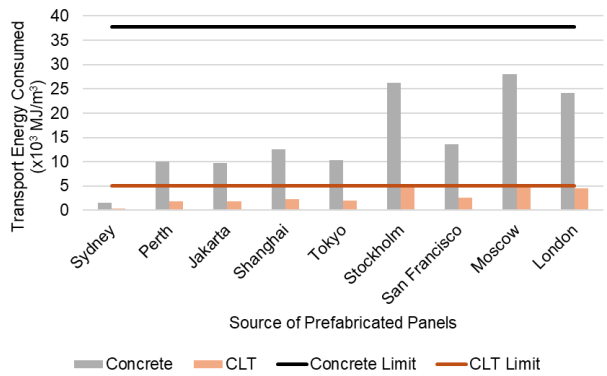

Figure 2. Energy consumed by transport for 1m^3 of (a) concrete panels (b) CLT panels for various locations

When energy consumed by transport (E_t) is plotted against the distance travelled (d) by the material, a linear trendline can be seen. The trendline equations for both concrete panels and CLT panels can be seen in Equations (1) and (2), respectively.

$$E_{t,concrete}\ (MJ/m^3) = 0.989d + 3119.7 \quad (1)$$

$$E_{t,CLT}(MJ/m^3) = 0.185d + 584.2 \quad (2)$$

The maximum distance that a material can be sourced from can be calculated by replacing the energy consumed by transport by the embodied energy of the material being reused including the processes required to reuse them while excluding the energy required for transport. The resulting maximum distance calculated from an environmental perspective (D_{env}) are 34,180.79 km and 22,272.43 km for concrete and CLT, respectively.

The next stage of the cost benefit analysis revolves around comparing the cost of transport and the cost savings brought on by reusing the materials. The price of the material in Australia can be assumed as AU$302 per m^2 of concrete panels and AU$863.32 per m^2 of CLT panels. Assuming the exchange rate for AU$1 is US$0.62, the price of concrete and CLT are US$187.24 per m^2 and $535.26 per m^2, respectively [23]. It is also assumed that the price for material transport is US$0.052, US$0.024, and US$0.018 per ntkm for road, rail, and ships, respectively [25]. Another assumption made in the cost analysis is that the thickness of the concrete panel is 200 mm and the thickness of the CLT panels is 135 mm.

A limit for the distance for the material source from an economic standpoint can be obtained. Table 2 below shows the distance limits for both concrete and CLT panels. From an economical perspective, the maximum distance limit for concrete is 19,180.03 km. This is obtained in the case when the concrete panels are obtained for free or in other words 100% discount. It is also shown that CLT panels can be sourced from all over the world and still be economically sustainable.

Table 2. Distance limit in kilometres depending on material discounts for concrete and CLT panels from an economical perspective

Percentage of Original Cost	Distance Limit (D_{econ}) (km)	
	Concrete Panels	CLT Panels
0%	19,180.03	314,542.25
20%	15,211.30	251,500.00
40%	11,242.84	188,457.75
60%	7,274.11	125,415.49
80%	3,305.39	62,376.06
100%	-663.39	-665.01

The maximum distance between the source of reused materials and the construction site can be obtained from both an environmental and economical perspective. Selecting the larger value from the two distances produces a comprehensive table with the de facto distance limitation. The equation used to decide on which distance to choose is shown below in Equation (3). Where D_{env} and D_{econ} are the distance limit from an

environmental and economical perspective, respectively. i is the material that is being analysed and r is the percentage of original cost for the selected material i.

$$D_{i,r} = \min\left(\frac{D_{env,i} + |D_{env,i}|}{2}, \frac{D_{econ,i,r} + |D_{econ,i,r}|}{2}\right) \quad (3)$$

Table 3 shows the distance limit of both economic and environmental sustainability of this construction technique. It is shown that the sustainability of reusing CLT panels is governed by the environmental limitations of the material. While concrete panels are governed by its economics. It is suggested that as the materials density increase, the main barrier for sustainability shifts from being an embodied energy to an economic limitation.

Table 3. Distance limit in kilometres depending on material discounts for concrete and CLT panels from both environmental and economical perspectives

Percentage of Original Cost (r)	Distance Limit (D) (km)	
	Concrete Panels	CLT Panels
0%	19,180.03	22,272.43
20%	15,211.30	22,272.43
40%	11,242.84	22,272.43
60%	7,274.11	22,272.43
80%	3,305.39	22,272.43
100%	0	0

Although this study shows that CLT panels are not environmentally sustainable when sourced from long distances, common industry practice has disregarded this fact. This is because of the significant cost savings that reusing CLT has, as shown in the cost analysis section of this paper. Due to the slim profit margins in the construction industry, cost savings takes priority over environmentally sustainable practices.

The values obtained from this section are unit values for both $1m^3$ of concrete and CLT panels. These values can aid designers in extrapolating necessary emission and cost saving calculations for various building types and applications.

5 Case Study

In this case study, an apartment building, located in Sydney, Australia, comprising of seven units was analysed. The apartment block is built on a site with an area of $686.95m^2$ and covers five levels ranging from a basement parking level, three levels for apartment units and a rooftop area. the 3D BIM model of the apartment block can be seen in Figures 3. This case study will serve as an example in which the framework developed in this paper is to be implemented in a real-life case study.

Figure 3. 3D BIM model of case apartment

During the analysis of this case study, the external walls are assumed to be made from the reused prefabricated concrete panels, and the internal walls are made of reused CLT panels. The external walls are supposed to be 200 mm thick, and the internal walls are 138 mm thick. The total volume of concrete and CLT panels used in the construction of the apartment are 246.53 m3 and 49.71 m3, respectively. Assuming the material is purchased at 20% of its new price. Table 4 below shows the sustainability of reusing prefabricated panels when implemented into the case study from both an economic and environmental point of view.

Table 4. Sustainability analysis of case building

Material	Concrete	CLT
Building Element	External Walls	Internal Walls
Sydney- Sydney		
Volume of Material (m^3)	246.53	49.71
Distance (km)	120	120
Energy Saved ($x10^6$ MJ)	9.03	0.23
Cost Savings (thousands of AUD)	291.2	177.8
Environmentally Sustainable?	✓	✓
Economically Feasible?	✓	✓
Stockholm – Sydney		
Volume of Material (m^3)	246.53	49.71
Distance Travelled (km)	23,339.64	23,339.64
Energy Saved ($x10^6$ MJ)	2.94	-0.23
Cost Savings (thousands of AUD)	-151.7	161.1
Environmentally Sustainable?	✓	×
Economically Feasible?	×	✓

The results from the case study shown in Table 4 shows that when the materials are sourced locally within Sydney, this reusing construction technique is both economical and environmentally sustainable. This is shown by the positive value for both cost and energy

savings. The sustainability benefits from the Sydney-to-Sydney case can be attributed to the distance between the donor and host building. Lower distance values lower the corresponding GHG emissions created through transport and minimizes the transport costs. However, this may not be the case for all location sources for these prefabricated materials. Some situations may result in a project being economically viable but not environmentally sustainable as shown in the case where CLT panels are sourced from Stockholm.

6 Conclusions

This research is set to answer the question of whether it is in the best interest of the construction industry to reuse prefabricated panels which can be harvested from buildings reaching the end of its useful life. As more new prefabrication parts are used in the construction industry, the significance of efficiently and sustainably handling a building's construction or demolition waste can no longer be ignored. This paper provides an alternative to project developers to adopt reusability into their design mandate. Additionally, it proves that reusing prefabricated materials has both economic and environmental benefits which can be used in favour of the developer. Lastly, a framework is created to quantify the distance limit in which prefabricated materials can be sourced before being either environmentally or economically unsustainable.

Based on the LCI flow diagram, this construction method has shown that significant energy savings can be achieved when prefabricated panels are reused. However, this energy savings decreases the further the material is sourced. Because there will be a rise in the energy consumption brought on from transporting the panels. Thus, from case studies involving different donor building locations, it is concluded that, environmentally, the maximum distance concrete panels can be sourced from is 34,925.85km and for CLT the distance is 23,869.14km. Apart from energy savings, there are also cost savings to be achieved with varying values. These values depend on the transportation method and cost of the reused panels when sourced from other projects. When factoring in the cost of the method, it is found that the distance in which concrete can be sourced is limited by the transportation cost which increases steeply due to the high density of concrete. In the other hand, the distance in which CLT panels can be sourced from is limited by the energy consumption of transport being higher than the energy saved from reusing the panels. This may result in situations where a product is environmentally sustainable but not economically feasible and vice versa.

The proposed framework provides designers and construction managers with a method to calculate the cost and embodied energy savings from reusing prefabricated panels. Reusing prefabricated panels may not be environmentally and economically sustainable in all cases and which highlights the need to quantify these savings to ensure that the project remains sustainable.

One of the main limitations of this paper is that the only items being analysed are the external and internal walls. When the entire bill of materials is considered for the whole building, the sustainability of the project may not be the same. Different materials have different embodied energies, and some materials may not be worth transporting from any location. Additionally, there are also limitations in terms of the regulations that each country may have regarding the import and export of second-hand construction products as well as different quality standards for these products. These obstacles may affect the viability of a project due to difficulties during the material procurement process. This can be overcome by creating more case scenarios where patterns can be recognized to produce an optimum source for these components. Future studies can the social impacts of using this construction technique, which includes the health impacts of the new construction technique towards the population living in the vicinity of the project. It can also include the inclusion of sustainability impact calculations as well as feasibility studies of using state-of-the-art transportation technologies.

Abstract –

To achieve net-zero targets in the transportation infrastructure sector, cost-effective carbon reduction measures are essential. Despite increasing efforts to explore such measures, their cost-effectiveness remains underreported and insufficiently studied. A database of best practices with 1,046 entries from UK National Highways is extracted to investigate the cost-effectiveness of its carbon reduction strategies. The analysis identifies "Project and programme management" as the primary focus area, with the construction stage being the most emphasized stage. Four "Carbon Quick Wins" approaches and the carbon reduction hierarchy (Avoid-Reduce-Switch) are the main strategies employed. Although "Avoid" has the greatest reduction impact and the highest hierarchy in decision-making, it is less frequently reported in the register of best practices than "Reduce" and "Switch" to low carbon material and energy. Using data mining techniques, the cost and carbon reduction data are extracted to evaluate the cost-effectiveness of carbon reduction using marginal abatement cost (MAC) indicator. The MACs of eighteen cases demonstrate significant variations, complicating the performance evaluation of these best practices. The study reveals a lack of data in most practices to measure the cost-effectiveness of carbon reduction initiatives. Even with available data, its granularity is rough, potentially influencing the selection of appropriate approaches. Standardized methods to measure the cost and wider impact of carbon reduction initiatives are recommended for future research along with data reporting policies.

Highway infrastructure; Carbon reduction; Carbon-cost effectiveness; Best practices; UK

1 Introduction

The transportation sector, particularly highways, is a significant contributor to carbon emissions, a primary driver of climate change [1]. In response, the transportation sector in different countries has implemented various strategies aimed at reducing these emissions to meet both national and international environmental targets. For example, UK National Highways (NH) aims to achieve net-zero corporate emissions by 2030, net-zero maintenance and construction emissions by 2040, and net-zero road user emissions by 2050 [2].Their carbon reduction strategies include avoiding high-emission activities and materials; switching to low-carbon materials and vehicles, and sustainable energy; and improving design and construction approaches, and road infrastructure services to support sustainable transportation. Evaluating the effectiveness of these strategies is crucial for selecting and prioritizing carbon reduction methods, ensuring cost-effectiveness, and accelerating progress toward net-zero targets. Other sectors and countries can also benefit by learning from the most effective practices, contributing to collective efforts in combating climate change.

In the highway sector, numerous efforts have been made to reduce carbon emissions, ranging from quick wins to more comprehensive long-term strategies. Quick wins, such as the adoption of energy-efficient technologies and low-emission vehicles, have shown immediate benefits as evidenced in the NH 2022-2023 annual progress report [3]. However, many initiatives focus solely on carbon mitigation without considering long-term costs, leading to sustainability challenges over time. Additionally, some promising strategies such as building more charging facilities are stalled due to budget constraints and await adequate funding to be implemented. Despite these efforts, overall progress in carbon reduction within the highway sector has been slow, and the effectiveness of these strategies remains largely unassessed. This presents a significant practice problem: without a thorough evaluation of both immediate and long-term impacts, and without proving the value-for-money, it is challenging to prioritize and implement the most effective carbon reduction measures.

Existing research has extensively explored the effectiveness of carbon reduction strategies in transportation infrastructure at various scales, comparing different design alternatives, scenarios, materials,

equipment, and measures within infrastructure projects. Studies have analyzed a wide range of scenarios related to road construction and maintenance, considering factors such as pavements, materials, machinery, transport distance, energy sources, and land-use change, to identify optimal emission reduction alternatives. It has been highlighted that the most effective strategies include using low-carbon and recycled materials during the construction stage and adopting sustainable energy sources for off-road machinery during the maintenance stage [4]. Similarly, a life-cycle analysis of highway reconstruction projects studied the contribution of materials, construction equipment, resource mobilization, traffic disruption, and life-cycle maintenance to whole project carbon emissions, finding that material choice is a major factor in reducing GHG emissions, while equipment contributes minimally [5]. Another study compared the GHG emission reduction potential of ten innovative techniques in road infrastructure construction and maintenance in the Netherlands, recommending the switch to renewable energy for lighting installations, the use of low-energy asphalt, and the application of rejuvenators to achieve significant reductions [6]. However, these studies, focusing on the effectiveness of the strategies, have not provided quantifiable and comparable evaluation of the cost effectiveness, revealing a significant gap in the current literature.

This paper sets out to answer two research questions: (a) What are the latest key carbon reduction strategies in the highway sector? and (b) How efficient are these carbon reduction strategies? To address these questions, a case study database with a total of 1,046 entries from the UK NH is analyzed. Text mining techniques are used to extract cost and carbon data from the documents. Quantitative analyses were conducted where quantitative data are available to summarize the key carbon reduction strategies and the cost effectiveness of carbon reduction.

The rest of the paper is organized as follows. The Methods section provides a description of the dataset, data collection and preprocessing procedures, and the analytical methods used. The Results section reports the findings of the thematic analysis, content analysis, cost-benefit analysis. The Discussion section interprets the results, discusses the implications for policy and practice in the highway sector in the UK and beyond, and provides some limitations of the study and suggestions for future research. Finally, the Conclusions section summarizes the study and its key findings and implications for the transportation sector.

2 Methods

The UK NH operates a "Lessons learnt reporting" scheme, where its staff and supply chain can share their experiences. The "National Highways Carbon Hub" is an internal database for the sharing of lessons learnt regarding net-zero tools and resources (including case studies, webinars, and other learning materials). New case studies and resources are continually added to the database. As of the data extraction date (27 June 2024), there are 1,046 entries, with the first one added on 30 November 2017. These entries include basic information of each case, including its name, main category and subcategory, relevant Project Control Framework (PCF) Stage covered, and the date it was added. Additionally, they include the "Lessons Learned Report" as an appendix. With permission granted to access and download these documents, the researchers can extract data for analysis.

Due to the vast volume of documents, manually extracting data is impractical. Data mining techniques are applied to extract the desired information from the documents using Python. The basic process involves converting documents of different formats (e.g., .pdf, .docx, .pptx, .jpg, .xlsx, and .mp4) to machine-readable text formats, then using natural language processing techniques to identify and extract specific cost and carbon data. By automating and iterating this process for all documents, the cost and carbon data are extracted and stored in a structured format (e.g., .csv) file for further analysis. The "pytesseract" module is used to identify and extract specific cost and carbon data. Out of the 1,046 entries, 252 have cost data and 78 have carbon data, with only 46 entries containing both. A follow-up screening ensures the relevance (whether the cost data and carbon data are about the savings of carbon and the cost associated) of the extracted data, resulting in 18 entries with data regarding cost effectiveness of carbon reduction for further analysis. Figure 1 shows the process of data extraction and analysis.

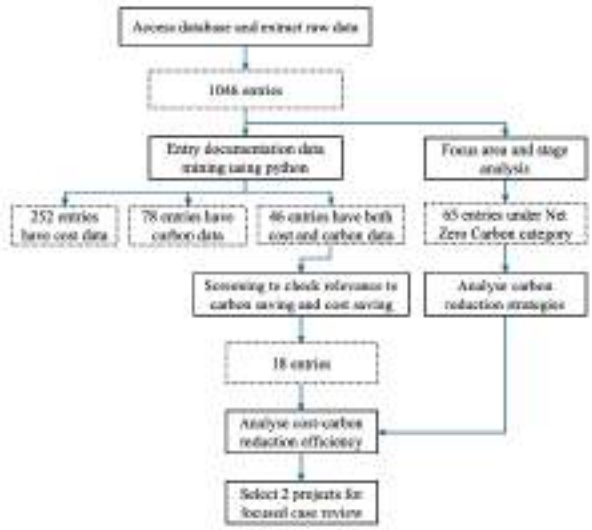

Figure 1. Data extraction and analysis process

diagram

For data analysis, the categories, subcategories, and PCF stage information are first mapped to identify the focus areas and stages of all cases in the database, as displayed in the right side of Figure 1. The strategy types are then summarized and categorized to address the first research question. Following this, the cost effectiveness of carbon reduction of the 18 cases is calculated for comparative analysis to answer the second research question. Finally, two cases are selected for a detailed investigation, examining how different strategies are employed and their respective benefits and challenges. It should be acknowledged that there is no means to assess the data trustworthiness of the data sources, therefore, the analyses are reliant on the quality of data being reported by those supplying them (i.e., NH and its contractors, suppliers). The assumption is that the database well represents the carbon management efforts in NH and its supply chain, although the extent of accuracy and comprehensiveness remains unclear to the researchers.

3 Results

3.1 Focus areas and stages

Carbon management is a very broad topic which is relevant to various project management aspects. The 1,046 entries in the "National Highways Carbon Hub" database are to share tools and resources relevant to carbon, however, some of the entries may mainly focus on other project management dimensions while carbon management was a minor focus. It is valuable to map put which areas the entries are focused while they directly or indirectly contribute to carbon management. The database classified the entries into 14 main categories including Project and programme management; Commercial and procurement; Construction; Customer and stakeholder; Carbon net zero; Consents, orders and planning; Design; Health and safety; Wellbeing and people; Environmental; Governance; Business case and funding; Specifications, standards and surveys; and Handover. Each main category contains multiple subcategories. This classification aligns with the organizational functional units and practices. Each case is classified based on the reporting unit or its closest relevance to a category (as some case may be relevant to several categories), with minor adjustments for similar terms such as merging "knowledge management admin" with "knowledge management," and "well being" with "well-being."

The Sankey diagram in Figure 2 maps out the distribution of categories and PCF stages. It shows that Project and programme management is the largest main category, with 347 entries, including major subcategories like knowledge management which include meetings, forums, workshops and competitions to share knowledge (210), innovation and continuous improvement (73). This focus reflects the critical role of strategic planning and management in achieving carbon reduction goals and underscores the importance of organizational learning and continuous improvement in carbon management. Construction cases are distributed among subcategories like road pavement (17), structures (17), earthworks (14), equipment and materials (10), road restraints (9), and traffic management (9). In the customer and stakeholder category, major subcategories include public liaison (27), roadworks customer experience (26), public consultation (15), and communication planning (14). For the commercial and procurement category, most cases fall under statutory undertakers (46), followed by social value (15 in total), contract management and supplier performance (13), and commercial assurance (11). The relatively lower number of cases in design (33 entries) indicates a potential area for improvement. Given that design and construction stages offer substantial opportunities for carbon reduction through innovative design solutions, material choices, and construction methods, it is crucial to enhance these categories during the construction and design phases for significant long-term carbon reduction benefits. Sixty-five cases fall within the Carbon net zero category, directly reporting the lessons learned about carbon management.

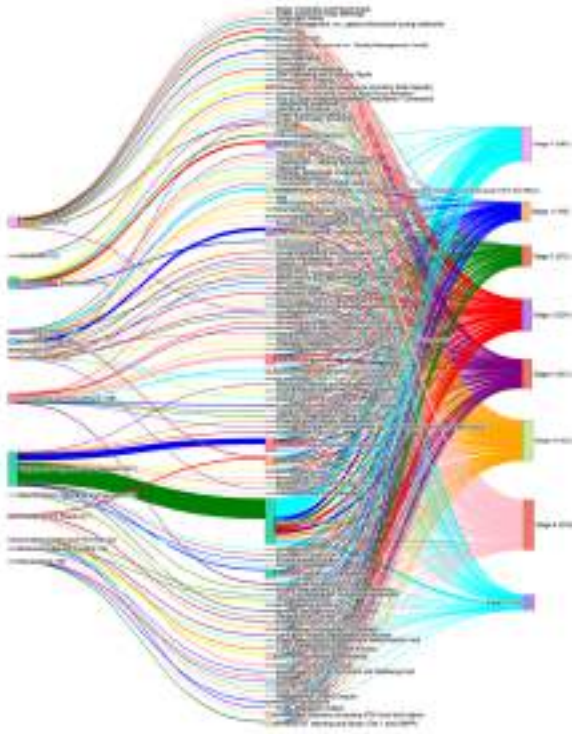

Figure 2. Category distribution of the cases

There are 8 PCF stages in total: Stage 0 to 7 from pre-project, to options, development, and construction

following the project lifecycle, as shown in Figure 3. It is worth noting that with the progress of the PCF stages, the ability to reduce whole life carbon decreases as prior decisions create commitments to particular pathway [7]. Figure 3 also lists the key carbon management activities of a major project across different PCF stages. According to Figure 2, most records in the database have covered Stage 6 (construction, commissioning, and handover) with 518 entries, followed by Stage 5 (construction preparation) with 422 entries, Stage 0 (strategy, shaping, and prioritization) with 365 records, and then Stages 3 and 4, both with over 300 records. Comparatively, Stage 1 and Stage 2 for the options identification and selection, which are crucial for carbon reduction, are not very well covered in the cases.

Figure 3. PCF stages and their abilities to reduce whole life carbon

The distribution of entries favors the development and construction stages, particularly Stage 6 (construction, commissioning, and handover) and Stage 5 (construction preparation). By the time projects reach these later stages, many decisions that significantly influence carbon emissions, such as material selection and design choices, have already been made. Consequently, the potential for reducing whole life carbon is considerably diminished at these stages. The underrepresentation of Stage 1 (options identification) and Stage 2 (options selection) is concerning. These early stages are critical for setting the groundwork for effective carbon reduction strategies. Decisions made during these phases have the greatest potential to influence the overall carbon footprint of a project. For instance, selecting low-carbon materials and technologies, optimizing design for sustainability, and incorporating carbon reduction goals into the project scope are best addressed early in the project lifecycle.

3.2 Carbon reduction strategies

To answer the first research question about what strategies are taken for carbon reduction, we thoroughly investigate the Carbon Net Zero entries in the "National Highways Carbon Hub" database. It is found from the reports that there are two guiding set of strategies: "Carbon Quick Wins" and carbon reduction hierarchy.

3.2.1 Carbon quick wins

To meet their Net Zero targets, NH has implemented a strategy called "Carbon Quick Wins" for major projects. This strategy is supported by a resource known as the "Low Carbon Opportunities Register", which contains a plethora of ideas to reduce carbon emissions throughout the design and construction phases. From the numerous opportunities available, the "Carbon Quick Wins" initiative advocates for the adoption of one or more innovative and mature solutions that offer additional benefits, including cost reduction or neutrality. This initiative targets projects in the design, development, and construction phases to drive carbon reduction efforts while ensuring consistency with current practices and establishing minimum expectations throughout the NH supply chain.

"Carbon Quick Wins" are required to meet five key criteria:

1. High Impact: The innovation should provide additional efficiency, health and safety, performance, and other co-benefits.
2. Cost Reduction/Cost Neutral: While there may be some initial up-front costs, the overall result should be cost-saving.
3. Carbon Reducing: The primary objective is to reduce carbon emissions.
4. No Departures from Standards: The innovation should not require additional approvals and should be supported by technical memos or pilot studies.
5. Mature Level of Innovation: The solution should have a maturity level of 4 or 5 and be applicable with little to no limitations.

Carbon quick win requirements

The "Carbon Quick Wins" strategy emphasizes both cost efficiency and carbon reduction, ensuring that initiatives provide tangible financial benefits while contributing to net-zero targets. This dual focus is crucial in gaining buy-in from stakeholders who may be hesitant to adopt new practices due to perceived costs. Ensuring that the "Carbon Quick Wins" do not require departures from existing standards is bounded by the bureaucratic hurdles and delays often associated with seeking additional approvals for new practices. This approach facilitates smoother implementation and integration of these innovations within current projects, reducing the risk of resistance from stakeholders accustomed to existing standards. Similarly, requiring a high maturity level (i.e., Innovation Capability Maturity Levels Four or Five which indicate innovation activities and resources are integrated and aligned, even synchronised [8] for the innovations ensures that the proposed solutions are well-tested and proven in real-world scenarios. By prioritizing mature innovations, NH can reduce the risk associated

with implementing new technologies and increases the likelihood of successful outcomes. Overall, the "Carbon Quick Wins" strategy represents a proactive, balanced, and pragmatic approach to achieving significant carbon reductions in the short term. By leveraging high-impact, cost-effective, and mature innovations that align with existing practices, NH can drive substantial carbon reductions while maintaining operational efficiency and stakeholder engagement.

Carbon quick win examples Four "Carbon Quick Wins" strategies NH has identified include: using warm mix asphalt, eliminating equipment idling, specifying alternative mixes for ancillary concrete, sourcing renewable energy. Table 1 provides an overview of the four example strategies. They are all applicable to PCF 3, 5, 6. Two of the strategies are about low carbon materials, asphalts and concrete which are two major materials used in road construction. They produce materials with same function using alternative methods while also save costs, which makes them "quick wins" as they are effective, practical, and economically viable for large-scale infrastructure projects. Eliminating equipment idling is a straightforward yet impactful strategy with significant reduction in both carbon emissions and fuel costs, with the ability to be widely adopted with minimal investment and training. The shift to renewable energy sources is one of the most impactful strategies with the potential for up to 90% carbon reduction, highlighting its transformative impact. The cost savings, although significant in the example provided, will vary depending on the scale and duration of projects. However, the long-term benefits of reduced reliance on fossil fuels and enhanced sustainability make this strategy highly desirable.

3.2.2 Carbon reduction hierarchy

There are three types of carbon reduction decision-making strategies: Avoid (e.g., build nothing), Reduce (e.g., build less), and Switch (e.g., build smarter). Avoiding any unnecessary building has the highest ability to reduce carbon and the highest priority in decision-making, reducing the amount of work and material if building is unavoidable comes second, and switching to smarter and cleaner ways when further reduction is impossible comes last. This hierarchy is based on the whole-life carbon reduction potential of each strategy: avoid is the most effective, followed by reduce, and then switch. These strategies are applied across various aspects: low carbon material and technology, design, and construction. As shown in Figure 4, of the 48 cases focused on low carbon material and technology, 37 involve switching and 11 involve reducing. For design, six cases involve switching, six involve reducing, and one involves avoiding. There are only four cases about construction, with one on avoiding, two on reducing, and two on switching. The relatively active learning area of low carbon materials demonstrates a commitment to incorporating sustainable practices in material selection and usage. Also, a big proportion of the cases focused on switching to low carbon energy including electricity, hydrogen, and hydrotreated vegetable oil (HVO). Also, the distribution of the sixty-five cases between switch, reduce, and avoid strategies suggests a need to emphasize "Avoid" and "Reduce" strategies more, as they offer higher potential for carbon savings.

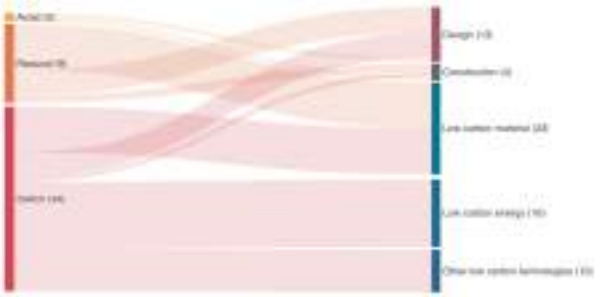

Figure 4. Carbon reduction strategies

3.3 Cost effectiveness of carbon reduction strategies

The Marginal Abatement Cost (MAC) is a key indicator for measuring the cost of carbon reduction [9]. It represents the marginal cost per tonne CO_2e abatement [10]. To assess carbon reduction cost effectiveness, the MAC is calculated by dividing the extra cost/benefit by the total carbon reduction. To answer the second research question, the authors extracted the data from the 18 database entries with both cost change data and carbon reduction data available and valid (which means the scope of cost change data and carbon reduction data aligns, as there are cost saving of the whole project while carbon reduction of a single initiative) and calculated the MACs, which are shown in the last column of Table 2, with the unit £/tCO_2e. Negative MACs indicate cost saving while reducing carbon, whereas positive numbers imply extra costs. Seventeen of the 18 cases have negative MACs ranging from -60£/tCO_2e to -11,111£/tCO_2e, indicating that in these cases, with one tonne of CO_2e reduced, £60 to £11,111 are saved. Only one project required extra investment, with a marginal cost of about £5 per tonne of CO_2e.

The data reveals that significant cost savings can be achieved alongside carbon reduction, as evidenced by the predominantly negative MAC values. However, the significant variance in MAC values among projects indicates that the cost-effectiveness of carbon reduction strategies can differ widely based on project specifics and

Table 1. Summary of Carbon Quick Wins strategy examples

Strategy	Explanation	Carbon reduction potential	Cost saving
Warm mix asphalts (WMAs)	Asphalt mixtures made at lower temperatures—up to 40°C cooler than regular Hot Mix Asphalts (HMAs).	5-10% in production compared to HMAs	Circa 20% shift output increase, saving around £70 million/year across NH
Eliminating equipment idling	Eliminating the operation of equipment, machinery, or vehicles while they are not actively engaged in productive work.	15-18.6% according to cases	£10,000 on fuel savings across 16 machines in one case
Specifying alternative mixes for ancillary concrete	Designated GEN (general) /RC (reinforced) /FND (foundation) concrete mixes are an alternative to Standardized prescribed (ST) concretes, with a more refined mix design compared and require less cement in the mixture to attain equivalent strength levels.	25-50%	Saving £9/m3 for non-structural concrete used
Sourcing renewable energy	Power sourced from naturally replenished resources such as sunlight, wind, water, geothermal heat, and biomass.	up to 90%	Save £3,700 over ten weeks using hydrogen power generation and photovoltaic panels compared to conventional diesel generators

Table 2. Marginal Abatement Cost of 18 cases

Case	Strategy	Category	PCF Stage(s)	Carbon Saving (tCO2e)	MAC (£/tCO2e)
C1	Avoid	Low carbon material	3,4,5,6	2,221.6	-3,632
C2	Switch	Design	3,5,6	5,721	-422
C3	Switch	Low carbon material	3,4,5,6	2,727	-2,180
C4	Switch	Low carbon energy	5,6	0.341	-352
C5	Switch	Low carbon energy	3	99,937	5
C6	Switch	Low carbon energy	4,5,6	164	-504
C7	Switch	Construction	5,6	498.56	-468
C8	Switch	Low carbon material	3, 5,6	8,100	-1,926
C9	Switch	Design	5,6	149.08	-60
C10	Switch	Low carbon energy	3	140	-250
C11	Switch	Low carbon energy	5,6	21.1	-175
C12	Switch	Low carbon material	6	70	-214
C13	Reduce	Low carbon material	3,4,5,6	115.4	-303
C14	Reduce	Design	3,4,5,6	408	-2,941
C15	Reduce	Design	6	130.5	-530
C16	Reduce	Low carbon material	3,4,5,6	339.7	-2,208
C17	Reduce	Construction	6	174	-3,448
C18	Reduce	Low carbon material	5,6	90	-11,111

implementation practices. Eleven of the eighteen cases adopted "Switch" strategy and only one reported "Avoid" as a guiding strategy. The "Avoid" strategy shows more significant cost saving than the average of "Switch" strategy which generally demonstrate cost savings, though with varying extents. Even the "Reduce" strategy (average MAC is -3,423.5 £/tCO_2e) seems more effective than the "Switch" strategy (average MAC is -595.09£/tCO_2e).

Twelve of the projects approached low carbon material, energy, and technology, with seven emphasizing materials, four using better design, and only two adopting better construction methods. The average MAC of low carbon material is -3,096.29 £/tCO_2e, it is -283.67 £/tCO_2e for low carbon energy, -212.5 £/tCO_2e for other low carbon technologies, -988.25 £/tCO_2e for design approaches, and -1,958 £/tCO_2e for construction approaches. While there is not a large dataset and there is a lot of variation in MACs, the adoption of low carbon materials is an area where lessons learnt reporting is indicating particularly cost effective, especially for the C18 case. The two construction cases, particularly C17, also achieved substantial cost-effectiveness, followed by design approaches. In contrast, low carbon energy and other technologies seemed less cost-effective.

The PCF Stages of implementation range from 3 to 6. Most cases introduced carbon reduction measures at Stages 5 and 6, which are relatively late in project life-cycle. Interestingly, the average MAC decreases from Stage 3 (-1,550.17 £/tCO_2e) to Stage 6 (-2,098.40 £/tCO_2e). The absence of early-stage interventions (especially Stages 0, 1 and 2) within the documented cases does not necessarily mean that the early stages were neglected in practice, it only links to the fact that the late

stage case studies were reported in the Carbon Hub dataset more than the earlier stages.

The C18 case, with the lowest MAC, indicates the best cost efficiency in carbon reduction. This £120 million highway construction project reduced emissions by collaborating with another nearby project (less than 6 miles away) for earthworks, reusing 73,350m^3 of spoil. This reduced the use of primary natural resources and material haulage distance by around 50,000 lorry miles, resulting in an estimated net cost saving of about £1 million. The carbon reduction of 90 tonnes CO_2e was primarily due to reduced lorry miles. In summary, this is a special case where the economic benefit is significant while the carbon reduction of 90 tonnes CO_2e may not seem as impactful.

The C5 case required extra investment. It assessed the Renewable Energy Guarantees of Origin (REGO) Certified Electricity at PCF Stage 3. This scheme involves using a tunnel boring machine to drill a tunnel at least two miles long. The machine is very energy-intensive, predicted to consume 197,407,795 kWh of electricity, with the total estimated electricity usage of the project being 202,194.47 MWh, which equated to 99,937 tCO_2e in 2018 coefficients. By using REGO Certified Electricity, grid emissions can be reduced to virtually zero. It was estimated to require £537,837.29 in additional costs in 2018 to buy REGO Certified Electricity, resulting in a MAC of £5.38/tCO_2e. While this is a positive number, it is relatively low, suggesting that the investment in REGOs is a cost-effective way to achieve significant carbon reductions.

Putting the MACs in the wider context, we can evaluate the cost effectiveness of the carbon reduction efforts in UK highway sector. The UK government assumed a traded carbon price of £70/tCO_2e at 2030 [11]. As estimated by Yue et al. [12], the transport sector can achieve full decarbonization in 2050 with MAC at €518/tCO_2e. Comparing to these benchmark numbers, the UK highway sector's carbon reduction strategies are very cost effective.

4 Discussion

The analysis highlights several critical issues that impede the effective evaluation and implementation of the cost effectiveness of carbon reduction strategies in the UK highway sector. Notably, the lack of comprehensive cost and carbon data significantly limits the ability to assess the cost-effectiveness of various measures. Out of 1,046 entries, only 46 contain both cost data and carbon data, and just 18 entries were suitable for comparative analysis after screening. Moreover, the current dataset's inconsistency and rough granularity further complicate the assessment process. The scarcity of detailed, granular data hampers robust evaluation and informed decision-making, underscoring the need for more thorough data collection and reporting to include detailed cost and carbon data for all projects.

The comparative analysis of 18 cases reveals significant variability in the MAC across different initiatives. This variability indicates that the same strategy may have different cost-effectiveness in different cases, depending on the specific context and implementation. The findings suggest that a standardized method for measuring the cost and impact of carbon reduction is necessary for future research.

"Carbon Quick Wins" offer practical, cost-effective measures with significant carbon reduction potential. Adoption and scaling of these low-carbon opportunities across NH projects can maximize their impact, with cost savings reinvested into further initiatives. Building on them, a balanced application of the "Avoid", "Reduce", and "Switch" strategies should be encouraged. Enhancing "Avoid" and "Reduce", integrating various carbon reduction strategies during the option and design phases can maximize carbon savings.

The study's limitations include the lack of comprehensive data of all the carbon management practices apart from the lessons learned and the lack of sources to validate the data trustworthiness [13, 14]. Future research should focus on developing standardized methods for measuring cost and carbon impact and collecting more detailed data [15, 16]. It is also recommended that government should drive the change to require organizations to report betterer quality cost and carbon reduction data with higher granularity. In the meantime, GHG and Environmental, Social, and Governance (ESG) reporting standards should provide clear guidance on how to report the cost and carbon data simultaneously. The technology sector is also encouraged to develop tools to capture carbon reduction and cost information together. Additionally, government policy should explore the long-term impacts and costs of carbon reduction initiatives to provide a more holistic view of their effectiveness and make the most cost-effective carbon reduction policies.

5 Conclusions

The analysis of the 1,046 "Lesson Learned Reports" on carbon management in the UK "National Highways Carbon Hub" found that the primary focus area is "Project and programme management", with a significant emphasis on the construction stage, which occurs late in the lifecycle and has limited impact on whole life carbon reduction. The study highlights the adoption of four "Carbon Quick Wins" approaches and the carbon reduction hierarchy (Avoid-Reduce-Switch), noting that "Avoid" strategies, although most impactful, are less frequently adopted compared to "Reduce" and

"Switch" strategies, as suggested by the number of lessons learnt reports. Filling the gap of cost effectiveness of carbon reduction methods, the analysis of 18 cases using marginal abatement cost (MAC) calculations revealed considerable variability. The results suggest that the cost-effectiveness of carbon reduction strategies can vary significantly depending on the natural of the initiatives and the context they were adopted.

Another key implication from case studies is the significant lack of comprehensive cost and carbon data, with only 46 entries containing both data types and a mere 18 cases suitable for comparative analysis. Even for these limited available data, it is difficult to ensure the data trustworthiness. This scarcity of detailed data impedes the robust evaluation of the cost-effectiveness of various measures, emphasizing the need for standardized and granular data collection methods.

Policy implications for the transportation infrastructure sector include enhancing the focus more on option and design phases, adopting a balanced strategy application. Developing standardized methods for measuring cost and carbon impact, collecting more detailed data, and exploring long-term impacts and costs will provide a more comprehensive understanding of the effectiveness of carbon reduction initiatives. By addressing these areas, the transportation sector can make substantial progress towards net-zero targets and contribute to broader climate change mitigation efforts.

Abstract

Optimizing waste diversion in construction and demolition projects is often indeterminate, imposing difficulties on deciding whether to reuse, recycle, or dispose of the materials. While data can be used to help bring objectivity to this process, the data collection process imposes numerous challenges (e.g., missing data, non-standardized data, different reporting requirements, etc.). To address waste diversion data collection difficulties, data requirements are first investigated based on a real-world case study of a building demolition project. Three challenges are then identified: isolated data management, propagation of uncertainty, and lack of standards and guidelines. Additionally, recommendations for data collection strategies including enhancing waste management plans, waste tickets, legal requirements, and incentive programs are provided. This study serves as a guideline for project managers on data definition and collection strategies in practice.

Keywords –

Data collection challenges; Waste diversion; Demolition; Economic assessment; Environmental assessment

1 Introduction

600 million tons of construction and demolition (C&D) debris is generated every year, more than double the annual municipal solid waste production [1]. Accordingly, strategic waste management is crucial to mitigate environmental pollution as well as landfill deficiency and save natural resources [2]. Spurred by a growing consciousness of sustainable C&D waste management and its urgency, waste diversion has garnered significant attention in the Architecture, Engineering, Construction, and Facility Management (AEC-FM) industry.

Waste diversion refers to redirecting materials from landfills through three major strategies: reduction, reuse, and recycling. Reuse and recycling are mainly considered in this study as reduction may not be applicable for some unavoidable waste [3]. To identify the optimal waste diversion solution, assessing the costs and benefits of each method is required [4]. Specifically, economic and environmental impacts, the two primary contributing factors, should be evaluated for effective decision-making.

Previous research using quantitative waste diversion analysis has commonly highlighted the significance of data in the process [5]. Mohareb et al. (2011) compared the methods used to calculate greenhouse gas (GHG) emissions, underlining the influence of onerous data requirements on the method selection [6]. Ratnasabapathy et al. (2020) examined the current status of waste diversion rate applications and illustrated the considerable importance of data quality [7]. Guerra et al. (2024) explored data mining technologies that are relevant to the existing data to predict project-level waste diversion rates [8]. Despite the agreement on the importance of the data, their availability was largely assumed to be present, yet in practice remains a significant challenge.

In contrast, general barriers and opportunities to C&D waste management have been investigated in multiple studies. For example, Yuan et al. (2017) holistically analyzed the drawbacks of current C&D waste management practices [9]. Jin et al. (2017) identified challenges in practitioners' perceptions of C&D waste diversion [10]. Although existing research has provided valuable insights into the practical adoption of waste diversion, they are focused on general challenges, not specifically on data. Therefore, further investigation into the data collection process is needed to address the basis of the waste diversion assessment.

This study aims to identify data collection challenges during the waste diversion assessment based on an actual building demolition case study project. Data requirements, typical data sources, and challenges are identified in order to evaluate the environmental benefits and economic costs of reusing, recycling, and landfilling three building materials in the case study. Data collection

challenges are then categorized with recommended strategies.

2 Case study

The Frank Erwin Center (ERC) demolition project is a case study used to investigate data collection challenges in waste diversion assessment. The Erwin Center, a large multi-purpose arena, was initially built in 1977 in Austin, Texas, United States. Its demolition commenced in July 2023 and was completed in October 2024. Environmental and economic impacts of three building components (i.e., doors, ceiling tiles, and carpet tiles) in the ERC were assessed. A widely adopted unit-based quantification algorithm is used in which total impact is the multiplication of the total quantity by the sum of unit cost, instead of a rough order of magnitude estimation for a more detailed analysis [11]. Cost items for all waste processing methods are identified from previous work but common expenses (e.g., sorting) are excluded for simplicity [12,13]. The authors (with an academic background in civil engineering and life cycle assessment experience in the industry) performed the case study.

3 Data sources and requirements

3.1 Data for waste quantity take-off

The total quantity of the target building components is required to assess both economic and environmental costs using the unit-based approach. As shown in Figure 1, which summarizes the data sources of cost items, the quantity take-off (QTO) can be done manually or retrieved from existing documents (e.g., inventory, bill of materials). Another method is automated QTO using building information modeling (BIM) or QTO software for 2D drawings. Notably, the quantity should be extracted in the unit of the impact factors. Unit conversion formulas would be necessary if the exact match is not available.

For the case study, doors were manually counted from 2D CAD since a BIM model was not provided. In contrast, the number of ceiling and carpet tiles was inferred from the summation of the area of rooms with tile finishing divided by tile size. Relevant rooms were filtered based on the site visits and room types denoted in floor plans. Existing construction documents that summarized the areas of all rooms in the building were used to map their areas. The tile sizes are defined as the standard dimension (carpet tiles 18”x18”; ceiling tiles 2’x2’). The case study also changed the unit. The doors, for instance, were first counted [EA] but converted to weight [kg] based on a rough estimate of the average door weight to follow the landfill cost unit [$/kg].

Item	Data source	Doors	Ceiling Tiles	Carpet Tiles
Quantity	Manual survey	•		
	Existing documents		•	•
	Automated QTO (BIM/CAD)			
Economic: Landfill	Landfill website	•	•	•
	Regional average cost			
Economic: Recycling	Manufacturer's recycling program		•	
	Recycling company	•		•
Economic: Reuse	Secondary market			
	Deconstruction company	•	•	•
Environmental	Environmental Product Declaration (EPD)	•	•	•

Figure 1. Data sources of waste diversion assessment cost items. The data sources for each building component of the case study are marked on the right.

3.2 Data for economic cost assessment

Unit economic costs involved in each waste processing method should be collected for the economic evaluation. Firstly, landfilling requires unit disposal charges and labor cost data. These can be obtained from the official dataset from the Environmental Protection Department [14, 15] or project-specific surveys such as adjacent landfill’s web pages [16].

In terms of the recycling cost, basic recycling charges and extra transportation costs were identified. General recycling costs can be discovered from websites about deconstruction or demolition, considering material type and regional characteristics. More detailed cost data can be scrapped from a product-specific recycling program operated by manufacturers. For example, the case study applied detailed cost data for ceiling tiles from the recycling program of Armstrong, one of the leading ceiling and wall system design and manufacturing companies [17]. However, due to data accessibility, carpet tile data were extracted from the cost analysis report by a carpet tile recycling organization [18].

The economic cost of reuse denotes the estimated resale price subtracted from the sum of transportation and installation costs. This information can be obtained from deconstruction service websites similar to recycling or by reviewing the prices posted on secondary market platforms such as Rheaply [19].

3.3 Data for environmental impact assessment

The environmental impact assessment requires the material’s environmental product declaration (EPD) that covers the unit global warming potential (GWP) of all relevant life cycle stages. The overall concept of the environmental impact assessment complies with a general life cycle assessment (LCA) method. The impact

is calculated by multiplying the total amount of materials and the sum of the applicable life cycle stages' GWP extracted from the corresponding EPD.

The relevant life cycle stages differ by the waste processing method as illustrated in Figure 2. The GWP from the life cycle stages encompasses those from the next life cycles in addition to the current ones. The A4-A5 (Construction) and B (Operation) stages are commonly eliminated from the calculation, assuming all waste management options have identical values. The environmental impact of landfilling, serving as the baseline, indicates the emission from the C (End-of-life) of the current and A1-A3 (Product) phases of the next life cycle. The current D (Beyond) stage is not but the next life cycle's A1-A3 are considered because the material is directly disposed of and it should be remanufactured from scratch. The recycling involves C1-C2 and D of the current and A3 from the next life cycle. C3-C4 stages are not considered because D is incorporated instead, replacing the need to extract raw materials (A1-A2). Similarly, reuse incorporates C1-C2 and D of the current lifecycle but even A3 of the next cycle is not added.

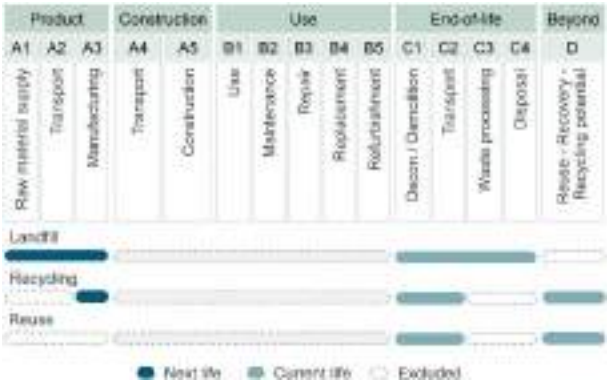

Figure 2. Classification of life cycle stages for the environmental impact assessment by the waste processing method. Different phases of current and next life cycles are applied to calculate the environmental impact of landfilling, recycling, and reuse.

In the case study, the specifications of the building components were unknown and EPDs with detailed information were unavailable. As a result, specific material's lower-level GWP (e.g., A3) was roughly approximated from the upper-level GWP (e.g., A) of a similar product's EPDs provided by its manufacturer.

4 Data collection challenges

Data collection challenges should be clearly identified to prevent them from cascading to future waste management practices which require reference data points to predict and validate the estimations. This section examines the challenges and outlines recommended data collection strategies.

4.1 Isolated data management

A poorly designed documentation plan for waste-related data in the earlier building life cycle phases adds obstacles to information retrieval. A great number of documents have already been generated through the existing practices. However, they cannot be used for the assessment as C&D waste management is not prioritized in the process [13, 20]. Accordingly, readily available documents lack details for waste diversion assessment and are difficult to search.

BIM models, often created during the design and construction phases, are more likely to be unavailable for demolishing buildings. A labor-intensive and error-prone manual QTO is thus prevalent, making the data collection more challenging.

Inventories and specifications generated for building construction and maintenance do not contain the data for waste (e.g., EPD, corresponding quantity, and the construction project manager's comments on future waste management plans). Finding an appropriate EPD that includes information for the end-of-life phase, for example, is challenging without enough description that only the design engineer or installer can provide. Even when the information exists, it is not organized well to search easily. Unstructured pieces of information were often scattered around the hundreds of pages in the case study.

Table 1. Insufficient data fields in the waste tickets from the ERC demolition project

Data Types	Fields
General	Contractor Project Manager
Logistics	Hauler Facility Date
Material Type	Metal Concrete Manifest Trash Trash
Analysis	Total Tons Total Recycling Recycling Rate

Moreover, waste tickets alone rarely support the process although they are required to be submitted. They usually do not designate the work type (e.g., new construction, demolition, renovation) and classify waste by only a few materials (e.g., concrete, metal, brick, wood, cardboard) instead of functional units as illustrated in the waste ticket data of the case study (Table 1).

Furthermore, waste tickets are restricted to the weight of recycled and landfilled waste. This discrepancy in the stakeholders' interests between the earlier phases and waste diversion blocks smoother and integrated data collection.

4.2 Propagation of uncertainty

Vast uncertainties exist in numerous variables of waste diversion, including item quantity, quality, historic value, and changing market needs [21,22]. The target level of detail of the assessment is one of the factors defining the variables. Waste recycling cost, for example, can be calculated at a high level based on the estimated waste type and regional recycling cost. However, it can also be decomposed into details by selecting a specific recycling facility of interest considering the distance from the site, accepted waste type, waste diversion rate, and more accurate waste estimation [14]. As the applicable variables differ by data requirements of the target level of detail, the degree of uncertainty changes accordingly.

Managing the uncertainty becomes more complicated as the uncertainty in one aspect of waste diversion is multiplied by assumptions from other variables. It is difficult to define an allowable range of differences for data collection. For instance, resale price includes uncertainty stemming from a market need for a specific material type; at the same time, material quantity can affect the pricing policy. The Erwin Center case had to consider three major compounded sources of uncertainty to calculate the reuse cost of ceiling tiles: 1) quantity unit conversion from area to weight, which propagates to estimating 2) the labor cost for tile removal that also varied by the project location, which affects 3) the resale price as it differs by the quantity, regional demand, and item condition. Concluding whether the final variance imposed from multiple sources is tolerable is difficult, and these ambiguities can therefore bring verbosity to waste diversion estimation.

4.3 Lack of guidelines and standards

Missing guidelines and standards, that could assist the data gathering on behalf of experienced human experts, impede the collection process. Skilled experts in waste diversion can use their own database or find the most suitable data sources but most experts still need assistance for the best practice. Due to the lack of well-established standards and guidelines in the waste diversion field, data collection efficiency is compromised [10,5].

In the case study, experienced experts' advice and standardized processes were mostly restricted or did not exist. Even the authors studying waste diversion had difficulties in determining a realistic resale price for reuse as the price changes by the fluctuating demand. Furthermore, an unstandardized dataset intensified the problem. There was no well-established guideline or standard listing crucial considerations and possible database to find the relevant data such as EPDs that perfectly match the material of interest. Unit conversion formulas and assessment methods also had to be modified multiple times following different EPD formats. When selecting EPDs of ceiling tiles, carpet tiles, and doors for the case study, the research team decided to prioritize EPDs that separately documented the global warming potential of Product stages (A1-A3) in addition to other basic requirements. These criteria for reasonable decision-making were developed from scratch as readily available resources were difficult to access and the EPDs were all distributed across different manufacturer's websites in varying formats.

It is currently infeasible to locate data sources that match all project attributes and variables. Hence, clear directions defining what is acceptable and how to adapt the data are necessary to ensure the reliability of the assessment. A centralized database and standardized criteria are needed to make the waste diversion assessment more accessible.

4.4 Recommendations

This research introduces four recommendations to enhance the data collection practices. The first strategy is to require contractors to submit a comprehensive waste management plan (WMP) in advance of a construction or demolition project. A WMP allows integrated data generation and management, addressing the limitation of isolated data management. The stakeholders can incorporate waste diversion in their plans before the project begins to minimize missing data and redundancy. Terminologies can also be standardized with WMP, which can contribute to communication efficiency. Furthermore, incorporating quantitative impact analysis and supply-demand simulation of reclaimed materials will enable WMP to play a more strategic and proactive role in waste diversion [23].

Restructuring the C&D waste post-reporting framework is also needed. Explicit descriptions of processing types, such as demolition/new construction and reuse/recycling/landfill, should be added to waste tickets. Categorization of materials in detail (e.g., plastic/furniture/contaminated, link to drawings/BIM elements) is also suggested for further analysis. This enables reducing uncertainty due to the lack of well-documented data.

Advanced legislation is another recommendation to motivate the execution of the strategies, and eventually, promote the better establishment of waste diversion guidelines and standards. Previous studies in waste recovery have demonstrated that financial incentives are

effective but need further support for practical implementation [24,25]/landfill, should be added to waste tickets. Categorization of materials in detail (e.g., plastic/furniture/contaminated, link to drawings/BIM elements) is also suggested for further analysis. Internal motivations of general contractors, demolition, or waste management specialists can drive the efforts but legislative actions can facilitate the change. In practice, the C&D ordinance has already been published or is under development in multiple states and cities to enhance the C&D waste management practices [26-28]. Recycle Colorado, a nonprofit organization to advance circular economies in Colorado, also provided a toolkit for policy development [29].

Similarly, enhancing certification programs such as Energy and Environmental Design (LEED) can provide societal and indirect financial motivations by providing constructive instructions. Indeed, the U.S. Green Building Council has already started a discussion to include Building and Materials Reuse credit in their new LEED v5 rating system to encourage more material reclamation and reuse [30]. Clear legislative and certification processes, accompanied by knowledge exchange and assistance from organizations such as Build Reuse Wiki [31], will accelerate the improvements in data collection.

5 Conclusions

This study analyzed data collection challenges for the environmental and economic assessment of waste diversion methods based on a case study. Calculating the impacts of landfilling, recycling, and reuse of building materials in a sample demolition project revealed data collection challenges (i.e., isolated data management, propagation of uncertainty, and lack of standards and guidelines). Recommendations for improved data collection are also presented according to the analysis.

This research analyzed practical difficulties experts can encounter when gathering data for the quantitative waste diversion assessment, a task often left to individuals to resolve. The findings will serve as a guideline to establish improved data collection strategies. It is also expected to assist the project managers and future studies in implementing them for more waste diversion.

Still, the study has a limitation in that it focused on investigating the case study-specific data collection challenges. The identified problems might not apply to other projects, or different difficulties can be identified in new regions and authorities. Future research is necessary to discover possible solutions for data collection in practice. Their feasibility and effectiveness should also be interpreted theoretically and through real-world applications.

Abstract -

The construction industry encounters significant environmental challenges, primarily due to concrete waste from demolitions and high CO_2 emissions from cement production. Concrete waste is recycled into aggregates, generating a significant amount of waste concrete powder (WCP) as a byproduct. However, the application of WCP in recycling processes is limited, leading to landfill disposal and environmental risks. This study explores the potential of combining carbon-neutral technology with large-scale concrete production by using WCP as a partial substitute for both cement and fine aggregates. Active carbonation is highlighted for its ability to capture CO_2 while improving the properties of recycled concrete aggregates (RCA) and WCP. Although technological advancements exist, a thorough evaluation of financial viability is essential. This research focuses on assessing the economic feasibility of integrating carbon-neutral technology into concrete recycling, particularly by carbonating waste concrete using flue CO_2 from cement plants. Thus, the paper proposes a method to incorporate environmental assessments into an activity-based costing (ABC) model, enabling a dual evaluation of financial costs and environmental impacts. By linking environmental impact assessment results to costs, this approach facilitates a comprehensive evaluation for involved stakeholders. An assessment of the Hong Kong market showcases the practicality of the proposed matrices. The comparison of recycling methods indicates significant environmental improvements, with 362% and 440% reductions in CO_2 emissions from cement plants and natural material processing, respectively, underscoring the potential of carbonization technology and the need for government support.

1 Introduction

The construction sector stands as a foundational component of the economic system, notable for its substantial energy usage and considerable carbon footprint. It has been documented that approximately one-third of worldwide carbon emissions can be attributed to the construction sector. Importantly, the adoption of recycled materials has been recognized as a powerful strategy to cut down on carbon emissions within this industry. Over fifty percent of construction and demolition debris is comprised of materials like waste concrete, as well as fractured bricks and blocks. These materials hold significant promise for lowering carbon emissions through recycling and reuse [1]. Research by Xiao, et al. [2] indicates that using recycled concrete has the potential to reduce carbon emissions by 12.4-52.2%, a percentage that is likely to grow in tandem with the escalation in recycled material usage. Furthermore, the employment of recycled concrete can help to mitigate the global scarcity of raw materials, like sand and aggregates. The adoption level of recycled concrete now serves as a critical measure within the green building evaluation frameworks of various countries.

While the advantages of waste concrete are widely recognized, the actual rates of recycling in numerous regions, including Hong Kong, still remain a concern for stakeholders. Waste concrete can be processed into recycled concrete aggregate (RCA), suitable for use in fresh concrete mixes. This recycling also leads to the creation of waste concrete powder (WCP), which can constitute 30-70% of the utilized concrete [3]. In countries such as China, the yearly output of WCP from recycling activities is estimated to be a staggering 60 million tonnes [4]. Instead of the prevalent method of landfill disposal, WCP could be used as a partial replacement for cement in concrete mixes. This substitution can lower the usage of cement-based materials, improve the rheological and mechanical characteristics of the concrete, and increase its durability.

Thus, incorporating WCP into the recycling process can further improve the recycling rate and sustainability.

Given the considerable promise of waste concrete, a multitude of research has been conducted in recent years. These studies have primarily concentrated on enhancing the attributes of recycled concrete through technical means. For instance, Poon and Chan [5] explored the properties of recycled concrete when applied to concrete pavement, offering various recommendations for enhancement. A method employed to improve the strength and quality of construction materials sourced from waste concrete is carbonation, which also supports strategies aimed at achieving carbon neutrality [6]. Carbonation refers to the reaction between carbon dioxide in the atmosphere and the calcium hydroxide present in cement paste. To achieve concrete carbonation, a high concentration of pure CO_2 gas (up to 99%) is typically employed [7]. As indicated by Ouyang, et al. [8], carbonation curing can enhance the compressive strength of RCA by 13%. Furthermore, carbonation enhances the material's resistance to corrosion and frost, thereby prolonging its lifespan [9]. The carbonation of RCA not only enhances their properties but also helps reduce the greenhouse effect caused by carbon dioxide emissions [10]. WCP, owing to its inferior physical and mechanical properties, is not suitable for direct incorporation into concrete mixes, and similarly, RCA requires a pre-carbonization procedure. Recent studies have demonstrated the promising potential of carbonizing WCP in terms of enhancing the strength of future concrete and its viability as a material for carbon sequestration [11]. Liu, et al. [12] and Wu, et al. [13] research indicates that WCP can absorb CO_2 up to 21% of its own weight.

Recently, anthropogenic gases, such as flue CO_2 from cement plants, have emerged as a promising source for concrete carbonation. Studies have demonstrated the feasibility of sequestering CO_2 from flue gases into materials like air pollution control residues, capturing 8–12% CO_2 by weight [14], while improving concrete properties such as compressive strength [15]. Research has also highlighted the cost-effectiveness and carbon reduction potential of integrating CO_2 capture in concrete production [16]. Pilot projects worldwide, such as those in Canada and the U.S., have validated large-scale mineral carbonation and technologies like Reversa, demonstrating their readiness for commercialization and compliance with industry standards [17, 18].

The carbonation of waste concrete for CO_2 sequestration not only supports carbon neutrality goals but also improves the strength of construction materials derived from such waste. While projects utilizing flue gases for CO_2 sequestration show promise, reliance on commercially captured CO_2 remains a drawback, potentially conflicting with sustainable processing. Additionally, the lack of economic analysis limits the understanding of its cost-effectiveness. Additionally, the integration of WCP into the concrete waste recycling process has yet to be fully explored, despite research suggesting that WCP can substitute for cement and natural fine aggregates in concrete formulations [19]. In response to these challenges, this study investigates the feasibility and environmental impact of active carbonation techniques for RCA and WCP derived from concrete debris, aiming to incorporate them into non-structural concrete mixtures. It also assesses the feasibility of using alternative CO_2 sources, such as flue gases from cement plants, to sustainably process concrete waste and incorporate both elements into the recycling process.

2 Model development

The research methodology comprises four key steps. First, a comprehensive literature review was conducted, providing insights into construction and demolition waste (CDW) management, the carbonization of demolished concrete, and the integration of this technology. Second, a cost estimation matrix was developed to evaluate financial costs and environmental impacts, with parameters selected based on the relevant processes involved. Third, a case study focused on the Hong Kong market was chosen to assess the feasibility of the proposed process with carbon-neutral technology integration, comparing it to traditional methods. Finally, the parameters were entered into a simulation environment to evaluate the model's practicality and analyze the individual cost components.

2.1 Parameters selection

In Hong Kong's traditional waste management system, all concrete wastes are first processed through crushing and separation before being sent to recycling facilities for conversion into RCA [20]. The RCA is then delivered to concrete production plants, while any excess WCP generated during the refinement of demolished concrete is disposed of in landfills [21]. Natural materials such as sand, gravel, and cement are sourced from approved suppliers to prepare the final concrete product. The emphasis on recycling WCP and utilizing flue CO_2 from cement plants has prompted the exploration of an alternative supply chain for concrete recycling. In this approach, demolished concrete from construction sites is transported to the recycling facility for processing into RCA and WCP. Flue CO_2 serves as an alternative gas source for carbonization and is transferred from the cement plant to the recycling plant. The carbonized RCA and WCP are subsequently sent to the concrete plant. Additionally, natural materials (sand, gravel) and cement are sourced from designated suppliers, though the

quantity of these materials is reduced due to their partial substitution with recycled aggregates and WCP. The processes discussed are illustrated in Figure 1, where black and blue arrows represent the traditional methods, while orange arrows indicate the proposed processes.

The activities carried out at various locations—such as suppliers, recycling facilities, cement plants, and landfills—are referred to as facility-based activities, with the associated expenses known as facility-based costs [22]. To achieve an accurate evaluation of all costs, an Activity-Based Costing (ABC) approach is utilized to allocate resources effectively to each process within a specific facility [23]. The energy (E) required for equipment operations at each facility and technology-related costs (AT) are quantified. The technology-related costs include expenses for acquiring additional equipment necessary for new concrete waste recycling processes. This encompasses equipment for capturing flue CO_2 and the enhanced capacity needed for carbonizing RCA and WCP. Additionally, the avoided effects are considered from an environmental perspective. Processes in the alternative scenario that replicate those in the traditional scenario are excluded from the model, as their impacts would remain consistent in both cases.

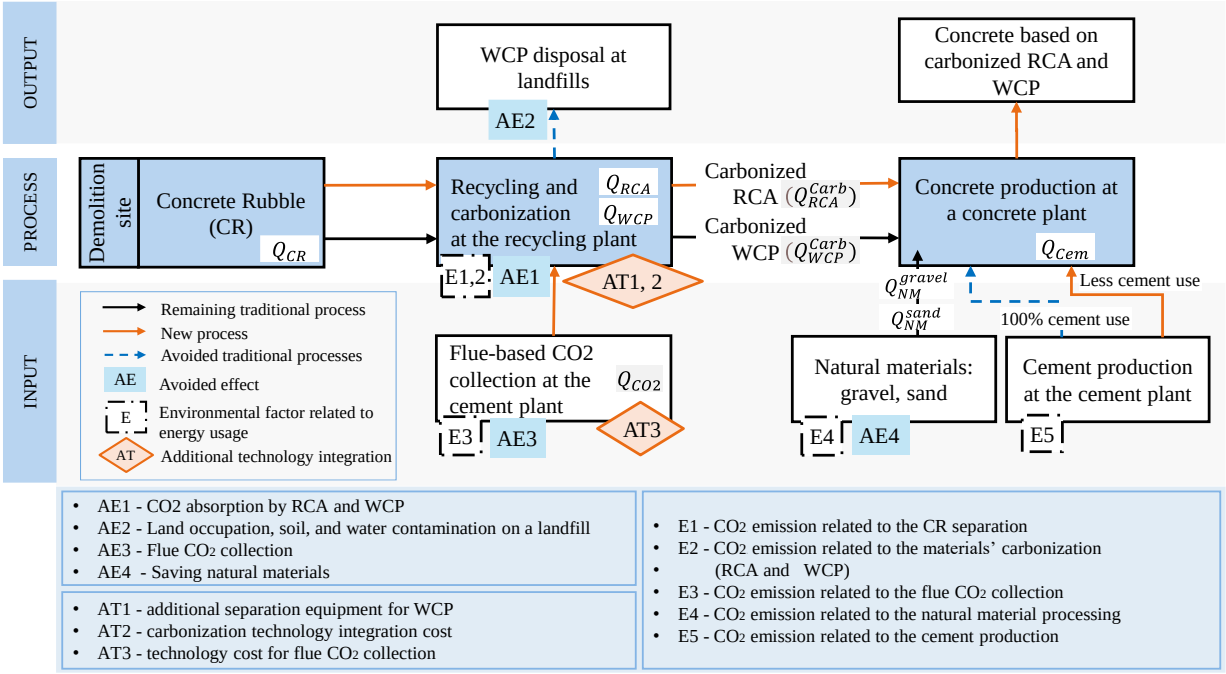

Figure 1. Identification parameters for the traditional and alternative concrete waste recycling processes

2.2 Model assumptions

The model assumes a one-way material flow, moving from demolition sites and suppliers to landfills or recycling centers, and ultimately to concrete plants, reflecting typical industry practices. No limits are imposed on the number of facilities at each stage to ensure scalability. All demolished concrete rubble (CR) delivered to recycling facilities is assumed to be fully processed into RCA or WCP, based on the efficiency of modern recycling technologies. Technology costs, reflected as depreciation, are based on initial purchase and installation expenses and are limited to equipment essential to the recycling process. Environmental benefits, including resource conservation and CO_2 emission reductions, are included to capture the sustainability advantages of substituting cement and natural aggregates with recycled materials. These assumptions are grounded in established practices and the specific context of this study.

2.3 Quantification of parameters

The quantification of parameters begins with the identification of activities within each facility and material flow based on Figure 1. The following material flow and related major facility-based activities can be determined:

a_1: Concrete rubble (CR) processing
a_2: RA processing
a_3: WCP processing
a_4: Anthropogenic CO_2 processing
a_5: Cement production
a_6: Natural materials processing (gravel)

a_7: Natural materials processing (sand)

For each type of activity, resources known as "activity drivers" will be allocated. An activity driver enables the allocation of economic transaction costs to an activity [24]. For instance, when processing concrete rubble (CR, represented as a_1) into RCA and WCP at a recycling facility, the resources utilized include the operational time of sieving and screening machines, as well as the energy consumed per unit of material processed. These resources can be represented as b_1 and b_2 respectively:

b_1: Usage of equipment (hours) per unit of processed material for CR processing into RCA and WCP (sieving and screening machines)

b_2 : Energy usage (kWh) of equipment per unit of processed material for CR processing into RCA and WCP (sieving and screening machines)

b_3: Usage (hours) of carbonization equipment per unit of processed material for RCA and WCP carbonization

b_4: Energy usage (kWh) of carbonization equipment per unit of processed material for RCA and WCP carbonization

b_5: Usage (hours) of CO_2 collection equipment per unit of processed material at the cement plant

b_6: Energy usage (kWh) of CO_2 collect equipment per unit of processed material at the cement plant

Environmental parameters were calculated using life cycle assessment (LCA) to evaluate the sustainability of the proposed materials and processes. An extensive LCA was performed following ISO 14040 and 14044 standards using OpenLCA 2.0.3 software. The Ecoinvent 3.9.1 database was utilized for the assessment due to its reliable and compliant data source. The environmental parameters were determined by considering the electricity required for processing recycled aggregates before their inclusion in the production cycle. Additionally, environmental parameters were calculated for the production of natural aggregates and cement. To ensure consistency and comparability, transportation was not included in the boundary conditions for CO_2 emission assessment. By focusing on the direct energy and material inputs, the study isolates the specific contributions of transformation, providing a clearer insight into the sustainability potential of recycled aggregates.

To create a comprehensive representation, resources can be allocated to each activity and illustrated as a matrix (Eq. 1). In this matrix, the horizontal rows represent the various activities (e.g., CR, RCA, WCP, CO_2 processing), while the vertical columns correspond to the types of resources utilized (e.g., energy, depreciation costs). For instance, 'b_{11}' denotes the equipment usage time for processing one unit of CR, while 'b_{12}' represents the energy consumption of the separation equipment for processing one unit of CR.

$$B = \begin{matrix} CR \\ RCA \\ \vdots \\ NM_{sand} \end{matrix} \begin{pmatrix} b_{11} & b_{12} & \cdots & b_{16} \\ b_{21} & b_{22} & \cdots & b_{26} \\ \vdots & \vdots & \ddots & \vdots \\ b_{71} & b_{72} & \cdots & b_{76} \end{pmatrix} \quad (1)$$

The costs of activity drivers (per unit) can be represented as a column vector (Eq. 2). For example, the unit costs of activity drivers $b_1 - b_6$ are as follows:

c_1: Depreciation cost of equipment per unit of processed CR (sieving and screening machines) (AT1)

c_2: Energy cost of equipment per unit for CR processing (sieving and screening machines) (AT1)

c_3: Depreciation Cost of carbonization equipment usage per unit of carbonized material (AT2)

c_4: Energy cost of carbonization equipment usage (AT2)

c_5: Depreciation cost of CO_2 collect equipment usage per unit at the cement plant (AT3)

c_6: Energy cost of CO_2 collect equipment usage (AT3)

$$C = \begin{pmatrix} c_1 \\ \vdots \\ c_6 \end{pmatrix} \quad (2)$$

Thus, vector AC consists of items that represent the costs of activities (per unit) computed using Eq. 3 :

$$AC = B \cdot C = \quad (3)$$

$$\begin{pmatrix} b_{11} & \cdots & b_{16} \\ \vdots & \ddots & \vdots \\ b_{71} & \cdots & b_{76} \end{pmatrix} \cdot \begin{pmatrix} c_1 \\ \vdots \\ c_6 \end{pmatrix} = \begin{pmatrix} ac_1 \\ \vdots \\ ac_7 \end{pmatrix}$$

The next step involves allocating the respective quantities to the activities for the final product. Figure 1 also visualizes the quantity of materials at each activity. For instance, $'Q_{\mathrm{CR}}'$ represents the amount of CR arriving at the recycling facility, while Q_{RCA} and Q_{WCP} represents the amount of materials arriving at the concrete plant. Thus, those parameters can be represented as follows:

q_1 : Material quantity (CR) transported from a demolished site to a recycling plant (Q_{CR})

q_2 : Material quantity at RF (RCA and WCP, not carbonized: Q_{RCA}, Q_{WCP})

q_3: Material quantity at cement plant (CO_2 and cement: Q_{CO2}, Q_{Cem})

q_4: Natural materials quantity transported to a concrete plant (gravel and sand: Q_{NM}^{gravel}, Q_{NM}^{sand})

Therefore, the matrix 'Q' represents the allocation of material quantities to each activity (Eq. 4). In this matrix, the horizontal lines represent the quantity of materials ($q_1 \ldots q_4$) at different facilities, while the vertical lines correspond to the different activities ($a_1 \ldots a_7$). For example, $'q_{11}'$ stands for the quantity of CR transported from a demolishing site (DS) to a recycling plant, while $'q_{22}'$ and $'q_{32}'$ represents the quantity of RA and WCP at the recycling facility correspondently (not carbonized).

$$\mathrm{Q}= \begin{matrix} DS \\ RF \\ CM \\ NM \end{matrix} \begin{pmatrix} q_{11} & q_{12} & \cdots & q_{17} \\ q_{21} & q_{22} & \cdots & q_{27} \\ q_{31} & q_{32} & \ddots & q_{37} \\ q_{41} & q_{42} & \cdots & q_{47} \end{pmatrix} \quad (4)$$

Final product cost (PC) can be determined by Eq. 5:

$$PC = Q \cdot \mathrm{A}C = \quad (5)$$

$$\begin{pmatrix} q_{11} & q_{12} & \cdots & q_{17} \\ q_{21} & q_{22} & \cdots & q_{27} \\ \vdots & \vdots & \ddots & \vdots \\ q_{41} & q_{42} & \cdots & q_{47} \end{pmatrix} \cdot \begin{pmatrix} ac_1 \\ ac_2 \\ \vdots \\ ac_7 \end{pmatrix} = \begin{pmatrix} pc_1 \\ pc_2 \\ \vdots \\ pc_4 \end{pmatrix}$$

For the environmental cost calculation, a matrix 'E' is utilized to represent the environmental cost per unit of the considered material. In this matrix, the horizontal rows correspond to various activities (a_1 to a_7) represented above, such as CR, RA, WCP, and CO_2 processing, while the vertical columns indicate CO_2 emissions per unit of material during specific processes (e_1). Environmental parameters are illustrated in Figure 1 as $E_1 - E_5$ and AE_1 - AE_4 and represented as column values below:

e_1: Amount of CO_2 emissions by each equipment per unit of material *(a_i)* during recycling and carbonization processing (E1, E2)

e_2: Amount of CO_2 absorption during the RCA and WCP carbonization (AE1)

e_3: An environmental effect associated with soil and water contamination, as well as land occupation in landfills (AE2).

e_4: Amount of CO_2 emissions by each equipment per unit of flue CO_2 collection (E3)

e_5: Amount of captured CO_2 per unit of flue gases at the cement plant (AE3)

e_6: Amount of CO_2 emissions per unit of cement produced (E5)

e_7: Environmental effect related to the unit of natural material (gravel) processing for the concrete manufacturing (E4)

e_8: Savings associated with the substitution of natural materials (gravel) per unit (AE4)

e_9: An environmental effect related to the unit of natural material (sand) processing for concrete manufacturing (E4)

e_{10}: Savings associated with the substitution of natural materials (sand) per unit (AE4)

The matrix 'E' is represented as Eq. 6. For instance, the matrix element $'e_{11}'$ indicates the amount of CO_2 emissions produced per unit of CR processed into RCA and WCP. In this context, CO_2 emissions are represented as negative values, while CO_2 sequestration is denoted as positive values.

$$E = \begin{matrix} CR \\ RCA \\ \vdots \\ NM_{sand} \end{matrix} \begin{pmatrix} e_{11} & e_{12} & \cdots & e_{1\,10} \\ e_{21} & e_{22} & \cdots & e_{2\,10} \\ \vdots & \vdots & \ddots & \vdots \\ e_{71} & e_{72} & \cdots & e_{7\,10} \end{pmatrix} \quad (6)$$

The environmental costs of activity drivers (per unit) can be represented as a column vector 'EC' (Eq. 7). The unit costs of activity drivers $\mathrm{e}_1 - \mathrm{e}_{10}$ are as follows:

$ec_1, ec_2, ec_4 - ec_7, ec_9$: Environmental cost related to the unit of material recycling and carbonization

ec_3: Environmental costs per unit of disposed material due to soil and water contamination and landfill occupation.

ec_8: Cost per unit of substituted natural materials (gravel)

ec_{10}: Cost per unit of substituted natural materials (sand)

$$EC = \begin{pmatrix} ec_1 \\ \vdots \\ ec_{10} \end{pmatrix} \quad (7)$$

Thus, vector 'EEC' consists of items that represent the environmental costs of activities (per unit) computed using Eq. 8:

$$\mathrm{EEC} = E \cdot \mathrm{E}C = \quad (8)$$

$$\begin{pmatrix} e_{11} & \cdots & e_{1\,10} \\ \vdots & \ddots & \vdots \\ e_{71} & \cdots & e_{7\,10} \end{pmatrix} \cdot \begin{pmatrix} ec_1 \\ \vdots \\ ec_{10} \end{pmatrix} = \begin{pmatrix} eec_1 \\ \vdots \\ eec_7 \end{pmatrix}$$

Final product environmental cost (PEC) can be determined by Eq. 9:

$$PEC = Q \cdot \mathrm{EEC} = \quad (9)$$

$$\begin{pmatrix} q_{11} & q_{12} & \cdots & q_{17} \\ q_{21} & q_{22} & \cdots & q_{27} \\ q_{31} & q_{32} & \ddots & q_{37} \\ q_{41} & q_{42} & \cdots & q_{47} \end{pmatrix} \cdot \begin{pmatrix} ec_1 \\ ec_2 \\ \vdots \\ ec_7 \end{pmatrix} = \begin{pmatrix} pec_1 \\ pec_2 \\ \vdots \\ pec_4 \end{pmatrix}$$

3 Case study

The Hong Kong concrete waste market was chosen as a case study due to the city's proactive approach in tackling local challenges. The government has implemented various initiatives aimed at enhancing CDW management and achieving carbon neutrality. Currently, the government's policy direction emphasizes further reduction of CDW and aligns with the global movement towards carbon neutrality. This strategy is reinforced by key government documents, including "Hong Kong's Climate Action Plan 2030+" [25], "Waste Blueprint for Hong Kong 2035" [26], and "The Chief Executive's 2022 Policy Address" [27]. The "Climate Action Plan 2030+" specifically outlines strengthened measures to combat climate change and establishes a target for reducing carbon emissions by 2030.

3.1 Data collection

To illustrate the practicality and feasibility of the proposed matrices, an assessment was conducted for the Hong Kong market, focusing on the Tseung Kwan O Area 137 Construction Waste Sorting Facility (TKO137SF) as a basis for integrating demolished concrete carbonization technology. Decisions and defined variables were quantified using reliable data obtained from a range of credible sources, including sustainability reports from government agencies, Hong Kong standards, a Life Cycle Assessment tool database,

the Chinese life cycle database V0.8, and production specifications for recycled concrete. This information was incorporated into the ABC model matrixes to produce final results and facilitate a comparison of the two scenarios under consideration. The average quantity of incoming demolished concrete was determined based on statistics from the Environmental Protection Department and the Census and Statistics Department. The estimated annual amount of concrete rubble (CR) is 80,002 tonnes [28], assuming that 15% of this recycled material is transformed into WCP [29]. Consequently, the capacities of all considered equipment were calculated based on the average daily and yearly waste turnover. Separate calculations indicate that carbonizing this quantity of CR byproduct requires a total of 8,144 tonnes of CO_2 annually. Additionally, the amounts of substitute cement, gravel, and sand were determined based on standard concrete mix proportions.

3.2 Data processing and discussion

The obtained data is utilized to populate the matrices (B, C, Q, E, and EC), which are necessary for subsequent calculations, ultimately leading to the formation of the 'PC' and 'PEC' matrices. The final matrices associated with the environmental cost of the traditional method are represented in Eq. 10 (PEC_{trad}). In this context, the final product cost matrix (PC_{trad}) is not included, as it only accounts for additional equipment and resources while keeping the existing recycling processes unchanged. Negative numbers represent the loss of CO_2, while positive numbers indicate preserved CO_2. The vector element $'pc_1'$ reflects the recycling of CR through traditional methods, excluding any consideration of additional equipment, which is consequently equal to '0'. The vector element 'pc_2' is quantified at 2.4 million HKD per year, signifying the environmental impact related to soil and water contamination, as well as land occupation in landfills, due to WCP being directed to landfills instead of being recycled. Additionally, the vector element $'pc_3'$ represents the annual CO_2 emissions resulting from cement production that could potentially be mitigated through the use of WCP to capture CO_2 from the cement plant, amounting to 1.5 million HKD. Similarly, 'pc4' illustrates the annual CO_2 emissions associated with the expenditure on natural resources, totalling 125,505 HKD.

$$PEC_{trad} = \begin{pmatrix} 0.00 \\ -2{,}400{,}060 \\ -1{,}495{,}289 \\ -124{,}505 \end{pmatrix} \quad (10)$$

The final matrices for the product cost in the proposed recycling process are represented in Eq. 11, which details expenses related to additional technology integration and energy consumption. The vector element $'pc_1'$, approximately 3,964HKD, indicates the annual amortization cost and energy consumption needed to upgrade the existing equipment for recycling the annual quantity of CR and producing WCP in addition to RCA. This cost is relatively low, as only an additional mobile vibrating screen for sieving is required alongside the current capabilities. The elements $'pc_2'$ and $'pc_3'$ represent the additional equipment amortization costs and energy consumption for the carbonization of RCA and WCP, as well as the flue CO_2 collection, respectively. The energy consumption of the CO_2 collection equipment is quite high (19 kWh/tonne), resulting in an annual cost of nearly 1.5 million HKD.

In terms of environmental impact (Eq.12), CO_2 emissions occur during the processing of CR into RCA and WCP with $'pec_1'$ equaling -736HKD. In the subsequent carbonization stage (with $'pec_2'$ costing 6.3 million HKD per year), the CO_2 absorbed by RCA and WCP significantly outweighs the emissions from the energy used in the process. Additionally, saving landfill space plays a crucial role in enhancing environmental benefits. The vector element $'pec_3'$, approximately 5.1 million HKD per year, represents savings in cement manufacturing due to flue CO_2 collection and the substitution of cement with WCP, which has a considerable environmental impact. The highest figure, 28.3 million HKD per year (represented by 'pec_4'), reflects the conservation of natural materials (gravel and sand) in terms of preserving these resources and avoiding energy expenditure for their processing.

$$PC_{altern} = \begin{pmatrix} 3{,}964 \\ 139{,}540 \\ 1{,}479{,}910 \\ 0.00 \end{pmatrix} \quad (11)$$

$$PEC_{altern} = \begin{pmatrix} -763 \\ 6{,}294{,}267 \\ 5{,}090{,}160 \\ 28{,}275{,}866 \end{pmatrix} \quad (12)$$

Figure 2 illustrates that the annual costs for additional equipment investment and energy consumption in the proposed approach closely match the environmental costs of traditional methods. This alignment indicates that the alternative approach offers significant environmental benefits across all facilities involved. Moreover, by reducing carbon emissions, these facilities can engage in the carbon credit market, allowing them to buy and sell carbon credits. This provides a financial incentive for adopting greener technologies while contributing to sustainability goals. In summary, the proposed approach not only balances economic and environmental costs but also creates opportunities for revenue through carbon credits.

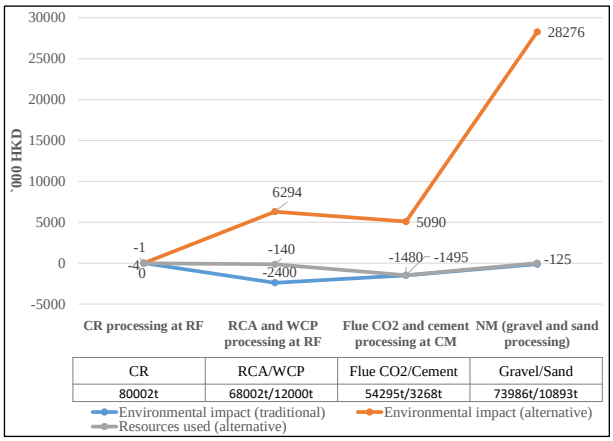

Figure 2. Cost comparison between traditional and proposed approaches.

4 Conclusions

This research explored the practicality and effectiveness of applying active carbonation techniques to WCP and RCA, using flue gases from cement manufacturing as a substitute source of CO_2 for the carbonization process. This innovative approach utilizes flue gases from cement plants for carbonation, significantly reducing the environmental costs associated with cement production and the processing and consumption of natural materials.

The comparison of environmental impacts between traditional and alternative demolished concrete recycling methods (PEC_{trad} and PEC_{altern}) reveals significant differences across all operations in the analyzed facilities. RCA and WCP processing at recycling facilities exhibits a 362% increase from traditional to alternative methods, transforming from -2,400 to 6,294kHKD. The collection of flue CO_2 and cement processing at the cement plant shows an even larger percentage change of 440%, rising from -1,495 to 5,090kHKD. The most significant difference is in natural material processing (gravel and sand), showing an increase of approximately 227kHKD in absolute terms, attributed to the conservation of natural materials and reduced energy expenditure for processing. These significant percentage increases and the shift from negative to positive values in most processes indicate a fundamental difference in environmental impact assessment between the two methodologies. Considering the environmental benefits of the proposed recycling approach that incorporates carbonization technology, the government should implement initiatives to promote this technology further, as it will enhance its ESG evaluation and align with overall policies aimed at reducing carbon emissions.

The universalization of the matrix can be expanded to adapt it to different configurations within the CDW supply chain. However, it's crucial to take into account specific conditions in the recycling market, such as issues related to illegal dumping, which may necessitate modifications to the model. The data were taken as the average quantity of demolished concrete, with other parameters adjusted to simulate and analyze the differences between approaches. The same matrices can be reused. Future research will explore broader implementation challenges, including logistical constraints and site-specific conditions, while examining how the Hong Kong-based model can be adapted to diverse global markets through considerations of varying regulatory frameworks, market maturity, consumer behavior patterns, and regional infrastructure development stages.

Harnessing Digital Twins for Construction Site Management

Ahmad Al Ayoubi[1] and Ashtarout Ammar[1], PhD

[1]Myers-Lawson School of Construction, Virginia Polytechnic Institute and State University, USA
alayoubi@vt.edu, aammar@vt.edu

Abstract

Digital Twins (DTs) is transforming construction by providing real-time, data-informed solutions that improve project workflows and can aid in achieving decarbonization objectives. In construction, DT was mainly implemented in the operation & maintenance phase. However, by combining DT's functionalities of real-time monitoring, predictive analytics, sophisticated simulations, and collaborative decision-making, construction site management can be revolutionized by enabling site managers and stakeholders to refine construction processes, enhance resource use, lower emissions, boost quality, and reduce expenses. These features tackle essential issues like operational inefficiencies, resource depletion, and communication failures, providing a more integrated and sustainable method for managing construction site activities.

This study uses a Systematics literature review (SLR) to thoroughly examine the function of DTs for onsite construction management, emphasizing their application in managing safety, logistics and material, emissions and energy, quality assurance and detection, real-time decision support, dust, noise, and vibration monitoring, digital collaboration and issue resolution, and real-time worker productivity tracking. Conversely, DTs can facilitate accurate monitoring of carbon emissions and encourage eco-friendly construction methods by integrating technologies such as Internet of Things sensors, cloud computing, and artificial intelligence. Furthermore, DT-driven workflows, including prefabrication and modular building, promote waste reduction and energy conservation, harmonizing onsite activities with net-zero carbon objectives. This research highlights the crucial functions of DTs in optimizing onsite construction workflows, showing their ability to transform the industry and aid in moving towards a more sustainable and decarbonized built environment.

Keywords – Digital-Twins, Decarbonization, Construction Site Management, Construction Planning

1 Introduction

The construction industry is at a pivotal juncture, facing persistent challenges such as inefficiencies, cost overruns, schedule delays, and the need to meet stricter sustainability standards [1]. Despite advances in project management tools and building techniques, construction companies continue to seek new technologies to enhance productivity, achieve sustainability goals, and improve customer satisfaction in an increasingly competitive and complex market [2]. Emerging technologies, particularly DTs, have garnered significant attention as a potential solution to these challenges due to their ability to provide real-time insights and predictive capabilities [3].

DTs present a breakthrough by creating dynamic virtual models of physical construction systems that integrate real-time data, predictive analytics, and advanced simulations. These virtual replicas imitate onsite conditions and processes, enabling stakeholders to monitor material conditions, track equipment performance, and visualize workflows in real time, fostering proactive decision-making and improved quality control [4]. The ability of DTs to merge the physical and virtual environments through data centralization significantly improves communication across stakeholders and reduces errors, aligning construction projects with sustainability and environmental standards [5].

One of the key contributions of DTs is their ability to support sustainability efforts by enabling real-time monitoring of emissions, energy consumption, and waste generation on construction sites. By integrating Internet of Things (IoT) sensors with cloud-based platforms, DTs provide comprehensive feedback loops that ensure construction activities remain aligned with sustainability targets [7, 8]. Moreover, the optimization capabilities of DTs allow teams to simulate and refine workflows before implementation, which is particularly valuable in complex projects where early identification of inefficiencies can save significant time and resources [8]. For instance, DT-enabled simulations of crane operations can help predict potential conflicts in crowded sites, allowing site managers to redesign workflows to prevent delays and accidents [9].

However, despite these promising capabilities, key research gaps remain. There is limited empirical evidence

demonstrating the impact of DT-enabled onsite workflows on decarbonization and operational efficiency. Additionally, the industry lacks standardized methodologies for implementing DTs in onsite construction, as well as case studies that illustrate best practices across various project types and regions. Addressing these gaps is essential for validating the role of DTs in transforming onsite construction.

To bridge this gap and improve the understanding of the potential of DTs for construction site management, this paper examines in detail the critical role of the four DTs' key functions (i.e., real-time monitoring, predictive analytics, simulation, and collaborative decision-making) in managing construction sites by optimizing schedules and enhancing safety. Depending on project site needs, site managers can integrate these functions to create various onsite applications, optimizing efficiency and decision-making [10]. Building on this concept, this study analyzes eight specific applications fundamental for efficient construction site management that result from these functions' combinations: 1) safety management, 2) logistics and material management, 3) emissions and energy management, 4) quality assurance and defect detection, 5) real-time decision support, 6) dust noise and vibration monitoring, 7) digital collaboration and issue resolution, 8) real-time worker productivity tracking.

By examining these four core functions and their eight applications (detailed in Section 3), this paper highlights how DTs can increase efficiency, reduce costs, time, and complexity, improve onsite construction workflows, address persistent industry challenges, and contribute to sustainable project outcomes, particularly in supporting decarbonization efforts.

2 Methodology

2.1 Systematic Literature Review Approach

This study adopts a systematic review methodology guided by the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) framework to ensure transparency, replicability, and comprehensiveness [11]. The PRISMA methodology was employed to identify, screen, and select relevant academic literature on DTs applications for on-site construction. The review focused on identifying peer-reviewed articles (i.e., peer-reviewed conferences and journals) that provide insights into DTs functionalities such as real-time monitoring, predictive maintenance, workflow optimization, and collaborative decision-making, as adopted from [10].

The systematic search for this study was conducted using two major academic/research databases, Web of Science and Google Scholar, for their extensive coverage of broad search capabilities and coverage of emerging research trends [12, 13]. To capture a comprehensive range of studies, we carefully chose search word strings. These search strings utilized Boolean operators and keywords aligned with the study's focus on DTs for on-site construction; the strings are as follows:
"Digital Twins" And "Construction Quality" Or "Real-Time Monitoring" Or "Predictive Maintenance" Or "Digital Twins" And "Construction" And "Simulation" And "Optimization" Or "Digital Twins" And "Workflow" Or "Digital Twins" And "Stakeholder Collaboration" And "Construction" Or "Construction Quality" Or "Digital Twins Applications" And "Sustainability" Or "Digital Twins" And "Construction" And "IoT Sensors" Or "Digital Twins" And "Construction Safety" Or "Defect Detection" Or "Digital Twins" And "Construction" Or "Material Management" Or "Digital Twins" And "On-Site Construction" Or "Digital Twins Framework" And "Construction Project Management."

These search strings were continuously refined based on the relevance and quality of the initial search results, ensuring a comprehensive and accurate representation of the topic. In addition to the search strings, multiple filters and inclusion/exclusion criteria, as presented in Table 1, were applied to ensure that only relevant papers were considered for a more comprehensive review.

Table 1. Inclusion criteria of the research.

Criteria	Inclusion Criteria
Publication Type	Peer-reviewed journal and conference papers.
Language	Papers published in English.
Timeframe	Studies that were published between 2018 and 2024.

The initial search resulted in 80 peer-reviewed articles extracted from Google Scholar and Web of Science databases. After applying the filters based on the inclusion/exclusion criteria and reviewing the full text to ensure that the extracted studies align with the research objective, 50 journals were considered for in-depth analysis. Figure 1 below outlines the study selection process, showing the breakdown of how many papers were extracted from each database and how they were filtered based on the inclusion/exclusion criteria.

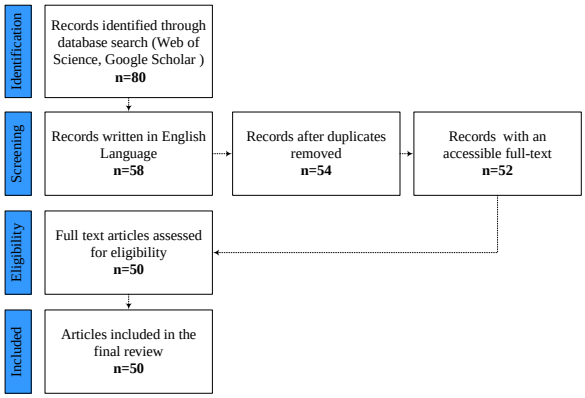

Figure 1. PRISMA Flow Diagram

2.2 Data Extraction and Synthesis

The 50 selected articles were then reviewed carefully, and key points and findings were extracted. The analysis focused on the contributions of DTs for on-site construction, and data was then categorized based on the following areas:

1. General Key Functions.
2. Specific applications.

This methodology provides a detailed account of the systematic review process used, adhering to the PRISMA framework, and highlights the search strings and criteria that were adopted.

3 Digital Twins Functionalities and Applications for Construction Site Management

The findings extracted from the reviewed articles were divided into two sections: the first section consists of the general key functions of DTs. In contrast, the second section consists of the on-site construction applications of DTs. The general key functionalities section goes over how each function works and how they can be applied. In contrast, the application section discusses in detail how when the functions are combined simultaneously, they can influence and improve the on-site construction processes and workflows, affecting the overall quality, efficiency, decarbonization, and sustainability goals.

3.1 General Key Functions of Digital Twins in Construction

3.1.1 Real-Time Monitoring and Feedback

Real-time monitoring is foundational to DTs, providing continuous visibility and insight into the on-site processes. Through IoT sensors and cloud-based platforms, DTs enable real-time tracking of material conditions, structural integrity, and equipment performance, such as cranes [9]. By monitoring performances, management can keep track of CO_2 emissions, keep track of idle time and fuel consumption for machinery, make instant decisions based on real-time data, or backup decisions that might be contradictory, such as switching to electric-powered equipment [14]. Real-time monitoring is essential in every application under the DT umbrella. By using real-time monitoring and feedback, the engineers and site teams can have insights and information from the virtual realm [15]. This empowers the site team to conduct modifications based on informative insights extracted from real-time data without wasting time, effort, money, and human resources, which brings projects closer to sustainability and environmental goals.

3.1.2 Predictive Analytics

Predictive analytics leverage DTs analytics to predict equipment failures, structural degradation, material shortages, and logistic needs. By using AI, DT can analyze historical and real-time data to identify patterns and anomalies that can indicate potential risks and failures, allowing for timely interventions [16]. For instance, vibration data from cranes monitored by DTs can detect stress or wear-and-tear, enabling teams to schedule maintenance before failures occur, extending the lifecycle of equipment, thus reducing the need for replacements and minimizing the environmental impact of manufacturing and transport [7, 17]. This information reflects on the current production flows and is essential for planning and control systems [18]. Currently, there is an underutilization of data, and this allows for missed opportunities to enhance maintenance efficiency and strategy, improving safety, and reducing costs. [19].

By optimizing equipment ‘health,’ machinery will operate more efficiently, consume less fuel, and emit fewer greenhouse gases. Through predictive analytics, DTs aids in improving on-site construction efficiency, reducing construction-related risks, and ensuring the overall quality of the project [20].

3.1.3 Simulation and Optimization

Simulations powered by DTs are invaluable for optimizing on-site construction workflows and validating designs before implementation. Performance simulation is the domain that duplicates and forecasts multiple aspects of construction by applying fundamental physical concepts and engineering methodologies to a computer-based mathematical model [21]. DTs allow teams to test alternative scenarios, identify inefficiencies, and optimize resource allocation. For instance, simulating crane movements on congested construction sites can help identify conflicts, optimize arrangements, enhance operational efficiency while minimizing risks, and reduce delays, as poor scheduling and planning often contribute to budget overruns in construction projects [9].

Simulation tools also drive decarbonization by enabling construction teams to assess the environmental impact of materials and methods before execution. For instance, DTs can simulate workflows and identify opportunities to minimize energy consumption, such as scheduling heavy equipment usage during off-peak energy hours to leverage cleaner electricity.

3.1.4 Collaborative Decision-Making

Collaboration is central to successful construction projects, and DTs facilitate this by providing a unified platform for data sharing and analysis. Cloud-enabled DT systems can accomplish near-real-time data exchange between a digital replica and the physical environment, which can help designers make management site execution decisions. [22].

In the context of decarbonization, collaborative platforms supported by DTs simulate built environmental changes and assist in decision-making for environmental

optimization through platforms, thus reducing the need to visit the site and delaying actions [23].

3.2 Applications for Digital Twins in On-Site Construction

In addition to the general key functions, DTs enables a range of applications in site construction by integrating multiple functionalities simultaneously. Rather than requiring multiple DTs, a single DT equipped with the necessary IoT sensors *(depending on the case and need)* can support eight key applications.

While not exhaustive, these applications represent essential site operations, demonstrating how four fundamental DT functions can drive efficiency, optimization, and sustainability for on-site construction management. By leveraging DTs technology, construction projects can enhance operational workflows while contributing to decarbonization efforts. This section examines eight critical applications where DTs play a transformative role in modern site operations in construction.

3.2.1 Safety Management

Safety management is a top priority in construction, and DTs enhance this by integrating IoT-enabled wearables and real-time monitoring systems. DTs can track worker locations, proximity to hazards, and adherence to safety protocols, preventing accidents and improving compliance [24]. As demonstrated by [25], site management can use drones to monitor potential hazards, allowing them to prevent incidents from occurring. Furthermore, by utilizing real-time analysis, DTs enables site teams in their preparedness to respond to possible accidents [26] properly. This allows the site to not only be prepared in case of emergencies but possibly prevent them altogether.

3.2.2 Logistics and Material Management

DTs streamline material tracking to ensure that resources are utilized efficiently and minimize waste. By monitoring material inventories and deliveries in real-time, DTs enable precise ordering schedules and prevent overstocking or spoilage [27]. Various technologies are adopted into DTs to be able to track materials and stay on top of logistics, such as Radio-Frequency Identification (RFID), which detects items, materials, or targets by utilizing radio frequencies for data processing [28] or Blockchain, which allows for traceability throughout chain activities that are fragmented or isolated [29]. While tracking is fundamental in material management and logistics, other important aspects result from it, such as recycling and waste reduction.

By tracking materials and always knowing the leftovers present on-site from deliveries, excavations, or demolitions, recycling and waste reduction become critical, easier, and needed for better sustainability and environmental metrics [30]. By tracking these activities, DTs can help identify the sources of high embodied carbon emissions (ECE) emissions that are present in materials and products in construction and buildings [31] in real-time [28]. It also includes the activities used to transform these materials for buildings [32]. Through this DTs application, a site can keep track of its material handling and quantity management, resulting in a better ability to manage recycling, reusing, and waste management.

3.2.3 Emissions and Energy Management

As of 2021, carbon emissions are currently on a global rise, with buildings making up to 37% of carbon emissions and 34% of energy consumption, with the construction industry (concrete, steel, and aluminum) occupying 4% and 9%, respectively [33]. These numbers are estimated to rise as the number of floor areas is estimated to rise by 75% between 2020 and 2050, of which 80% will be in developing economies, which is equivalent to the floor area of Paris being constructed every week till 2050 [34].

With the use of DT, reducing energy consumption and carbon emissions has become easier. DTs can calculate shadow areas, allowing project managers to use renewable energy resources (RES) and hybrid systems better and monitor and simulate energy expenditure, thus contributing to reducing the site's dependency on fossil fuels and furthering the decarbonization agenda [35].

Furthermore, DTs can provide transformative solutions by utilizing real-time data, predictive analytics, and sensors such as smart meters to reduce emissions and energy usage and identify areas that require improvement [43, 44]. This helps site management know if something is left operating by mistake, ensure no consumption occurs when not needed, and keep a better eye on energy expenditure.

3.2.4 Quality Assurance and Defect Detection

For quality assurance and defect detection, DTs can delve into details that are not purely construction-based and are often carried out on-site. For instance, DTs can be applied to the welding of large excavation motor arms [38]. Also, DTs can be used to form a model that can adapt to a variety of situations to monitor the quality of spot welding (i.e., structural steel welding) to achieve dynamic control over welding quality and ensure product stability [39].

Early defect detection reduces the material and energy demands associated with rework. By preventing this waste, DTs can directly contribute to lower emissions and resource conservation. By utilizing predictive analytics and real-time feedback, DTs provide the ability to predict the condition of machines and prevent unplanned halts in work. In some cases, such as diesel-operated motors, it can lead to a reduction in air pollutants produced by ill-maintained diesel engines.

3.2.5 Real-Time Decision Support

Decision-making has been revolutionized for on-site applications by DTs. By integrating IoT devices and sensors, DTs allow for a dynamic decision-making environment. By using up-to-date real-time deviations, DTs enhance planning and scheduling and optimize modular construction processes while ensuring seamless integration and minimizing disruption in cases like precast concrete assembly [40]. As mentioned previously in Section 3.2.2, DTs improve material management by providing visibility and traceability of resources [41]. This feature allows site managers to anticipate and resolve material shortages and enable predictive decision-making to forecast risks and bottlenecks to ensure uninterrupted progress [42]. Also, as discussed in section 3.2.4, when DTs provides a prompt to perform maintenance preemptively, it can provide advice on when to perform it and ensure that the site management is well-informed to understand the implications better and take a well-informed approach.

Furthermore, DTs also support the reduction of the carbon footprint by optimizing resource use, reducing waste through real-time decision-making, and performing energy consumption planning to adjust energy use [43].

3.2.6 Dust, Noise, and Vibration Monitoring

Dust, noise, and environmental monitoring are becoming increasingly important. With DTs, site managers can monitor these factors continuously to improve the management of environmental risks. This data helps mitigate health hazards associated with dust exposure, implement noise-reduction strategies, and offer comprehensive monitoring solutions for construction operations to reduce vibrations [44].

In a case study conducted by the authors of [1], DT models were able to control tunnel dust levels, ensure safe working conditions, and adhere to environmental guidelines. These applications underscore DTs' potential in reducing and possibly in the future eliminating environmental impacts and ensuring regulatory compliance with green metrics [37].

3.2.7 Digital Collaboration and Issue Resolution

In construction projects, conflicts often occur. This might be due to miscommunication, design discrepancies, scheduling clashes, or multiple other reasons. Multiple approaches can be used to reduce such conflicts. The authors of [45] showed how DTs could create a shared platform for all stakeholders to access real-time data, reduce misunderstandings, and accelerate the decision-making process, while [46] integrated data mining with building information modelling (BIM) in a DTs platform to enhance project management, and allow for swift changes in the schedule by detecting conflicts and inconsistencies. Similarly, the authors of [47] noted that DTs can foster collaboration between practitioners, stakeholders, and authorities by providing a unified interface for problem-solving and discussions. When such platforms are applied, conflict resolution significantly improves through the decision-making capabilities of DTs by creating an accountable record of decisions and changes [48]. By reducing conflicts, rework also decreases significantly, reduces construction time, and improves construction/project management. This implies that DTs not only improve project outcomes but also significantly contribute to the industry's social and environmental goals [43].

3.2.8 Real-Time Worker Productivity Tracking

DTs are reshaping worker productivity tracking. The authors of [40] highlighted how the use of synchronized DTs for managing workflows in construction ensures worker productivity aligns with project milestones.
DTs can identify worker output inefficiencies by using a cyber-physical system, which allows them to provide actionable insights to improve workforce performance [49].

While some approaches focus on human productivity monitoring, other approaches focus on increasing human productivity via human-robot collaboration to optimize both human and machine productivity [50]. Productivity doesn't always decrease due to uncontrollable events. They might be caused due to fatigue or health issues. To avoid such issues, the authors of [51] discussed how wearable devices can monitor laborers' health and avoid problems that might arise due to such issues.

By offering real-time insights, DTs empower construction managers and superintendents to monitor and improve worker productivity dynamically without sacrificing health, cost, and quality.

4 Results & Conclusion

This study highlights the potential of DT technology in on-site construction, demonstrating how it integrates real-time monitoring and feedback, predictive maintenance, simulation and optimization, and collaborative decision-making to enhance site management, efficiency, and decarbonization efforts. By applying these four key functions using the eight applications discussed in section 3, DT can address safety concerns and maintenance issues, monitor and track workers & worker productivity, enhance decision-making & collaboration, increase quality of work and reduce the effort needed for recycling and material management.

The findings illustrate that DTs play a crucial role in ensuring that site management has a proper hold on what is going on on-site. With DTs receiving real-time feedback, tracking inventory, prompting action when an incident might occur, and tracking workers, site management will be able to manage better and relay

progress to the higher-ups, increasing collaboration efficiency and critical decision-making.

Beyond efficiency gains, DTs significantly contribute to sustainability and decarbonization. By minimizing rework, reducing waste, preventing equipment failure, reducing fossil fuel dependency, and optimizing energy consumption, DTs help construction projects lower carbon emissions and overall environmental impact. Their ability to monitor pollutants, track emissions, and support recycling & material reuse efforts further strengthens their role in site decarbonization initiatives. Figure 2 below illustrates how the four functions are applied to support each of the eight identified specific applications, ultimately contributing to decarbonization efforts in on-site construction.

In essence, DTs represent a major advancement in modern site operations, offering a scalable, data-driven solution to enhance overall productivity. As the industry continues to embrace digitalization and sustainability, DTs will be critical in driving innovation, improving resilience, and shaping a more efficient, collaborative, and eco-friendly built environment. Future research should focus on standardized DTs frameworks to allow for one DT to perform seamlessly between projects and improve interoperability further to enhance automation and predictive capabilities in site construction.

Abstract

Embodied carbon in the construction industry is a significant contributor to global carbon emissions. With growing emphasis on carbon neutrality and carbon pricing, the need for effective carbon accounting has become increasingly important. However, inefficient carbon information sharing, driven by the complex and fragmented nature of construction supply chains and the complicated quantification process, hinders carbon accounting. A blockchain-based system is believed to offer a potential solution, but limited research exists on its application. Additionally, existing blockchain-based studies often focus on computable metrics during evaluation, overlooking system design objectives and industry stakeholders' needs. To address these gaps, this study proposes a public blockchain-based carbon management system for embodied carbon information sharing and quantification in the construction industry. It also introduces a comprehensive evaluation framework to verify and validate the system. The research's contributions include: (i) exploring the application of blockchain for sharing and quantifying embodied carbon information in construction supply chains, and (ii) introducing a comprehensive evaluation framework to assess the functional suitability, performance efficiency, usability, system effectiveness, and industry impacts of a blockchain-based system.

Keywords –

Embodied carbon, Information Sharing, Blockchain, Evaluation, Verification, Validation

1 Introduction

According to the World Green Building Council, the construction industry accounts for 39% of global energy-related carbon emissions [1]. A building's life cycle comprises four phases: production, construction, operation, and demolition [2]. Among these, embodied carbon—which encompasses all emissions associated with materials and construction processes, from manufacturing to disposal—accounts for 11% of global carbon emissions [1].

During the 26th United Nations Climate Change Conference (COP26) in 2021, a call was made to achieve net-zero emissions for all new and existing assets by 2050 [3]. Additionally, the Intergovernmental Panel on Climate Change (IPCC), in its Sixth Assessment Report, emphasized the significance of carbon pricing as a key tool for cost-effective climate change mitigation [4]. These developments highlight the rising importance of accounting for embodied carbon in the industry.

Many researchers agree that poor carbon information sharing is a significant issue, including inaccurate and insufficiently detailed carbon data [5], [6] and a lack of data transparency and traceability [6], often due to traditional database systems. Blockchain technology, with features such as immutability, traceability, and transparency, has been explored for applications in the construction industry, including information management [7], [8] and carbon management [9], [10]. Consequently, blockchain is believed to offer promising solutions for improving carbon information sharing. While blockchain-based approaches for embodied carbon management have improved data integrity and privacy [11], challenges remain in ensuring the traceability of carbon information sharing and the quantification process

Moreover, existing blockchain-based solutions for the construction industry primarily focus on computable performance metrics (e.g., network latency, system transactions per minute), neglecting usability, adaptability and effectiveness. There is a lack of comprehensive evaluation methods to verify and validate blockchain-based systems, particularly in assessing whether they meet their intended objectives, align with stakeholder needs, and have long-term adoption potential.

This research investigates how blockchain enhances carbon information sharing and quantification, and proposes a comprehensive evaluation framework for the blockchain-based system. Therefore, this research aims

to address the following two research questions:

- How can a blockchain-based carbon management system enhance traceability in information sharing and the quantification process of embodied carbon in the construction supply chain?
- How can a comprehensive evaluation framework be developed to verify and validate a blockchain-based carbon management system?

2 Related Works

2.1 Blockchain applications in construction industry

Unlike traditional databases, where data is controlled and accessed by a central authority, which can lead to potential risks such as data tampering and reduced trust among participants [12] , blockchain is a decentralized ledger technology enabling secure, transparent transactions on a peer-to-peer network. Transactions are validated by consensus mechanisms and linked in blocks with unique hashes [13]. Therefore, the key characteristics of blockchain include transparency, immutability, traceability, and smart contracts executed by self-executing code [14]. Due to its capabilities and feasibility, researchers have begun exploring its potential applications in the construction industry since 2017. Two key areas of focus for blockchain in the construction industry are information management [7], [8] and supply chain management [15], [16]. Several studies have explored the application of blockchain to carbon management. For instance, blockchain has been integrated into certification and supply chains [9] [17], life cycle assessment [18], and embodied carbon estimation [10] and tracking [11]. However, while blockchain has been applied to carbon management in these contexts, existing studies tend to focus on simplified supply chain models. These models overlook the complexities involved in the carbon quantification process within the construction supply chain. This paper expands on previous research by incorporating smart contracts into the quantification process while maintaining data traceability.

2.2 Evaluations of blockchain-based in construction industry

There are several studies related to blockchain-based systems that have been developed in various areas, such as supply chain management. Examples include blockchain-based systems for transforming personal protective equipment supply chain operations [19], facilitating inventory sharing between suppliers and retailers [20], and enhancing product traceability in the healthcare supply chain [21]. These systems are typically evaluated through smart contract validation, which focuses on functionality, error resolution, and transaction simulation, alongside additional assessments such as cost analysis and security evaluations. Security assessments often include factors such as confidentiality, data integrity, availability, non-repudiation, and protection against man-in-the-middle attacks.

In the construction industry, several blockchain-based systems have been proposed with distinct evaluation methods. For example, a study aimed at improving supply chain traceability and information sharing in precast construction focused its evaluation on information sharing management, real-time control of scheduling, information traceability (e.g., number of transactions per minute), and economic performance at a macro level [7]. Another study on cross-border logistics supervision and data sharing in modular construction evaluated product accountability, data traceability (e.g., time to record and trace information), and system security, including data immutability, authentication, and authorization [22]. Additionally, research linking permissioned blockchain to IoT and BIM platforms for off-site production management in modular construction assessed metrics such as storage cost, IoT data transaction integrity, authorization, and authentication [23]. Similarly, a blockchain-based framework for carbon management toward construction product certification was evaluated based on security, performance, blockchain network latency, and cost [17].

However, their evaluations often focus on computable metrics without addressing other important dimensions, such as the usability and effectiveness of the systems. This reliance on traditional metrics fails to capture the holistic value of blockchain systems and how they address industry-specific challenges inherent in their design. This study expands on previous research by adopting a more comprehensive evaluation approach for evaluating the performance and effectiveness of the proposed blockchain-based system.

3 Methodology

This study employs the Design Science Research (DSR) methodology [24], a structured approach that supports systematic problem-solving activities in research. The methodology begins with the identification of research problems and objectives, accomplished through a comprehensive literature review of existing studies on blockchain-based applications and their evaluation methodology, as identified in Section 2.

Following this, the system framework of the blockchain-based carbon management system and the comprehensive evaluation framework for blockchain-based systems were designed and developed. Subsequently, a system prototype will be created based

on the designed framework and demonstrated through a real-life case study in the construction industry to validate its feasibility. The prototype will then be rigorously evaluated using the proposed comprehensive evaluation framework to verify and validate how well it meets its design objectives and addresses the identified challenges. Finally, both the system framework and the evaluation framework underwent practical assessment through structured communication with relevant stakeholders.

3.1 Design and Development

3.1.1 System Framework

Referring to the previous conference paper [11], the study focuses on the integration of blockchain technology with carbon management across the entire construction supply chain to enhance the quality and traceability of embodied carbon data. A system framework and operational workflow were proposed. In the framework, the system consists of traditional off-chain carbon management functions, encompassing user registration and data input, and a decentralized public database (on-chain) with self-executing smart contracts is utilized to store significant project information and carbon emissions data to make carbon footprints transparent, reliable, and trackable. The stakeholders involved are developers, architects, consultants, contractors, and product suppliers. Carbon data input parameters are divided into three groups based on the building life cycle: Materials in New Construction (A1–A3), Upstream Transportation (A4), and Construction Site Activities (A5). Besides, the study introduced three technical highlights: (i) Role-Based Access Control for Functionality, allowing every stakeholder to have a clearly defined role and functionality within the system, (ii) Hierarchical Hashing Strategy for Validation, enabling multiple validations by various parties to ensure data quality before data is stored on-chain, and (iii) Selective Data Disclosure Before On-chain, allowing input parties the right to select the data to be disclosed or protected before uploading it to the blockchain and sharing it with the public.

The proposed system framework improves carbon information sharing by enhancing data integrity, transparency, and privacy through recording carbon data on-chain. However, the embodied carbon quantification process, which is integral to information sharing, is a complex task that cannot be accomplished solely by a single recording smart contract. To address this challenge, the smart contract functionality has been advanced to incorporate both recording and quantification capabilities.

The Smart Contract - Carbon Quantification & Recording functionality quantifies total carbon emissions while ensuring that key carbon information is accurately recorded and shared on the blockchain. It also allows stakeholders to protect sensitive information by recording only its corresponding hash value on-chain. The smart contract owners can be suppliers (responsible for permanent materials and upstream transportation emissions) or contractors (responsible for temporary materials and site activity emissions). To ensure accuracy and integrity, all data must be validated by designated parties, while input parties retain the ability to select which parameters are disclosed on-chain. Inputs to the system include, but are not limited to, product specifications, emission factors, quantities, and transportation distances. Outputs generated by the system encompass key carbon information (e.g., emission source information, emission factor, transportation distance), hash values of carbon and validation process data, and total project emissions. Both input and output data are combined to form a transaction that is recorded on the blockchain, ensuring immutability, traceability, and transparency for the project team and the public. Figure 1 presents the updated system framework.

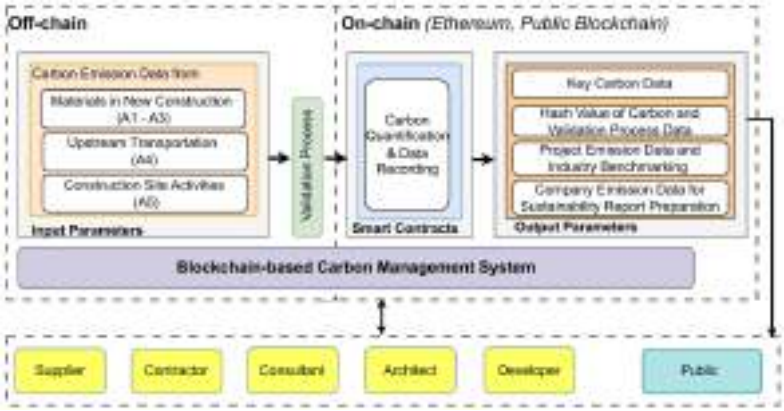

Figure 1: System framework

The updated operational workflow (Figure 2) begins with the architect creating a project account, inputting project details, and adding stakeholders. Suppliers and contractors then input carbon data, which senior staff review and validate before submitting it for further

validation. Once validated, senior staff confirm the data for blockchain upload and select key data for public disclosure before invoking the smart contract. Finally, the developer quantifies and records the total project emissions, holding the final authority in the process.

In summary, the proposed blockchain-based carbon management system enhances embodied carbon information sharing by improving data integrity, traceability, and transparency while preserving privacy. It also leverages smart contracts to automate and streamline the quantification process, ensuring accurate and reliable carbon data management.

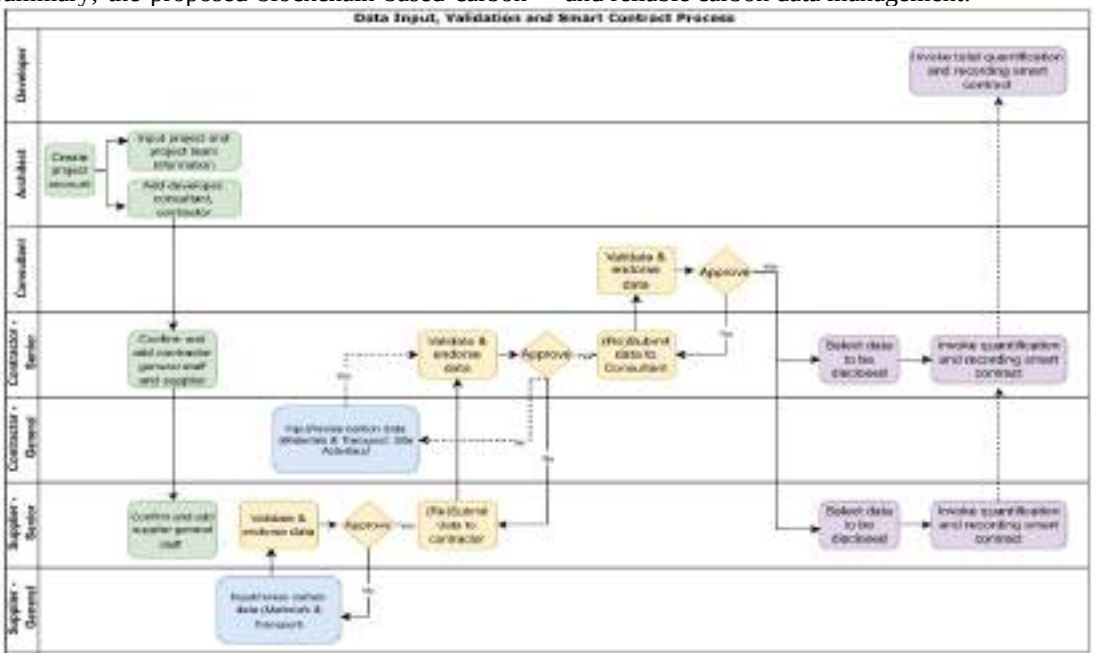

Figure 2: Operational workflow (Green - User/Project Initialization; Blue – Data Input; Orange – Validation Process; Purple - Smart Contracts)

3.1.2 Evaluation Framework

In DSR methodology, evaluation focuses on measuring performance, collecting feedback, and determining how closely the artifact aligns with its stated objectives. This typically includes verifying how well the artifact meets its specified design objectives (verification) and validating whether it effectively solves the identified problem and meets stakeholder needs (validation).

ISO 29119 [25] is a software testing standard that outlines key concepts of software testing, including test processes and techniques. It defines eight testing types: functional suitability, performance efficiency, compatibility, usability, reliability, security, maintainability, and portability. For the verification and validation of the proposed blockchain-based system, three testing types have been identified as priorities: functional suitability, performance efficiency, and usability. These testing types evaluate how well the system addresses its core functionalities, ensures efficient operation, and is practical for adoption by stakeholders. On the other hand, the proposed systems are usually a standalone solution specifically designed for blockchain-based deployment, making compatibility and portability testing less relevant at this stage. Furthermore, reliability testing and security may not prioritized in this phase of development due to the inherent resilience and cryptographic safeguards provided by the public blockchain platform, which inherently ensures data integrity and fault tolerance. Similarly, maintainability is not a focus, as the system remains in the prototype development phase.

For functional suitability testing, the functionality of the system should first be clearly identified. Blockchain-based systems are typically dual-systems, comprising a traditional management system (off-chain) and a decentralized database (on-chain). Each component serves distinct purposes with specific objectives and enhancements, making it essential to evaluate functionality across these two integrated parts. The functionality of the system can be broadly categorized into two areas: (i) Core System Functions and (ii) Functional Enhancement Features. Core System Functions include fundamental operations such as project and project team registration in the off-chain system, as well as data recording and the execution of smart contracts in the on-chain system. These functions are essential for the system's basic operation and compliance with its design objectives. Functional Enhancement Features encompass advanced strategies and mechanisms designed to address critical challenges, such as concerns related to data integrity, traceability, and privacy.

For Performance Efficiency, the testing attributes

typically include scalability, cost, response time, and transaction latency. These attributes are critical for evaluating the system's ability to handle increasing workloads efficiently, maintain operational cost-effectiveness, and deliver acceptable performance under varying conditions. However, the relevance and emphasis of these attributes may vary depending on the specific characteristics and nature of the blockchain-based system being tested. For example, systems with concerns about response time and transaction latency would prioritize these attributes due to the need for immediate updates and decision-making.

Moreover, as noted earlier, the proposed blockchain-based systems often incorporate specific enhancement features aimed at addressing various challenges and achieving distinct objectives. These features, such as enhanced transparency, traceability, and data integrity, are designed to meet the unique demands of their application contexts. Consequently, system effectiveness should be one of the key metrics in the evaluation framework, as it is important for assessing whether the system successfully fulfills its intended objectives.

Table 1: Proposed evaluation framework for the blockchain-based system

Stage		Test attributes	Test Techniques	Test method	Participants
Verification: Meets design objectives		• Functional Completeness • Functional Correctness • Compliance and Non-Compliance Conditions	• Scenario testing	• Prototype Testing	• System designer
Validation: Solves problem and meets needs	(i) Performance Efficiency	• Scalability, cost, response time, and transaction latency (varies in relevance depending on the characteristics and nature of the system being tested)	• Worst-case Scenario Analysis	• Case-based simulation	• System designer
	(ii) Usability	• Functional Appropriateness • User Satisfaction • User Experience • Learnability • User Error Protection	• Use Case Testing	• Surveys (quantitative & qualitative)	• Testing parties
	(iii) System Effectiveness	• Subject to specific enhancement features of the system being tested	• Use Case Testing Comparison with Existing Tools	• Simulation • Sensitivity analysis • Surveys (quantitative & qualitative)	• System designer • Testing parties
	(iv) Industry impacts	• Adoption Challenges • Short-term and Long-term Benefits/Changes (which vary depending on the objectives of the system being tested)	• Impact Assessment • User acceptance testing	• Surveys (quantitative & qualitative) • Semi-structured interviews	• Testing parties • Stakeholders in industry

In addition, industry impacts should be incorporated into the evaluation framework, encompassing both short-term and long-term effects, as well as the adoption of the blockchain-based system within the industry. Since the proposed blockchain-based systems often represent significant innovations, immediate evaluation results from functional, performance, and usability testing may not fully capture their overall value. Assessing industry impacts provides valuable insights into how the system contributes to broader industry goals over time. This dimension is particularly important for understanding the system's potential to influence industry standards and practices, especially regarding long-term development.

Based on the above, a comprehensive evaluation framework for the blockchain-based system has been developed and is divided into two primary stages, as outlined in Table 1: verification and validation. The verification stage focuses on ensuring that the system meets its design specifications and objectives by evaluating attributes such as functional completeness, functional correctness, and compliance through scenario-based prototype testing. The system designer, who possesses the most in-depth knowledge of the system's architecture, functionality, and expected outcomes, serves as the participant in this process.

The validation stage assesses the system's ability to

address the identified problem and fulfill stakeholder needs. It is divided into four dimensions: (i) performance efficiency, which evaluates scalability, cost, response time, and transaction latency through worst-case scenario analysis and case-based simulation, varies in relevance depending on the characteristics and nature of the blockchain-based system; (ii) usability, which tests functional appropriateness, user satisfaction, user experience, learnability, and error protection through case testing and surveys with participants ; (iii) system effectiveness, which is evaluated based on specific enhancement features using use case testing and comparisons with existing tools, both in quantitative approaches (e.g., simulation models and sensitivity analysis) and qualitative approaches (e.g., surveys); and (iv) industry impacts, which assess adoption challenges as well as short-term and long-term benefits, are evaluated through impact assessments, user acceptance testing, surveys, and semi-structured interviews. Testing parties and industry stakeholders should be included in the interviews to ensure more representative results and enhance the potential for practical implementation.

This comprehensive framework provides a robust evaluation of blockchain-based systems by assessing both technical performance and practical usability to ensure the systems meet their design objectives, deliver short-term changes and long-term value to stakeholders.

4 Implementation and results

4.1 System Framework

A prototype was developed using Ethereum for blockchain deployment and Etherscan for monitoring transactions. Figure 3 shows the prototype's user interface, and Figure 4 displays an example of data uploaded in the blockchain transaction.

Figure 3: User interface of the prototype

- *Project Background:* This module captures key project information, including project details and team member information.
- *Create and View Upfront Carbon:* This module supports the input and visualization of data related to the substructure and superstructure phases, managing materials, specifications, transportation, quantities, emissions, and site activities to ensure accurate upfront carbon recording.
- *Blockchain Integration:* This module manages the blockchain-related aspects of the system, including transaction execution, the recording of hash values, and ensuring data traceability, linking off-chain data while preserving carbon information integrity.

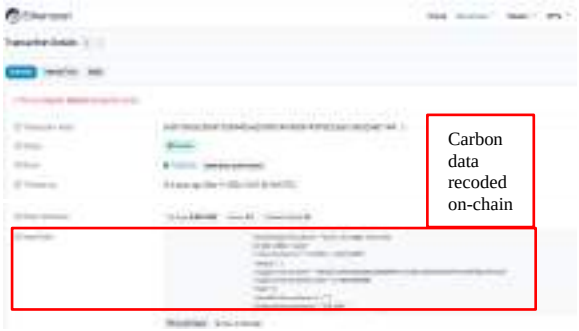

Figure 4: An example of Etherscan transaction

4.2 Evaluation Framework

Referring to Section 3.1, the proposed blockchain-based carbon management system consists of both off-chain and on-chain components. Its objective is to support embodied carbon information sharing and the quantification process in the construction industry, with enhancements in data integrity, transparency, traceability, and privacy achieved through three highlighted approaches and strategies. Based on the characteristics and nature of the proposed system, corresponding verification items based on its functionalities have been identified and summarized in Table 2, while the framework for validation is summarized as follows.

- *Performance Efficiency*: Scalability, cost estimation and transaction latency are considered. Scalability is a critical issue for the application and adoption of blockchain-based systems, ensuring the system can handle increasing data volumes and transaction loads effectively. Cost estimation addresses stakeholder concerns and ensures the system's long-term feasibility, while latency is a key factor in real-time performance.
- *Usability*: The testing parties are divided into three groups: stakeholders involved in the input and validation process (e.g., suppliers, contractors, and consultants), stakeholders responsible for the total project carbon quantification process (e.g., developers), and other stakeholders (e.g., architects and the public). These groups are assessed using data collection methods such as the System Usability Scale, task completion times, and error rates in surveys.
- *System Effectiveness*: This focuses on evaluating

the system's ability to meet its objectives, particularly in enhancing data integrity, transparency, traceability, and privacy, both through quantitative approaches (e.g., simulation models and sensitivity analysis) and qualitative approaches (e.g., surveys).

- *Industry Impacts*: This evaluates adoption challenges, as well as the short- and long-term impacts of the proposed system on carbon management practices in the construction industry. The impact assessment may include performance indicators related to short-term impacts (e.g., behavior change scales, level of stakeholder collaboration and data accessibility) and long-term industry impact (e.g., sustainability impact, adoption motivations and barriers at the project, company, and industry levels). The interviews will include testing parties and key stakeholders directly affected by the system (e.g., contractors and developers), as well as industry policy bodies (e.g., councils). This approach ensures representative results, enhances practical implementation potential, and provides a roadmap for long-term adoption.

Table 2: Verification Framework Summary for the Proposed Blockchain-Based Carbon Management System

	Verification items		Off-chain	On-chain
Core System Functions	i) Information Sharing and Reporting	Data Collection (input parameters)	✓	
		Data Reporting (output parameters)		✓
	ii) User Authentication and Authorization	Role-based Access Control Approach	✓	
		Authentication and Authorization	✓	✓
	iii) Smart Contract	Quantification and Recording		✓
Functional Enhancement Features	i) Data Integrity	Hierarchical Hashing Validation Strategy	✓	
		Immutable Records of Validation Process Data		✓
	ii) Transparency	Open Access to Data		✓
	iii) Traceability	Transaction Logs		✓
		Hashed Detailed Data and Validation Records		✓
	iv) Privacy	Selective Data Disclosure before Chain		✓

5 Conclusion

Embodied carbon in construction significantly contributes to global emissions, but poor information sharing hinders its accounting. Blockchain offers a solution, but is underexplored. Also, most studies focus on computable metrics during evaluation, neglecting critical aspects of how blockchain systems align with their design objectives. This study proposes a public blockchain-based system to enhance carbon information sharing in construction supply chains and develops a comprehensive evaluation framework. This study uses the DSR approach, including the identification of problems and research objectives, the design and development of the system, and its comprehensive evaluation framework .

The contributions of this study: First, it explores how a public blockchain-based carbon management system supports the embodied carbon information sharing and quantification process in the construction industry. Second, it introduces a novel evaluation framework that extends beyond traditional metrics, offering a holistic approach to assess functional suitability, performance efficiency, usability, system effectiveness, and industry impacts. A key research limitation is the reliance on stakeholder participation, which is essential for successful system implementation and evaluation but requires additional time and resources, restricting adoption without incentive mechanisms. Future research will focus on developing a framework to utilize the proposed system to support green finance and incentivize adoption within the construction industry.

A Comprehensive Approach for Automated Anomaly Detection and Enhancement of EPC Datasets for Decarbonisation

Sahar Mirzaie and Zhihao Zhang

Institute for Sustainable Built Environment, Heriot-Watt University, UK
s.mirzaie@hw.ac.uk, zz5001@hw.ac.uk

Abstract

Energy Performance Certificates (EPCs) are pivotal for evaluating building energy efficiency, informing decarbonisation policies, and supporting retrofit. However, errors in EPC datasets compromise their reliability. This study develops an automated anomaly detection framework integrating Machine Learning (ML) and auxiliary datasets to enhance EPC data accuracy at scale. By reviewing validation methods and identifying gaps, this paper proposes a systematic framework for improving data quality assurance, reinforcing EPCs as a key resource for policy and decarbonisation efforts.

Keywords –

Energy Performance Certificates (EPCs), Machine Learning, Data Validation, Automating Quality Assurance, Decarbonisation

1 Introduction

Energy Performance Certificates (EPCs) have emerged as a cornerstone of energy efficiency policy across Europe [1], providing standardised metrics to evaluate the energy performance of buildings. Introduced in 2007, EPCs facilitate the monitoring of policy progress, guide retrofitting initiatives and inform decisions regarding financial incentives. In the United Kingdom (UK), an EPC is mandatory when a building is constructed, sold, or rented, are required for various funding schemes (e.g. the Green Deal) and remains valid for ten years. With 27 million domestic EPCs in the UK, these datasets offer key insights into national building energy performance [2].

In the UK, the Minimum Energy Efficiency Standards (MEES), introduced in 2018, prohibit private landlords from renting properties with an EPC rating of F or G, with the effectiveness of MEES heavily reliant on EPC accuracy [2,3]. Stock models use adapted EPC calculations to estimate input uncertainties and energy efficiency policy impact at scale [4].

Despite their extensive use, EPCs have faced criticism due to frequent errors and inconsistencies, such as discrepancies in assessments of the same property [3,5,6]. These issues undermine their credibility as policy tools and limit their application in areas such as retrofitting and carbon reduction planning. Addressing these challenges requires the implementation of rigorous validation and editing methodologies to ensure data accuracy and reliability.

Several studies have examined the accuracy of average assessment using the UK EPC dataset, as summarised in Table 1. They acknowledge that the results are not necessarily applicable to a single EPC. Yuan and Choudhary [3] compared the original and renewed EPCs of office buildings with small cooling and heating systems published between 2010 and 2020, looking at changed asset rating using clustering analysis. The non-domestic EPCs offer little information about the building's physical conditions, therefore they assumed a change in the recommendations reflects a change in the building conditions. They conclude that buildings with unchanged conditions can obtain a decreased or increased EPC rating in subsequent assessments.

With residential buildings responsible for a significant share of carbon emissions and the majority of the 2050 building stock already in place, ensuring the accuracy and reliability of EPCs as a tool for evaluating progress for decarbonisation of the domestic building stock is vital. Therefore, this work focuses on domestic EPCs.

To produce an EPC for a residential building, certified energy assessors collect data and, in many cases, make assumptions about the building's energy-related features, such as construction materials, heating systems, and insulation. This information is processed using the Government's Standard Assessment Procedure (SAP) for new builds or the reduced Standard Assessment Procedure (rdSAP) for existing

homes. The SAP algorithm models the building in a steady-state condition to calculate theoretical heat loss, using estimated thermal properties, standardised heating patterns and occupancy, and fixed fuel price assumptions. It then assigns an Energy Efficiency Rating (EER) on a 100-point scale, based on energy costs per square metre, along with an associated EPC band ranging from A (most efficient) to G (least efficient) [2].

SAP and rdSAP are set to be replaced by the Home Energy Model (HEM) in the second half of 2026. Unlike SAP's steady-state modelling approach, HEM will utilise dynamic modelling and updated methodologies to provide a more accurate representation of real-world energy usage, carbon emissions and heating demand [7]. Calculation methodologies change over time, and assessors use different software and have different approaches to assessment. All these cause variations in the results [5,8]. This study however is not concerned with the causes of these variations but rather identifying potential EPC errors for a dwelling. Comparison of the gap between the modelling results and actual energy use of the building is beyond the scope of this work. That said, similar to other studies, it is assumed that the dwelling's rating should not change in repeated assessments unless there has been a change to the fabric or systems, reflected in their recommendations [3,8].

This study evaluates existing EPC validation methods, focusing on their strengths and limitations, particularly for enabling automated EPC data applications. It explores the integration of auxiliary datasets and machine learning (ML) techniques to enhance the automation of validation processes and data quality. While much prior research has concentrated on repeated EPC assessments [3,5,8,9], this paper adopts a broader approach by examining variables and inputs involved in generating a single EPC as well. Through this wide-ranging analysis, this study proposes a comprehensive framework to improve automation of EPC data quality assurance, contributing to the enhancement of EPC reliability, thereby supporting their effective application in energy efficiency policies and broader research contexts.

2 Literature Review

To understand how EPCs have been validated a comprehensive literature review of Scopus database was conducted, using 'Energy Performance Certificate' or 'EPC' in the title, with a particular focus on domestic properties and validation techniques. Additional studies were incorporated using the 'snowball' approach. The search results indicated that relevant publications on this topic emerged from 2016 onwards.

Table 1. Overview of EPC Validation Studies in the UK: Key Characteristics, Approaches, and Analytical Methods

Ref.	Year	Country	Domestic	Sample Size	Sample Period	EPC values	Validation Approach	Validation levels	Statistical or Machine Learning Approach
[3]	2023	England and Wales	N	5400 simple office buildings	2010-2020	Asset Rating, Standard Emission Rate (SER), Building Emission Rate (BER), Recommendations	Changed asset rating using clustering analysis.	2	Local weighted polynomial regression to study the distribution. Clustering analysis for association pattern recognition: GMM.
[5]	2017	England and Wales	D	145 audits of 29 dwellings	2016	EER, age, construction, and property type, physical properties such as floor area, fabric and systems efficiency	At least 4 independent energy assessments	3	-
[8]	2019	England and Wales	D	1.6 million EPCs from 13 million dwellings	2009-2016	EER	Repeated EPC assessments and change in EER. Exploratory data analysis to decide how to apply this model to available data.	2	A semi-parametric statistical model of how measurement error contributes to variation between repeated measurements
[9]	2019	England and Wales	D	8324 dwellings with at least 3 EPCs for RF 9772 dwellings with at least 3 EPCs at the postcode for RF	2008-2016	EER, inspection & lodgement dates, physical properties such as built form, floor area, flat floor level, fabric description, glazing type	EPCs for the same properties and inconsistent data across properties with same postcode.	1,2	ML (Random Forest) to identify anomalies

EPCs have been examined from three angles in

academic literature: their accuracy and reliability, their function as policy instrument, and lastly the value of the input data used for alternative applications [3]. To reliably use EPCs for the latter objectives, it is essential to understand the accuracy of the data as EPC records commonly contain errors.

2.1 Validating EPC Data

Studies using EPCs for policy and alternative applications often incorporate validation methods, though these vary in depth and scope. For policy-oriented applications, such as enforcing energy efficiency standards or guiding retrofit programmes, researchers commonly validate EPC data by comparing it with independent energy audits or alternative building datasets. For instance, Jenkins et al. [5] highlighted inconsistencies in EPC ratings through cross-validation with third-party assessments, emphasising the need for greater accuracy to support policies like the MEES.

Pasichnyi et al. [10] adapted the six-level validation framework by Simon [11] to EPC data validation, ranging from basic structural checks (Level 0) to cross-referencing with external datasets (Level 5):

- Level 0, Data Structure Validation: Evaluates the format and structure of the EPC dataset, checking variable types and overall organisation but not the data itself.
- Level 1, Intra-Dataset Validation: Conducts variable consistency checks between EPCs by applying physical and numerical validation procedures.
- Level 2, Longitudinal Dataset Validation: Tracks changes over time by comparing different versions of the same dataset, therefore it is referred to as inter-dataset checks. Both EPC corrections (revision checks) and updates (time-series checks) are level 2 validation.
- Level 3, Mirror Validation: Compares the EPC dataset against alternative data sources, such as data from independent energy audits, alternative energy models, or smart meter data, to identify discrepancies. Mirror checks are inter-source intra-dataset checks.
- Level 4, Within Data Collector Validation: Cross-references the EPC dataset with additional datasets from the same data collector, such as government records or organisational databases.
- Level 5, Between Data Collectors Validation: Integrates external datasets from other organisations or regions, such as geographical or taxation data.

The source of data used for validation separates these validation levels from each other. Besides level 0 that looks at data structure, 1 and 2 validation levels are based on the same source of data (e.g. EPC dataset in isolation). In level 3 to level 5, auxiliary data sources are used. Simon [11] states that the higher levels are more challenging due to dataset accessibility, but do not necessarily mean increased accuracy or reliability. Most existing EPC accuracy studies, however, concentrate on Levels 0–3, which involve consistency checks within datasets or across repeated assessments of the same property [3,5,8,9].

Most EPC auditing studies assess accuracy by comparing inputs from repeated EPCs for the same property (level 2). In other words, they are consistency checks. This is a useful approach to identify anomalies when at least 2 EPCs are available for comparison. However, it does not determine which EPC is correct or improve the data. Additionally, many properties have only one EPC record. For example, this limited the study of Yuan and Choudhary [3] to 4% of the target building type.

Hardy and Glew [9] analysed EPCs for the same properties (level 2) and reported significant errors in EPC data, estimating that 27% of records contained at least one issue, often due to variations in assessors' interpretations of building features. The errors include duplicate records differing only by dates, unlikely changes in building features such as wall or roof types over time, and anomalies in energy efficiency products (e.g. reduced insulation or glazing performance). Many errors result from differences in opinion among EPC assessors regarding building features such as age band, floors, walls, and systems or difficulties in assessing the location of flats or maisonettes within a building or the surrounding conditions [3,9]. In interviews with 20 assessors, Gledhill et al. [6] discovered that in some cases, these variations could be intentional: "*EPCs for sale and rental market are manipulated sometimes to make a property more attractive by the estate agent and the EPC isn't as accurate as it should be*".

Errors in EPC building characteristics vary across different variables. Built form classification, particularly for end-terrace or semi-detached properties, is the most inconsistent [9]. Errors in floor and wall types were observed in 10-15% of EPCs, while wall insulation and glazing performance errors occurred in around 5% [9]. Another study found that roof efficiency and total floor area exhibited the least consistency across samples. In contrast, heating system and wall efficiency data were the most consistent [5,6]. Hardy and Glew [9] found that flats and maisonettes present more errors, often due to difficulties in assessing their location within a building or the surrounding conditions, and because the built form of flats and maisonettes is not used in SAP calculations, the assessor might not pay attention to the built form. In another study, Crawley et al. [8] found that the magnitude of error decreases as the building performance increases, whereby G-rated dwellings have more errors than A-rated ones.

Quantifying the magnitude of these errors and their impact on EER is a subject of debate. Jenkins et al.'s EPC 'Mystery Shopper' study [5] quantified the effect of these errors on EER through a level 3 mirror

validation against known building info. At least four assessors evaluated the same 29 volunteer households across England and Wales, leading to an average variation of 11 points per dwelling, with one property differing by over 30 points. The results are similar to a Swedish domestic building by Hårsman et al. [12] who identified 20% variation across assessors and Crawley et al. [8] who found that the size of error could even result in wrong EPC rating. Hardy and Glew [9] concluded that an individual mistake on an EPC assessment is unlikely to make a considerable difference in the EER. In other words, identifying a single error does not necessitate removing an EPC from the analysis, although this is the most common pre-processing approach as described in section 2.2.

Higher-level validation approaches (Levels 3 to 5) leverage auxiliary datasets, such as geographic information systems (GIS), property registers, and socioeconomic data, to cross-check EPC data against other datasets. While these methods provide a more comprehensive perspective on data quality, their application is limited by challenges in accessing and integrating diverse datasets.

There is a wide range of place-based data from the Census, mostly published at, at least, one of the following geographies that were primarily designed for the publication of the Census statistics. Output Areas (OAs) are the lowest level of geographical areas. Lower Layer Super Output Areas (LSOAs) group OAs, usually four or five, containing between 400 and 1,200 households and have a resident population between 1,000 and 3,000 people. LSOAs are nested within the boundaries of Middle Layer Super Output Areas (MSOAs), which are nested within the boundaries of Local Authority Districts (LADs). These geographical areas are homogenous in terms of population size. So, one can compare like-for-like when looking at changes over time and when comparing different areas [13].

Building energy efficiency varies locally [14], with low-income households bearing higher costs of low-carbon policies in the UK due to a higher percentage of their income on energy bills [15]. EPC data linked with socioeconomic information can help identify areas at higher risk of fuel poverty [16]. Socioeconomic data at LSOA cannot be used for quantification but can be used for comparison across small areas, changes over years, and the domains/types of deprivation, particularly for financial aid and policy. For example, Yuan and Choudhary [3] demonstrated how combining EPC data with domestic gas consumption and social factors can inform a more locally tailored design of residential heating policies. No study has validated these levels to date; this study addresses that gap.

Studies focused on building energy retrofitting often use EPC recommendations and auxiliary data like GIS and property registers. Gupta and Gregg [17] designed retrofit packages for UK domestic buildings based on EPC carbon emissions and used a city-level energy mapping model to identify suitable neighbourhoods and houses for targeted retrofits, promoting bulk installations to reduce costs.

In alternative applications of EPCs, such as assessing retrofit potential, analysing fuel poverty, or evaluating the impact on real estate market value, validation often involves linking EPC data with auxiliary datasets. These include socioeconomic data, property transaction records, and GIS-based spatial analyses. For example, studies have combined EPC ratings with the Index of Multiple Deprivation (IMD) to identify areas of high energy inefficiency or fuel poverty risk [3,14]. However, these studies frequently lack systematic validation of the underlying EPC data itself, relying primarily on the end-use metrics rather than scrutinising the quality of inputs. This gap underscores the importance of integrating rigorous validation frameworks into studies leveraging EPC data for broader applications.

2.2 Improving EPC Data

Following data validation, the identified errors are either removed or corrected through substitution or imputation during the data editing stage [11]. Yet, most studies do not correct the EPC data but instead remove without quantification of the acceptable level of error in EPC data. Removing EPCs or datapoints from evaluations can introduce a bias into the results. Besides, in studies that aim to utilise EPC values for alternative applications, removing is not an option as it is necessary to determine the most accurate estimates.

One of the applications of EPCs studies their impact on property sales and rental prices [18–20]. These studies associate physical, locational, and neighbourhood characteristics to the property value. Fuerst et al. examined if there is an economic case for energy efficient dwellings in rental and purchase price. They found that 37% and 17% of EPCs in Wales from 2003 to 2014 did not record the age and number of bedrooms in turn. These EPCs were excluded from their study and whether a systematic bias was presented in non-recording EPCs is not known [18].

Not all EPC variables hold the same level of importance in analyses, and the decision to include or exclude an EPC with missing data depends on which variable is missing. Similarly, when comparing repeated EPCs, not all variations represent significant inconsistencies that warrant reporting. For instance, in existing dwellings assessed using RdSAP, certain variables are assigned default values. For example, the dwelling's type and age are used to estimate window areas, while age and wall type are used to infer U-values for walls, roofs, and floors [18]. Consequently, age (or vintage class) emerges as a critical variable.

Hardy and Glew [9] showed that ML has the potential for improving EPC auditing by identifying inconsistencies across houses within the same postcode (level 1) and EPC updates for the same house (level 2). They limited the selection to postcodes and houses with at least three EPCs, with both analyses misclassifying 7% of ‘correct’ data as errors while identifying 62% and 80% of the errors, respectively.

3 Methodology

A comprehensive EPC validation and improvement framework was developed following a systematic review of validation approaches within the literature, publicly available databases, and domestic EPC records in England and Wales. The framework was implemented in Python and follows the flowchart shown in Figure 1 and described below.

Leeds, the second most populous area and an important economic hub in the UK, was chosen as a case-study to illustrate the approach. Domestic EPC records in Leeds were sourced from the UK's Open Data Communities platform published by the Ministry of Housing, Communities and Local Government [21].

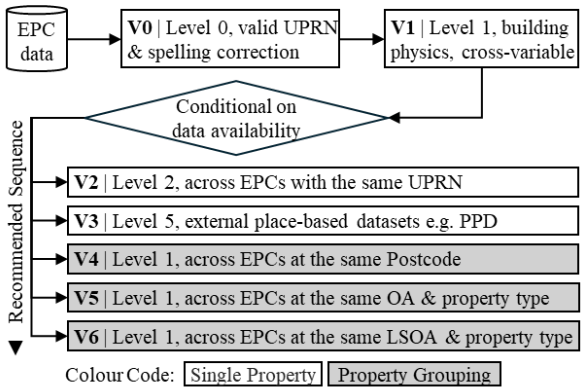

Figure 1. EPC Data Validation Engine

The six-level validation framework was applied to assess data quality of EPCs using publicly available datasets. Validation was applied based on reliability, prioritising property-specific checks over area-based analysis. This distinction is reflected in Figure 1, where property-specific validations are marked in white (V0 to V3), while validations based on property groupings are shaded in grey (V4 to V6).

Level 3 can benefit from manual user inputs or independent energy audits for mirror validation. It could include smart meter data load shape analysis and energy use disaggregation [22]. This study however is focused on automated approaches in the absence of access to building specific information. Moreover, due to unavailability of other data from the data collector, no level 4 validation is considered.

In the UK, unique property reference numbers (UPRN) are used to record anonymised public EPCs. Therefore, the level 0 validation (V0) ensures that all EPCs have a valid UPRN and no spelling inconsistencies. The dataset was then filtered to include valid EPC records within the latest 10 calendar years (2014 up to 2024), acknowledging the 10-year validity of EPCs.

Level 1, internal consistency within dataset, involves applying building physics and numerical validation procedures. V1 building physics validation is informed by leveraging insights from the literature and domain expertise. While statistical validation occurs at different tiers of geographical areas, i.e. properties within the same postcode (V4), OA (V5), and LSOA (V6). In higher geographical areas, other than properties with the same postcode, the validation is more for inconsistency checks or potential anomaly detection rather than value correction through statistical analysis and ML.

As shown in Figure 1, proceeding to the next steps beyond building physics and cross-variable checks, depends on the availability of sufficient data. For example, Level 2 (V2) compares former EPC reports of the same dwelling using UPRN, if available.

Level 5 involves cross validation with external place-based datasets, including socioeconomic data. These datasets provide contextual insights that also assist with extending the application of validated EPC data. To append auxiliary socioeconomic data, the ONS Postcode Lookup library [23] was used to retrieve OAs and LSOAs for every postcode. V3 utilises HM Land Registry Price Paid Data (PPD) [24] as an example of auxiliary property-level data. PPD reports property sales in England and Wales in every calendar year [24]. To maximise matched records for better analysis, PPD was mapped to EPCs using all possible postcode and address line combinations, ensuring inspection and price year align.

To construct datasets for anomaly detection, this study applies and enhances the approach proposed by Hardy and Glew [9], where artificial errors were introduced by modifying subsets of EPCs. UPRN and postcode were used as two identifiers to group EPCs. Only groups containing at least three EPCs were retained in V2 and V4. Within each sub-dataset, about one-third of the EPCs were randomly selected, with single building parameters replaced by the values randomly drawn from a different group. The modified EPCs were labelled as 'False', while the remaining ones were labelled as 'True'. Categorical variables were transformed based on their similarity within the same group. For example, if a postcode had three EPCs with roof types of flat, pitched, and pitched, the similarity values would be 0.33, 0.66 and 0.66, respectively. Numerical variables were transformed into percentage values relative to the mean. For example, if a UPRN has three EPCs with floor areas of 30, 40, and 50, the percentage values would be 0.75, 1, and 1.25. These features allow the Random Forest (RF) model to detect potentially erroneous records.

To further develop their approach, this study also considers two additional identifiers: (1) the combination of OAs and property types (V5) and (2) the combination of LSOAs and property types (V6). Given the larger number of properties within higher geographical areas such as OAs and LSOAs, only groups with at least ten EPCs were retained. Furthermore, they trained the model on an entire sub-dataset, which increases the risks of data leakage and model generalisation ability, causing it to perform overoptimistic conclusions due to the absence of testing datasets [25]. To mitigate this issue, the four

sub-datasets were split into an 80% training set and 20% testing set, as it is empirically the best division into the training and testing sets [26]. Due to their fast computation speed and efficiency, gradient boosting classification models including CatBoost, LightGBM and XGBoost were also applied for anomaly detection, along with the RF model [27].

4 Results

391,441 EPCs were identified in the Leeds LAD (GSS code E08000035). 9,750 of these were removed due to null UPRNs (V0). 190,221 EPCs were within the considered 10 calendar years.

V1 identifies intra-variable inconsistencies in EPCs. Improving the EPC values was achieved as per the following steps depending on the variable class: numeric, e.g. floor height, or character, e.g. hot water description. Categorical variables were assessed by unique values. For example, in Leeds, there are more than 250 unique wall, floor, and roof type descriptions. In validation level 0, spelling errors that resulted in unique values were corrected. Many of these unique values refer to the same construction composition and properties, thus can be combined into a smaller list of variations. The process of standardising these variables results in creating a rule-based dictionary that associates relevant variables to cross-check values and improve the properties where needed.

The key categorical variables are the construction age bands and property types, which were harmonised. Property type can also be compared to PPD database in level 5 validation (V3) to ensure accuracy. These key variables are essential because they are the basis for assumptions about the fabric construction and systems in the building. For example, rdSAP makes assumptions about the wall composition and thermal resistance properties based on these. One example of intra-variable improvement is entries with 'Tenure' labelled as 'Unknown', whereby conditional logic was applied based on the 'Transaction type' column to infer likely tenure types. Transactions marked as private or social rentals were reassigned accordingly.

One focal example of categorical variables is when looking across fields related to the heating source and system, where gas might be mentioned as the 'main fuel', while 'mains gas flag' might be listed as N and 'main heat description' might suggest electric storage heaters. A detailed intra-variable logic was developed to review all heating and hot water related properties. Combined with other level 1 and 2 validations, these were identified and revised where possible.

Figure 2Figure **2** summarises the accuracy evaluation of various ML models (V2, V4, V5, and V6). CatBoost achieved the highest accuracy of approximately 85% in the postcode-based dataset (V4). In the UPRNs-based dataset (V2), CatBoost also outperformed other models with an accuracy of around 81%, closely followed by LightGBM, while RF showed the lowest performance. For the sub-dataset based on the combination of LSOAs or OA and property types (V5 and V6), RF showed superior performance, achieving around 84% and 85% accuracy, respectively. Overall, CatBoost and RF were the top-performing models.

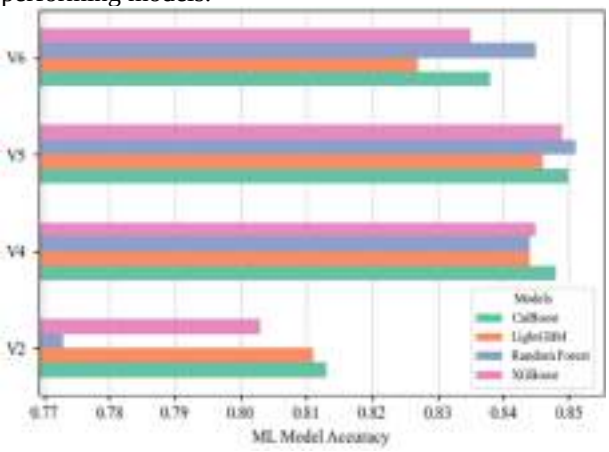

Figure 2: Accuracy comparison of ML models

Based on the accuracy results, the best-performing ML model for each validation was selected for further analysis using confusion matrices, as shown in Table 2. In V2, the model correctly classified 2622 'True' and 967 'False' EPCs, and misclassified 311 as 'False' and 517 as 'True'. While in V4, the model correctly predicted 27660 'True' and 11008 'False' records but misclassified overall 6949 EPCs.

Table 2: Confusion matrices for the best ML models

Level		False	True	Class Error
V2	False	967	517	0.34
	True	311	2622	0.10
V4	False	11008	4240	0.27
	True	2709	27660	0.08
V5	False	10740	4063	0.27
	True	2569	27103	0.08
V6	False	10532	4664	0.30
	True	2436	28150	0.07

5 Discussion

This study develops a data-driven EPC validation framework, addressing key research gaps. By integrating ML and rule-based corrections, it detects anomalies and refines data quality. Results highlight the value of auxiliary datasets, multi-level validation, and ML in anomaly detection.

5.1 Evaluation of ML Model Performance

ML models performed well across validation levels, with CatBoost and RF as top performers. In the postcode-based dataset (V4), CatBoost achieved the highest accuracy of 85%, while in the UPRNs-based dataset (V2), it led with 81% accuracy, followed by LightGBM. These results suggest location-based

grouping improves predictions, likely due to spatial correlations in EPC characteristics.

For datasets combining geographical areas and property types (V5 and V6), RF excelled (85% accuracy), indicating hierarchical property aggregation enhances anomaly detection. This aligns with prior studies [9] on validation accuracy through geographical grouping. However, False Positives remain an issue, with misclassified 'True' EPCs slightly increasing in V6 (0.30) from V4 and V5 (0.27). While True class error consistently improved (0.10 in V2 to 0.07 in V6), distinguishing erroneous records remains a challenge as the dataset scales.

5.2 Implications of EPC Validation and Policy Relevance

The effectiveness of EPCs as a policy tool depends on their accuracy. The UK government's EPC reform [28], set for 2026, aims to improve reliability by introducing a fabric efficiency rating, heating system type, and an emissions classification. The proposed reforms highlight the increasing reliance on EPCs for energy policy, financial incentives, and decarbonisation planning. However, EPC accuracy issues can undermine their effectiveness in these applications [3,5,9]. The findings reinforce the need for incorporating systematic validation frameworks into EPC auditing to ensure reliability.

This study also demonstrates that auxiliary datasets, such as HM Land Registry PPD, can enhance EPC validation, offering a new avenue beyond traditional consistency checks. While previous studies linked EPCs to property pricing [18–20], this research shows that they can also be leveraged to validate EPC inputs. Future policy reforms should consider integrating external datasets into EPC validation frameworks to improve reliability at scale.

5.3 Challenges and Future Considerations

While the proposed methodology has proven effective, several limitations warrant further research. First, geographical validation (postcode, OA, LSOA) detects anomalies but does not pinpoint specific errors in EPCs. While property-level validation (V3) improves accuracy, future studies should explore hybrid approaches that integrate spatial validation with assessor verification. Mirror validation (Level 3), using smart meter data or thermal imaging, could further enhance real-world accuracy.

This framework does not account for assessor-related inconsistencies, despite evidence that assessor experience, software versions, and subjective interpretation influence EPCs [5,6]. Future research should examine assessor-driven variations and develop standardised correction mechanisms to further refine EPC datasets.

6 Conclusions

This study demonstrates that systematic validation frameworks, integrating both rule-based corrections and ML techniques, can significantly enhance EPC reliability. By applying a multi-level validation approach and leveraging auxiliary datasets, this research identifies key limitations in conventional EPC validation methods and offers a scalable, data-driven pathway for improvement. ML models achieved up to 85% accuracy, highlighting the potential of automated anomaly detection. However, False Positives and rating imbalances remain challenges, requiring further refinement. Future research should expand access to external datasets, integrate mirror validation techniques, and develop scalable, interoperable validation systems to further improve EPC accuracy and utility.

Abstract

The construction sector faces significant challenges in balancing environmental sustainability, economic feasibility, and compliance with required strength standards. This study investigates the potential of recycled materials, specifically waste concrete fine aggregates (WCA), for use in geopolymer mortar for 3D concrete printing as a sustainable alternative to conventional construction methods. The research examines the fresh and hardened properties of 3D-printed geopolymer mortar. Experimental results demonstrate that WCA-based mixtures achieve superior compressive strength and dimensional stability compared to natural fine aggregates (NFA). Life cycle analysis (LCA) further highlights the environmental benefits of WCA-based 3D mixture, showing a 3.4% reduction in global warming potential (GWP) and a decrease in terrestrial acidification compared to NFA. The study also underscores the importance of orientation in 3D printing, with significant improvements in compressive strength observed in all tested directions: perpendicular (64.2%), lateral (77.2%), and longitudinal (57.7%). This research emphasizes the promise of 3D concrete printing with recycled materials as a transformative approach to sustainable construction, reducing environmental impacts while maintaining structural performance.

Keywords – Waste concrete; Geopolymers; Life cycle analysis; Environmental impact.

1 Introduction

The construction sector is undergoing a transformation driven by the integration of technologies, with 3D concrete printing emerging as a revolutionary approach to construction processes [1]. This method allows the direct conversion of digital building models into physical structures, eliminating the need for labor-intensive and resource-demanding formwork [2]. The advantages of 3D concrete printing include faster project completion, reduced material waste, and the ability to create intricate geometries with precision and minimal labor costs [2].

In addition to improving construction efficiency, 3D concrete printing presents an opportunity to incorporate recycled materials, such as fly ash (FA) [3], ground granulated blast furnace slag (GGBS), and waste concrete-based recycled fine aggregates [4,5]. These materials not only mitigate environmental issues associated with industrial and construction waste disposal but also reduce dependency on traditional resources like Ordinary Portland Cement (OPC). The use of OPC is a significant contributor to carbon emissions and resource depletion, necessitating sustainable alternatives [6]. According to an estimate, the manufacture of each ton of OPC requires the mining of 1.5 tons of limestone and releases around 0.5 tons of CO_2 into the atmosphere [6]. OPC production accounts for 5-7% of overall greenhouse gas emissions, making it the fourth most major source after petroleum, coal, and natural gas. [7] Moreover, the use of OPC in 3D concrete printing technique has a variety of constraints due to its setting characteristics. These environmental and technical challenges highlight the need for alternative low-CO_2 binders. In this context, geopolymers have emerged as a promising solution, as they can be formulated using industrial by-products [3], thereby reducing waste disposal in open environments and mitigating carbon emissions.

In recent years, the recycling of construction and demolition waste, such as recycled concrete, crushed brick, and ceramic aggregates, has gained significant research interest. Utilizing waste concrete as a substitute for natural resources has led to the development of recycled aggregate concrete, a sustainable product addressing both resource scarcity and waste disposal

challenges [8]. Ding et al. [9] investigated recycled fine aggregates in 3D-printed concrete, reporting slightly lower compressive and flexural strengths compared to natural sand, with significant anisotropy in mechanical properties. Panda and Tan [3] conducted a study on fly ash-based geopolymer mortar for 3D concrete printing and found that the mixture with a sand-to-binder ratio of 1.5 exhibited the best extrudability with a yield stress of 0.6 kPa. The optimal open time for printing was 15–20 minutes, preventing deformation of the lower layers. The mixture was successfully used to print a 60 cm model in 20 minutes with good interlayer adhesion. In 3D printing processes, the integration of FA, GGBS and WCA presents unique challenges and opportunities. Unlike standard concrete, 3D printing requires precise control over rheological properties, buildability, and layer adhesion, which necessitates a more tailored approach to mix design. The ongoing research in 3D printing is focused on optimizing these supplementary materials to ensure printability without compromising mechanical performance or sustainability benefits. While FA, GGBS, and recycled aggregate are already used in traditional concrete, their adaptation to 3D printing remains an evolving area of study aimed at maximizing their potential in automated construction processes.

This study investigates the application of geopolymer binders and WCA in 3D concrete printing, focusing on their fresh and hardened properties, environmental impacts, and compliance with strength standards. By evaluating the performance and sustainability of these materials, this research aims to demonstrate the viability of integrating recycled resources into 3D concrete printing as a pathway toward more sustainable and resilient construction practices.

2 Materials and Research Methodology

2.1 Materials and Methods

Class F fly ash, adhering to the ASTM C618 standard, and GGBS, conforming to the C989 standard, were utilized as precursors. Industrial-grade sodium hydroxide pellets were used as the alkaline activator for the binder. Silica sand with an average particle size of 0.5 μm served as the natural fine aggregate, while recycled fine aggregate derived from waste concrete (WC), with a similar particle size, was employed as a replacement for the natural fine aggregate.

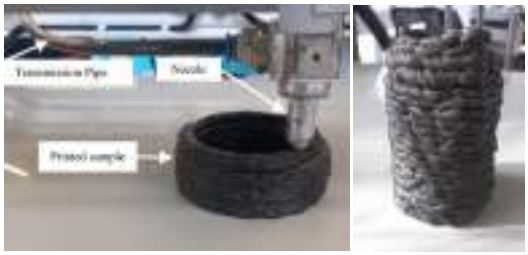
The mix design for the two samples, 3D-NFA (natural fine aggregate) and 3D-WCA (waste concrete aggregate) is as follows: For the 3D-NFA sample, the binder consists of 60 g of FA, 25 g of GGBS, and 15 g of sodium hydroxide. The aggregate used is 100 g of natural fine aggregate, with no recycled fine aggregate included. The water-to-binder ratio is 0.20, and no admixture is added. For the 3D-WCA sample, the binder composition remains the same, with 60 g of FA, 25 g of GGBS, and 15 g of sodium hydroxide. However, the aggregate used consists of 100 g of recycled fine aggregate, with no natural fine aggregate included. The water-to-binder ratio is increased to 0.25, and 0.1 g of sucrose-based admixture is added. The mix composition for the two specimens was determined through preliminary laboratory experiments, optimizing the water content and sodium hydroxide dosage based on the findings of these tests.

The printing experiments involved producing a slab measuring 200 mm × 100 mm × 100 mm and a hollow cylinder with a diameter of 100 mm and a height of 200 mm, using both natural and recycled fine aggregates. The layer height and width were set to 10 mm and 30 mm, respectively. The material extrusion rate during the printing process was maintained at 0.55 m^3/h, and the printhead speed was consistently set to 30 mm/s. The printed sample using geopolymer binders with waste concrete and fly ash is presented in Figure 1.

To evaluate the anisotropic behavior of 3D-printed mortars, specimens were tested under perpendicular, longitudinal, and lateral loads relative to the printing direction. The printing orientation was defined as the longitudinal direction. Compression tests were conducted at a strain rate of 1 mm/min, with each test repeated three times to obtain average compressive strength values.

2.2 Life cycle analysis

To evaluate the environmental impact of materials and construction methods, a comprehensive life cycle analysis (LCA) was conducted in accordance with ISO 14040 and 14044 standards. The analysis was performed using OpenLCA 2.0.3 software, with the Ecoinvent 3.9.1 database serving as a reliable and compliant data source. The cradle-to-gate approach was adopted for the LCA, covering the production processes of key raw materials. The analysis applied the ReCiPe 2016 midpoint (H) method, focusing on critical environmental impact categories such as global warming potential (GWP), stratospheric ozone depletion, terrestrial acidification, freshwater eutrophication, fossil resource scarcity, water consumption, and fine particulate matter formation, as recommended by the Product Environmental Footprint Category Rules (PEFCR).



Case study data for LCA are summarized in Table 2.

To assess the environmental impact of recycled concrete aggregates in construction, the performance of concrete containing recycled aggregates was compared to that of concrete using NFA.

Table 2. Case study data for LCA

Parameters	Value and unit
Printing speed	250 mm/s
Printing time	1.381 h
Printer power	19.06
Mixing time	1.547 h
Mixer power	9 kW
Pumping/flowing time	8.738 h
Pump power	22 kW

Figure 1. 3D printed sample using geopolymer binders with waste concrete and fly ash.

3 Results and discussion

The fresh property results showed that the slump flow and spread diameter for mixtures with NFA were 14.3 mm and 138.2 mm, respectively. In contrast, replacing natural aggregates with WC aggregates increased these values to 14.5 mm and 143.2 mm, respectively, indicating reasonable flowability for all mixtures.

The maximum number of layers printed was 28 for the mixture with NFA and 24 for the mixture with WC aggregates. The Vicat value for the mixture with natural aggregates ranged between a lower limit of 5±1.5 mm and an upper limit of 21±6 mm, whereas for the mixture with artificial aggregates, the upper limit was slightly higher at 24±6 mm. These results are consistent with those previously presented in the work by Papachristoforou et al. [11].

Figure 2 presents the compressive strength results for two different mixtures (3D-WCA and 3D-NFA) tested along three principal directions: perpendicular, lateral, and longitudinal. The results reveal a significant influence of the material's extrusion process and orientation on its compressive strength. The specimens 3D-WCA and 3D-NFA exhibited higher strength values of 5.9 MPa and 3.7 MPa, respectively, along the longitudinal direction. This increase in strength can be attributed to the extrusion process, where the material is compacted and densified as it is pushed through the nozzle to print the layers. This densification leads to enhanced bonding and material integrity along the longitudinal direction, resulting in higher compressive strength. When tested in the perpendicular direction, competitive compressive strength values of 5.9 MPa and 3.5 MPa were observed for 3D-WCA and 3D-NFA, respectively. These results suggest that the material's structure in this orientation maintains a significant level of bonding and compaction. The introduction of waste concrete aggregate place as a replacement for NFA further contributed to an overall improvement in strength in this direction. In contrast, the lateral direction exhibited the lowest compressive strength among the three tested orientations. This can be explained by the lower pressure exerted during the extrusion process in this direction.

In general, when using natural aggregates, particularly sand, the printed material tends to expand and settle more freely, resulting in weaker bonding and a less compacted structure, which subsequently leads to reduced strength. A comparison of the results shows a clear trend: replacing natural aggregates with WC has significantly improved the compressive strength in all tested directions. Specifically, the compressive strength in the perpendicular direction increased by 64.2%, while the lateral and longitudinal directions showed enhancements of 77.2% and 57.7%, respectively. These improvements highlight the potential of WCA to enhance the mechanical performance of 3D-printed concrete, particularly by improving bonding and compaction in critical load-bearing directions.

The pumpability results showed a significant difference between the two mixtures. The average pumpability for 3D-NFA was 1580 mm^3/sec, whereas for 3D-WCA, it was lower at 1400 mm^3/sec. This indicates that incorporating waste concrete aggregates may reduce the ease of material flow through the pump. The lower pumpability of 3D-WCA can be attributed to the higher water absorption and irregular shape of WCA particles, which increase friction and resistance in the pumping system. Moreover, the rough texture and porosity of WCA may lead to greater water demand, affecting the overall workability of the mixture. While WCA enhances compressive strength, these findings suggest that adjustments in mix design, such as optimizing aggregate gradation, increasing superplasticizer dosage, or modifying water-to-binder ratios, may be necessary to improve pumpability and ensure smooth extrusion in 3D printing applications.

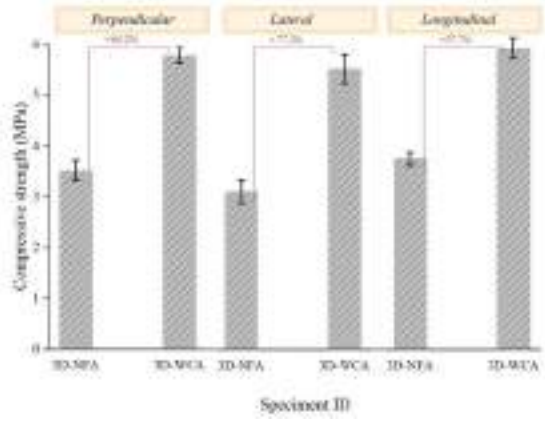


Figure 2. 7-day compressive strength of 3D printed specimens using NFA and WCA.

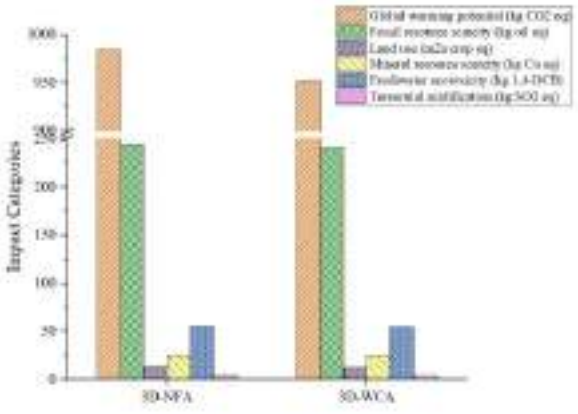

Figure 3. Comparative analysis of life cycle impact categories for 3DP-NFA and 3DP-WCA.

In LCA, GWP quantifies the amount of infrared radiation absorbed by greenhouse gases over a specified time, referenced to 1 kg of CO_2 equivalent. It measures heat trapped by greenhouse gases, which contributes to rising temperatures, extreme weather, sea-level rise, and shifting climate patterns. Analysis reveals that incorporating recycled WCA reduces GWP by 3.4% in 3D printing (Fig. 3), consistent with findings by Habibi et al. [10]. Sodium hydroxide significantly contribute to GWP due to their energy-intensive production processes.

Terrestrial acidification, another critical impact category, reflects emissions that acidify soils through the deposition of compounds like NOx, NH_3, and SO_2, evaluated relative to SO_2. These emissions lower soil pH, release heavy metals, and reduce buffering capacity, negatively impacting plants and animals. The analysis shows that using NFA results in the highest acidification potential (3.63 kg SO_2 eq), which decreases to 3.45 kg SO_2 eq when replaced with recycled aggregates. The NFA extraction process, involving blasting and quarrying, directly and indirectly, releases acidifying compounds through fossil fuel combustion, contributing more to acidification than recycled aggregates.

Despite the promising results obtained in this study, certain limitations should be acknowledged. One of the primary challenges in evaluating the fresh and hardened properties of 3D-printed concrete is the influence of the extrusion process on the material's structural integrity. Variability in extrusion pressure and nozzle geometry may introduce inconsistencies in layer bonding, potentially affecting compressive strength, particularly in the lateral direction. Additionally, while the substitution of NFA with WCA demonstrated improvements in compressive strength, further investigation is required to assess its long-term durability.

4 Conclusion

This study demonstrates the potential of recycled waste concrete for sustainable 3D concrete printing. Experimental results confirm that replacing NFA with waste concrete fine aggregate improves the hardened properties of the mixtures. The compressive strength showed significant improvements in the perpendicular (64.2%), lateral (77.2%), and longitudinal (57.7%) directions when the recycled aggregates were applied.

The LCA highlighted the environmental benefits of recycled fine aggregates, including a 3.4% reduction in global warming potential compared to natural aggregates, as well as lower terrestrial acidification potential. The reduced environmental impacts are attributed to the minimized reliance on resource-intensive natural aggregate extraction and the effective reuse of waste materials. Additionally, 3D concrete printing with waste concrete fine aggregates eliminates the need for formwork, further reducing material consumption and environmental burdens. These findings underscore the feasibility of integrating recycled materials into 3D concrete printing to achieve sustainable construction practices, offering a pathway to reduce carbon emissions, resource depletion, and environmental degradation. Future research should explore optimizing material compositions and scaling up 3D-printed structures to further validate their environmental and structural performance.

Abstract –

The construction sector's considerable environmental impact has led to a growing demand for sustainable construction technologies. This study aims to compare the cost and environmental impact of traditional construction and 3D printing construction processes, starting from the supply of raw materials to the final construction and construction waste disposal. Based on the factors identified (raw material, printing equipment, transportation, warehousing, construction and waste disposal), traditional construction and 3D printing value streams are mapped to assess the potential factors or activities contributing to the cost and environmental burden. The results showed that 3D printing offers nearly 80% lower cost at the construction phase than traditional construction. However, 3D printing hardly reduces the total cost by only 0.96% and even produces significantly higher greenhouse gas (GHG) emissions than traditional construction due to the significant transportation cost of raw materials and 3D printing equipment. The higher transportation costs in 3D printing are mainly due to the lack of a well-established market for 3D printing equipment and raw material supply. Futuristic scenario analysis revealed that 3D printing could reduce the total construction cost (starting from raw material and equipment supply to construction waste disposal) by 61% when the infrastructure for 3D printing is established in the same way as traditional construction. The findings of this study explored the sustainability potential of 3D printing and offered insights for its application in construction projects.

Keywords – 3D printing; traditional construction; cost analysis; value stream mapping; GHG emissions

1 Introduction

As the global population continues to grow, the demand for new construction has surged, leading to significant expansion in the construction industry. This sector consumes 40% of natural resources, including minerals and fossil fuels, and is responsible for nearly 40% of greenhouse gas emissions among industrial sectors. With projections estimating a global population increase of 9.8 billion by 2050 and up to 11.2 billion by 2100 [1], the strain on mineral and fossil resources is expected to escalate dramatically. In light of this environmental impact, the adoption of smart construction technologies is essential to mitigate damage. One promising solution is 3D printing, also known as additive manufacturing, which creates components by layering materials. This technology has emerged as a sustainable alternative in construction, enabling the production of buildings and components through successive layers of concrete with minimal human intervention. 3D printing (3DP) offers a significant advantage by reducing the cost and environmental impact associated with traditional plywood and metal formwork [2], as it can produce self-supporting concrete layers. Unlike conventional methods, 3D printing minimizes economic and environmental burdens while allowing for the creation of complex geometries with less reliance on intricate formwork [3].

In the construction industry, 3D printing has offered significant benefits by reducing labor costs, material waste, and construction time. In addition, 3D printing streamlines the supply chain by enabling just-in-time delivery of equipment and raw materials directly to the construction site, eliminating the need for large inventories of raw materials and formwork. In 2020, the global 3D printing market experienced impressive growth, surging by 21% compared to 2019 and reaching an estimated value of $12.6 billion [4]. Owing to these benefits, several studies have conducted an extensive economic analysis for 3D printing with reference to

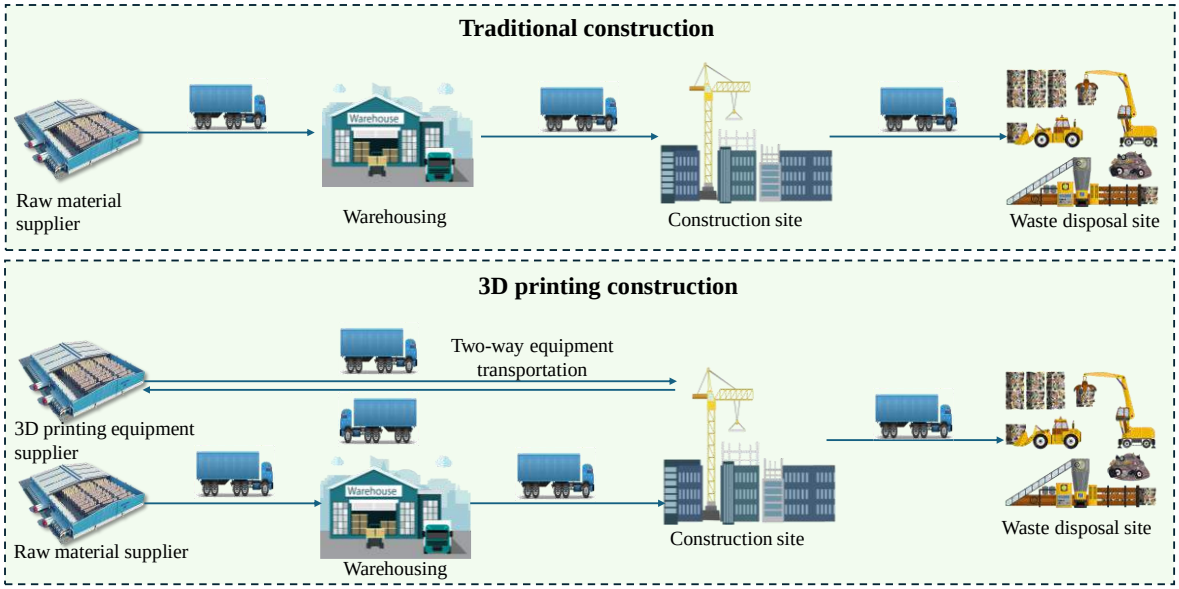

Figure 1. Supply chain configuration for traditional and onsite 3D printing construction.

traditional construction. In their study, Markin et al. [5] analyzed the cost components of 3D printing and found that labor costs contribute just 21%, while material costs account for 70% of the total construction expenses for 3D printing with foam concrete.

Weng et al. [6] conducted a comparative analysis of 3D printing and precast construction. Their findings revealed that 3D printing offered 34% less cost than precast construction. Batikha et al. [7] compared the cost of a two-story building using different construction methods. Their results showed that 3D printing yields 21% less construction cost than precast modular construction. Tobi et al. [8] conducted a cost analysis of a 3D printed house in the UK and revealed that the 3D printing method offers nearly 30% less construction cost than traditional methods. The findings of Allouzi et al. [9] revealed that the 3D printing method has the potential to reduce the material consumption cost by 65%. Abdalla et al. [10] conducted a comparison of formwork and raw material costs between construction 3D printing and traditional construction methods, revealing that 3D printing incurs a capital cost that is 78% lower, primarily due to the elimination of formwork and reduction in concrete consumption. Han et al. [11] considered a case study of a cylindrical silo for the comparative analysis of 3D printing and traditional construction methods. Their findings revealed that the construction cost (labor, electricity, formwork and fuel for operating equipment) of 3D printing is nearly 80% lower than conventional construction.

Apart from cost effectiveness, 3D printing also aids in reducing the environmental impact generated by the consumption of materials and energy due to their efficient utilization. Alhumayani et al. [12] examined the environmental effects of 3D printing compared to traditional casting methods in large-scale construction. Their findings indicated that the overall environmental impact of 3D concrete printing (3DCP) is 50% lower than that of conventional construction. In a study, Weng et al. [6] revealed that traditional construction produces nearly 86% higher carbon emissions than 3D printing construction. Batikha et al. [7] performed a comparative analysis of five construction methods—3D concrete printing (3DCP), prefabrication, cast in-situ, reinforced concrete, and both hot-rolled and cold-formed steel—for building a two-story structure. Their results showed that 3DCP generates 32% lower carbon emissions, whereas prefabricated modular construction has the highest carbon emissions among the methods studied. Han et al. [11] conducted a comprehensive sustainability analysis and revealed that 3D printing offers 2.9% less greenhouse gas emissions than conventional construction during the construction phase. Based on the extensive literature review, it can be believed that 3D printing can be a better alternative to conventional construction due to its cost-effectiveness and reduced environmental impact during the construction phase. However, Besklubova et al. [13] revealed that 3D printing construction is only cost-effective at the construction phase. In their study, it was observed that the logistics cost of 3D printing is significantly higher than that of traditional construction, which ultimately increases the overall construction cost of 3D printing. Based on the extensive literature review, it has been observed that most of the studies have compared the economic and environmental impact of 3D printing with traditional methods at the construction phase considering major factors such as labor hours, energy/fuel consumption, material consumption, and

equipment usage. Therefore, there is a need for studies on the comprehensive economic and environmental impact analysis considering the entire supply chain starting from the supply of raw materials to the waste disposal phase.

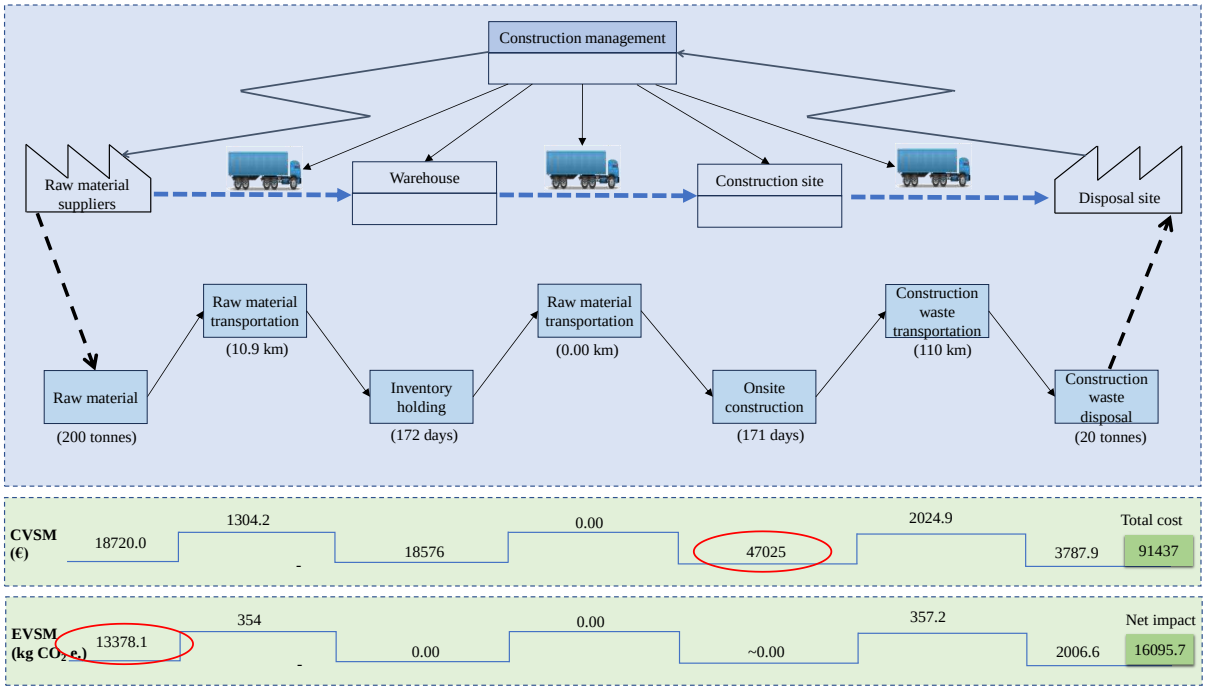
Even though 3D printing has sustainability potential due to a higher level of automation, it has been reported that the higher logistics cost can hinder its real-time application [13]. Therefore, there is a need to investigate the potential reasons for its higher logistics cost and to enhance its economic benefits. This study aims to conduct a comprehensive economic analysis to determine the potential factors contributing to the higher cost and throughout the value stream of 3D printing construction and highlight its possible economic benefits by considering a hypothetical scenario representing the future state of the 3D printing market in the construction industry. Moreover, this study also focused on the analysis of the environmental impact of both 3D printing and traditional construction and features potential environmental perks in the future state.

2 Methodology

This section covers the selection of major factors or activities for traditional construction and 3D printing that incur costs and cause environmental burdens. In the next step, the methodology for mapping these activities on the value stream is presented. After mapping the value streams, real-time case studies have been considered to assess the activities that experience significant costs and contribute to the environmental burden.

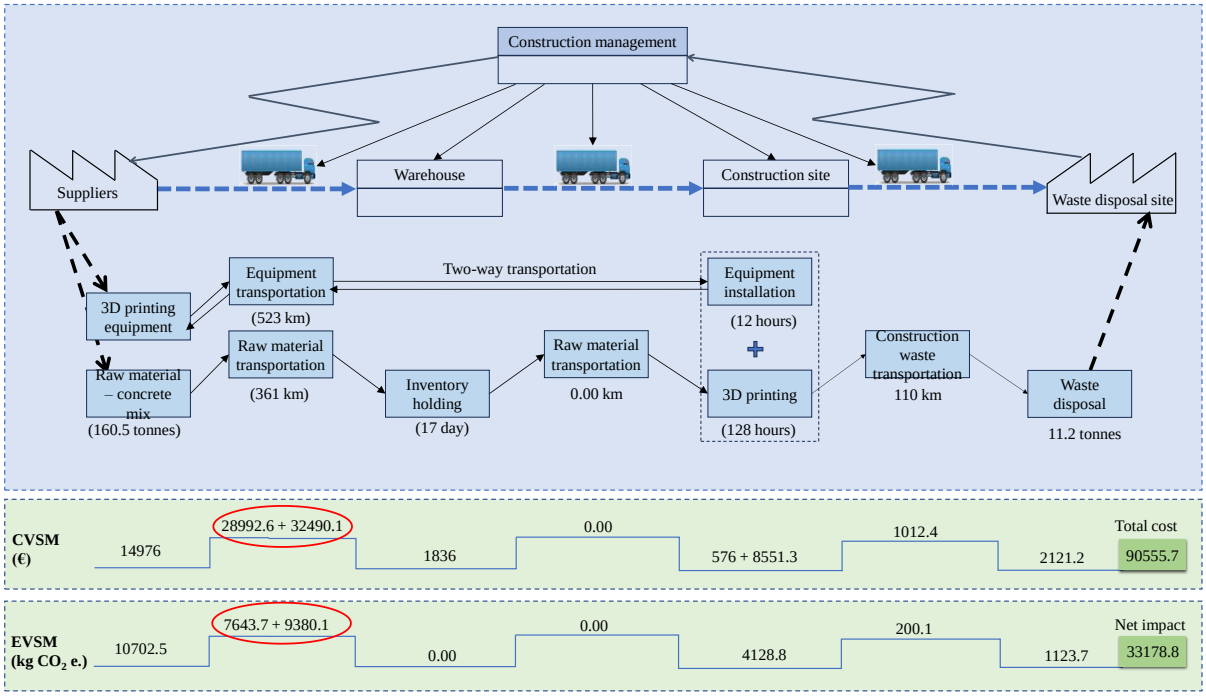
2.1 Parameters identification

First of all, the activity-based costing (ABC) approach has been used to highlight the activities that incur the resources and costs at the different phases of the construction process. The ABC method offers more precise cost information, facilitating effective monitoring of supply chain and construction strategies. In both construction methods, activities are highlighted, from the supply of the raw materials to the construction waste disposal to estimate the cost. All activities are further disintegrated into several other small factors. For transportation, the amount of material to be transported, distances, labor cost, handling cost, fuel cost and environmental cost are considered. For the construction phase, factors including labor cost, construction time, equipment depreciation, energy cost, material cost, and environmental cost are encountered. Apart from the cost, the factors contributing to the greenhouse gas emissions, including fuel (for transportation), energy and construction materials in different construction phases, are also highlighted.



2.2 Mapping the value streams

Value stream mapping was used to highlight the cost- and emissions-intensive phases of the construction processes. Value stream mapping is a valuable tool for visualizing and quantifying activities across the construction supply chain. Figure 1 illustrates the supply chains for both traditional and 3D printing construction, which aid in the development of value streams. Within the value stream, activities related to 3D printing and traditional construction processes are clearly delineated into facility-based and non-facility-based activities. Facility-based activities include warehousing and onsite construction, while material and equipment handling and their transportation between these facilities are classified as non-facility-based [14]. For traditional construction, the value stream starts with the supply of raw materials from the suppliers to the warehouse and then to the construction site, which finally ends with the transportation of construction waste material from the construction site to the disposal site. The value stream of onsite 3D printing is nearly the same as traditional onsite construction; however, it also involves the two-way transportation of 3D printing equipment from the supplier to the construction site and back to the supplier (upon project completion). After highlighting the processes, the cost and carbon emissions are highlighted for each stage of the value stream for both traditional construction and 3D printing processes. Upon mapping the cost and environmental value streams, critical stages are highlighted in order to reduce their economic and environmental impacts.



2.3 Case study and data collection

This section outlines the application of the proposed model to evaluate the feasibility of 3D printed projects in comparison to traditional construction methods. For this analysis, case studies of residential buildings in Berlin and Beckum, Germany, were selected. The onsite 3D printed project, a joint venture involving PERI, COBOD, and others, was chosen for its unconventional design and onsite construction, which aligns with industry interests. This project has received a building permit from the local authorities in Beckum, providing valuable insights. The study gathered data from open-access articles, reports, and official websites to design a technical questionnaire for operational employees, focusing on project specifics, resource logistics, and costs. Follow-up interviews with senior management addressed gaps and enriched insights. Collected data was then applied to a model to validate the feasibility and practical implementation in the case studies, demonstrating the utility of the results.

In contrast, a traditionally built house in Berlin, constructed with sand-lime blocks and having a similar floor area, was selected for comparison. Bricks or sand-

(a)

(b)

Figure 2. CVSM and EVSM for (a) traditional construction (b) 3D printing construction.

lime blocks are chosen over cast-in-place concrete in small-scale construction because they have lower structural needs (sufficient strength for low-rise buildings), are less expensive (no formwork, easier labor and logistics), and can be built more quickly (no curing delays). They are easier to manage in tight places and provide greater thermal/acoustic performance, reduced dead loads, and shrinkage-free stability. These projects meet the criteria for the case study as they are real-world examples from the same country, use the same currency, and involve a similar scope of work, offering comprehensive data on various aspects. Although the

projects were implemented in cities of different sizes (Berlin and Beckum), the cost calculations were based on average values for Germany, considering factors such as materials, equipment, and waste transportation, which often require intercity logistics. Based on the parameters identified and mathematical models developed by Besklubova et al. [13], the cost-based value streams have been determined for the comparative analysis of traditional construction and 3D printing. To assess the environmental impact of both construction techniques, a detailed methodology of Life cycle analysis presented by Raza et al. has been adopted [15].

3 Results and discussion

This section provides a comparative analysis of the traditional and 3D printing construction techniques in terms of cost and environmental impact. To illustrate the cost incurred and environmental impact produced at different stages of construction, cost-based value stream mapping (CVSM) and environmental value stream mapping (EVSM) for both traditional and 3D printing construction are considered.

3.1 Cost-based value stream mapping

Cost-based value streams of traditional and 3D printing construction are mapped to investigate the costs at the different phases. In the case of value streams, costs associated with raw materials, transportation, warehousing, labor, and construction waste disposal are considered for a low-rise building. Value streams start with the supply of raw materials, and raw material cost is incurred in the first stage. From Figure 2, it can be seen that the raw material cost of 3D printing (14976 €) is lower than that of the traditional construction process. This is primarily due to the fact that traditional construction consumes more material due to cutting, shaping, and fitting materials in intricate shapes, leading to the consumption of more material. On the other hand, 3D printing does not require any excessive material in the case of complex designs. The next step involves transporting raw materials from the supplier to the warehouse or construction site. It has been observed that traditional construction suppliers are available quite close (10.9 km) to the construction site. However, 3D printing requires specialized composition or formulation of concrete material, which is not commonly available in the market; therefore, the raw material is procured from a specific supplier from a distant place. Increased distance (361 km) between the supplier and warehouse or construction site significantly increases the transportation cost to 32490.1 €. 3D printing also involves the transportation of large sized 3D printing equipment. Similarly, in the case of 3D printing material supply, printing equipment is also delivered by particular suppliers which are not commonly available. Transportation of printing equipment involves the delivery of a large-sized gantry system, piston pump, batching plant and a silo, and equipment is returned to the supplier upon the completion of the project.

Two-way transportation from a distant place (523 km) incurs a significant transportation cost of 28992.6 €. Warehousing cost is also a distinguishing factor between traditional and 3D printing construction. The warehousing cost of traditional construction is significantly higher (18576 €) as construction materials are held for a longer time as the construction time of traditional construction is almost 171 days; therefore, material holding is considered for almost the same duration with an additional one day. On the other hand, 3D printing time is significantly shorter; therefore, raw materials are held for a short period of time (17 days). In this case study, the warehouse is considered close to the construction site; therefore, the transportation of materials from the warehouse to the construction site is negligible. On the construction phase, typical construction cost involves labor, energy and equipment cost. In traditional construction, low-rise buildings typically involve manual operations for small-scale projects, leading to substantial labor costs. As a result, the construction phase incurs significantly higher expenses, amounting to approximately €47025. Equipment and energy costs are negligible compared to labor costs. However, 3D printing involves the printing of material, which requires few operators for its installation and printing process and consumes energy. Due to the significant level of automation, the cost of the

Figure 3. Locations of construction companies in Germany are highlighted with yellow icons on the map [16].

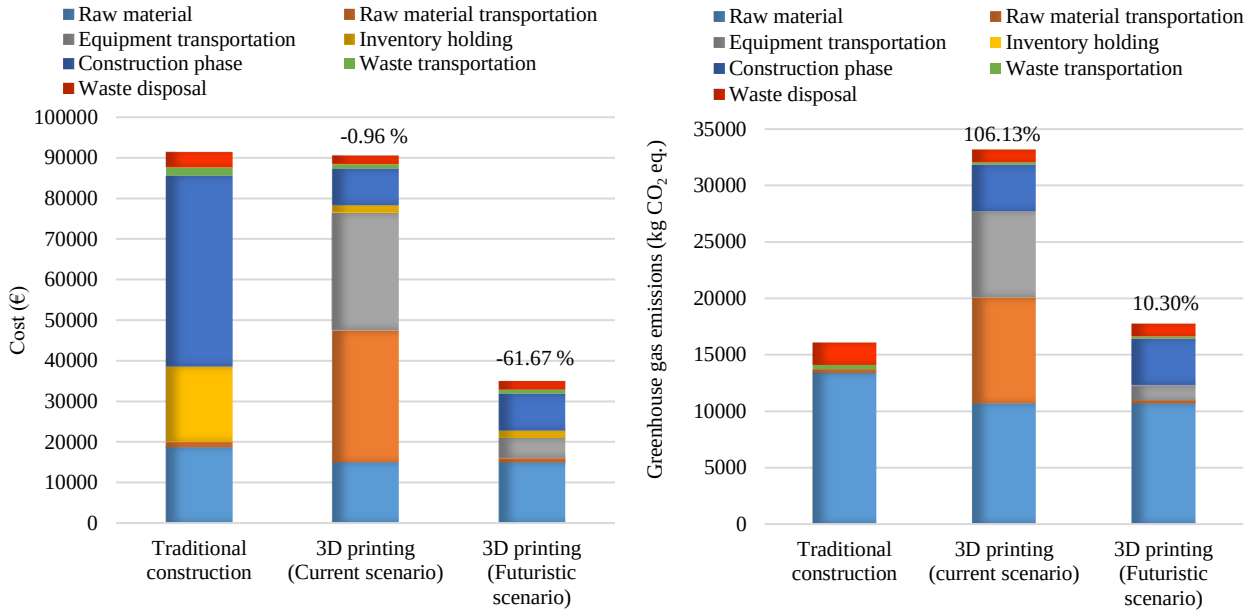


Figure 4. Comparative analysis of traditional construction with a futuristic scenario of 3D printing for (a) total construction cost (b) total greenhouse gas emissions.

construction phase is observed to be 9127.3 €, which is nearly 80% lower than that of traditional construction. In the case of waste disposal, nearly the same distance is considered for both construction methods. Analysis shows that the waste disposal cost of 3D printing (2121.2 €) is lower than that of traditional construction (3778.9 €), which is due to the lower amount of waste produced. Comparative analysis shows that even though 3D printing offers significantly lower construction costs due to a higher level of automation, its total cost (90555 €) is still quite close to the traditional construction cost (91437 €). The prime reason for the higher total cost of 3D printing is the transportation of raw materials and 3D printing equipment from distant places or facilities due to the lack of a well-established market for 3D printing.

3.2 Environmental value stream mapping

EVSM is a valuable tool used to assess the potential sources of greenhouse gas emissions throughout the value stream of the construction process [15]. The analysis shows that GHG emissions from the raw material (13378 kg CO_2 eq.) are significantly higher than any other activity in the value stream. However, the GHG emissions from the raw material for 3D printing (10702.5 kg CO_2 eq.) are lower than those from traditional construction due to the relatively lesser amount of material used. The transportation of raw materials and 3D printing equipment contributed to the GHG emissions to a significant extent of 17023 kg CO_2 eq. which are mainly due to the large distances between the suppliers and construction site. On the other hand, traditional construction hardly commits 353.98 kg CO_2 eq., which shows that transportation is the decisive factor for the selection of environmentally friendly alternatives. In the next phase of construction, 3D printing also contributes 47025 kg CO_2 eq. to the GHG emissions, which are associated with the energy consumed during the concrete mixing, pumping and printing process. As (in this study), a low-rise building is considered where most of the operations are performed manually in traditional construction; therefore, negligible GHG emissions are observed during the construction phase.

However, in the case of high-rise buildings or large construction projects, a significant amount of energy is also consumed in the concrete mixing and pumping process, which generates a competitive amount of GHG emissions. In the case of construction waste transportation and disposal, 3D printing outperformed by producing 200.05 kg CO_2 eq. and 1123.70 kg CO_2 eq. respectively, due to the generation of less construction waste than traditional construction. Net GHG emissions analysis depicts that traditional construction produces almost 51% less GHG emissions than 3D printing construction.

3.3 Futuristic scenario for 3D printing construction

From the previous discussion on value stream assessment, it has been observed that traditional construction outperformed 3D printing in terms of cost and environmental impact for low-rise buildings. The

prime reason for the higher cost and environmental impact was observed to be the larger distances between the suppliers and construction sites for 3D printing. The market and infrastructure for traditional construction are well established, and raw material suppliers (for traditional construction) are frequently available. Moreover, most of the traditional construction companies are located within a 100-kilometer radius, as shown in Figure 3. Conversely, 3D printing technology is not yet fully developed, and suppliers of its equipment and raw materials are not consistently accessible. Thus, it would be premature to conduct a comparative analysis of both techniques at this stage. Therefore, this study presents a futuristic scenario for 3D printing by considering the equipment supplier at 90 km and the raw material supplier at the same as traditional construction (10.9 km). In the current scenario, it has been observed that 3D printing hardly reduces the total cost by 1%, as shown in Figure 4a (the negative sign depicts the percentage reduction). A futuristic scenario for 3D printing shows that 3D printing could reduce the overall cost by 61.67% as compared to traditional construction. In the case of environmental impact, it has been observed that the current scenario produces almost 106% higher GHG emissions, which could be reduced to 10% higher than that of traditional construction (Figure 4b). The higher GHG emissions are associated with energy consumption due to higher levels of automation. However, in the case of large construction (where traditional construction processes also use machines for mixing and pouring), 3D printing has the potential to offer even lower GHG emissions than traditional construction.

4 Conclusion

This study outlines the key factors and activities in traditional construction and 3D printing that incur costs and impact the environment. It then presents the methodology for mapping these activities on the value stream. Finally, real-time case studies are analyzed to evaluate the activities that significantly contribute to costs and environmental burdens. The following conclusions are drawn from the findings of this study.

- In traditional construction, the primary factors driving total costs are raw materials, warehousing, and labor. In contrast, for 3D printing, transportation of raw materials and printing equipment significantly influences overall costs, primarily due to the absence of a well-established infrastructure compared to traditional construction.
- In the case of environmental burden, raw material is the major source of GHG emissions for traditional construction due to the significant amount of material used. On the other hand, transportation of raw materials and equipment remains a significant factor for 3D printing due to the large distances from the suppliers.
- In the construction phase, 3D printing offers nearly 80% less cost than traditional construction, which is mainly due to the significant automation involved. In contrast, labor remained the major factor in the higher cost of traditional construction.
- To assess the potential of 3D printing, a futuristic scenario has been presented, revealing that 3D printing can reduce overall construction costs (including transportation, warehousing, construction, and waste disposal) by nearly 61.67% if raw materials and equipment are available close to the construction site, similar to traditional construction.
- The environmental impact of 3D printing is 106% higher than that of traditional construction, which can be reduced to only 10% higher (for low-rise buildings or small-scale construction) if the raw materials and equipment are readily available. However, the environmental burden of traditional construction could be even higher than 3D printing in large-scale construction projects due to the energy consumption by batching plants and piston pumps.

This study revealed that 3D printing offers an even higher cost and environmental burden at this stage due to the lack of well-established infrastructure same as traditional construction. However, 3D printing could be the potential alternative to traditional construction due to its potential to limit the overall construction cost and environmental burden.

Abstract –

Building energy research faces challenges in predicting complex interactions, integrating renewable energy, bridging real-world applications, addressing economic feasibility, and designing buildings to adapt to climate conditions. Zero energy building (ZEB) is an innovative approach aiming to generate renewable energy equivalent to building demand, but its development is hindered by industry flexibility and complexity. The research explores the feasibility of achieving near ZEB by utilizing roof photovoltaics technology for energy production and optimizing consumption in four US climate regions. Building Information Modeling (BIM) was used in this study to simulate the building operation energy. Actual Location and real weather data were used to adopt results accurate enough for the study objective. Additionally, the local energy prices were used to costly-wise introduce an effective feasibility. Colorado's model has the highest energy and cost percentages, at (75.34%) and (88.61%), respectively. Georgia ranked second in terms of energy savings (71.21%). Due to the high local energy prices, San Francisco, Ca achieved the largest cost-saving percentage (88.61%), which is like Colorado, despite having a lower percentage of energy savings (59.83%). The study found that wall and roof construction, along with HVAC system types, are effective in optimizing building energy consumption, but its results are limited by climate regions and office building types.

1 Introduction

Urban regions are moving toward sustainable energy by converting the infrastructure into energy-efficient systems. Advanced energy analysis techniques and Building Information Modeling (BIM) are being employed to forecast energy generation and demand to support self-sufficient, and energy-independent communities [1], [2]. Computational techniques provide an accurate and reliable way to address uncertainty and sensitivity analysis in energy efficiency buildings, addressing intricate linkages [3], [4], [5]. The building industry is still in the developing stage for sustainability due to the high complexity of building systems and the involvement of many stakeholders [6]. Therefore, computational techniques are used to overcome this difficulty [7], [8]. Energy and environmental concerns are addressed by integrating renewable and energy-efficient technologies [9], [10], [11]. There are many barriers to the adoption of renewable energy [12]. Reaching the point of optimal building energy performance could be impacted by several factors [13], [14], [15].

The World Green Building Council (WGBC) and the United Nations Framework Convention on Climate Change (UNFCCC) are collaborating to create a common approach for assessing and grading building sustainability. Most scholars use generative computation for aesthetic form-finding without using zero-energy-driven global performance standards, and there is no standard seal or measure for Net-Zero Energy buildings [16]. Using a Digital Twin model, ZEB buildings in the UK have successfully integrated renewable technology into their current buildings. The model has shown a 23-year return period for solar panels and wind turbines but does not provide design recommendations for new buildings [17]. The study [18] revealed that countries plan to convert traditional buildings to Zero Energy, despite challenges like high initial costs for renewable energy systems compared to overall building costs, gaining more interest and support. The study [19] analyzed cost barriers to Zero Energy Building (ZEB) implementation, revealing gaps in energy-saving calculations, comparative studies, life cycle cost analysis, and high initial costs.

BIM and cloud optimization platforms are popular building energy simulation software for simulating building materials and geometry. Cloud-based optimization tools were used to analyze an academic building in Pakistan, focusing only on roof isolation and building orientation, demonstrating the effectiveness of BIM in optimizing energy efficiency [20]. The cloud tools were utilized in an evaluation strategy for the Middle East and North Africa, analyzing building energy use and identifying solutions to reduce it. The study focused on photovoltaic panels and HVAC system enhancement, not considering alternative construction materials [10]. Furthermore, computational design methods were used to improve the energy performance of concrete residential towers in cold climates [21], and pre-trained language model-based methods were used to transform the building information model into an energy model [22].

According to the literature review, the impact of climate on designing a new ZEB or retrofitting existing buildings was not well understood. Additionally, little is known about how climate influences design factors. By examining design features and using special design scenarios to rebuild a sustainable and highly energy-efficient building using BIM software, this paper will bridge this gap by examining four different climates for an office building to achieve near Zero-Energy objective.

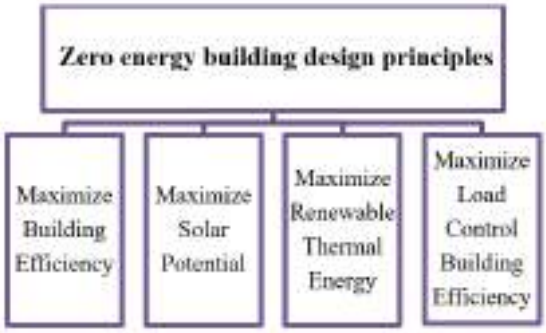

Figure 1. Zero energy building design principles adapted from [25].

Zero energy building (ZEB) is an innovative approach aiming to balance building energy demand and renewable energy production. This study aims to identify the impact of climate on achieving near ZEB by analyzing the unique design scenarios of factors such as location, design, renewable energy use, energy consumption trends, and budget when planning, erecting, restoring, and reconstructing such a high-efficiency building. The literature examining the building designs that can achieve the high-energy performance building concept is severely lacking [18], [19], [23], [24]. This study will cover this gap by modeling the operation performance of an office building using BIM, Energy analysis, and optimization tools. It also applies distinctive design scenarios for each design parameter to achieve near ZEB requirements. Finally, the optimization values for each design parameter were determined based on the impact of reducing the overall building energy consumption and cost. Figure 1 summarizes the main key steps optimize a ZEB.

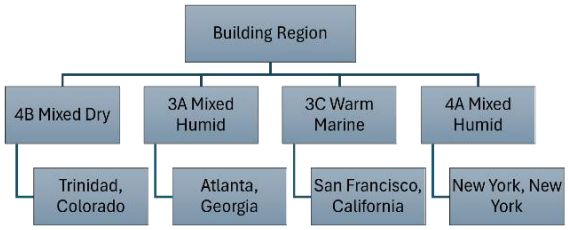

Figure 2. Different building regions

This study aims to fill the literature gap and provide a roadmap for designers and practitioners to adopt passive solar design for high-performance buildings and sustainable targets. It aims to accelerate zero-energy buildings by reducing energy consumption and introducing energy production techniques. The paper investigates the influence of climate region on building energy consumption and solar energy production in four different regions as shown in Figure 2. The climate regions classification is according to Building America and the International Energy Conservation Code (IECC) 2021 Updates as shown in Figure 3. The four locations were selected from different climate regions after excluding extreme climates that are expected to consume very high energy due to the weather.

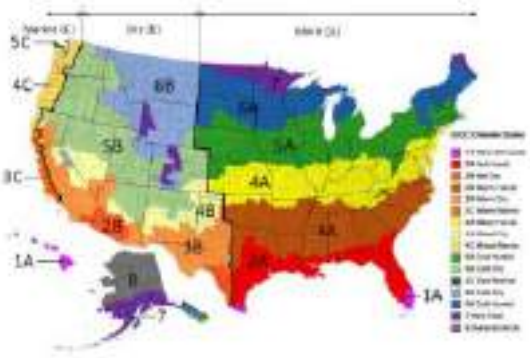

Figure 3. Climate Zone by County according to Building America and International Energy Conservation Code (IECC) 2021 Updates adapted from [26].

The study aims to identify the feasibility of adopting ZEB. It utilizes BIM simulation tools to connect the effects of different variables and deal with the complexity of the building systems. The fundamental presumptions of this research are as follows.

- The selected building represents its local

location for weather and environmental parameters.

- The results generated from the simulation tools are accurate enough for the study objective to compare energy savings for different cases.
- The secondary simulation parameters have a negligible impact when comparing different scenarios.

The study focuses on office buildings and considers the standard energy usage rates for simulating different energy modules. However, additional studies should be conducted to expand the scope due to limited case studies and climate regions.

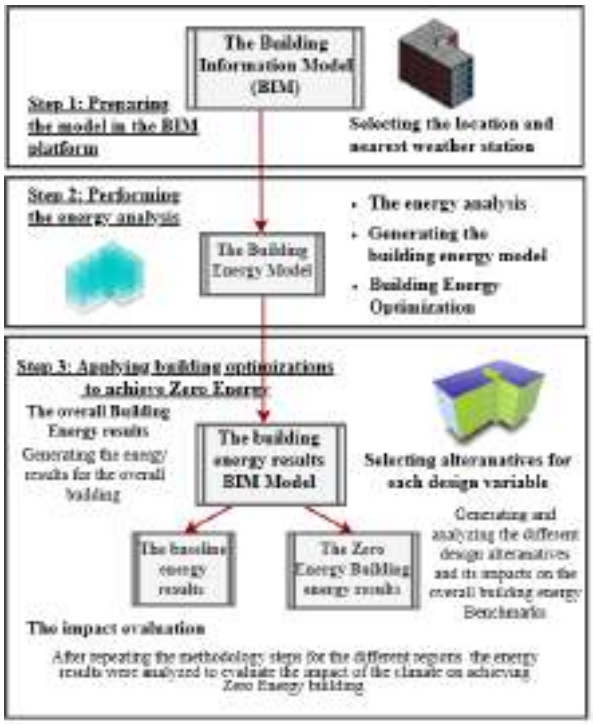

Figure 4. The Study Methodology Flow Chart.

2 Methods

This study is examining the building operation performance in 4 different locations through applying three main steps for each location, as illustrated in Figure 4, starting with step 1: Preparing the model in the BIM platform. Following that, the energy analysis is performed in step 2 to generate the building energy model. In step 3, the building energy model will be used to apply the energy optimizations to reduce the energy consumption and optimize the photovoltaic energy production trying to achieve near ZEB. Finally, the baseline energy and cost will be compared to the near ZEB energy and cost for each location.

Figure 5: BIM Model, Energy Model, and Optimization results model. (BIM model source [27])

2.1 Preparing the model in the BIM platform

Autodesk Revit was used as the BIM tool to model the building geometry and materials. Additionally, its integrated GIS (Geographic Information System) functionality enabled the incorporation of location-specific weather data, enhancing the analysis with real-world environmental conditions.

Figure 6: The selection of the building location and the nearest Weather Station.

Figure 5 illustrates BIM Model, Energy Model, and Optimization results model. For instance, Figure 6 shows the selected location and the nearest available weather station, and Figure 7 reports the monthly temperature rates for first location.

Figure 7. The monthly temperature rates in the selected location.

2.2 Performing the energy analysis

The energy analysis tools were used to perform a complete energy analysis. Figure 5 shows the generated building energy model.

Finally, the energy model for each location were exported to the optimization platform. At this step, different variables for each design parameter were applied, which gave different results for each variable. For example, different wall construction types including (R13 Wood- Uninsulated- R2CMU- R3 Metal- R13+R10 Metal- 14-inch ICF- 12.25-inch SIP- R38Wood) gave the Energy Use Intensity (EUI) results shown in Figure 8. Figure 5 illustrates the results of the BIM model generated in the optimization platform.

Wall construction Types	R13 Wood Uninsulated	R2CMU	Baseline (BIM)	R3 Metal	R13+R10 Metal	14-inch ICF	12.25-inch SIP	R38Wood
Energy Impact (kwh/m²/yr.)	+50	+30	+10	0	-5	-45	-48	-49	-50

Figure 8. The energy impact of using different Wall Construction Types in Trinidad, CO - 4B Mixed Dry region.

2.3 Applying building optimizations to achieve zero energy

Different energy scenarios are achieved by setting distinctive design parameters to a specific value. For example, wall construction materials can be set to different types. A total of 24 design parameters were used in the optimization process as given in Figure 9. A new scenario is added to the results after setting all the design parameters to a specific value. This study applied the scenario that achieves the ZEB target to compare it with the baseline scenario. The design parameters were determined based on the impact of energy consumption and cost reduction. The findings of this study were analyzed and compared at the end of this paper.

Design Parameters

- Building Orientation (Degrees)
- Daylighting & Occupancy Controls
- HVAC Types
- Infiltration (ACH)
- Lighting Efficiency
- Operating Schedule
- Panel Efficiency
- Payback limit
- Plug Load Efficiency
- Roof Construction
- Surface Coverage
- Wall Construction
- Window Glass Types - North
- Window Glass Types - East
- Window Glass Types - West
- Window Glass Types- South
- Window Shades - East
- Window Shades - North
- Window Shades - South
- Window Shades - West
- WWR - Eastern Walls
- WWR - Northern Walls
- WWR - Southern Walls
- WWR - Western Walls

3 Results

The study results were analyzed to visualize and evaluate each building location for constructing or retrofitting existing buildings to become a near ZEB. Figure 10, and Figure 12 explain the comparison analysis for the building energy consumption and cost, respectively for the four building locations for the baseline scenario. Figure 12, and Figure 13 compare the results of building energy consumption values for the four building regions for the near ZEB scenario with the baseline results.

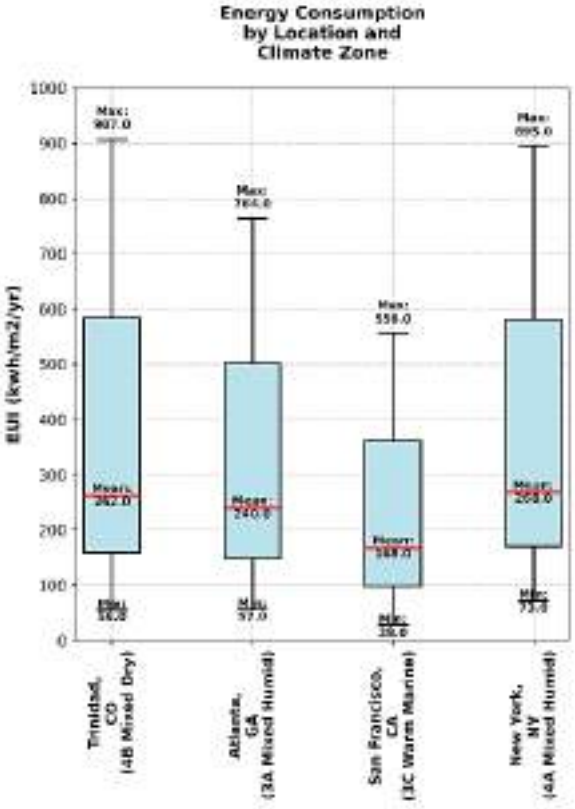

Figure 10. Comparing the Minimum, Mean, and

Maximum building energy consumption results by location and climate zone for the baseline scenario.

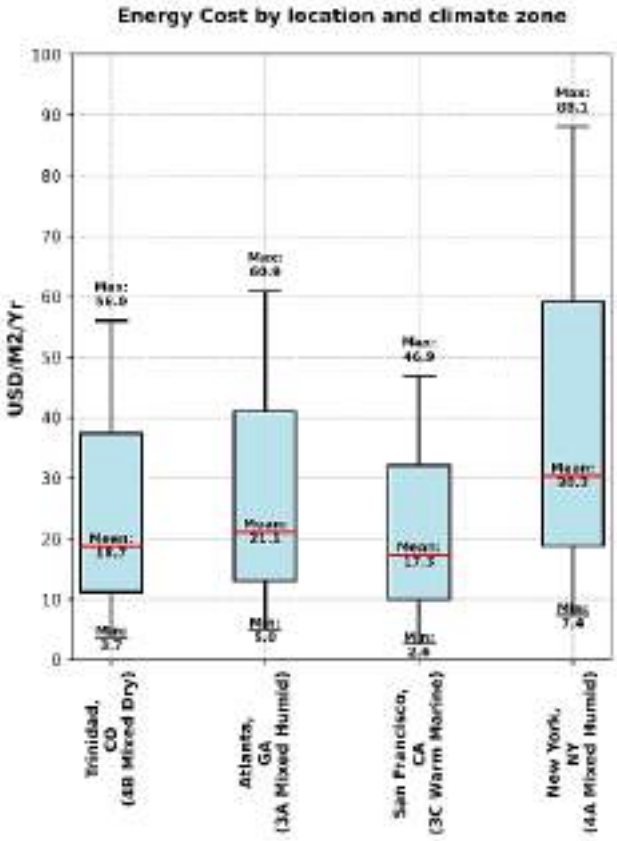

Figure 11. Energy Cost by location and climate zone for the baseline scenario.

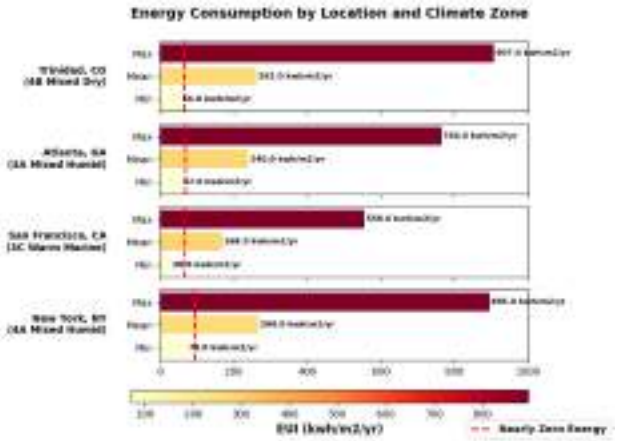

Figure 12. Comparing the building energy consumption results by location for the near ZEB scenario with the baseline results.

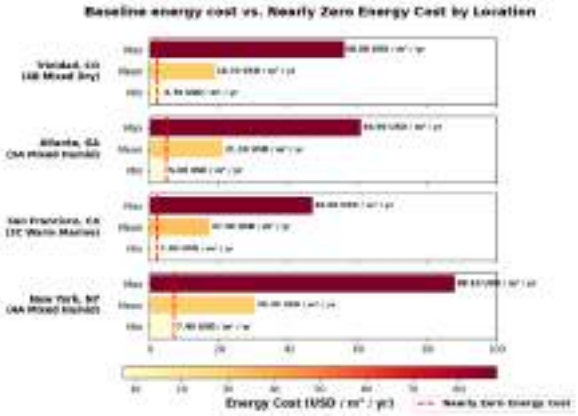

Figure 13. Comparing the building energy cost results by location for the near ZEB scenario with the baseline results.

The near ZEB results were compared with the baseline mean values to visualize the feasibility in energy and cost savings between the four locations as illustrated in Figure 14, and Figure 15.

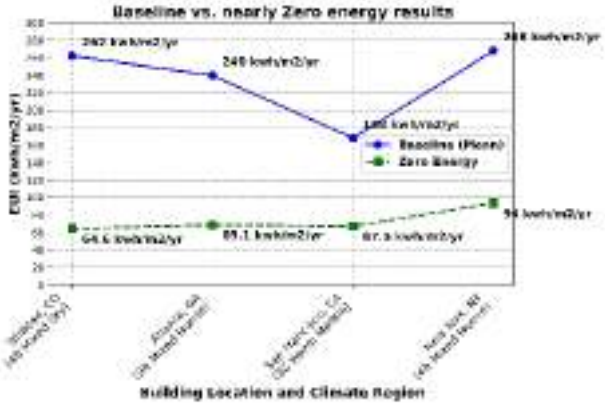

Figure 14. Comparing the near ZEB energy with the baseline Mean results.

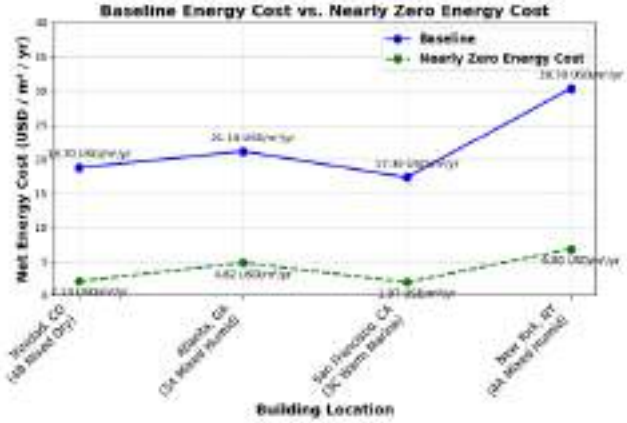

Figure 15. Comparing the near ZEB cost with the baseline Mean results.

Finally, the percentages of energy and cost savings were calculated and plotted in Figure 16

to find the best near ZEB locations. The model in Colorado recorded the best energy and best cost with (75.34%) and (88.61%). Georgia was the second-best location in energy savings (71.21%). However, the lower percentage of energy savings (59.83%) in San Francisco, CA, it recorded the highest cost saving percentage (88.61%) same as Colorado, due to the high local energy prices. New York was the 3rd in energy and cost saving percentages recording (64.93%) and (77.56%), respectively.

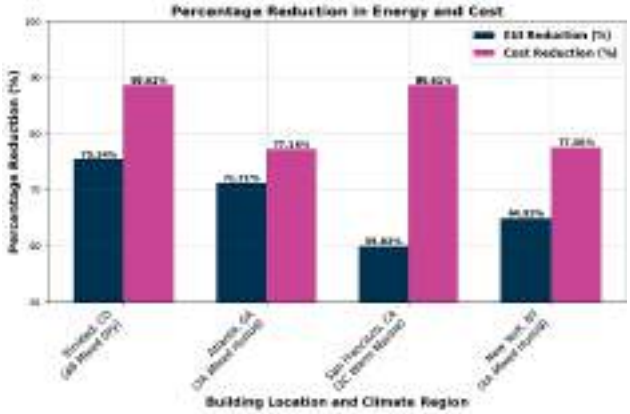

Figure 16. Comparing the percentages of reduction in energy and cost by location.

4 Discussion and Conclusion

This study assessed the influence of building location on operational performance by examining four distinct office building locations in different climate regions in United States including Colorado, Georgia, San Francisco (California), and New York. Retrofitting strategies were implemented to enhance operational efficiency and achieve the objectives of a near Zero Energy Building (ZEB). The baseline energy consumption of each location was first simulated, and subsequent performance outcomes were evaluated after applying various design alternatives. Building Information Modeling (BIM) was employed to simulate building geometry, while energy optimization tools generated energy analysis models. These models were further analyzed using an optimization platform. The evaluation adhered to the World Green Building Council's zero-energy building standards, assessing the feasibility of retrofitting, restoration, or reconstruction and the potential energy and cost savings across the four climate regions.

The study results revealed that the operation performance is highly sensitive to the building location. The model in Colorado recorded the best energy and cost savings (75.34%) and (88.61%), Respectively. Georgia was the second-best location in energy savings (71.21%). However, the lower percentage of energy savings (59.83%) in San Francisco, CA, it recorded the highest cost savings (88.61%) same as Colorado, due to the high local energy prices. New York was the 3rd in energy and cost savings (64.93%) and (77.56%), respectively.

The results are limited to the four climates included in this study and office buildings. Future work is highly recommended in other climates and for other building types. Future work will focus on validating the proposed method using real-world data to further assess its accuracy and performance. Also, simultaneously simulating a group of buildings may have additional impacts on overall building consumption. This paper contributes to the acceleration of ZEB targets and sustainable buildings by introducing an evaluation of the energy and cost savings for designers, stakeholders, and governments. This study contributes to the field by applying existing methods, such as BIM simulations and energy modeling, to specific climate regions, highlighting the importance of location-specific factors in optimizing energy efficiency. This approach offers valuable insights for real-world applications, demonstrating the potential for significant energy and cost savings based on regional conditions.

Abstract -

Human-robot collaboration (HRC) in the construction industry depends on precise and prompt recognition of human motion intentions and actions by robots to maximize safety and workflow efficiency. There is a research gap in comparing data modalities—signals and videos—for motion intention recognition. To address this, the study leverages deep learning to assess two different modalities in recognizing workers' motion intention at the early stage of movement in drywall installation tasks. The Convolutional Neural Network–Long Short-Term Memory (CNN-LSTM) model utilizing surface electromyography (sEMG) data achieved an accuracy of around 87% with an average time of 0.04 seconds to perform prediction on a sample input. Meanwhile, the pre-trained Video Swin Transformer combined with the transfer learning technique, harnessed video sequences as input to recognize motion intention and attained an accuracy of 94% but with a longer average time of 0.15 seconds for a similar prediction. This study emphasizes the unique strengths and trade-offs of both data formats, directing their systematic deployments to enhance HRC in real-world construction projects.

Keywords -

Human-Robot Collaboration (HRC); Motion Intention Recognition; Surface Electromyography (sEMG); Convolutional Neural Network–Long Short-Term Memory (CNN-LSTM); Video Swin Transformer

1 Introduction

Human-robot collaboration (HRC) refers to the mutual coordination between humans and robots in a collaborative workspace, where robots can understand the environmental context, and human actions and can make decisions to supplement human tasks. Due to recent advancements in hardware, software, and deep learning algorithms, the performance of construction robots has increased in construction projects in terms of safety, efficiency, and productivity of construction workers [1]. Despite the advancements, construction robots still face challenges due to the dynamic and rapidly changing environments where understanding human behaviors with precise timing is essential [2]. Hence, it is critical to recognize workers' motion intention to enable HRC in construction [3].

Human motion intention recognition is being researched and implemented by modeling machine learning algorithms on two primary modalities: sensor and video data. Among sensor-based approaches, surface electromyography (sEMG) sensors have been utilized to capture the muscle activity of human because they represent muscle movements and their acquisition is easier due to their non-intrusive nature [4]. Meanwhile, videos are also being extensively utilized to analyze human motion with emerging computer vision and image processing technologies [5]. Videos can be used to predict the motion trajectories of workers, equipment, and harmful actions to enable safety monitoring in construction sites [6, 7].

However, these two modalities have their limitations. EMG signals are prone to noise and variability across different subjects which make generalizing patterns difficult [4]. It may be uncomfortable for workers to carry sensor with them. On the other hand, videos require high computational power for model training and inference. Video-based approaches are vulnerable to occlusions, varying viewpoints, background clutters, etc. There have been studies exploring these approaches separately, but the existing studies lack a solid comparison of these modalities in this recognition task, especially in construction.

To address this research gap, this study proposes a comprehensive comparison of the applications of sEMG and video-based modalities as input to deep learning algorithms in human motion intention recognition in construction. This research implements a Convolutional Neural Network–Long Short-Term Memory (CNN-LSTM) model to analyze sEMG signals and utilizes a pre-trained Video Swin (Shifted Window) Transformer model to train on video input. Finally, the performance of these two models is evaluated and compared. This proposed system could provide insights into tradeoffs between their performance and drawbacks, which can help to choose an appropriate approach among the two options for HRC in construction.

2 Literature Review

To enable adaptive and seamless cooperation between human workers and robotic systems, the construction industry has centered on integrating human motion recognition and behavioral analysis into HRC. This included sensors, wearable devices, computer vision, and machine learning models, to capture and interpret human movements in real-time [1, 8]. This section reviews the state-of-the-art studies in human motion recognition using two primary modalities and their applications in construction.

2.1 Signal-based Methods

sEMG and other signal-based methods are extensively adopted in industrial and construction applications [3]. These methods can predict human movements before they occur which can enhance safety and operational efficiency of exoskeleton robots [9]. sEMG signals were also used to recognize hand gestures and control industrial robots in the context of a smart factory [10].

Shah and Kim [3] proposed an sEMG-based motion intention recognition system at an early stage by analyzing the first 1-second muscle activity from four muscle sensors. They implemented a CNN-LSTM model and achieved an accuracy of 98.5% in classifying four construction-related activities. Combining convolutional layers with gated recurrent unit layers (GRU), a hybrid model was trained on sEMG signals [10]. This model was tested on 11 subjects and obtained around 96% accuracy in detecting 10 types of hand gestures. A CNN-LSTM-based system was developed to predict various motion intentions in a squat activity which represents lifting motion in industrial environments [9]. This methodology can catch the movement initiations 0.3 seconds ahead using sEMG signals with an accuracy of 84.02%.

While sEMG plays a key role in human motion detection, several studies show that these signals are prone to variability created by factors such as electrode placement, muscle fatigue, skin impedance, environmental weather conditions, and subject-level bias in terms of gender and age, which leads to noise that can hamper accuracy in action detection [4, 11].

2.2 Video-based Methods

Tang et al. [7] presented a methodology for utilizing the LSTM model's encoder-decoder architecture combined with multi-head prediction modules to predict the future paths of workers and equipment on construction sites using video data. A transformer-based model [6] was proposed for recognizing unsafe gestures on construction sites which applied transformer and 3D CNN to extract spatial and temporal features. It achieved a precision of 88.7% on a customized dataset outperforming baseline methods. For swimming action recognition, a novel multimodal approach called Swintrans Net [12] was presented, building upon the Swin-Transformer's [13] superior feature extraction and adaptability.

Video-based motion recognition systems on construction sites also encounter several challenges. Blocked camera views by frequent obstructions from materials, machinery, and workers, result in incomplete or inaccurate motion data. With constantly changing layouts, equipment, and the dynamic nature of these environments, it is difficult to develop robust systems capable of adapting to unpredictable conditions [2]. Real-time motion detection can be a technical problem due to the processing time of high-resolution videos. Additionally, varied lighting conditions, such as low light, shadows, and glare, can further degrade the performance [14].

2.3 Research Gap

Comparative analysis between sEMG and video data sources in motion intention recognition is relatively scarce, specifically in the context of HRC in construction. One potential reason is due to the limitation of publicly available datasets containing both sensor and video data types that represent similar experimental settings [5]. Two data types can be utilized in analyzing human motion in their own way, but they also have some shortcomings. This presents an opportunity to compare the two approaches in terms of dataset dimensions, deep learning models, accuracy, performance, and prediction latency. This systematic comparison can aid researchers in developing more effective motion intention recognition systems tailored to specific needs and tasks. For the sEMG, we chose a CNN-LSTM model since it outperforms non-recurrent models in time series analysis [15]. Video Swin Transformer model was chosen for its advantage over 3D CNNs in capturing long-range spatial and temporal dependencies in video sequences using self-attention mechanisms [6, 12].

3 Proposed Methodology

The proposed methodology starts with data acquisition of raw sEMG signals and videos which are then preprocessed as inputs to the models. The obtained training curves and test evaluation metrics are interpreted for a comparative analysis. The system workflow is depicted in Figure 1.

3.1 Signal-based Approach

3.1.1 Data Acquisition and Preprocessing

The sEMG signal data was captured from 3 subjects performing four drywall installation activities multiple times. This data consists of four channels representing signals

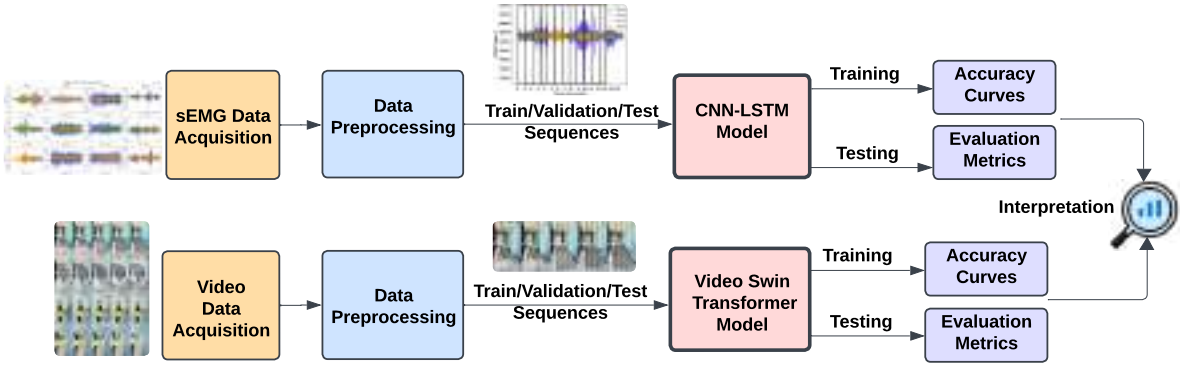

Figure 1. Overall System Architecture

coming from four EMG electrodes, which were attached to the biceps brachii, triceps brachii, shoulder, and forearm muscles of the dominant hand, respectively. These sensor placements are effective in capturing the muscle activity of these actions [3]. A baseline reference node was attached to the subjects on top of the wrist of the same hand. This data was stored in a text file in a tabular format in which rows are time series data points with each point containing 4 columns corresponding to the 4 channels. Hence, one such text file represents the muscle signals captured during one subject doing one of the drywall activities one time.

The activities were divided into "Intention" group, which constitutes the first 1 second of the activity, and the rest as "Actual" group. The time series signals were divided into fixed-size sequences. A sequence represents a small fraction of continuous movements. Consequently, the motion detection task was translated into a classification task with 2 classes (corresponding to the two groups) per each activity, totaling 8 labels. In this way, the whole dataset of text files was divided into overlapping chunks with a sliding window approach. Due to the small length of the intention group, the number of chunks that belong to this intention group became significantly smaller compared to chunks in the actual group which can lead to a major class imbalance within the groups. To tackle this, minority intention classes were randomly oversampled by duplicating the existing samples by 2 times ensuring uniform distribution across activities. This dataset was then divided into train, validation, and test splits ensuring stratification for a uniform and representative distribution of each activity and subject type. A random Gaussian noise was added to the training set consistently to each data point in a sequence as part of the data augmentation. Consequently, these three sets were normalized using a standard scaler that transforms the data to have a mean of 0 and a standard deviation of 1.

3.1.2 Deep Learning Model

The proposed model architecture consists of two 1D CNN blocks followed by two LSTM layers and two fully connected dense layers at the end as shown in Figure 2. This hybrid model can process both spatial and temporal features inherent in sEMG data. The initial 1D CNN layers are designed for the extraction of local patterns in the form of spatial features from the multichannel signals. Next, the output activations are normalized across the batch using the batch normalization (Batch Norm) layer. After this, max-pooling layers are employed to retain only the most useful patterns. To mitigate overfitting, dropout layers are integrated to randomly nullify the contributions of a fraction of input units during training. This can make the model generalize well to the training data by preventing it from overly relying on specific hidden units. The second CNN block is added with an increase in filter size from 64 to 128 (see Figure 2). Following this second block, LSTM units are deployed to exploit their inherent feedback connections in the form of memory gates and cells [3]. This enables the analysis of temporal dependencies in the sEMG sequences without the problem of vanishing gradients. The multidimensional output from the LSTM layers is transformed into a 1D vector using a flatten layer before passing them to fully connected dense layers. Finally, these learned attributes are mapped to the 8 desired output classes using a dense layer with softmax activation.

3.2 Video-based Approach

3.2.1 Data Acquisition and Preprocessing

While the subjects performed the activities equipped with the sEMG sensors, videos were recorded using a typical smartphone at the same time. A single data point in this context refers to a single image frame. One video file corresponds to the action sequence generated by one

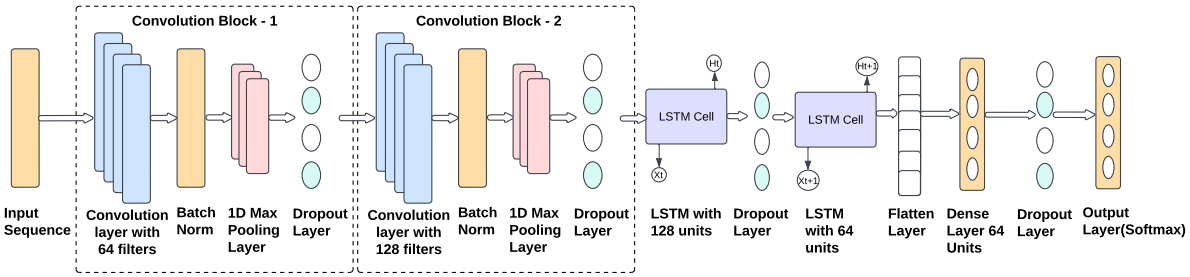

Figure 2. Proposed CNN-LSTM Model Architecture

subject performing one type of activity at a time. Each video was also partitioned into Intention and Actual activity groups with the first 1 second interval labeled as Intention classes. All the videos were resized to 224×244. The pixel values were normalized to have a range between 0 and 1 to improve model convergence and stability during training. These frames were further segmented into overlapping sequences that represent small fragments of continuous movements. The created chunks were divided into train, validation, and test splits such that they contained a representative distribution of sequences in terms of actions and subjects. The labeling strategy used in the signal-based approach was deployed in the video-based approach. Common image data augmentations were applied to the training dataset, ensuring all the frames in a sequence receive the same transformation. This sequence-level augmentation virtually increases training data size, so that models can generalize over varying noise, occlusions, and other real-world conditions.

3.2.2 Deep Learning Model

In this study, the Video Swin Transformer architecture was implemented for the classification task from videos [16]. Initial tokenization followed by a patch merging layer maintains the hierarchical structure of the model. The Video Swin Transformer block [16] starts with a 3D window-based multi-head self-attention (MSA) module, which processes tokens within independent 3D windows to capture specific spatiotemporal relationships in the video. This block also employs a 3D shifted window approach between layers which integrates context from adjacent areas and frames. This lets it recognize long-running complex interactions and actions throughout the video input. To learn more detailed patterns, multilayer perceptron (MLP) is applied after the MSA module to transform features non-linearly.

The proposed approach uses the existing base version of the Video Swin model (Video Swin-B) which was pre-trained on a dataset called Kinetics 600 [16]. We employed a transfer learning strategy, starting with these pre-trained weights frozen for training. The final MSA module, layer normalization, and dense layers of the last transformer block in Stage 4 are unfrozen to update their weights (see Figure 3). However, the MLP layer was retained to be frozen to preserve the high-level non-linear feature transformations learned during pretraining. This makes the model fine-tune to only the attention-driven feature extraction process, reducing complexity and overfitting. Finally, a custom classification head is added that contains a dense output layer with 8 neurons (corresponding to the target classes) at the end, as shown in Figure 3. This head is added to scale complex representations extracted by the transformer and finally map the reduced features to class probabilities using softmax activation.

4 Experiment

4.1 Data Acquisition

We conducted an experiment that involved 3 subjects performing four drywall installation tasks as displayed in Figure 4. These tasks [3] were selected because of their potential to be supported by construction robots. Each subject performed these tasks four times with varying durations while carrying four sEMG muscle sensors and a reference electrode. Simultaneously, these activities were recorded using a smartphone camera. Using OpenSignals software, the sEMG signals (see Figure 4) were collected and stored in a ".txt" format at a frequency of 500 Hertz (Hz), implying that for one second 500 data rows, each with four channel columns would be produced. Videos were filmed in ".mp4" format at a resolution of 1920×1080 pixels with 60 frames per second (FPS). In this way, the original raw dataset of sensor signals contains 16 text files for each subject with 4 files per activity per subject, totaling 48 files for the 3 subjects. The video dataset also contains the same number of video files. Table 1 provides a comprehensive overview of the experimental setup including the raw data point counts.

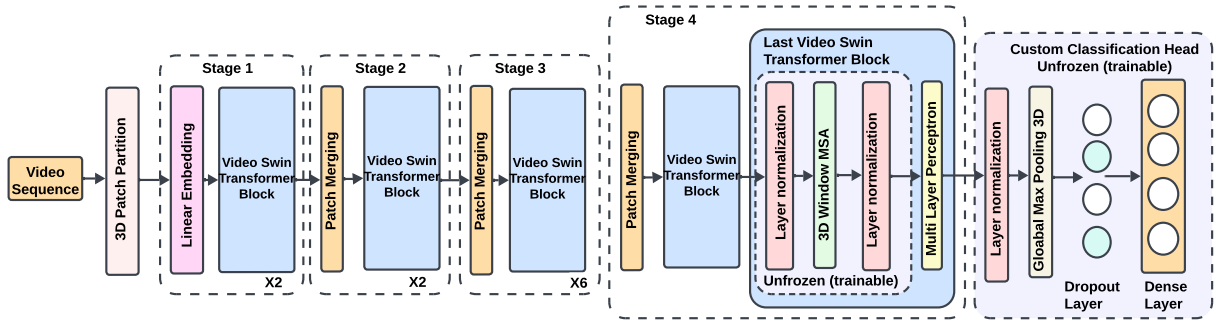

Figure 3. Video Swin Transformer (Base version) Architecture with Custom Classification Head

Table 1. Data Comparison Between Signal-Based and Video-Based Approaches

Method	Data	File Format	Frequency	File Count	Data Point Count
Signal	sEMG signals	.txt	500 Hz	48	195,450
Video	RGB Videos	.mp4	60 fps	48	20,690

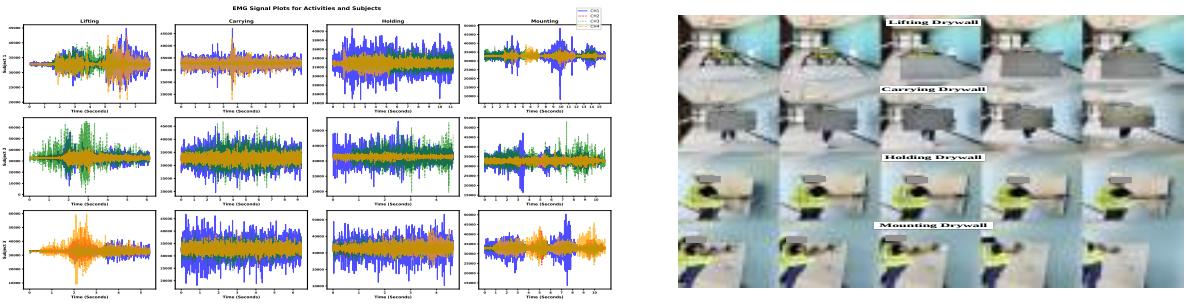

Figure 4. Sample sEMG Signals (Left) and Video Frames (Right) of activities performed by 3 subjects

4.2 Data Preprocessing

Following Shah and Kim [3], the first 1 second of each activity was regarded as the Intention group and the rest as the Actual group. As a result, 8 target classes, namely Lifting Intention, Actual Lifting, Carrying Intention, Actual Carrying, Holding Intention, Actual Holding, Mounting Intention, and Actual Mounting, were formed. This can enable robust recognition of motion triggers and their transition to actual motion. For implementation purposes, the intention groups from the video dataset were divided into separate video clips, producing a total of 96 videos. Due to the size of the sensor data points being significantly higher compared to videos, the video files were increased by 2 times using data augmentations, yielding a final dataset of 288 videos. The signal data was processed into sequences in each of 100 data rows, while each sequence extracted from videos contains 32 frames. Thus, a sequence of signals equates to 0.2 seconds of movement and a video sequence encloses 0.5 seconds of motion. Such an individual sequence becomes the single unit of input to the models. To increase the classification accuracy, both datasets were fragmented into overlapping sequences with a ratio of 50%. To overcome the imbalance between "Intention" and "Actual" classes, the intention sequences were oversampled 3 times for signal data, but the video sequences were kept unaltered since they were already increased.

The EMG sequences were split into train, validation and test splits in the ratio of 70:15:15 respectively. The individual video files were first divided into train, validation, and test splits in the ratio of around 67%, 17%, and 17% respectively, maintaining the representative distribution of activity and subject types. Random Gaussian noise was applied to signal training examples. For the video training dataset, along with Gaussian noise, image, augmentations like random horizontal flip, hue, brightness, saturation, and contrast were employed. Finally, the sensor data was scaled using a standard scaler whereas the image frames were resized to a resolution of 224×244 and then scaled by dividing pixel values by 255.

Table 2. Comparison of Data Preprocessing: Signal-Based vs. Video-Based Approaches

Method	Intention Group	Resolution	Seq. Length	Overlap	Oversampling
Signal	1 second	1 row, 4 channels	100	50%	3x
Video	1 second	1 Frame (224x224, RGB)	32	50%	None

4.3 Training and Hyperparameter Tuning

The CNN-LSTM model was trained on the signals training dataset and the pre-trained Video Swin-B model was partially fine-tuned on the training video sequences. A dedicated validation dataset was used for guiding the model selection process due to its capability of offering an unbiased estimate of model performance. For both models, sparse categorical cross-entropy loss was used to handle the integer encoded true labels and Adam optimizer with fixed learning rate (LR) was employed to leverage the adaptive learning rate. Class weights were incorporated during training to tackle the imbalance across the activity classes. The majority classes were assigned lesser weights compared to the minority labels based on the inverse frequency of the classes and the loss was scaled dynamically using these computed weights. The sensor-based and video-based models were trained for 1000 and 100 epochs with batch sizes of 128 and 32 respectively. The intermediate dropout layers and the final dropout layer in the proposed CNN-LSTM model were given a dropout rate of 0.4. Ridge (L2) regularization was applied to the 1D convolutional and LSTM layers in the form of the kernel and recurrent regularizers, respectively. Analogously, an L2 rate of 0.1 and a dropout value of 0.5 were utilized for the last output and dropout layers in the custom head of the proposed video model. A grid search method was deployed to identify the best combinations of L2 rate and dropout values, with L2 ranging from 0.0001 to 0.1 in steps of 0.05 and dropouts from 0.1 to 0.5 in the same increments. The best hyper-parameter values are outlined in Table 3.

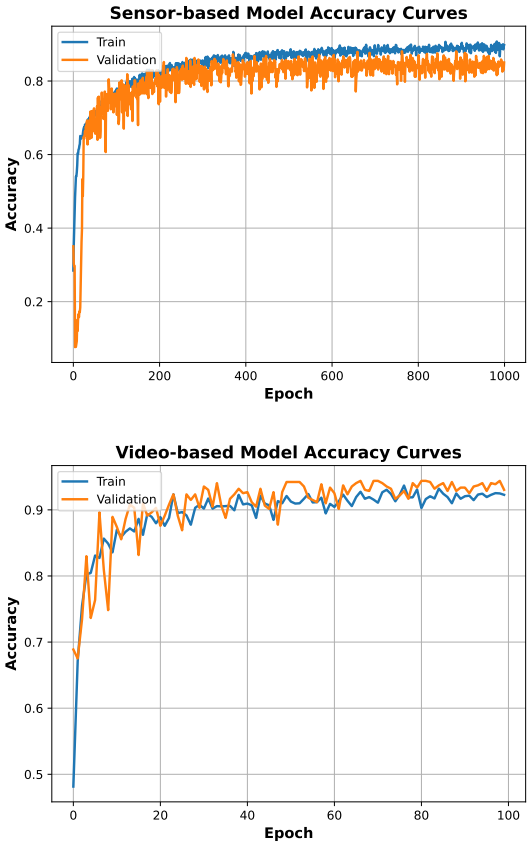

Figure 5. Training and Validation Accuracy curves for signal-based (top) and video-based models (bottom).

5 Results

The accuracies of training and validation data over the iterations were recorded and plotted as indicated in Figure 5. The video-based model achieved consistently higher accuracy, with training and validation curves stabilizing above 90%, indicating robust generalization and minimal performance fluctuations. On the other hand, the CNN-LSTM model exhibited a slower rise in accuracy, stabilizing around 85%, with higher variability in the validation accuracy curve. Overall, both the models were trained without overfitting.

After the training was completed, test sets were used to evaluate the models' performances. Based on test predictions, confusion matrices (Figure 6) were computed to assess the performance in individual classes. Due to the imbalance in the classes, overall weighted F1 scores were also determined. The Video Swin-B model demonstrates high accuracies for categories such as 'Actual Mounting' (95.72%), 'Actual Lifting' (98.1%), and 'Actual Holding' (100%). It also distinguished intentions effectively, correctly predicting all 18 instances of 'Carrying Intention' and 'Lifting Intention'. In contrast, the CNN-LSTM model shows greater variability in performance, with higher misclassifications. 'Actual Carrying' showed more confusion with 98 out of 129 instances being correct and 11 'Actual Lifting' instances being mislabeled as Lifting Intention. The model faced challenges in distinguishing intentions, as shown by the lower performances on 'Carrying Inten-

Table 3. Training and Testing: Signal-Based vs. Video-Based Approaches

Method	Model	LR	Epochs	Batch Size	Dropout	L2	Accuracy	F1 Score
Signal	CNN-LSTM	0.001	1000	128	0.4	0.05	86.82%	86.79%
Video	Video Swin-B	0.001	100	32	0.5	0.1	94.05%	94.22%

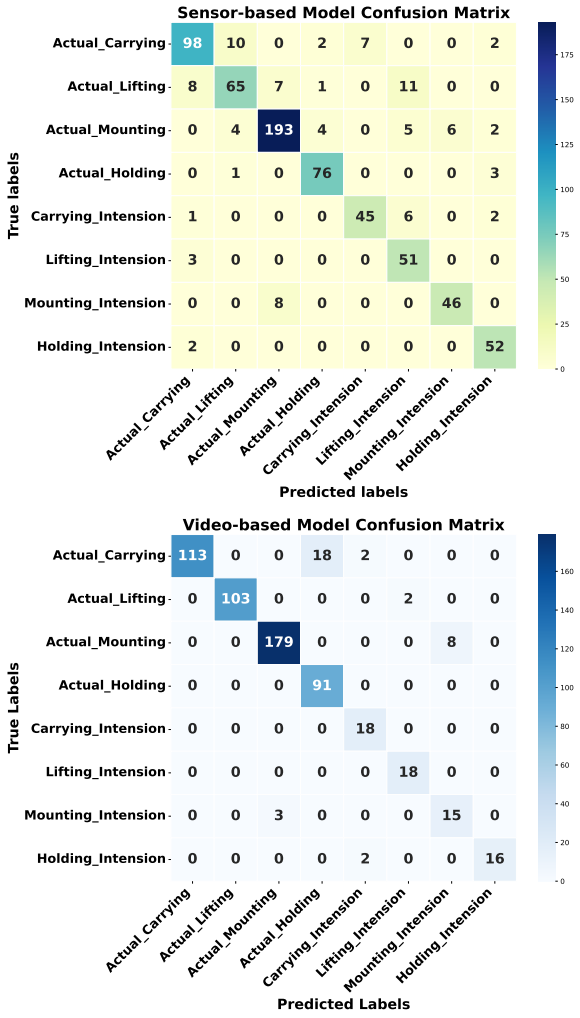

Figure 6. Confusion matrices for signal-based (top) and video-based models (bottom).

tion' and 'Mounting Intention' classes.

This demonstrates that the video-based model with 94.05% accuracy outperformed the sensor model with 86.82% accuracy, in terms of stability and classification performance, as mentioned in Table 3. Given identical hardware resources, the CNN-LSTM model took around 40 milliseconds, and the Video Swin-B model took approximately 150 milliseconds on average to carry out a prediction on one test sample.

6 Discussions

The proposed study implemented motion intention recognition systems using two kinds of modalities (sEMG and Videos). There was an inherent imbalance between the 8 classes and the "Actual" and "Intention" groups caused due to the varying durations and nature of the tasks. The two proposed models performed well in classifying human activities despite this significant imbalance. This shows the robustness and generalization of these trained models across multiple subjects. The technique of oversampling of intention classes and the application of class weights to the loss function majorly improved the classification ability of the models.

The performance scores from Table 3 clearly state that video-based data could be preferred to sensor signals. However, the signal-based model was around 3.7 times faster in making predictions on test data. This suggests that for time-sensitive applications, e.g., safety hazard monitoring, muscle signals can be a better choice. Unlike video systems, sensors provide consistent input signals even in varying environmental conditions like lighting, visibility, and obstructions. sEMG sensors are attached directly to the skin, making them highly portable compared to a stable camera setup. Hence, in use cases like material transportation, and pavement construction that involve dynamic surrounding factors and long-distance movements of workers, muscle signals can be more efficient. However, with advancements in transformers, video-based methodologies are attaining higher accuracy in action detection with relatively reduced latencies. Videos can capture the full visual context of surroundings, unlike EMG sensors which only collect motion cues from specific target muscles. Therefore, for operations that involve interactions with multiple workers, and complex behaviors, videos could be a more suitable approach.

7 Conclusion

In conclusion, the construction industry can be revolutionized by the integration of mutual collaboration between workers and robots. The proposed system conducted experiments with 3 subjects involving sEMG and video data collection followed by data processing. Finally, a hybrid CNN-LSTM model and a fine-tuned Video Swin Transformer model were implemented to handle muscle signal and video sequences respectively. This study includes comprehensive comparisons and discussions on

these modalities which conclude that both are competent in their unique ways and there cannot be a universal approach.

Future advancements can involve experiments with a larger subject pool and broader construction tasks to provide more comprehensive validation of the results obtained. This study can be expanded to build a prototype of HRC in construction sites by deploying models on robots with control interfaces. Inference optimization techniques can be integrated to reduce model latency when deployed on edge devices. Fusion model architectures that can exploit the complementary strengths of both modalities can also be considered.

Abstract

The integration of robotics into construction is transforming industry, necessitating that Construction Engineering and Management (CEM) education programs adapt to prepare future professionals for increasingly technologically driven workplaces. Traditional lecture-based methods often lack interactivity and fall short in imparting practical skills needed for emerging technologies. This study explores the potential of virtual reality (VR) as a teaching tool to enhance student presence and self-efficacy in human-robot collaboration (HRC) education within the construction sector. A VR-based immersive environment was developed, including modules for robot exploration, application tutorials, and hands-on operational training. Forty students from diverse backgrounds participated in the study, experiencing the VR environment and assessing their sense of presence and self-efficacy through validated instruments: the ITC Sense of Presence Inventory (ITC-SOPI) and the New General Self-Efficacy Scale (NGSE). Results indicated high spatial presence (M = 4.2, SD = 0.6) and ecological validity (M = 4.1, SD = 0.4), with minimal negative effects (M = 2.0, SD = 0.7), validating the environment's realism and comfort. Self-efficacy scores averaged 4.1, suggesting strong confidence among students in managing HRC tasks in construction sites. These findings validate VR as a tool that enhances student presence and self-efficacy in learning HRC in construction setting.

Keywords –

Virtual Reality; Human-Robot Collaboration; CEM; Student Presence; Self-Efficacy

1 Introduction

The landscape of technology is rapidly transforming, with robotics playing a pivotal role in revolutionizing various sectors. [1,2]. Notably, the construction industry is poised for major changes, driven by robotic technologies. Research suggests that within the next two decades, 81% of construction firms globally anticipate integrating robotics into their workflows [3]. This shift underscores the need for construction engineering and management (CEM) education programs to adapt by embedding essential technological competencies in their curricula to prepare future professionals for the evolving demands of the industry.

In conventional CEM education, passive instructional methods like lecture-based sessions are commonly used, but these approaches often fall short in effectively teaching emerging technologies [4]. Lecture-based learning typically lacks the necessary interactivity, which is crucial for students to truly understand and engage with complex technological concepts. Passive learning tends to present information in a linear and structured manner, which does not capture that nuanced, real-world challenges and ambiguities that students will face when working with cutting-edge tools and methodologies. This can lead to a superficial understanding of technological advancements, where students may grasp theoretical knowledge but lack the ability to translate that into real-world problem-solving. Emerging technologies, particularly in the construction sector, are dynamic and often require a flexible, hands-on learning approach to develop critical thinking and adaptability. In contrast, integrating virtual environments that mimic real-world construction scenarios can offer a more immersive and engaging way to teach these technologies [5–8]. In virtual environments, learners can interact with virtual tools, robotics, and other advanced systems, gaining valuable experience without the safety risks and costs associated with physical experimentation. This "learning by doing" approach allows students to explore complex concepts in a safe, controlled setting, where they can make mistakes, troubleshoot, and learn from their experiences.

By actively engaging with the virtual environment, students are better equipped to understand the intricacies of construction technologies and how they apply to real-world situations. This method not only fosters deeper learning but also encourages exploration and creativity, as students are given the freedom to experiment, problem-solve, and adapt in ways that passive learning methods do not typically allow. Ultimately, such hands-on experiences prepare students for the practical challenges they will face in the construction industry, equipping them with the skills needed to confidently handle emerging technologies.

Immersive learning environments are increasingly central to innovation in construction education, yet their success hinges significantly on two factors: student presence and self-efficacy within these virtual settings. Student presence, or the degree to which learners feel actively involved and engaged in the virtual learning process, is crucial for the effectiveness of educational technologies. This sense of presence can greatly influence engagement levels, learning outcomes, and overall satisfaction with the educational experience. Self-efficacy, defined as a students' belief in their ability to accomplish specific tasks, also plays a critical role in the dynamics of learning environments. When students perceive themselves as capable, it not only boosts their motivation but also enhances their engagement, leading to more effective learning. Environments that foster high self-efficacy help students take initiative, face challenges confidently, and persist in solving complex problems, which are essential skills in the construction industry

Towards this end, the aim of the research to assess the effectiveness of virtual reality (VR) as a teaching tool in enhancing student presence and self-efficacy within HRC education in the construction sector. As robots are getting popular in construction operations, the use of safety training module will equip the students with pragmatic safety knowledge for working alongside these robots. The research intends to explore how VR-based learning impact student presence and self-efficacy. Insights from the research will provide valuable guidance on designing and implementing VR-based educational tools, enhancing their effectiveness and usability for construction curricula and beyond.

2 Impending Adoption of Robotics Technology in Construction Sector

The construction industry is experiencing an unprecedented transformation through the integration of advanced robotic technologies. This shift represents a strategic response to several deeply entrenched challenges that have long hindered the progress of construction sector, including stagnant low productivity, an increasingly severe shortage of skilled labor, and ongoing safety concerns that drive up the operational costs [9–13]. While the inherently chaotic and unstructured nature of the construction site, combined with the constant interplay of heavy machinery and human workers poses significant barriers to implementing fully autonomous robotic systems, innovative solutions are emerging to address such complexities.

The construction industry had undergone a paradigmatic shift, moving away from the pursuit of complete automation to embrace a more nuanced approach that emphasizes HRC over complete automation. Such a strategic pivot acknowledges that human expertise- including problem-solving abilities, and adaptability remains irreplaceable in construction operations. The development of collaborative robots, or cobots, represents a breakthrough in this direction, offering systems that harmoniously combine cognitive abilities with the mechanical advantages of robotics [13–15]. These collaborative systems excel in precise execution of repetitive tasks, enhanced physical endurance for demanding operations, consistent performance in standardized procedures [16–19]. Importantly, these systems are specifically engineered to function as supportive tools rather than replacements for human workers, creating a symbiotic relationship that enhances overall project efficiency and safety.

This technological evolution brings new challenges and requirements for CEM professionals. The integration of the advanced robotic systems demands the development of new technical competencies, enhanced understanding of HRI protocols, cultivation of trust in automated systems, adaptation to technology-driven work environments, and mastery of new interface systems and control mechanisms. The construction site of the future is increasingly envisioned as an environment where human workers and robotic systems work in tandem, each contributing their unique strength to project success. The construction education landscape must evolve substantially. CEM curricula need to incorporate comprehensive training in human-robot interaction principles, ensuring that future professionals are well-prepared to navigate complex HRC environments, implement effective safety protocols for mixed human-robot teams, and optimize workflow processes that involve both human and robotic elements.

3 VR-based Learning of Human Robotic Collaboration in Construction Curriculum

Traditional CEM education has long relied on conventional teaching methods that often fall short in preparing students for the complex realities of construction environments. This gap between classroom learning and practical application has prompted educators to explore more effective pedagogical approaches, with immersive technologies emerging as a promising solution. VR technology stands out as a transformative tool in CEM education, offering students the opportunity to gain hands-on experience in simulated construction environments without exposure to real-world risks. Students can practice programming and operating collaborative robots, learn safety protocols specific to HRI, and understand the capabilities and limitations of various robotic systems. VR simulations can recreate diverse construction scenarios, from simple

repetitive tasks to complex operations requiring sophisticated human-robot coordination. These virtual environments can also simulate potential hazards and emergency situations, allowing students to develop appropriate response strategies without real-world risks. Through detailed visualizations of robot components and functionalities, VR helps students gain a deeper understanding of robot capabilities, limitations, and potential applications in construction. The simulated environment also allows students to learn how robots integrate with other construction systems and processes, providing a holistic view of modern construction environments. VR-based HRC training can present students with challenging scenarios that require quick thinking and problem solving, allowing them to practice making decisions and manage unexpected issues that may arise when working with robots on construction sites. Implementing VR-based HRC training can also be more cost-effective than traditional methods, reducing the need for physical robot prototypes and simulating a wide range of construction environments without the expense of setting up real-world training sites. Furthermore, VR-based learning modules can be designed to progressively increase in complexity, matching students' growing proficiency in HRC principles. This structured approach helps develop comprehensive understanding and practical skills essential for managing future construction projects where humans and robots work together. The integration of such technology-driven learning methods in CEM curricula ensures that graduates are well-prepared to lead and manage the increasingly automated construction sites of tomorrow.

Immersive learning environments are increasingly central to innovation in construction education, yet their success hinges significantly on two factors: student presence and self-efficacy within these virtual settings. Presence, as defined by Constructivist Learning Theory [20,21], refers to the extent to which students feel connected and engaged with their learning environment and content. This theory emphasizes that learning is most effective when students are actively involved in constructing their own understanding through meaningful interactions. A strong sense of presence helps students perceive their education as relevant and closely tied to real-world applications. When students perceive a direct connection between what they learn in the classroom and what they observe on actual construction sites, their understanding of theoretical concepts is enhanced. This connection ensures that the knowledge they acquire is not abstract but seen as directly applicable and impactful in their future careers. On the other hand, self-efficacy in CEM education is crucial for student motivation and success. Self-efficacy involves students' beliefs in their abilities to successfully perform tasks and solve problems they will encounter in their professional lives. According to Social Cognitive Theory [22], self-efficacy is developed through mastery experiences, vicarious experiences, verbal persuasion, and physiological feedback. In CEM, where projects often involve significant challenges-from logistical issues to managing diverse teams-self-efficacy determines a student's perseverance and resilience. Students who believe in their capabilities are more likely to take on challenging projects, persist through setbacks, and innovate under pressure. Students are also more inclined to pursue leadership roles and advocate for necessary changes in safety practices, sustainability measures, and technological adaptations. By leveraging Constructivist Learning Theory, educators can design VR-based modules that enhance presence through immersive, scenario-based learning. Simultaneously, applying Social Cognitive Theory principles within these modules—such as enabling practice in a safe environment—can significantly boost self-efficacy. This dual approach ensures that students are not only deeply engaged with their learning but also equipped with the confidence to apply their knowledge decisively and effectively in real-world situations.

4 VR-Based Learning of Human Robotic Collaboration and its Impacts on Student Presence and Self-Efficacy

The primary objective of this research is to assess the effectiveness of VR as a teaching tool in enhancing student presence and self-efficacy within HRC education in the construction sector. The study is divided into two phases (Figure 1): Development of an Immersive Learning Environment for Teaching Human-Robot Collaboration and Evaluation of the Developed System on Students' Sense of Presence and Self-efficacy. Initially, a virtual learning environment was created to offer comprehensive insights into the human-robot collaboration in the construction sector. Subsequently, the immersive learning environment was analyzed to determine its impact on students' sense of presence and self-efficacy. To conduct a comparative analysis between the VR-based approach and conventional methods, a cohort of 40 students from diverse educational backgrounds was recruited for this study. The participants represented a mix of undergraduate and graduate students, with varying levels of experience in the construction sector, ranging from no experience to up to two years of practical experience through internships or academic projects. However, none of the participants had prior experience with VR technologies. All the recruited students took turns in experiencing the developed learning environment, respectively. Then, a self-assessment technique was leveraged to measure the students' sense of presence and self-efficacy across the

two learning scenarios. Student sense of presence was evaluated using ITC Sense of Presence Inventory (ITC-SOPI) [23]. Likewise, self-efficacy (i.e., beliefs in an individual's capability to organize and execute the actions required to complete a particular task successfully [24]) will be evaluated by using a New General Self-Efficacy Scale (NGSE Prior to commencing the study, all participants provided informed consent and were briefed on the confidentiality of data and their rights as participants. Health-related information was also collected, with all participants reporting normal or corrected vision, and no indications of oculomotor or neurological issues.

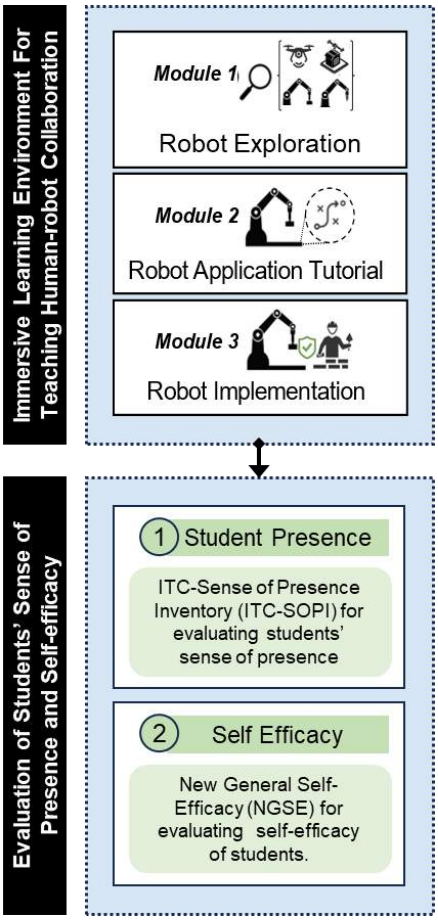

Figure 1: Proposed Steps for Investigating Immersive Learning Environment for Teaching Construction Robotics on Users' Sense of Presence and Self-efficacy

4.1 Development of Immersive Learning Environment for Teaching Human-Robot Collaboration

The developed learning environment included a detailed simulation of a real construction site, complete with educational modules that highlighted various aspects of working alongside construction robots.

For this, a construction site was meticulously designed using Autodesk Revit and then transferred into the Unity game engine for further development. Within Unity, various elements of the immersive environment were designed as Game Objects equipped with collider and Rigidbody components to simulate realistic physical interactions. The various elements within the virtual space were developed using a combination of 3D modeling software like Blender and Unity's native creation tools, allowing for precise control over the environmental details and interactive features. The developed learning environment consists of three modules, as shown in Figure 2.

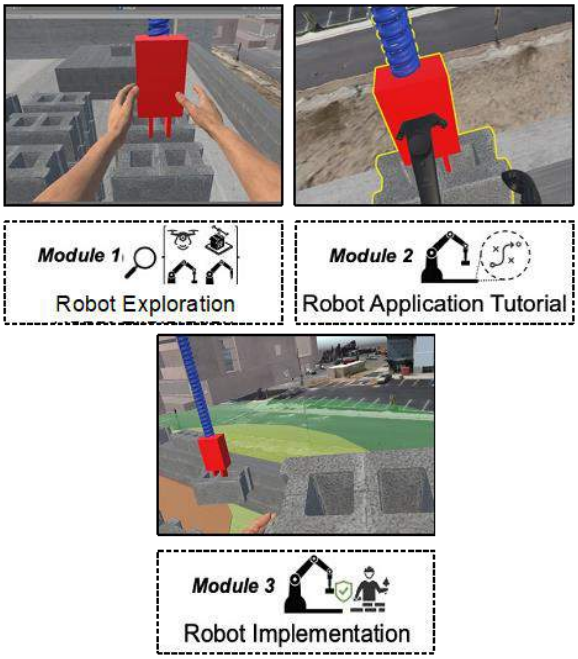

Figure 2: Modules of the Developed Immersive Learning Environment

1. ***Module 1- Robot Exploration***: This module served as an interactive introduction to various construction automation technologies. Students could navigate through a comprehensive catalog of construction robots, including advanced systems like concrete printing machines, automated bricklaying units, and aerial drones. The interface featured an intuitive menu system allowing learners to select and study different robotic systems. When examining each robot, students could interact with specific components - from robotic manipulators to control interfaces and actuator systems - with detailed technical specifications appearing in contextual text displays upon component selection. Interaction was facilitated through MANUS haptic gloves, allowing

users to intuitively grab, manipulate, and explore virtual objects. The gloves provided haptic feedback to simulate tactile sensations, enhancing realism by mimicking the feel of surfaces and resistance when interacting with robotic components.

2. ***Module 2- Robot Application Tutorial****:* This module delivered in-depth guidance on utilizing robotic systems to enhance construction safety and efficiency. A key feature of this module was the integration of a virtual instructor, represented by an animated 3D human figure capable of demonstrating proper robot deployment techniques. This digital mentor could perform realistic movements while providing verbal explanations and demonstrations of correct robotic implementation procedures, helping students understand proper placement and operational protocols based on established safety criteria and best practices. Students mirrored the instructor's actions using MANUS gloves, with haptic feedback providing physical cues to guide correct hand positioning and movement.
3. ***Module 3– Robotic Implementation:*** This module emphasized hands-on operational experience through practical task completion. This section was designed as an interactive training ground where students could develop proficiency in robot control and operation. The module provided step-by-step instruction in fundamental robot control principles, followed by practical exercises requiring students to complete specific construction-related tasks. The MANUS gloves enabled precise hand-based control of virtual joysticks, buttons, and control panels, offering haptic feedback to replicate the physical resistance and tactile response of real-world equipment. The iterative nature of these exercises allowed learners to refine their skills through repeated practice and progressive improvement.

4.2 Inferences on Student Presence and Self-Efficacy

To understand if the developed immersive setting makes the student feel present in the environment as intended: the sense of the presence of the users was evaluated via the ITC-SOPI questionnaire [25]. Further, self-efficacy (i.e., beliefs in an individual's capability to organize and execute the actions required to complete a particular task successfully [24]) will be evaluated by using a refined self-efficacy scale [26], modified by the experts from industrial collaborators for construction-specific purposes.

To assess participant's sense of presence, a validated 44 item 5-point Likert scale (ranging from 1 to 5) questionnaire originated from Lessiter et al. [23], ITC-SOPI was selected due to its cross-media comparison capabilities. The instrument is divided into four factors: Spatial Presence (19 items), Engagement (13 items), Ecological Validity/ Naturalness (5 items), and Negative Effects (6 items). Spatial presence refers to the ability to physically control and manipulate aspects of the displayed environment. Ecological Validity refers to the believability, realism of the content, and naturalness of the environment. Negative effects reflect headache, eye strain, tiredness, and other negative effects that may be associated with the virtual environment. To validate the consistency of the student presence evaluation, the author performed a reliability analysis on the ITC-SOPI using the Cronbach's alpha test. The analysis results in Cronbach's alpha of 0.83, indicating a good level of internal consistency.

Likewise, self-efficacy will be evaluated by using NGSE. NGSE assesses an individual's belief in their ability to achieve goals and overcome challenges across various situations. NGSE consists of 8 statements that respondent's rate on how well each reflects their self-belief. The statements were rated on a 5-point Likert scale, where 1 indicate "Strongly Disagree," 2 indicate "Disagree," 3 indicate "Neither Agree nor Disagree," 4 indicate "Agree," and 5 indicate "Strongly Agree." To derive a general self-efficacy score, the responses to each of the eight items are averaged, yielding a single score that ranges from 1 to 5. Higher scores indicate a stronger belief in one's ability to manage and succeed in a variety of situations. To validate the consistency of the self-efficacy evaluation, the authors performed a reliability analysis on the NGSE using Cronbach's alpha test. The analysis resulted in Cronbach's alpha of 0.86, indicating a good level of internal consistency.

5 Results and Discussion

The ITC-SOPI questionnaire results demonstrated significant levels of presence across multiple dimensions, as detailed in Table 1. Spatial presence exhibited the highest mean score (M = 4.2, SD = 0.6) on the 5-point Likert scale, indicating that participants experienced a strong sense of physical interaction within the virtual construction environment. This was followed by ecological validity (M = 4.1, SD = 0.4) and engagement (M = 3.8, SD = 0.5). Notably, negative effects demonstrated the lowest mean score (M = 2.0, SD = 0.7), suggesting minimal adverse physiological or psychological reactions to the virtual environment. The high spatial presence score (M = 4.2) is particularly significant as it surpasses previous studies in construction-based virtual environments, where mean scores typically range from 3.5 to 3.9 [citation needed]. The ecological validity results (M = 4.1) suggest strong environmental verisimilitude, crucial for transferring skills from virtual to real construction scenarios. The relatively low standard deviations across presence

metrics (ranging from 0.4 to 0.7) indicate consistent participant experiences, supporting the robustness of the implementation across different user profiles.

Table 1. Results of metrics for ITC-SOPI

Metrics	Mean	Standard Deviation
Spatial Presence	4.2	0.6
Engagement	3.8	0.5
Ecological Validity	4.1	0.4
Negative Effects	2	0.7

The analysis of the NGSE data, presented in Table 2, yielded an overall mean self-efficacy score of 4.1 (SD = 0.5), with individual statement scores ranging from 3.8 to 4.3. The detailed examination of NGSE components revealed that participants exhibited highest confidence in goal achievement and task performance capabilities. The statement *"I will be able to achieve most of the goals that I set for myself"* received one of the highest ratings (M = 4.3, SD = 0.6), along with *"I am confident that I can perform effectively on many different tasks"* (M = 4.3, SD = 0.6). These strong endorsements suggest that exposure to the virtual environment particularly enhanced participants' goal-oriented self-efficacy, a crucial finding for construction education where clear goal visualization and task completion are essential components of professional development. The data further indicated robust self-efficacy in managing construction-related challenges. Participants expressed high confidence through their responses to *"When facing difficult tasks, I am certain that I will accomplish them"* (M = 4.2, SD = 0.7) and *"I will be able to successfully overcome many challenges"* (M = 4.2, SD = 0.7). These closely aligned scores suggest that the virtual environment effectively cultivated resilience and problem-solving confidence among participants.

Table 2. Results of NGSE metrics for assessing self-efficacy of students in developed immersive environment

Statements for NGSE	Mean $\pm$ SD
I will be able to achieve most of the goals that I set for myself.	4.3 $\pm$ 0.6
When facing difficult tasks, I am certain that I will accomplish them	4.2 $\pm$ 0.7
In general, I think that I can obtain outcomes that are important to me	3.8 $\pm$ 0.8
I believe I can succeed at most any endeavor to which I set my mind.	4.1 $\pm$ 0.6
I will be able to successfully overcome many challenges.	4.2 $\pm$ 0.7
I am confident that I can perform effectively on many different tasks.	4.3 $\pm$ 0.6
Compared to other people, I can do most tasks very well.	4 $\pm$ 0.8
Even when things are tough, I can perform quite well	4.1 $\pm$ 0.7
Overall Self Efficacy Score	4.1 $\pm$ 0.5

Participants also demonstrated strong self-efficacy in comparative performance and resilience metrics. The statement *"Compared to other people, I can do most tasks very well"* yielded positive results (M = 4.0, SD = 0.8), while "Even when things are tough, I can perform quite well" showed similarly strong outcomes (M = 4.1, SD = 0.7). The statement *"I believe I can succeed at most any endeavor to which I set my mind"* also received favorable ratings (M = 4.1, SD = 0.6). These findings suggest that the virtual environment not only enhanced individual capability beliefs but also strengthened participants' confidence in their relative competence within the field. Notably, while all NGSE components received positive evaluations, the statement *"In general, I think that I can obtain outcomes that are important to me"* showed relatively lower scores (M = 3.8, SD = 0.8), though still represents a positive self-efficacy level.

The combined results from both instruments suggest that the immersive environment successfully creates an engaging, realistic learning experience while building student confidence in construction-related capabilities. The high spatial presence and ecological validity scores from ITC-SOPI align well with the strong self-efficacy results, indicating that the realistic environment contributes to students' confidence in their abilities. These findings align with previous research suggesting that immersive environments can enhance learning outcomes through increased presence and engagement []. The particularly strong scores in spatial presence and ecological validity, combined with minimal negative effects, suggest that the technical implementation of the environment effectively balances realism with user comfort.

While the results indicated that the developed immersive environment the results indicated that the developed immersive environment effectively supports a sense of presence and bolsters self-efficacy among students, there are limitations to consider that could be addressed in future studies. First, the study was conducted with a relatively small sample size of 40 students, all from a specific academic background, potentially limiting the generalizability of the findings. A larger, more diverse sample could yield insights that are

more broadly applicable across different educational and professional settings. The study also relied on short-duration sessions in the virtual environment, which might not reveal the full spectrum of user engagement and potential negative effects such as fatigue or cognitive overload. Prolonged exposure assessments could provide a more comprehensive understanding of how extended use impacts both presence and self-efficacy. Furthermore, while the simulation focuses on human-robot collaboration, the lack of physical robot interactions limits students' opportunities to develop hands-on skills that are essential in real-world settings. Incorporating augmented or mixed reality elements that allow physical interaction with robots could improve skill transferability.

6 Conclusion

This study evaluated the effectiveness of VR as a teaching tool in enhancing student presence and self-efficacy within HRC education in the construction sector. The findings demonstrate that the virtual environment provides a robust sense of presence, particularly in spatial presence and ecological validity, which are essential for realistic and engaging learning experiences. Additionally, the high self-efficacy scores indicate that the environment supports students' confidence in their ability to achieve goals and tackle challenges related to construction tasks, which are key attributes for success in construction engineering and management. The VR-based modules, including robot exploration, application tutorials, and hands-on operational exercises, appear to effectively prepare students for real-world HRC applications by promoting engagement and fostering practical skills in a safe, simulated setting. The low negative effects observed further underscore the usability and comfort of the environment, suggesting that students can engage in immersive learning for extended periods without adverse physiological or psychological impacts.

However, the study has some limitations. The sample was drawn primarily from CEM students, which may not fully represent the broader range of students or professionals who may benefit from VR-based learning. Additionally, the exposure to the virtual environment was limited in duration, and future studies could explore the effects of extended exposure to VR learning environments to assess the long-term retention of skills and the sustainability of enhanced self-efficacy. Furthermore, the study did not include physical robot interaction, which could enhance the realism of certain tasks. Future research could integrate augmented or mixed reality (AR/MR) elements or provide opportunities for physical robot interaction to improve the hands-on nature of the training.

Future directions for research could also include expanding the sample to include participants from various academic disciplines and professional backgrounds to better understand the broader applicability of VR training. Investigating the long-term impact of VR training on skill retention and career readiness would be valuable, as would the integration of AR/MR technologies offer more immersive and physically interactive learning experiences.

Overall, this research provides valuable insights into the design and implementation of VR-based tools in construction education. By integrating such immersive learning environments into CEM curricula, educational institutions can better equip future professionals with the skills and confidence needed to navigate the increasingly automated construction industry. This study underscores the potential of VR-based training to bridge the gap between theoretical learning and real-world application, paving the way for more comprehensive and effective construction education.

Abstract

The real-time estimation of human activity level in indoor environments is crucial for thermal comfort prediction and optimizing HVAC systems, as well as supporting health monitoring and ergonomic assessments. Existing methods typically categorize activities into predefined types and therefore are not efficient for new activities. Furthermore, the transition between activities is not captured in these classification methods. To address these limitations, we propose a novel Activity Intensity Score (AIS) framework that provides a continuous, non-intrusive assessment of human activity intensity. The proposed AIS framework uses kinematic parameters derived from video-based pose estimation to calculate a dynamic intensity score. Key kinematic parameters, such as angular speed, angular acceleration, range of motion, movement frequency, and rotational energy, are extracted from pose landmarks using MediaPipe. These parameters are then normalized and combined to generate a continuous AIS that reflects real-time variations in movement intensity. The proposed approach was validated through controlled experiments with participants performing activities of varying intensities, including low (e.g., sitting), moderate (e.g., walking), and high (e.g., jumping jacks). Results showed that the AIS effectively distinguishes between different activity intensities, with higher AIS values corresponding to more intensive activities. The proposed method addresses the need for a more granular understanding of activity levels beyond simple categorical classification. This research contributes to real-time activity estimation, which has applications in optimizing indoor environmental conditions, health monitoring, and dynamic ergonomic assessments.

Keywords – Activity Intensity Score; Real-Time Estimation; Kinematic Chains; Computer Vision

1 Introduction

In indoor environments, the real-time estimation of human activity intensity plays a crucial role in optimizing environmental control systems, such as HVAC, as well as supporting health monitoring and ergonomic assessments [1], [2], [3], [4], [5]. Traditional HVAC systems operate with predefined control settings that do not respond to changes in occupant behavior or environmental conditions [6]. Dynamic HVAC systems that adapt to real-time changes in occupant activities can significantly enhance both comfort and energy efficiency. Therefore, such systems are essential for addressing the dynamic requirements of occupants, since they provide intelligent, responsive adjustments that improve overall indoor conditions. With recent progress in AI-driven models, the autonomous HVAC control systems have been developed to adjust the settings by considering energy efficiency and thermal comfort of occupants. However, typically in these models the role of human activity in thermal comfort is simplified by assuming comfort as a function of environmental parameters such as temperature [7], [8], [9], [10], which often leads to either excessive energy consumption or inadequate thermal comfort for the occupants.

The activity intensity is a key determinant of a building occupant's thermal comfort perception, as it directly influences the body's energy expenditure, similar to how metabolic rate (MET) is used in thermal comfort models like PMV [11]. This energy expenditure impacts the thermal conditions required for maintaining comfort, making activity intensity an essential parameter for dynamic HVAC adjustments. Since dynamic HVAC systems require real-time adjustments to occupant behavior, understanding activity levels is crucial for enabling these systems to respond effectively to varying thermal demands [12], [13]. For example, an individual engaging in physical activity generates more body heat compared to someone resting, requiring different temperature regulation to maintain comfort [14]. By integrating activity intensity information, environmental

control systems can achieve a better balance between energy consumption and occupant comfort. Additionally, human activity level estimation can support health monitoring, as sudden changes in activity patterns may indicate health issues that need attention [3], [14].

Although understanding occupant activity intensity is essential for dynamic HVAC adjustments, most existing approaches focus on activity recognition, which involves categorizing activities into distinct types such as walking, sitting, or running [15], [16]. These activity recognition methods face limitations in addressing the needs of adaptive environmental control, as they typically focus on discrete classifications rather than providing a continuous measure of activity intensity [1]. This not only limits their functionality for certain defined activities, but also fails to provide the nuanced understanding required for optimizing HVAC systems. For HVAC control, a more granular understanding of activity intensity is beneficial, as it allows for finer adjustments to the environment in real time. Furthermore, many existing approaches rely on wearable sensors, which present practical limitations due to being intrusive and uncomfortable for users [12], [17], [18], [19]. As a result, there is a need for a non-intrusive, real-time solution that provides a continuous measure of activity intensity, overcoming the limitations of predefined activity categories, and effectively linking activity levels to their impact on energy expenditure and thermal comfort.

To address these challenges, this research proposes a novel Activity Intensity Score (AIS) framework that uses movement data to provide a continuous measure of activity intensity. The AIS framework is designed to overcome the limitations of existing activity recognition methods by providing a detailed and dynamic assessment of activity intensity rather than discrete activity classes. This approach integrates various kinematic parameters, such as angular speed, angular acceleration, range of motion (ROM), and cumulative effort index (CEI), to generate a continuous intensity score that reflects real-time movement variations across different parts of the body. By focusing on these parameters, the AIS framework provides a more detailed and dynamic assessment of activity intensity, which is crucial for optimizing HVAC systems and supporting health monitoring while addressing the need for accuracy and adaptability. Importantly, AIS can be calculated using any image data, including thermal imaging or visible-light cameras, allowing flexibility in its application. The key contributions of this work include the development of a novel AIS framework that estimates human activity intensity based on thermal imaging data. The proposed approach has been validated through real-world experiments, demonstrating its capability to assign a proper score for differentiating various activity levels.

2 Methodology

The proposed activity intensity estimation framework, as depicted in Figure 1, aims to continuously assess the activity intensity of building occupants by analyzing movement data derived from image frames. The framework consists of five phases that together provide a comprehensive approach for estimating activity intensity. First, human body landmarks are detected using pose estimation to create a time series representation of body movements. Next, specific body segments, known as kinematic chains, are selected, and joint angles are computed to analyze movement patterns. Then, key movement parameters such as angular speed, acceleration, and range of motion are extracted and normalized. These normalized parameters are combined to compute the Activity Intensity Score (AIS) for each kinematic chain. Finally, AIS values from all kinematic chains are aggregated to produce an overall measure of activity intensity. Each phase is explained in detail in the following sections.

2.1 Pose Estimation and Landmark Detection

The first phase focuses on extracting accurate human body landmarks from video frames to enable kinematic analysis. This phase uses the MediaPipe Pose, an advanced pose estimation library developed by Google [20]. MediaPipe Pose is a machine learning-based framework that detects and tracks human body landmarks from video frames, providing real-time and high-confidence estimations. MediaPipe utilizes a combination of deep learning and computer vision techniques to effectively identify 33 key human body landmarks, including major joints such as shoulders, elbows, wrists, hips, knees, and ankles.

The pose estimation algorithm processes each video frame and extracts the 3D coordinates (x, y, z) of these relevant body joints. These coordinates are then used to construct a time series representation of the subject's body landmark positions, capturing the dynamic movements over time. The outcome of this phase is a comprehensive dataset of body landmark positions, which provides the foundation for subsequent kinematic analyses, such as joint angle computation and movement parameter extraction.

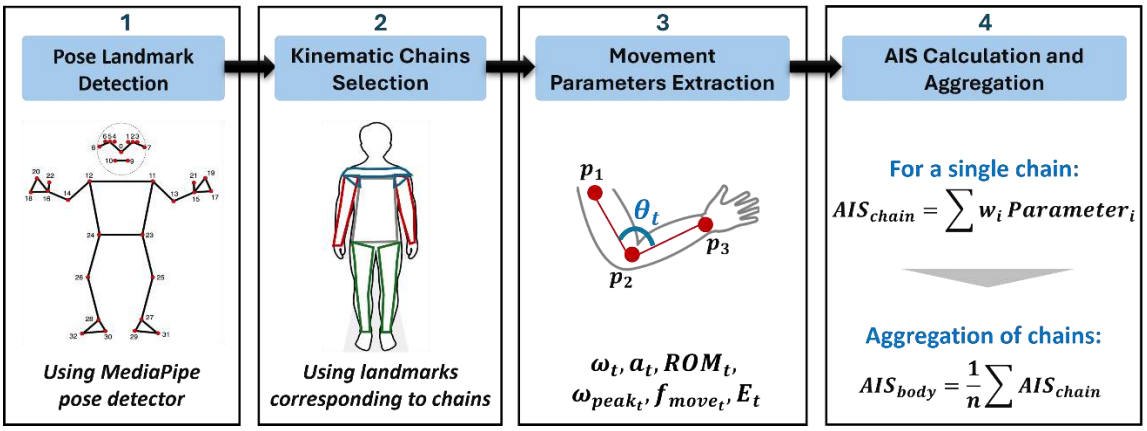

Figure 1. Proposed activity intensity estimation framework

2.2 Kinematic Chain Selection and Joint Angle Computation

In this phase, specific body segments, or kinematic chains, are defined, and joint angles are computed to analyze movement patterns. Kinematic chains represent interconnected body segments that work together to perform complex movements [21], [22]. In this study, the kinematic chains considered include the arms, legs, spinal segment, and other significant body segments, such as the neck and shoulder girdle. These chains are selected because they effectively capture the primary movements and joint dynamics of the human body, which are most relevant for assessing activity intensity in indoor environments. Table 1 provides an overview of the kinematic chains used in this study and the corresponding landmarks selected for each chain.

Each kinematic chain is defined by selecting three key landmarks that form two segments meeting at a joint. For example, the arm kinematic chain is defined by the shoulder, elbow, and wrist (see Figure 2), where the angle at the elbow joint is computed to represent arm movement. Joint angles are calculated using vector mathematics, with vectors formed from the selected landmarks. The joint angle (θ) is computed using Equation (1).

$$\theta = arccos\left(\frac{(p_1 - p_2).(p_3 - p_2)}{|p_1 - p_2| \times |p_3 - p_2|}\right) \quad (1)$$

Where p_1 , p_2 and p_3 are the joints in the corresponding chain. This calculation yields the angle at the intersection of these segments, which provides insight into the movement pattern of the body.

Table 1. Kinematic chains and corresponding landmarks used in the study

Kinematic chain	Landmarks selected
Arm (Left)	Left Shoulder, Left Elbow, Left Wrist
Arm (Right)	Right Shoulder, Right Elbow, Right Wrist
Hand-Wrist (Left)	Left Elbow, Left Wrist, Left Index
Hand-Wrist (Right)	Right Elbow, Right Wrist, Right Index
Neck-Head	Shoulder Center, Neck, Head
Shoulder Girdle	Left Shoulder, Spine, Right Shoulder
Torso	Shoulder Line, Hip Line
Spinal	Hip Center, Shoulder Center, Neck
Leg (Left)	Left Hip, Left Knee, Left Ankle
Leg (Right)	Right Hip, Right Knee, Right Ankle
Lower Leg (Left)	Left Knee, Left Ankle, Left Foot Index
Lower Leg (Right)	Right Knee, Right Ankle, Right Foot Index
Full Body	Head, Spine, Feet

The rationale behind using kinematic chains is that they allow for a more detailed understanding of human movement by focusing on specific body segments. By analyzing the joint angles of these chains, we can effectively capture the intensity and dynamics of movement, which is crucial for applications like HVAC control that depend on accurate assessments of occupant activity levels. This phase yields time series of joint angles for each selected kinematic chain, which will be used in the subsequent phases to extract movement parameters and compute the AIS.

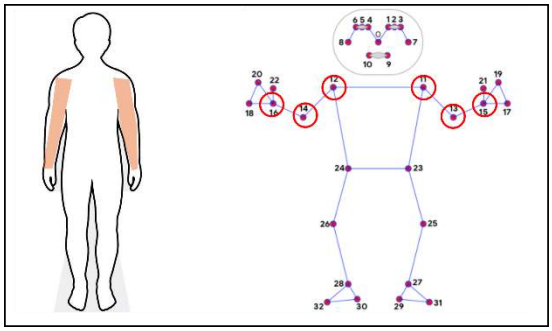

Figure 2. Illustration of sample kinematic chains and the selected landmarks from MediaPipe

2.3 Movement Parameter Extraction and Normalization

The third phase involves the extraction of key movement parameters from the joint angle data and their normalization for AIS computation. The goal is to derive meaningful metrics that reflect the movement intensity of different body segments. The following key parameters are derived, each representing a particular aspect of the activity intensity.

2.3.1 Angular Speed

Angular speed is computed as the first derivative of joint angles with respect to time, representing how quickly a joint angle changes. Since we have discrete angle measurements at each frame, numerical differentiation is used (see Equation (2)).

$$\omega_t = \left|\frac{\theta_t - \theta_{t-1}}{\Delta t}\right| \quad (2)$$

Angular speed captures the velocity of rotational movement, providing insight into the dynamic nature of the activity. High angular speed indicates rapid movement, contributing significantly to the overall activity intensity.

2.3.2 Angular Acceleration

Angular acceleration is the rate of change of angular speed, computed as the second derivative of joint angles with respect to time. Again, since we have discrete data, numerical differentiation is used (see Equation (3)).

$$\alpha_t = \left|\frac{\omega_t - \omega_{t-1}}{\Delta t}\right| \quad (3)$$

Angular acceleration measures sudden changes in movement speed, highlighting periods of rapid acceleration or deceleration. This parameter helps to identify bursts of activity that contribute to increased intensity.

2.3.3 Range of Motion

Range of motion (ROM) is defined as the difference between the maximum and minimum joint angles within a sliding window, as defined in Equation (4).

$$ROM_t = max(\theta_{t-\Delta t:t}) - min(\theta_{t-\Delta t:t}) \quad (4)$$

ROM represents the extent of movement for a specific joint. It indicates how much a joint moves during an activity. A higher ROM suggests more extensive movement, which is directly linked to higher activity intensity.

2.3.4 Peak Angular Speed

Peak angular speed is the maximum angular speed within a sliding window, presented in Equation (5).

$$\omega_{peak_t} = max(\omega_{t-\Delta t:t}) \quad (5)$$

Peak angular speed helps capture rapid bursts of movement that may not be reflected in the average speed. It is an important parameter for understanding the highest intensity levels within a given time frame.

2.3.5 Movement Frequency

Movement frequency is defined as the number of distinct peaks in the joint angle data within a sliding window. Equation (6) shows the movement frequency definition, calculated using peak detection algorithms.

$$f_{move_t} = Number\ of\ peaks\ in\ \theta_t\ within\ [t - \Delta t: t] \quad (6)$$

Higher movement frequency indicates more frequent changes in joint angles, which is often associated with increased physical activity levels.

2.3.6 Rotational Energy

Rotational energy is computed as the integral of the squared angular speed over a given time period. Since the data is discrete, it is calculated as the sum of the squared angular speeds, multiplied by the time interval, as presented in Equation (7).

$$E_t = \sum_{i=t-\Delta t}^{t} (\omega_i^2)\Delta t \quad (7)$$

Rotational energy provides a measure of the sustained effort involved in movement. It accounts for both the speed and duration of movement, making it a valuable indicator of overall activity intensity.

Each of these parameters is normalized to a scale between 0 and 1 using predefined expected ranges based on prior data. This normalization makes it possible for all the parameters to have equal contribution to the AIS irrespective of the range of their scales.

2.4 AIS Computation

In this phase, the AIS is computed by combining the

normalized movement parameters. Each parameter contributes differently to the overall activity intensity, and as such, weights are assigned to each parameter based on their relative importance. These weights can be determined through expert consultation, sensitivity analysis, or empirical studies. The AIS for each kinematic chain and at each time frame is computed using the weighted sum of the normalized parameters, as defined in Equation (8), to provide a quantitative measure of activity intensity that reflects the combined effects of speed, acceleration, ROM, movement frequency, and rotational energy. $w_1, \dots, w_6$ are weighting factors.

$$AIS(t)_{chain_i} = w_1(\omega_t)_i + w_2(\alpha_t)_i + w_3(ROM_t)_i + w_4(\omega_{peak_t})_i + w_5(f_{move_t})_i + w_6(E_t)_i \quad (8)$$

2.5 AIS Aggregation Across Kinematic Chains

The final phase integrates the AIS values from multiple kinematic chains to obtain an overall activity intensity measure. As defined in Equation (9), AIS values computed for all selected kinematic chains are aggregated for each time window, in this research using an average to compute the overall AIS. However, alternatively, a weighted average can be used if certain chains are deemed more influential. If certain kinematic chains are not detected, missed, or unavailable in the frame, their AIS values are excluded from the aggregation and average calculation. Alternatively, a weighted average can be used if certain chains are deemed more influential. The outcome of this phase is a unified AIS that represents the overall activity intensity at frame time, which can be used for thermal comfort prediction, dynamic HVAC control or other real-time applications. Here, N is the number of kinematic chains.

$$AIS(t)_{body} = \frac{1}{N}\sum_{i=1}^{N} AIS(t)_{chain_i} \quad (9)$$

3 Implementation

To test and validate the proposed AIS framework, a controlled data collection experiment was conducted to capture various movement intensities using a single standard camera in an indoor setting. The data collection was carried out at the North Dakota State University (NDSU) campus. A phone camera was positioned at waist height to ensure a full-body view, capturing video at 30 frames per second (fps). Three adults (two males, one female) were participated for the experiment.

To capture a range of movement intensities, participants were instructed to perform a set of predefined activities at low, moderate, and high intensities [14]. In this study, low-intensity included sitting, standing still, typing, and light stretching. Activities in moderate-intensity were walking at a regular pace, repeated arm movements, desk organizing, and dusting. Finally, heavy exercises like jogging in place, jumping jacks, push-ups, and squats comprised high-intensity activities [14], [23]. Activities were performed for approximately 80-90 seconds with a 1-minute rest interval in between to avoid fatigue. To enhance generalizability, participants performed different activities within each intensity level; for example, in the moderate-intensity category, one participant performed dusting, while another walked at a regular pace.

The selected activities are frequently observed in indoor settings, from workplaces to healthcare facilities, where real-time movement intensity estimation would be most applicable. They are common movements that reflect typical energy demands in such environments. For instance, a casual indoor pace (walking) contrasts well with intense exercises (jumping jacks). Furthermore, selected activities engage different body parts and movement dynamics. For instance, Sitting and Standing engage primarily the lower body and torso, while Jumping Jacks and Squats involve multi-joint movements. This diversity is beneficial to validate that AIS is responsive not just to movement intensity but to various kinematic patterns.

The AIS is calculated for each second (30 frames) of corresponding footage. For ROM, peak angular speed, movement frequency, and rotational energy, the time window is set on 30 timesteps (one second), while the instantaneous parameters (i.e., angular speed, angular acceleration) are calculated on the last frame of the past 30 frames. Weights in the AIS formula were chosen based on logical considerations of the role each parameter plays in characterizing movement intensity. Angular speed and acceleration are considered core parameters that directly reflect movement dynamics; hence they were given weights of 20 each. The remaining parameters—ROM, peak speed, movement frequency, and rotational energy—were each assigned a weight of 15, resulting in a total weight of hundred. Sample frames of the method implementation are shown in Figure 3.

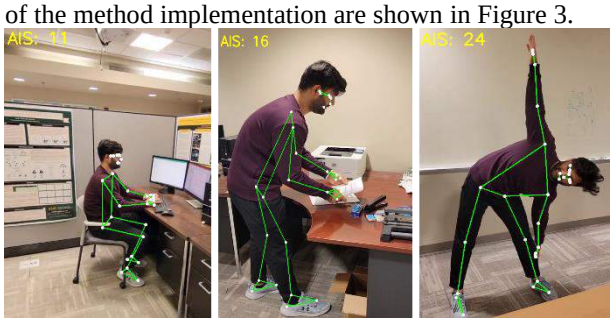

Figure 3. Implementation of the proposed approach on collected data (screenshots taken from videos). From left to right: light, moderate, and high intensity

4 Results

This section presents the findings of applying the proposed AIS estimation method on the collected data. Figure 4 illustrates the time-series plots of AIS values for a range of activities. Each plot shows the AIS variability across activities, highlighting clear differences in AIS between low-intensity, moderate-intensity, and high-intensity activities, for both participants.

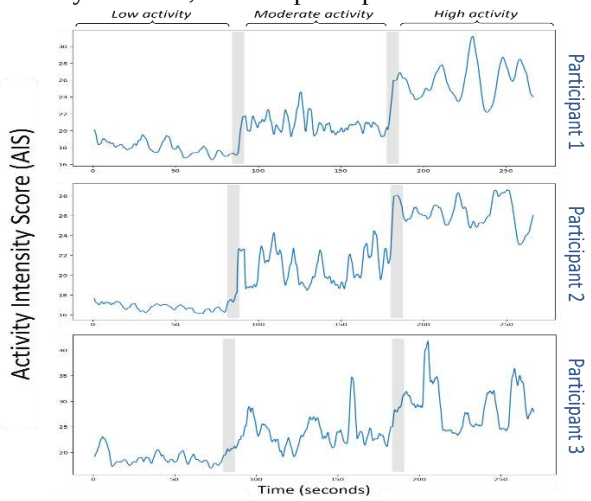

Figure 4. AIS values for different activities over time

These time-series graphs indicate that AIS values increase proportionally with activity intensity, which aligns with the purpose of the framework in capturing the expected differences in movement dynamics. To better confirm that, Figure 5 illustrates the average AIS across three participants for low, moderate, and high activity levels. The AIS increases as the activity level intensifies, confirming the method's ability to distinguish varying movement intensities. Small variations among participants reflect individual differences in movement styles (e.g., limb speed or range of motion). However, each participant shows a clear progression from low to high AIS values in accordance with activity intensity. These findings validate that the proposed AIS framework captures meaningful distinctions in movement intensity.

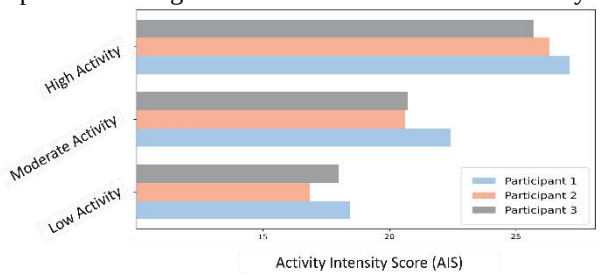

Figure 5. Mean AIS values for different activity levels

In addition, Figure 6 presents boxplots of the AIS constituent movement parameters across the three defined activity levels (for participant 1 as sample). These boxplots indicate a visual summary of the distribution of each parameter within each activity level and could illustrate the differences in movement characteristics associated with each activity level. The clear separation and trends observed among the boxplots suggest that both the AIS and individual movement parameters increase with higher levels of physical activity. This finding supports the validity of the AIS and its components as reliable indicators of activity intensity.

Finally, it should be noted that in some frames, not all kinematic chain landmarks could be detected by the pose estimation algorithm (see Figure 7). This issue primarily occurs when the subject is not fully visible from the camera angle. To address this anticipated limitation, the AIS calculation only includes kinematic chains that are fully detected in the corresponding frame.

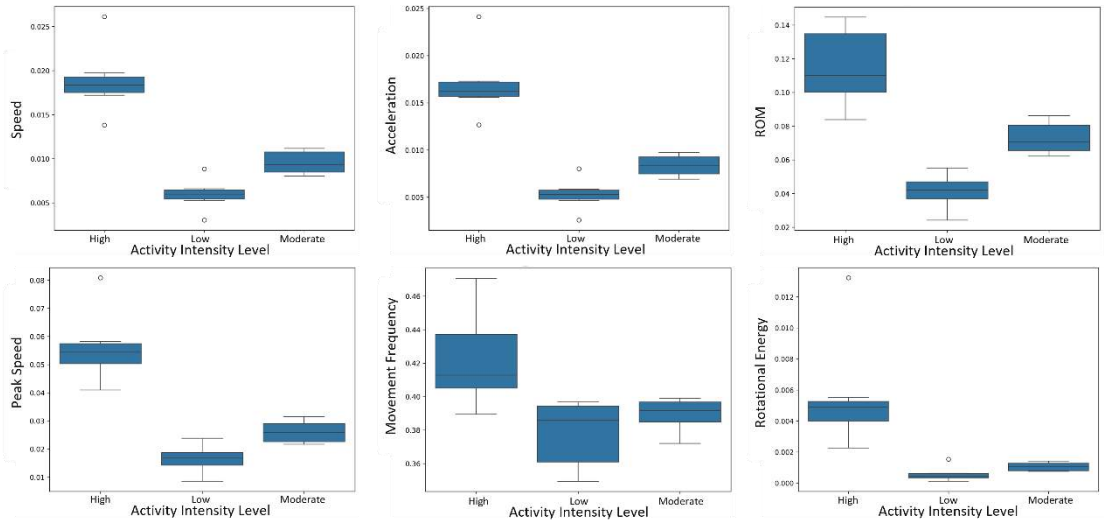

Figure 6. Distribution of AIS parameters within each activity level (normalized values)

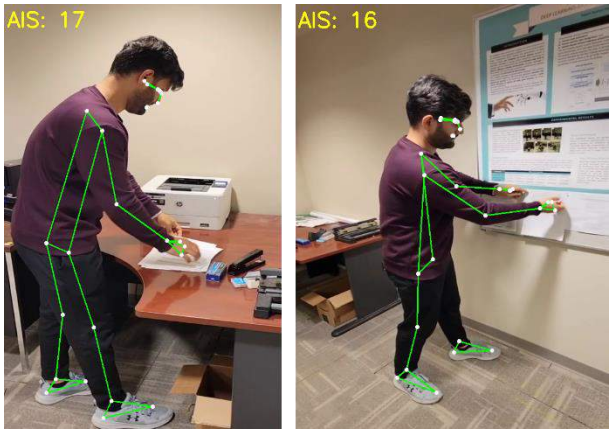

Figure 7. Missed pose landmarks (Left: left hand not detected; Right: left leg not detected)

5 Discussion

The results indicate that the proposed AIS framework effectively captures variations in human activity intensity and distinguishes between low, moderate, and high activity levels across different participants. The estimated AIS provides a real-time measure of occupant movement, which is crucial for optimizing HVAC systems by dynamically adjusting thermal conditions based on occupant activity levels. In the same conditions, higher activity levels generate more body heat, reducing the need for heating, while lower activity levels may require increased heating to maintain comfort. Therefore, AIS could be considered as an input factor when developing a thermal comfort prediction model to be utilized in HVAC control. On the other hand, integrating AIS alone may not be sufficient for HVAC optimization. Other factors, such as the duration of activity (to distinguish brief movements from sustained exertion), occupants' body temperature, and occupants' clothing insulation level should be considered. Future work could incorporate these factors alongside AIS to develop a more adaptive and efficient HVAC control strategy.

Although this study provided significant findings, some challenges remain to be addressed in future research. One limitation is the reliance on a single camera, which can lead to occlusion issues and missing pose landmarks [24], [25]. Additionally, the current framework uses a standard camera, which might raise privacy concerns for some users. Using thermal cameras is a potential solution to these privacy issues. Furthermore, future work could focus on optimizing the weights of AIS parameters.

6 Conclusion

In this study, a novel Activity Intensity Score (AIS) framework was developed to provide a continuous, real-time estimation of human movement intensity in indoor environments. The AIS integrates various kinematic parameters, including angular speed, acceleration, range of motion, movement frequency, and rotational energy, into a single measure that reflects the intensity of movement. Experimental validation confirmed the effectiveness of AIS in differentiating movement intensities, demonstrating its potential for applications such as adaptive HVAC control, ergonomic assessment, and health monitoring. While the framework offers a non-intrusive and scalable approach, future work should focus on improving robustness against occlusion, optimizing AIS parameter weights, and integrating additional physiological signals to further enhance its accuracy and practical implementation.

Abstract –

Human-robot collaboration (HRC) holds significant potential to enhance productivity and efficiency in modular construction (MC). While existing studies in construction HRC have predominantly focused on technical advancements, limited attention has been paid to human factors and the cognitive impacts of robots on workers during collaboration. This study addresses this gap through an experimental investigation. A controlled experiment was conducted to compare conditions with and without a collaborative robot (cobot). Work performance metrics (e.g., time efficiency, angular accuracy, and screwing quality) and human factors (e.g., fatigue levels, individual effort, and stress states) were assessed using statistical analysis and self-report questionnaires. Results of work performance indicate that cobot integration significantly increased task completion time (TCT) (Est. = 0.314, t = 5.18, p < 0.001), with variations observed across tasks (p = 0.00452). Results of human factors revealed increased fatigue (mean scores rising from 18.9 to 22.0), mental effort (mean scores rising from 40.2 to 50.1), and distress (mean scores rising from 12.2 to 15.9) under the cobot condition, suggesting additional cognitive demands during collaboration. These findings underscore the importance of addressing task complexity and cognitive challenges when implementing cobots in MC workflows. This research contributes to advancing robotics integration and safeguarding worker well-being in modular construction.

Human-robot Collaboration; Work Performance; Human Factors; Collaborative Robots; Modular Construction

1 Introduction

To address the lack of labors and improve productivity, modular constriction (MC) has gained significant attention and development in the construction industry recently [1]. MC refers to an innovative construction approach that transfers on-site works to highly controlled and standardized environments in MC factories. Robotics have been increasingly applied in MC to enhance both efficiency and safety in prefabrication and assembly processes [2-4]. For instance, this promising technique has been successfully integrated into prefabricated component assembly [5], robotics welding [6] and robotics platforms [7]. Among these advancements, collaborative robots (cobots) have emerged as a transformative tool, offering the benefits of flexible manufacturing and cost-effectiveness. As a result, human-robot collaboration (HRC) is poised to play a significant role in the future development of MC.

Human involvement remains essential in HRC due to unique cognitive and reasoning abilities, while robots excel at performing repetitive, precision-demanding and hazardous tasks [8]. Despite this, existing studies in MC primarily focus on technological advancements, such as robotic programming and automated assembly systems, while giving less attention to the effects of HRC as a novel working paradigm on human workers. Previous research [9, 10] indicated that working with robots may increase workers' cognitive load and mental stress. However, there remains a need for a systematic evaluation of how robots influence workers' performance and well-being in MC workflows.

This study aims to address this gap through an experimental investigation of the effects of robots on construction workers. A controlled experiment was conducted to isolate variables and compare conditions with and without the cobot. Statistical analysis and questionnaire surveys were employed to assess work performance and workers' cognitive and physical responses. The outcomes of this research will provide insights into the impacts of cobots on both work performance and human factors. Furthermore, this study offers practical recommendations for optimizing human-

robot collaboration by managing task complexity and reducing cognitive load, supporting the effective integration of cobots in MC workflows.

2 Literature Review

This section begins with an overview of the applications of cobots in modular construction and then provides a detailed analysis of their impact on human workers.

2.1 Cobots' Application in MC

The integration of cobots in MC has gained increasing attention for their ability to enhance efficiency, safety, and precision in prefabrication and assembly processes. By shifting construction activities from unstructured on-site environments to highly controlled factory settings, MC provides an ideal platform for HRC [8]. Cobots are designed to complement human workers by performing repetitive, precision-demanding, and hazardous tasks, thereby enabling greater flexibility and productivity in production workflows.

In MC factories, cobots have been successfully applied in various tasks, including component assembly [5], 3D printing [11], and automated welding [6]. For example, Kyjanek et al. (2019) investigated HRC in timber prefabrication, where cobots achieved precise positioning of timber components while humans performed tasks requiring dexterity, such as screwing [12]. The use of augmented reality facilitated real-time communication and task sequencing, ensuring seamless collaboration between workers and robots. Similarly, Zhu et al. (2021) proposed a smart component-oriented method for multi-robot coordination in prefabricated housing [13]. By utilizing smart construction objects within a Building Information Modeling (BIM) environment, tasks such as transporting and assembling components were efficiently allocated, improving coordination and streamlining collaborative workflows.

While these applications demonstrate the potential of cobots to streamline MC processes, the integration of cobots also introduces new challenges. Existing research has primarily focused on the technical advancements of cobot systems, such as programming optimization, sensor-based control, and hardware innovations [5, 6, 14]. However, limited attention has been given to understanding how cobots affect human workers, particularly regarding their performance and well-being. This highlights the need for a systematic evaluation of cobot integration from a human-centered perspective.

2.2 Impact Evaluation of HRC

Despite the importance of understanding cobots' impact on construction workers, research in this area remains limited. Existing studies primarily rely on methods such as self-report questionnaires, interviews, and simulations [15]. For example, Bademosi and Issa (2021) used interviews and surveys with industry experts to explore the challenges of implementing automation and robotic technologies in construction [16]. Similarly, Wu et al. (2022) developed a simulation-based framework to assess the impact of HRC on construction productivity [17]. However, controlled experimental methods are relatively scarce, even though experiments offer stronger empirical evidence and better reflect real-world conditions, making them more persuasive for evaluating cobots' practical impacts.

Work performance is one of the key metrics for evaluating human-robot interaction in HRC. Human factors are equally critical in assessing HRC, as the introduction of cobots should remain human-centered. Baltrush et al. (2022) identified four key job quality factors relevant to HRC: cognitive workload, collaboration fluency, trust, and acceptance and satisfaction [19]. However, construction tasks often involve significant physical labor, highlighting the need to assess physical fatigue and exertion. For example, experimental research conducted by Fang et al. (2015) highlighted the importance of fatigue on construction workers performance [20]. Therefore, this study focuses on fatigue levels, individual effort, and stress levels to comprehensively evaluate the human factors associated with cobot integration in construction.

3 Methodology

Experimental analysis method was used in this study to evaluate the impact of cobots on human workers in terms of work performance and human factors. Figure 1 illustrates the overall methodology and process of this study. A typical manufacturing task for a wooden wall panel was designed and decomposed into 9 subtasks. Next, a total of 6 subjects were recruited and a controlled experiment was designed to eliminate the impact of extraneous variables. After setting up an experiment workspace, hardware devices, software system, and tools, each subject was asked to individually conduct experiments in both with/without a cobot for comparison. While the work performance was evaluated from time efficiency, angular accuracy, and screwing quality, human factors were investigated through self-report scales in terms of fatigue levels, individual effort, and stress states.

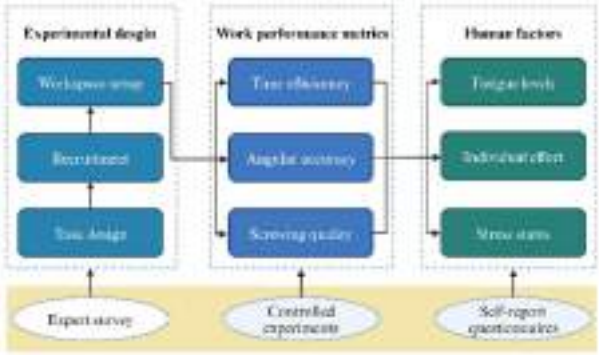

Figure 1. The overall methodology of this study

3.1 Task Design

A typical wooden wall panel manufacturing task in MC was designed for this study. Wood framing is a primary building method in MC for residential, commercial, and industrial structures [21]. Among these, wooden wall panels play a critical role as both structural and functional components. To enhance production efficiency and quality, cobots are increasingly integrated into manufacturing tasks. However, their integration requires close collaboration with human workers, raising concerns about potential impacts on human performance and well-being. Therefore, it is crucial to investigate these impacts in the context of wooden wall panel manufacturing.

The manufacturing task was decomposed into nine subtasks: assembling the framework (T1), screwing to connect the framework (T2), covering with an OSB board (T3), screwing to attach the board to the framework (T4), flipping the panel (T5), adding insulation (T6), covering with another board (T7), screwing again to attach the board (T8), and finally moving the completed product (T9). These tasks were designed to replicate a realistic production process, requiring both physical and cognitive effort from human workers.

To compare the effects of conditions with and without a cobot on human workers, a controlled experiment was designed with two groups. In the baseline group, workers completed the entire task in the same workspace with the cobot powered off. In the cobot group, the cobot was activated and assigned to perform subtask 1, which involved picking and placing wooden strips to assemble the framework. The cobot continuously repeated this task throughout the experiment, while human workers completed the entire sequence of subtasks 1 through 9. Each participant was required to complete both the baseline and cobot conditions on different days to minimize the impact of task repetition.

3.2 Recruitment

A total of six participants, all aged 18 or older, were recruited for the study. The group consisted of three male and three female undergraduate students from the Department of Civil, Environmental, and Geospatial Engineering at Michigan Technological University (MTU). None of the participants had a history of back disorders. This group was selected because of their experience with construction-related activities, making them well-suited to simulate real-world workers while ensuring safety during the experiment.

The recruitment process complied with guidelines with approval from the MTU Institutional Review Board (IRB), under IRB #: IRB-2024-90. All participants signed informed consent forms, voluntarily agreeing to participate with the option to withdraw at any time.

3.3 Workspace Setup

The experimental setup included a UR10e robot equipped with a Robotiq 2F-85 gripper, programmed and controlled using RoboDK software, as shown in Figure 2. The UR10e robot is a versatile and flexible collaborative robot widely used for industrial tasks [6, 22], offering high precision and adaptability for various assembly operations. RoboDK software provides a user-friendly interface for programming and simulating robot tasks [23], making it ideal for ensuring accurate control and program efficiency during experiments.

Figure 2. Experimental workspace setup

A dedicated workspace was enclosed with safety barriers to ensure controlled and interference-free experimental conditions. Wooden wall panel components were scaled down to half their actual size (1:2 ratio) to fit the workspace, with all wooden strips and boards pre-cut and pre-drilled to facilitate assembly. Safety equipment, including helmets, safety glasses, and woodworking gloves, is required within the workspace. Prior to the experiment, safety training and an operation test on the use of an electric screwdriver were conducted. The entire experiment was overseen and safeguarded by an experienced safety assistant.

3.4 Measurement on Work Performance

The impact of cobots on work performance was evaluated in terms of time efficiency, angular accuracy, and screwing quality. Time efficiency was quantified by recording and comparing the task completion time (TCT) for each subtask between the baseline and cobot groups. To stabilize variance and make the data more suitable for linear modeling, a log transformation was applied to the time variable. For further analysis, two linear mixed-effects models (LMMs) were developed using RStudio. LMMs are appropriate for data that include both fixed effects (predictors of interest) and random effects (sources of variability that must be accounted for but are not the primary focus). The first model examined the effects of experimental conditions (baseline and cobot groups), subtasks (T1 to T9), subjects (individual participants), and trial progression (repeats per participant) on time performance. To better understand the interactive effects among these factors, the second model analyzed how the impact of the cobot condition varied across different subtasks.

Figure 3. Distribution angles for the framework

Angular accuracy was assessed by evaluating the total accuracy of the assembled wooden framework and comparing it to the design specifications. Figure 3 shows the distribution of the eight defined angles at each lumber connection within the framework. Raw angle data were collected using a digital angle finder. The accuracy of each joint was calculated using Equations (1) and (2), with the total accuracy of the structure determined using Equation (3) [15]:

$$err = \frac{M_e - M_t}{M_t} \times 100\% \quad (1)$$

$$acc = 1 - \underset{joint\ 8}{err} \quad (2)$$

$$acc_{total} = \prod_{k=joint\ 1} acc_k \quad (3)$$

where err = percentage error; M_e = experimental values measured during assembly; $M_t = 90°$, which is the theoretical design value; acc = percentage accuracy, acc_{total} = the total accuracy of an assembled wooden framework (from joint 1 to joint 8); and acc_k = percentage accuracy of each individual joint.

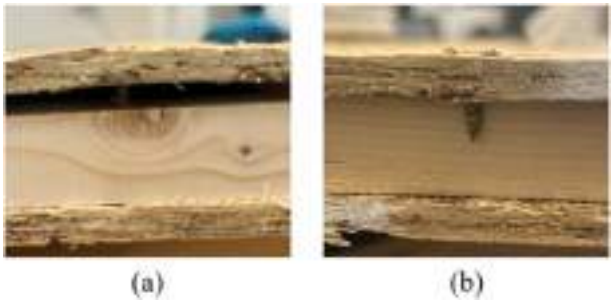

Figure 4. Two types of failed screws

Screwing quality was evaluated as the percentage of failed screws relative to the total number used in the product. Failed screws included two types: those that did not fully penetrate the structure (Figure 4(a)) and those that fully penetrated but failed to connect to the substructure (Figure 4(b)).

3.5 Measurement on Human Factors

The impact of cobots on human factors was evaluated based on fatigue levels, individual effort, and stress states. Data for these dimensions were collected through self-report questionnaires administered after each complete round of nine subtasks. The process was facilitated by the Psychology Experiment Building Language (PEBL) [24], an open-source platform that enables the design and execution of psychological experiments, streamlining the collection and analysis of scale-based data.

Fatigue levels were assessed using the Fatigue Assessment Scale for Construction Workers (FASCW) [25], a 10-item scale where each question is scored on a 5-point scale. The total score is obtained by summing all 10 items. The FASCW comprises two factors: lethargy and bodily ailment. Lethargy, primarily associated with mental fatigue, is calculated as the sum of questions 1, 3, 5, 7, and 9, while bodily ailment, reflecting physical fatigue, is derived from the sum of questions 2, 4, 6, 8, and 10.

Individual effort was measured using Borg's Rating of Perceived Exertion (RPE) [26] for physical effort and Zijlstra's Rating Scale for Mental Effort (RSME) [27] for mental effort. The Borg RPE is a numerical scale ranging from 6 to 20, where participants rate their overall exertion, considering physical stress and fatigue during the task. The Zijlstra RSME, a unidimensional scale, measures subjective mental workload. It consists of a 0–150 scale marked with nine descriptive anchor points representing increasing levels of mental effort.

Stress states were assessed using the Short Stress State Questionnaire (SSSQ) [28], a 24-item scale where each question is rated on a 5-point scale. The SSSQ

comprises three factors—distress, engagement, and worry—each represented by eight questions. Distress reflects negative states such as unpleasant mood, tension, lack of confidence, and perceived loss of control. Engagement captures positive states, including task interest, motivation, energetic arousal, and concentration. Worry focuses on cognitive interference, self-focused attention, and self-esteem.

4 Results and Discussion

A total of 12 experimental groups were conducted, involving six participants under two experimental conditions: baseline and cobot. Each group completed two repetitions of the entire process consisting of nine subtasks. However, four groups were excluded because participants #3 and #4 did not complete the entire process. As a result, 16 data groups (4 participants × 2 conditions × 2 repetitions) were included in the analysis.

4.1 Results of Work Performance

This section examines the impacts of cobots on human work performance from three perspectives: time efficiency, angular accuracy, and screwing quality. Figure 5 illustrates the TCT results under baseline and cobot conditions. Figure 5(a) shows the distribution of TCT in seconds, while Figure 5(b) presents the log transformed TCT distribution for improved clarity and visual comparison. Figure 5(c) displays the mean log transformed TCT across the nine subtasks. In most subtasks, the cobot group exhibited longer completion time compared to the baseline group. However, for subtasks 5 (flipping the panel) and 6 (adding insulation), the differences were minimal or reversed.

To further analyze the effects of experimental conditions, subtasks, subjects, and trial progression on time performance, two LMMs were developed using RStudio. In the first LMM, experimental conditions, subtasks, and trials were included as fixed effects, while subjects were treated as a random effect. The response variable was defined as $LogTCT = \log(time)$ to stabilize variance and improve model fit.

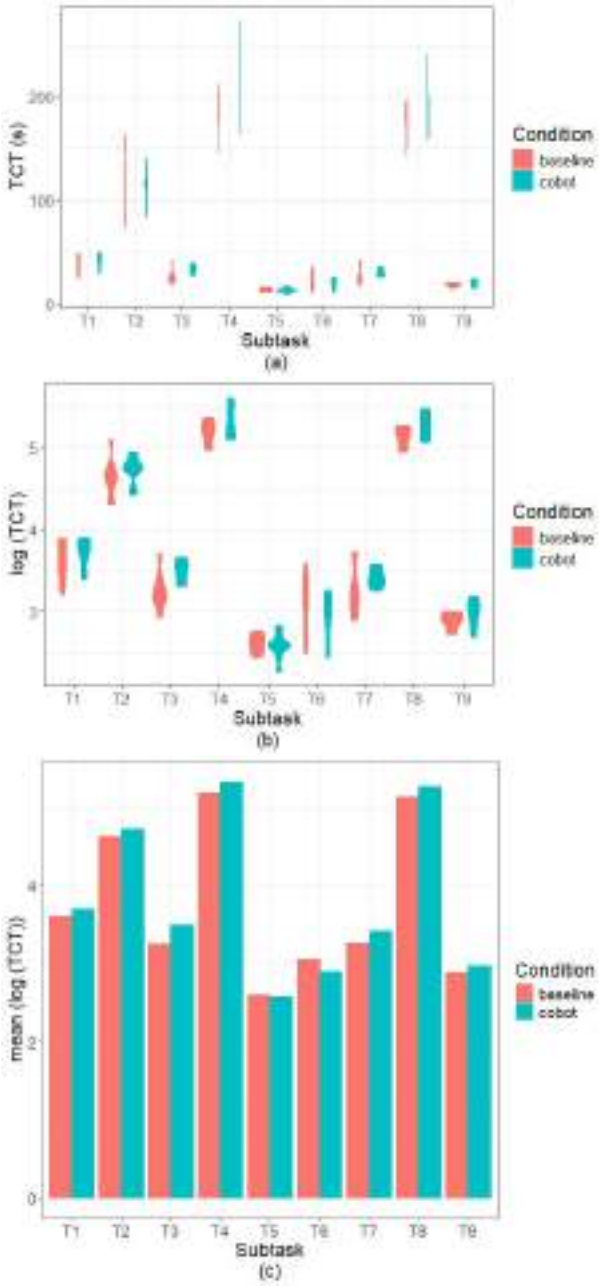

Figure 5. Performances of time efficiency

Table 1. Summary of the LMM coefficients

Groups	Est.	SE	t-value	p-value
Intercept	3.761	0.088	42.94	< 2.2e-16
Condition	0.314	0.061	5.18	< 2.26e-07
Trials	-0.058	0.014	-4.15	< 3.29e-05
Subtasks	df = 8, Significant, p < 2.2e-16			
Subjects	Var = 0.0199, SD = 0.141			
Residual	Var = 0.0213, SD = 0.146			

Table 1 summarizes the LMM results. The "cobot" condition significantly increased $logTCT$ compared to

the baseline data ($Est. = 0.314, t = 5.18, p < 0.001$), suggesting that cobot involvement slowed task completion, potentially due to worker distraction or mistrust of the robot. Trail progression also had a significant effect on time performance ($Est. = -0.058, t = -4.15,\ p < 0.001$), indicating that task completion times decreased with repetition, likely reflecting learning and adaptation. Subtasks significantly influenced time performance ($p < 0.001$), with varying effects observed across different tasks. Additionally, the inclusion of a random effect for subjects ($Var = 0.0199, SD = 0.141$) accounted for individual differences in time efficiency, such as variations in skill or experience. Residual variance of the model was 0.0213 ($SD = 0.146$), reflecting some unexplained variability in the data.

Given the significant influence of both condition and subtasks, the interaction between them was further examined using a second LMM. Results revealed a significant "condition * subtasks" interaction ($p = 0.00452$), indicating that the cobot condition's impact on TCT varied across subtasks. Specifically, the main differences observed in subtasks 5 and 6 may be attributed to the nature of these tasks, which require less direct interaction with the cobot. These findings suggest that the cobot's influence on time efficiency is task-dependent, highlighting the need for further investigation into the underlying mechanisms.

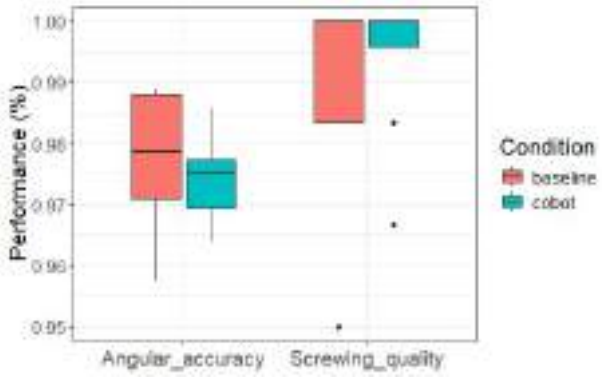

Figure 6. Performances of angular accuracy and screwing quality

Figure 6 presents the results for angular accuracy and screwing quality under the two experimental conditions. Angular accuracy was evaluated by comparing the total structural accuracy of the assembled wooden framework with the design specifications. The results indicate a slight reduction in angular accuracy in the cobot condition. This minimal effect can be attributed to the framework's structural properties, where the extrusion between wooden strips naturally constrains angular deviations, reducing observed variability.

Screwing quality, measured as the percentage of failed screws, showed negligible differences between the two conditions. The simplicity of the screwing task likely contributed to the lack of observable differences. These results suggest that for straightforward tasks, such as screwing, collaborative robots have a limited impact on the performance of screwing quality. Future studies should consider increasing task complexity to better assess the influence of cobots on such outcomes.

4.2 Results of Human Factors

This section examines the impact of cobots on human workers from three human factor perspectives: fatigue levels, individual effort, and stress states. Figure 7 presents the results of fatigue levels measured by the FASCW. The total average FASCW score shows an increase from 18.9 to 22, suggesting that participants experienced greater fatigue under the cobot condition. Specifically, both FASCW factors—lethargy (associated with mental fatigue) and bodily ailment (associated with physical fatigue)—demonstrated upward trends, with lethargy showing a more pronounced increase.

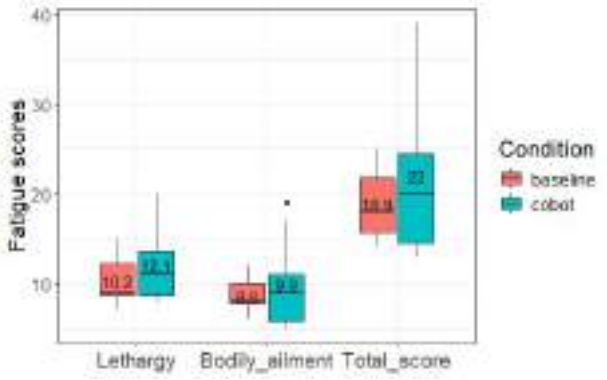

Figure 7. Results of fatigue levels

Figure 8 illustrates the results of physical and mental effort, measured using Borg's RPE scale and Zijlstra's RSME, respectively. The results reveal a slight increase in RPE scores (mean rising from 11.1 to 11.9) and a more substantial increase in RSME scores (mean rising from 40.2 to 50.1) under the cobot condition. This indicates that collaboration with robots resulted in a greater increase in mental effort compared to physical exertion.

These findings on individual effort align with the fatigue results, as both measures highlight increases in cognitive or mental dimensions (i.e., lethargy and mental effort). The observed effects may be attributed to the increased cognitive load and potential distractions introduced by the cobot.

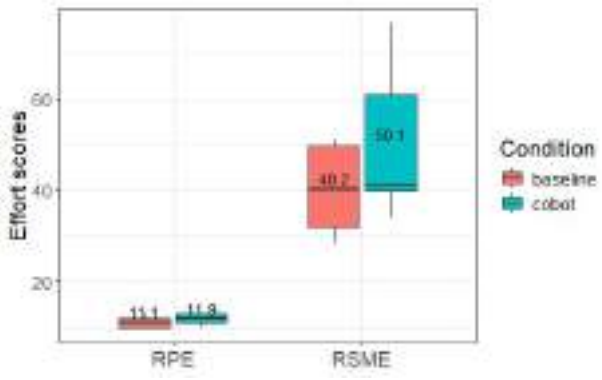

Figure 8. Results of individual effort

Figure 9 presents the results of the SSSQ for assessing the stress levels. The findings reveal a significant increase in distress scores (mean rising from 12.2 to 15.9) under the cobot condition, while engagement and worry exhibited only slight changes. This suggests that collaboration with cobots increases emotional strain and discomfort, distinguishing it from the psychological interference associated with worry and the motivational focus represented by task engagement.

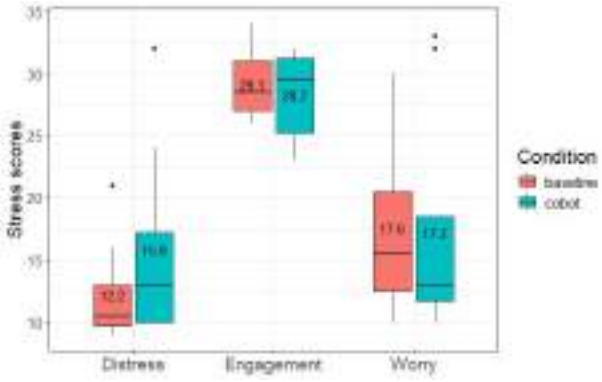

Figure 9. Results of stress states

4.3 Limitations and Future Works

This study has certain limitations. The sample size was relatively small (N=6), and the participants were undergraduate students rather than experienced construction workers. While these participants had relevant construction-related knowledge, their responses and performance may not fully represent those of seasoned professionals. Future research should involve a larger and more diverse participant pool, including experienced construction workers, to enhance the generalizability of the findings.

While cobots offer significant potential for enhancing productivity, their cognitive impact on human performance and well-being must be carefully managed. Future research should explore more complex tasks and diverse working scenarios to gain deeper insights into the dynamics of human-robot collaboration. By incorporating tasks that more closely mimic real-world MC workflows, future research can provide more practical and actionable insights for optimizing cobot integration in industrial settings.

5 Conclusion

The study assessed the impacts of collaborative robots on construction workers' work performance and human factors. Work performance was assessed in terms of time efficiency, angular accuracy, and screwing quality, while human factors were examined through fatigue levels, individual effort, and stress states. The results showed that cobot involvement significantly increased task completion time (Est. = 0.314, t = 5.18, $p < 0.001$), with variability observed across different task types ($p = 0.00452$). Angular accuracy showed a slight decline, though structural constraints reduced deviations, while screwing quality remained largely unaffected due to the task's simplicity. Human factor results revealed increased fatigue levels, with mean scores rising from 18.9 to 22.0, mental effort scores increasing from 40.2 to 50.1, and distress scores rising from 12.2 to 15.9 under the cobot condition. These findings suggest that collaborating with robots increases cognitive load and emotional strain among workers, highlighting the need for careful consideration of task complexity and worker cognitive demands when integrating cobots into MC workflows.

Abstract –

Drones are increasingly used in construction projects to facilitate tasks such as progress tracking, safety monitoring, and quality inspection. Despite their advantages, the presence of drones may introduce distractions that compromise workers' ability to identify hazards, thereby elevating the risk of accidents. While limited studies have conducted quantitative assessments of drone-induced distractions among construction workers, the interplay between specific drone flight configurations and the degree of distraction remains underexplored. This study investigated the influence of varying drone flight configurations on workers' attentional focus through quantitative experiments. Seven virtual construction site scenarios were developed to simulate both the visual and auditory stimuli associated with drones. A total of 17 participants engaged in simulated construction tasks within these scenarios, utilizing virtual reality systems and an omnidirectional treadmill. Their situational awareness was evaluated through a detailed analysis of gaze fixation times and counts. The results indicated that the presence of drones significantly distracted participants, with distraction levels intensifying as the drones approached closer. These findings contributed to the understanding of how drone proximity impacts worker attention and safety and established a basis for refining safety protocols in construction environments where drones are increasingly employed.

Keywords –

Unmanned aerial vehicles (UAVs); Visual attention; Eye-tracking; Virtual reality; Worker safety

1 Introduction

The increasing applications of drones in construction projects have gained significant attention from the industry due to their potential to enhance efficiency and safety. However, concerns have emerged regarding the safety risks and hazards that drone operations may introduce to construction sites. These risks extend beyond the physical hazards of collisions with workers, equipment, or site infrastructure within drone operating zones [1]. The presence of drones has the potential to divert workers' attention, leading to visual, auditory, and cognitive distractions [2]. For example, Union Pacific Corp railroad workers reported being distracted by drones flying over rail yards, causing them to look upwards rather than focusing on their tasks, even in the presence of 200-ton locomotives and railcars in motion [3].

The impact of distraction on workers' focus has been widely documented in other domains. For example, Mark et al. showed that external interruptions in office environments could delay workers' return to full task concentration by up to 25 minutes [4]. Similar interruptions were observed in construction settings, where distractions caused by drones can impair hazard recognition and safety risk assessment [5] [6]. Such distractions increase the likelihood of errors, endangering both the distracted worker and others on-site [7].

The workers at heights are vulnerable to drone-induced distractions since the drones often fly above buildings on construction sites. These distractions may cause workers to overreach or lose balance on elevated platforms cluttered with tools or areas lacking protections such as unguarded edges and openings. Consequently, the risk of falls, slips, and trips increases, often resulting in serious injuries or fatalities. The Bureau of Labor Statistics (BLS) reported that falls, slips, and trips accounted for 38.4% of all fatalities and 47.4% of nonfatal injuries in the construction industry in 2022; and

most fatal falls, slips, and trips happened to those workers at heights who fell to a lower level [8]. Moreover, a survey of over 1,200 safety professionals identified distraction as the leading cause of these incidents [9].

Although previous studies have acknowledged the safety challenges posed by drones in construction, much of the existing research relies on surveys, expert opinions, and conceptual analyses, with limited experimental data to evaluate the extent of drone-induced distractions [10], [11]. To address these limitations, Albeaino et al. provided initial experimental data, demonstrating that drones can cause measurable distractions among construction workers [12]. However, the influence of specific drone flight configurations on distraction levels remains unexplored.

This study aims to address this gap by examining how drone flight height and approach direction affect workers' safety and attention. These variables were chosen because they are key factors influencing the degree to which drones capture workers' attention. For instance, a drone's flight height can alter its visibility and audibility, while the approach direction (e.g., from the front or back) may impact how quickly workers become aware of its presence. To investigate these effects, a few virtual construction environments were developed, and participants were tasked with performing material handling activities. Gaze fixation times and counts were collected to evaluate visual attention toward hazardous areas. By analyzing this data, our study provided a quantitative assessment of how drone flight configurations influence workers' hazard awareness, contributing to a deeper understanding of drone-induced distractions and their implications for construction site safety.

2 Literature Review

2.1 Drone Application in Construction Sites

Drones, or unmanned aerial vehicles (UAVs), are aircraft that can be remotely controlled or autonomously flown to perform various tasks on construction sites. Equipped with sensors such as RGB, multispectral, thermal, or LIDAR, drones can quickly capture substantial aerial data [13]. This data can be transmitted to computers through drone software, enabling users to analyze and interpret it efficiently. These capabilities enhance construction project efficiency, support better project management, and improve the thoroughness of inspections.

Drones have numerous applications in construction, including topographic mapping, equipment tracking, remote monitoring, and worksite inspection. For topographic mapping, drones significantly reduce the time needed to survey a site's landscape by covering large areas quickly. The high-resolution images captured can be converted into 3D models to identify site challenges and assist with layout planning before construction begins. For instance, Jiang et al. [14] advanced image-based modeling techniques for real-time 3D construction site modeling, proving effective for rapid layout planning in hoisting projects. Additionally, drones help track equipment locations on-site, record operational errors, and monitor construction quality. Sun [15] proposed a UAV-based system to track road construction machinery, enhancing paving quality. Furthermore, drones allow companies to visually inspect large structures or those in hard-to-reach areas more efficiently and at a lower cost. For example, de Melo et al. demonstrated that UAV-collected visuals can improve safety inspections by providing better visibility of job site conditions [16].

2.2 Drone Safety Analysis in Construction Sites

The Federal Aviation Administration (FAA) has implemented regulations for remote pilot certification and operational guidelines for small unmanned aircraft in civil applications, aiming to address safety concerns associated with drones in commercial settings [17]. From April 21, 2021, the FAA permits drones to operate over people, contingent upon the level of risk they pose to individuals on the ground [18]. While these regulations provide a foundational standard for safe drone operations in workplace environments, they do not specifically account for the potential distractions drones may cause, particularly for workers working at heights.

Recently, the potential safety risk related to drone applications on construction sites attracted more attention. Based on the survey of 56 and 69 construction experts and professionals, drone-induced distraction is one of the primary safety concerns in construction projects [10][11]. Moreover, Jeelani and Gheisari investigated different drone applications on construction sites and identified their negative impacts on related workers' health and safety [2]. Fan and Saadeghvaziri identified drone-induced distraction as a key challenge in the planning, design, construction, and maintenance of civil infrastructure [19]. Costa et al. also highlighted that drone-induced distraction may cause issues with workers, concentration, safety, and productivity [20]. These earlier qualitative studies showed that drone-induced distraction can impact construction worker safety.

Thus, further studies started to quantify how drone-induced distraction, because it can provide more solid evidence for the decision-making process of drone use on construction sites. For example, Monte Carlo simulations were used to quantify the direct and indirect risks of drones to construction workers [21], [22]. Although the

simulations can provide valuable insights, they did not study the actual reactions of the workers. Thus, Albeaino et al. conducted human study experiments to investigate the impact of drone-induced distractions on workers [12]. The study revealed that participants spent approximately 18 seconds observing the drones during a 2.5-minute task, highlighting the considerable potential for distraction in active work settings.

2.3 Drone Distraction Studies Using Virtual Reality

To study how drones distract construction workers and impact safety, we need to observe worker responses with and without drone distractions. Since real-life testing poses safety risks, we use virtual reality (VR) to simulate high-risk environments safely [23]. VR replicates real-world conditions in a controlled, risk-free manner and has been shown to produce results closely aligning with real-world experiments in both behavioral outcomes and self-reported measures [24]. It has been widely used in transportation and construction safety research to assess drone-induced distractions on drivers and workers.

In the transportation domain, Barlow et al. employed a VR-based driving simulator to investigate the impact of drone flights near roadways on participants' visual attention and their potential contribution to distraction [25]. Their findings led to the recommendation of a policy requiring drone operations to maintain a minimum distance of 25 feet from the edge of a lane. Similarly, the Oregon Department of Transportation utilized a VR simulator to conduct a randomized factorial experiment evaluating the effects of three independent variables—lateral offset, flight path, and lane use—on driver distraction caused by drone operations near roadways. The study revealed that the frequency and duration of glances at drones increased when drones were positioned closer to the roadway, with unsafe glances exceeding 2 seconds observed at lateral offsets of 0 feet, 25 feet, and 50 feet [26]. In another study, Ryan et al. employed a driving simulator featuring an actual driver's seat within a real vehicle and a screen positioned in front of the driver. Their findings indicated that drivers were distracted by drones, with critically long glances observed in 11% of cases [27]. These studies collectively demonstrated that VR and simulator-based approaches are effective tools for examining drone-induced distractions in driver participants. They used monitors to display the virtual environments for the drivers.

In the construction domain, the researchers adopted VR headsets to facilitate human-subject experiments and training. VR headsets allow construction worker participants to engage deeply with virtual construction environments, creating a highly immersive setting for studying distraction effects. Jeelani and Gheisari utilized virtual reality to simulate a construction site for conducting experiments aimed at evaluating the impact of drone presence on workers' attention and stress levels. The findings indicated that unmanned aerial vehicles (UAVs) could distract workers, especially when operating at distances of 12 feet and 25 feet. However, the drones did not have a significant effect on workers' emotional or psychological distress [28]. Albeaino et al. employed virtual reality to create a simulated construction site, enabling the evaluation of the attentional impact of drones on construction professionals at varying distances. The study revealed that drones positioned at greater distances resulted in more frequent and prolonged visual fixations on drones, emphasizing their potential to distract workers and providing insights into safer operational distances for drone use on construction sites [29].

Most of the existing studies focused on how the presence of drones diverts participants' visual attention from their primary tasks. However, they did not explore how this diversion of attention affects participants' ability to recognize and identify hazards.

2.4 Experimental Design for Drone-Induced Distraction

To study the human's visual attention to drone-induced distraction, the approaches of human study experiments from previous studies can be divided into two categories. First, some studies adopted between-subject design [2], [12], [29]. A between-subjects design is a research method in which different groups of participants are exposed to distinct experimental conditions, allowing comparisons to be made between groups without the influence of repeated exposure [30]. Second, other studies adopted within-subject design [25], [26], [27]. A within-subjects design, also known as a repeated-measures design, is a research method in which the same participants are exposed to all experimental conditions, allowing researchers to compare their responses across different treatments while controlling for individual variability.

The studies collected the participants' fixation time and/or count to analyze their visual attention during distractions. Studies using a within-subject design exposed participants to the same set of conditions, which may cause sequence effects, where the order of exposure impacts the outcomes. Thus, usually, participants will experience the same set of conditions but with different sequences. The design helps the researchers to investigate if there is any sequence effect. Some of the studies fit the variables for evaluation into and linear mix model to check if the sequence effect is significant or not. Then, the variables are further analyzed by analysis of variance (ANOVA) to determine the significance of variables across different conditions.

3 Problem Statement, Objective, and Research Question

Existing studies emphasized the potential hazards posed by drone-induced distractions for construction workers. Although they have investigated several aspects of drone-related distraction, a systematic examination of the influence of specific drone flight configurations on workers' situational awareness remains unexplored. Thus, this study aims to analyze workers' visual attention to hazards in response to drones operating at varying heights and directions. The research question of this research is: "How is the amount of distraction related to drone flying height and direction?"

4 Experiment Design and Implementation

4.1 Procedure

Figure 1. A participant performing material handling tasks in a virtual construction environment using a VR headset and omni-directional treadmill.

In the beginning, participants were provided with an IRB-approved consent form, which they were required to read and sign before participation. The consent form detailed the purpose of the study, emphasizing its focus on drone safety in construction site environments. As shown in Figure 1, participants were equipped with a VR headset (Meta Quest Pro) and positioned on an omni-directional treadmill (ODT) (KAT Walk C2+). The VR headset facilitated full immersion in virtual construction environments developed using Unity. The virtual environments provide a realistic and immersive experience by incorporating real background construction noises and drone flying sounds. Using Unity further enhances this realism by enabling spatially accurate drone sounds, allowing participants to hear the drone's flying noise in stereo based on its distance and location. The ODT enabled participants to navigate the virtual environments by physically walking, replicating the physical demands of real-world construction tasks. After a 5-minute training process, the participants then move on to the official experiment scenes.

For our experiment settings, they included three independent variables, namely, drone presence (Yes and No), height of drone (16, 48, and 82 ft.), and direction of drone (Back and Front). Three heights of drones were chosen since they are the working heights of the drones for visual inspections [31]. By these three independent variables, there were a total of six combinations of drone height and direction, along with a seventh condition where no drone was present.

For our experiment design, a repeated measures design was adopted to minimize variability across participants and enhance the reliability of the findings [32]. Thus, each participant was exposed to all seven scenes in a randomized order to minimize learning effects and bias. To be more specific, participants were randomly divided into seven groups. The participants in different groups experienced different sequences of scenes. The design of the sequence in each group follows a Latin Square design [33], which ensured an approximate balance in the sequence of scene presentations.

In each scene, participants were tasked with carrying a 16.5" x 12" x 14" box along a designated route from a starting location to an endpoint twice. During the task, a virtual drone (DJI Mavic 3 Pro) appeared randomly in one of the two trials. The selections of drone type and required task are made in consultation with Mortenson, a construction company, to ensure the relevance of construction practice. Figure 2 illustrates a virtual construction scene, where the participant's route is depicted by the yellow lines (dashed and solid). To ensure the drone appears from either the front or behind the participant, each virtual construction site included a straight segment of the route, represented by the solid yellow line. The drone's flight path is marked by the red dashed line.

Figure 2. A sample of the virtual construction site

4.2 Data Collection, Processing, and Analysis

This study aims to investigate the situation awareness of workers through their visual attention to hazards. Thus, eye gaze fixation time and count on danger areas were chosen as our dependent variable for analysis. The danger areas included openings and edges and the fences around them in the virtual environment.

During the experiment, the participants' gaze points were collected by VR headset with a frequency of 100 Hz. The raw data consisted of gaze points recorded sequentially over time, resulting in a total of 57,600 data points. For each scene, fixation time and count were computed by summing the fixation events occurring within predefined danger areas. This approach enabled the determination of the total fixation time and count on danger areas for each scene.

To analyze the effects of different drone flying configurations on participants' fixation time and count, a repeated measures linear mixed model was applied. Due to the occurrence of zero fixation times and counts, the model was applied to the natural logarithm of fixation time plus one (*ln*(TP1)) and fixation count plus one (*ln*(CP1)) to enhance the normality of residuals. TP1 denotes "time plus one," while CP1 represents "count plus one." The model included six variables, with participant variability treated as a random effect. Fixed effects included the sequence of scenarios experienced, drone flight configurations, their interaction, and a constant term. A Type III ANOVA was used to evaluate the statistical significance of each fixed effect, particularly the influence of drone flight factors. Results were considered statistically significant if the p-value was less than 0.05. All analyses were performed using the lme4 and lmerTest packages in R [34], [35].

5 Preliminary Results and Discussion

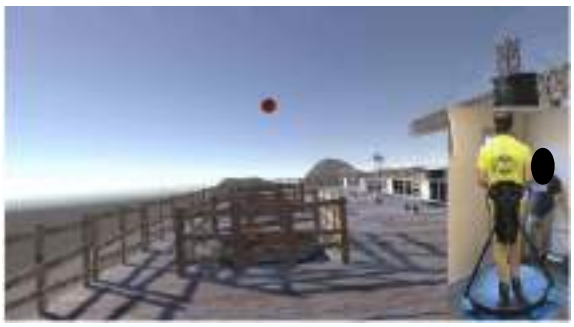

Figure 3. A sample of a construction worker doing our experiment using a VR headset and an ODT.

So far, a total of 17 test participants (12 males and 5 females) were invited, including construction interns, professionals, managers, and workers. Figure 3 illustrates the first-person perspective of a construction worker, represented as our test participant, performing a material handling task within a virtual construction environment. The red dot in the figure indicates the participant's eye gaze point.

From the preliminary results, there were three findings. First, Figure 4 shows the participants' 95 percent confidence intervals for fixation time on danger areas in all 7 different scenes. In the horizontal axis, "F" means the drone flying from the participants' front, and "B" means the drone flying from their back. The number after the latter means the drone flying heights in feet. Since the fixation time in no drone scene is significantly higher than in all the other scenes, drones reduced participants' fixation time on danger areas. Second, Figure 5 compares the participants' 95 percent confidence intervals for fixation time on danger areas in different drone flying heights. The fixation time on danger areas of a drone flying at 82 feet is much higher than a drone flying at 16 feet. Drones flying at lower heights (16 feet) significantly reduced fixation time on danger areas. Figure 6 shows the comparison of the 95 percent confidence intervals for fixation time on the sky in different drone flying directions. The presence of drones approaching from the front results in a significant increase in fixation time on the sky. Overall, the findings suggest that participants experienced greater distraction when the drone approached from the front below 48 feet.

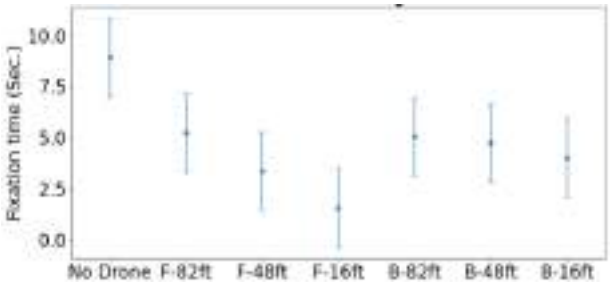

Figure 4. Fixation time on danger areas in different scenes.

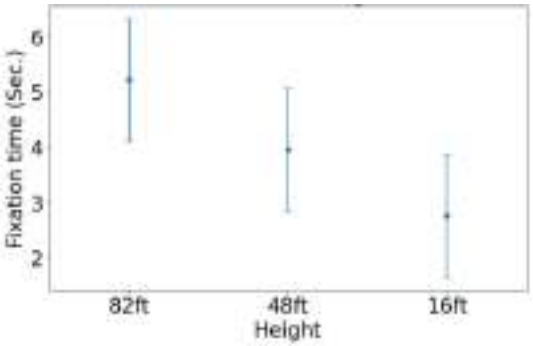

Figure 5. Fixation time on danger areas in different flying heights.

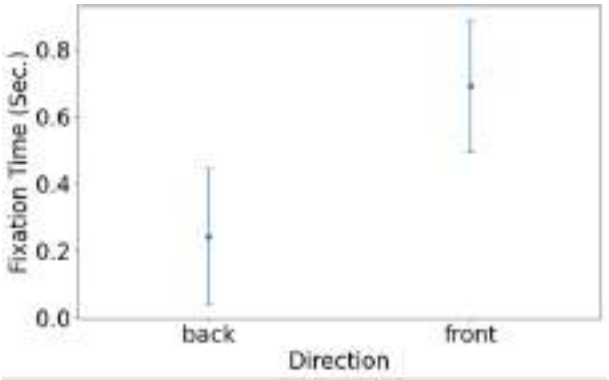

Figure 6. Fixation time on the sky in different flying directions.

6 Discussion

The findings of this study contributed to understanding the influence of drone flight height and direction on the visual attention of construction workers. Specifically, our results indicated that participants experienced greater distraction when drones approached from the front, particularly at lower altitudes (16 ft and 48 ft). These findings aligned with prior research demonstrating that drone interventions can disrupt workers' visual focus, while also extending the literature by examining how specific drone conditions modulate the degree of distraction.

When drones approached at heights of 16 feet and 48 feet, the participants' fixation time on danger areas significantly decreased, potentially impairing their ability to maintain attention on hazardous zones. This has critical implications for construction site safety, as diminished focus on danger areas increases the risk of accidents such as slips, falls, and trips. Furthermore, post-experiment interviews revealed that half of the participants reported feeling distracted by the presence of drones, reinforcing the need to address drone-related safety concerns in dynamic construction environments.

Despite these important contributions, this study has few limitations. First, the experiment only used a single type of virtual drone in the experiment. Drones differ in attributes such as sound, size, and intended purpose, all of which could influence distraction levels. For instance, larger drones with louder noise might induce greater distraction compared to smaller, quieter drones. Future research should investigate the effects of various drone types to assess their specific contributions to worker distraction.

Second, the study focused on a material handling task. However, construction work encompasses a wide range of activities, such as operating vehicles or heavy machinery, where the consequences of drone-induced distractions may vary. For example, the impact of distractions on excavator operators or truck drivers may differ significantly from their effects on workers performing material handling tasks. Future studies should explore a broader array of construction tasks to provide a more comprehensive understanding of how drone interventions affect worker safety across diverse job roles.

Third, to maintain experimental control and isolate the effects of drone distractions, we designed the virtual environment with a simplified construction setting. A more complex and dynamic environment could introduce additional variables, such as moving equipment or other workers, which may confound the results. By minimizing unnecessary distractions, we ensured that participants' visual attention responses were primarily influenced by drone presence rather than other environmental factors. However, real construction sites might be more complex, and future studies should incorporate more realistic elements to enhance the ecological validity of the findings.

7 Conclusion

This study provided valuable insights into how drone flight configurations affect construction workers' visual attention, particularly their focus on hazard areas. Using a VR-based experiment, the research showed that drones significantly distract workers, especially when flying at lower heights (16 ft and 48 ft) or approaching from the front. These conditions reduced fixation times on danger areas, impairing hazard recognition and increasing accident risks. The results underscores the need for carefully planned drone operations and defined safety parameters in construction environments.

Despite its contributions, this study has several limitations that highlight opportunities for future research. The experiment utilized a single type of virtual drone and focused solely on material handling tasks, limiting the generalizability of the findings to other drone models and construction activities. Additionally, to isolate the effects of drone distraction under different flight configurations, the virtual environment was intentionally simplified, excluding other potential distractions such as moving machinery and additional workers. Future studies should examine how different drone attributes impact workers across various construction tasks within more complex and dynamic site conditions to enhance the applicability of the findings.

The findings highlight the need for safety protocols to mitigate drone-induced distractions, such as restricting drone altitude, flight paths, and directions, especially in high-risk areas. While workers may adapt to drones over time, new or inexperienced workers may still face distraction risks from drone. These insights can inform training programs that expose workers to drone distractions before they start to work on a real

construction site. Which can help them adapt in advance and reduce the risk of safety incidents from unexpected attention shifts.

8 Data Statement

All data collected from our test participants during the study are proprietary or confidential in nature and may only be provided with restrictions. Specifically, the de-identified data can only be requested by the National Institute for Occupational Safety and Health, UW-Madison regulatory and research oversight boards and offices. Some or all code generated or used during the study are available from the corresponding author by request.

9 Acknowledgments

This research was supported by the National Institute for Occupational Safety and Health (NIOSH), and the authors would like to express their gratitude for NIOSH's valuable contribution. The research was also supported by projects 1R21OH012455-01A1 and 5R21OH012455-02. The findings and conclusions presented in this paper are solely those of the authors and do not necessarily reflect the views of NIOSH. The authors are also grateful to M. A. Mortenson Company and their workers for participating in our experiment. Any mention of specific companies or products is for informational purposes only and does not imply endorsement by NIOSH, Mortenson, or the authors.

Abstract –

Drones have become indispensable in construction projects, performing tasks such as site surveying, 3D mapping, progress monitoring, and inspecting hazardous or hard-to-reach areas. Their integration has significantly enhanced efficiency, precision, and safety. However, effective human-drone interaction remains challenging due to the complexity of construction environments and the necessity for precise drone control, which requires workers to undergo extensive training. Traditional training programs primarily focus on task-specific skills, often neglecting the influence of workers' cognitive and physiological states on learning effectiveness and performance. This oversight can lead to increased cognitive fatigue, reduced learning outcomes, and heightened safety risks. To address these limitations, this study introduces a Virtual Reality (VR)-based adaptive training platform designed to optimize worker-drone interactions by monitoring cognitive load through physiological indicators such as heart rate and skin conductance. Utilizing a Long Short-Term Memory (LSTM) model, the platform accurately predicts cognitive load in real time and dynamically adjusts the training pace to align with individual cognitive states. In experimental evaluations, the adaptive training platform achieved a cognitive load prediction accuracy of 92% and reduced task completion time by 69.9%, outperforming non-adaptive training methods by 27.6% in worker-drone interaction scenarios. By personalizing the training experience based on real-time cognitive assessments, the platform enhances worker preparedness, promoting safer and more efficient drone operations on construction sites. This research underscores the critical role of integrating physiological data into adaptive training systems to meet the multifaceted demands of modern construction environments.

Virtual Reality; Human-Drone Interaction; Physiological signals; Adaptive training

1 Introduction

Drones, or unmanned aerial vehicles (UAVs), have revolutionized the construction industry by performing a wide array of tasks such as site surveying, 3D mapping, progress monitoring, and inspecting hazardous or hard-to-reach areas. Equipped with advanced sensors and high-resolution cameras, drones provide precise data collection from multiple angles, offering invaluable insights into onsite conditions [1]. Their versatility and adaptability to diverse environments have led to widespread adoption, transforming project management and execution into more efficient and innovative processes [2]. Studies indicate that incorporating drones into construction workflows can boost productivity by up to 94.48%, accelerate operations by 35.41%, and reduce costs by as much as 78% compared to traditional methods [3]. These improvements underscore the significant role drones play in enhancing efficiency, precision, and safety on construction sites [4].

Despite advancements in drone automation, effective deployment in construction settings still necessitates substantial human oversight. Construction sites are inherently dynamic and unpredictable, with constantly changing conditions such as weather variations, movement of workers and equipment, and shifting project requirements. While drones can autonomously execute predefined tasks, they often lack the flexibility to adapt to real-time, unforeseen changes. Complex operations like navigating confined spaces or conducting detailed inspections demand precise, context-specific control that only skilled human operators can provide [5]. This active human-drone interaction ensures that drone operations align with project objectives and adapt to the specific needs of the construction site.

The complexity of drone operation, encompassing both hardware and software components, requires operators to possess a robust foundation of theoretical knowledge and practical skills [6]. Moreover, the unpredictable nature of construction environments necessitates that drone operators are highly adaptable and capable of making swift, informed decisions to

effectively address real-time challenges [7]. Consequently, comprehensive training programs are essential to prepare workers for the multifaceted demands of drone operation in construction settings. These programs aim to equip workers with the ability to operate drones safely and effectively under a variety of real-world conditions by training them to process large volumes of situational and operational information, make complex decisions, and maintain sustained concentration.

However, such intensive training requirements can significantly increase the cognitive demands on workers [8]. Cognitive load, defined as the mental effort required to process information and perform tasks, is influenced by both task complexity and individual capacity. Excessive cognitive load can impair workers' ability to process information efficiently, perform tasks accurately, and ultimately diminish the overall effectiveness of the learning process [9]. Current training systems for construction workers typically emphasize the development of task-specific skills, such as maneuvering drones or performing specialized construction-related operations [5]. While these systems have proven effective in skill acquisition for specific tasks, they often inadequately address fluctuations in cognitive load, which can significantly impact learning efficiency and task performance.

To address these limitations, this study develops and evaluates a Virtual Reality (VR)-based adaptive training platform designed to enhance worker-drone collaboration in construction environments. The system utilizes real-time physiological data, including heart rate and skin conductance, to predict users' cognitive load and dynamically adjust the complexity and frequency of training tasks accordingly. By monitoring cognitive load through physiological inputs, the platform can tailor the training experience to individual cognitive states, ensuring that workers are neither overwhelmed nor under-challenged during training. The ultimate goal of this research is to enhance worker performance and ensure safer, more efficient human-drone collaboration on construction sites. By leveraging adaptive immersive technologies, the proposed system addresses the challenges posed by dynamic construction environments, equipping workers with the necessary skills and adaptability to effectively integrate drones into modern workflows and meet the demands of increasingly complex construction projects.

2 The Multifunctional Role of Drones in Transforming the Construction Landscape

Drones, or Unmanned Aerial Vehicles (UAVs), are advanced aircraft systems designed to operate without an onboard human pilot. Equipped with advanced sensors, high-definition cameras, and GPS systems, drones can perform a variety of tasks with remarkable precision, such as capturing real-time data, generating accurate 3D models, and conducting remote inspections [10]. These features have established drones as versatile tools across multiple industries. In construction, preliminary studies and practical applications have demonstrated their potential to offer significant improvements in efficiency, precision, and safety compared to traditional methods [11]. For instance, drones are increasingly utilized in site surveys, mapping, progress monitoring, and safety inspections, indicating their growing relevance in addressing the complex demands of modern construction projects [12].

However, the integration of drones into construction workflows presents significant challenges While drones possess autonomous capabilities for executing predefined tasks, the dynamic and unpredictable nature of construction environments poses substantial safety risks. For instance, simulations recorded 773 collisions over 230 runs under autonomous control [13], underscoring the critical need for skilled operators to provide remote supervision and control. Studies have shown that worker operators trained in navigating complex terrain, managing sophisticated drone functionalities, and adapting to evolving site conditions reduce operational errors, significantly improving safety and effectiveness in drone operations [5]. This underscores the critical importance of comprehensive training programs aimed at enhancing worker-drone cooperation. Such training must encompass both theoretical understanding and practical application, emphasizing drone operation in complex and dynamic environments[14].

However, the inherent complexity of these training requirements can lead to fluctuations in cognitive load, which may affect training outcome [15] s. Current training programs for drone operation in construction often prioritize the development of technical skills, such as basic navigation and task-specific maneuvers [16]. While these foundational competencies are essential, such programs frequently place less emphasis on the cognitive challenges that operators face during the training process. Cognitive fluctuations are common when operators process complex information, multitask, and make real-time decisions, which, if unmanaged, may compromise their ability to make decisions and execute tasks effectively [17]. These limitations highlight the necessity for more advanced, adaptive training systems that not only equip operators with technical proficiency but also enhance their capacity to navigate the complexities and cognitive demands of drone operation in dynamic and unpredictable construction environments.

3 Impact of Cognitive Load on Training for Enhanced Drone Operation

Cognitive load, defined as the mental effort required to process information and perform tasks, plays an important role in influencing the efficiency and accuracy of drone operators, particularly within the dynamic and high-stakes environment of construction [19] . High cognitive load refers to a state where the mental demands of a task exceed an individual's capacity to process information effectively, leading to reduced performance and increased likelihood of errors [18]. Drone operators often need to process complex spatial, technical, and safety-related information in real time, which can amplify cognitive demands [6]. In construction settings, operators often navigate intricate and constantly changing sites, execute precise maneuvers, and respond to unforeseen challenges such as equipment malfunctions, changing environmental conditions, or sudden safety hazards [15]. Excessive cognitive load has been observed during drone operations, where it negatively impacts human performance by inducing mental fatigue, impairing situational awareness, and compromising decision-making processes [19]. Mental overload can hinder the operator's ability to process critical information, leading to reduced efficiency, operational delays, and increased risks of accidents or safety violations. As construction projects increasingly rely on drones for tasks such as surveying, monitoring, and inspection, understanding and mitigating cognitive load becomes essential for enhancing overall system performance and safety.

However, despite its importance, existing literature on drone operation training for construction lacks a comprehensive understanding of how cognitive load influences learning outcomes and task performance [4]. Most current training programs overlook the dynamic variations in cognitive load experienced by users during drone interaction training, failing to account for individual differences and task complexity. This generic training methodology risks overloading operators with excessive cognitive demands, potentially reducing training effectiveness, impairing task performance, and increasing the likelihood of operational errors [20]. Such an approach fails to prepare operators for the cognitive demands posed by real-world construction scenarios, where task complexity and situational variability are significant.

To address this gap, there is an urgent need for an adaptive training environment that dynamically adjusts task complexity based on the trainee's cognitive load. By incorporating real-time cognitive load assessment into training frameworks, task difficulty can be tailored to individual capabilities, fostering optimal learning conditions. Adaptive training has the potential to enhance learning retention, improve task performance, and better prepare operators to handle the cognitive challenges of drone operation in construction. Such a system would ensure that trainees are neither overwhelmed nor insufficiently challenged, thus promoting a balanced cognitive load that facilitates skill acquisition and long-term proficiency.

4 Method: Adaptive Human-Drone Training Platform Based on Cognitive Load For Construction Workers

This study designed and implemented an LSTM-driven adaptive training system for drone operation in a VR environment (Figure 1). Physiological signals for cognitive load assessment are processed using a preprocessing pipeline to enhance signal quality and consistency. The pre-processed physiological data is then fed into the LSTM-based adaptive training system for cognitive load prediction. Finally, the adaptive system is integrated into the VR-based training program to provide users with a dynamic and immersive simulated training environment.

4.1 Physiological signals for cognitive load assessment and data preprocessing

To assess cognitive load during training, this study utilizes two widely recognized physiological signals: heart rate variability (HRV) and galvanic skin response (GSR) [15], [21]. HRV, derived from photoplethysmography (PPG) [22], measures the variation in intervals between consecutive heartbeats, with low HRV indicating a potential state of high cognitive load. GSR, obtained from electrodermal activity (EDA), indicates changes in skin conductivity driven by sweat gland activity, with higher GSR values often associated with emotional arousal or stress. These physiological signals are continuously recorded during the training process to provide an objective assessment of the user's cognitive load. The collected data undergoes preprocessing to standardize and smooth the signals, ensuring consistency and reliability. PPG data were filtered using a fourth-order Chebyshev II filter with a passband range of 0.5–5 Hz and a stopband attenuation of 30 dB to minimize motion artifacts while retaining physiologically relevant HRV components. To align sampling frequencies across signals, EDA data were upsampled using linear interpolation to match the PPG data. Subsequently, EDA signals were processed with a third-order Butterworth low-pass filter with a cutoff frequency of 0.5 Hz.

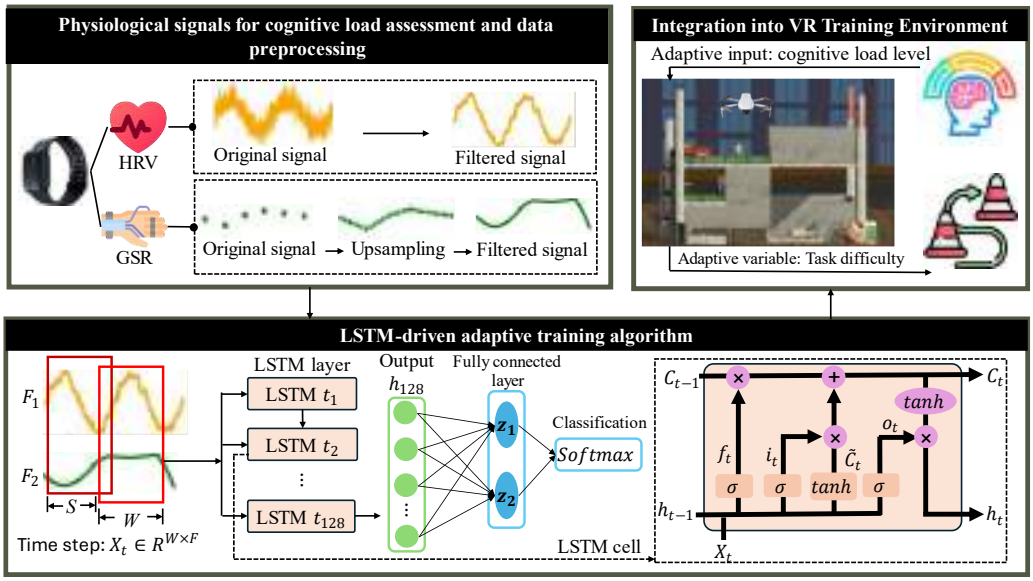

Figure 1. Overview of LSTM-driven adaptive VR training system

4.2 LSTM-driven adaptive training algorithm

The LSTM-driven adaptive training system is designed to dynamically adjust training tasks in real time based on cognitive load predictions. The goal is to maintain users within an optimal cognitive load range, balancing task difficulty and cognitive engagement for effective learning outcomes. The system is underpinned by an LSTM-based cognitive load prediction model, which processes sequential physiological signals to predict cognitive load levels. LSTM networks are particularly suitable for this task due to their ability to capture long-term temporal dependencies while selectively retaining or forgetting information through gating mechanisms.

To train the LSTM model, ground truth cognitive load labels were established by engaging. participants in tasks of systematically increasing complexity. Physiological signals, including HRV derived from PPG and GSR from EDA, were continuously recorded. Ground truth labels were determined using the NASA-TLX, a validated subjective workload assessment tool. Participants rated their perceived workload and aggregated the score into composite scores S_i , normalized as $S_i^{norm} = \frac{S_i - S_{min}}{S_{max} - S_{min}}$, where S_{min} and S_{max} are the dataset's minimum and maximum scores. The normalized scores were discretized into two cognitive load categories, "low" and "high," to serve as the ground truth labels for cognitive load classification.

Pre-processed HRV and GSR data were segmented into 10-second sliding windows with a 3-second update interval for cognitive load monitoring. The data were organized into a feature matrix $X \in R^{W\times F}$, where W is the sequence length and F is the feature dimension. The feature matrix was used as input to the LSTM-driven adaptive algorithm network. The hidden layer followed by the input layer contains 128 units. Each hidden unit processes the input sequence X by maintaining a cell state c_t and producing a hidden state h_t at each time step t. The dynamics of the LSTM are governed by its gating mechanisms, including the input gate i_t, forget gate f_t, output gate o_t, and the candidate cell state $\tilde{c_t}$. These are computed as follows [23]

$$f_t = \sigma\left(W_f[h_{t-1}, x_t] + b_f\right) \quad (1)$$
$$i_t = \sigma(W_i[h_{t-1}, x_t] + b_i) \quad (2)$$
$$o_t = \sigma(W_o[h_{t-1}, x_t] + b_o) \quad (3)$$
$$\tilde{c}_t = \tanh\left(W_c[h_{t-1}, x_t] + b_c\right) \quad (4)$$
$$c_t = f_t \odot c_{t-1} + i_t \odot \tilde{c}_t \quad (5)$$
$$h_t = o_t \odot \tanh\left(c_t\right) \quad (6)$$

where W_f, W_i, W_o, W_c and b_f, b_i, b_o, b_c are the weight matrices and biases for the respective gates, σ represents the sigmoid activation function, $tanh$is the hyperbolic tangent function, and $\odot$ denotes the element-wise multiplication. The final hidden state h_{128}, capturing the temporal dependencies in the input sequence, is passed through a fully connected dense layer where a linear transformation is applied, given by $z = W_z h_{128} + b_z$, where W_z and b_z are the weight matrix and bias for the dense layer, and $z = [z_1, z_2, z_3]$ represents the outputs corresponding to each class. Subsequently, the output z is passed through a softmax activation function to predict the probability distribution over cognitive load levels $\hat{y} = \frac{e^{z_k}}{\sum_{i=1}^{C} e^{z_i}}, k = 1,2,3$, where $\hat{y}$ is the probability distribution over the cognitive load classes, and C corresponds to the number of cognitive load classes.

4.3 Integration into VR Training Environment

A virtual construction environment was developed to simulate realistic and dynamic construction site conditions, providing a platform for users to learn and practice drone operation. The environment was designed to replicate the complexities of high-rise construction sites, incorporating detailed architectural structures such as multi-level buildings, scaffolding, and construction equipment. Dynamic objects, including moving machines such as cranes, excavators, and forklifts, were programmed to operate autonomously, simulating real-time activities. Additionally, virtual workers were included, designed to mimic human movements and interactions within the construction site, creating a realistic sense of activity and unpredictability. To further enhance the fidelity of the environment, Rigidbody components are added to objects and collision detection was incorporated for drone collision error detection. A dual-view setup, featuring both a drone monitor and a drone's first-person view, is provided to enhance situational awareness and support precise navigation.

The LSTM-driven adaptive training system was integrated into the virtual construction environment to adjust task difficulty based on real-time cognitive load predictions. As cognitive load levels fluctuate, the system dynamically modifies elements such as drone flight paths (the number of waypoints n and the distance between waypoints d) and the behaviour of dynamic obstacles (the velocity of dynamic obstacles $v_j(t)$, and their trajectory complexity $r_j(t)$).

When a high cognitive load is detected ($\hat{y} = 3$), the system adjusts to prevent cognitive overload and enhance learning efficiency. Task complexity is reduced by simplifying drone flight paths (reducing n and increasing d), minimizing the number and movement speed of dynamic obstacles $v_j(t)$, and decreasing their trajectory complexity $r_j(t)$. Additionally, the system provides step-by-step guidance or visual cues to assist in task execution. If high cognitive load persists, short rest intervals are introduced to allow cognitive recovery before resuming training. Conversely, when a low cognitive load is detected ($\hat{y} = 1$), the system gradually increases task difficulty to ensure continued engagement and skill development. This is achieved by introducing more intricate drone flight paths (increasing n and decreasing d), introducing Gaussian noise to the velocity of dynamic obstacles ($v_j(t) \sim v_j(t) + N(0, \sigma^2)$), and selecting more complex trajectories $r_j(t)$ that simulate real-world challenges such as wind disturbances. For moderate cognitive load ($\hat{y} = 2$), the system evaluates task completion time (T) as an additional parameter. If $T > T_{threshold}$, task difficulty remains unchanged to allow further adaptation. If $T < T_{threshold}$, task complexity is incrementally increased to maintain an optimal level of challenge without inducing excessive cognitive strain.

5 Case Study: Evaluating the Effectiveness of Cognitive-Based Adaptive VR Training for Construction Worker-Drone Interaction

The experiment was designed to evaluate the effectiveness of the LSTM-driven adaptive training system for drone operation in a VR environment. The virtual environment was developed using Unity and code with Visual Studio with C# and deployed on the SteamVR platform, providing a dynamic and immersive training scenario. Physiological signals including HRV and GSR were measured using the Empatica E4 wristband. An IRB-approved study was conducted, with all participants providing informed consent before data collection. 20 Participants were divided into two groups: one group trained with the adaptive system, while the other followed a non-adaptive VR training protocol for comparison. Each participant underwent multiple training sessions consisting of tasks with systematically varying levels of difficulty. For the adaptive training group (ATG), the task difficulty was dynamically adjusted in real time based on cognitive load predictions generated by the LSTM model. In contrast, the non-adaptive training group (NATG) followed a fixed sequence of tasks with predetermined difficulty levels. During the training sessions, physiological signals, including HRV and GSR of ATG, were continuously recorded to monitor cognitive load. The adaptive system used these signals to adjust task parameters dynamically, aiming to maintain participants within an optimal cognitive load range.

Performance metrics were evaluated using both cognitive load prediction accuracy and task performance indicators. To assess the accuracy of the LSTM-based cognitive load prediction model, an initial validation study was conducted in which participants completed a series of training sessions with progressively increasing difficulty levels. After each session, participants provided self-reported ratings of their perceived cognitive load using the NASA Task Load Index (NASA-TLX), a widely recognized tool for workload assessment. These self-assessments provided a baseline for comparing the model's predictions.

To evaluate the effectiveness of the adaptive training system, pre- and post-training assessments measured task completion times as an indicator of operational efficiency. Task completion time was chosen as an objective metric to quantify the training's impact and facilitate a comparative analysis between adaptive and standard training methodologies. By integrating cognitive load prediction accuracy with performance improvements, the

experiment aimed to validate the hypothesis that adaptive training not only enhances learning outcomes but also significantly improves task efficiency.

6 Results

6.1 Accuracy of the LSTM Model

The LSTM-based cognitive load prediction model demonstrated high accuracy in distinguishing between the three cognitive load levels, achieving an overall accuracy of 92%. Key performance metrics, including precision, recall, and F1-score for each class, are summarized in Table 1. It highlights that the model achieved perfect precision, recall, and F1-score for Class 1. Similarly, Class 3 demonstrated strong performance with an F1-score of 0.92. However, the recall for Class 2 was slightly lower at 0.78, indicating minor misclassification challenges for moderate cognitive load levels.

Table 1 Key Metrics for Cognitive Load Prediction

	Class 1	Class 2	Class 3
Precision	1.00	1.00	0.85
Recall	1.00	0.78	1.00
F1-Score	1.00	0.88	0.92

Figure 2 presents a confusion matrix heatmap, where the color intensity corresponds to the recall percentage for each class, normalized by row totals. Darker shades highlight higher recall values, emphasizing areas of strong predictive accuracy, while lighter shades indicate potential misclassifications or areas requiring further evaluation. The cell annotations display the absolute counts of predicted and actual classifications, providing a detailed overview of model performance.

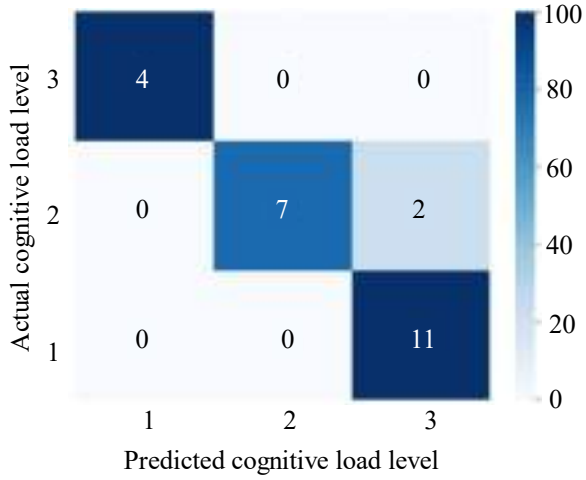

Figure 2. Cognitive Load Prediction Accuracy of LSTM-Based Adaptive Training System

6.2 Task Completion Time

Participants demonstrated significant improvements in task performance following training as Figure 3 shows. In the ATG group, the pre-training task completion time was 266.8 ± 27.5 seconds (mean ± SD), while the post-training time was reduced to 81.6 ± 11.5 seconds. This represents an average reduction of 69.4% in task completion time compared to the pre-training baseline. Similarly, in the NATG group, the pre-training task completion time was 262.1 ± 38.7 seconds, and the post-training time decreased to 110.0 ± 34.0 seconds, reflecting an average reduction of 58%. Furthermore, participants in the ATG group outperformed those in the NATG group, completing tasks 25.8% faster on average during the post-training assessments. These results highlight the effectiveness of the adaptive training system in enhancing task performance and improving operational efficiency by reducing task completion time and maintaining participants within an optimal cognitive load range during training.

7 Conclusion

This research successfully developed a cognitive load-based adaptive training system to enhance drone operation training for construction workers. By leveraging physiological indicators, specifically HRV and GSR, the system effectively monitored user's cognitive load and dynamically adjusted training complexity through a LSTM neural network. The adaptive training system significantly outperformed traditional non-adaptive training methods, with participants using the adaptive system completing tasks 69.9% faster compared to their pre-training performance, while the non-adaptive group saw a 58.1% reduction in

task completion time. Additionally, the LSTM-based cognitive load prediction model achieved an impressive 92% accuracy, demonstrating its reliability in assessing cognitive states.

The system's ability to adjust training complexity in real-time ensured that trainees were neither overwhelmed nor under-stimulated, leading to a more engaging and efficient learning experience that fostered better skill acquisition. Additionally, this dynamic approach inherently exposes trainees to varying levels of cognitive demands, helping them develop the ability to operate under pressure and adapt to unpredictable conditions. By adjusting task complexity and introducing real-time environmental variability, the training framework fosters resilience and stress management skills, better preparing workers for real-world drone operations. This personalized approach mitigates cognitive fatigue and improves overall task performance, contributing to more effective human-drone collaboration.

This study has certain limitations that present opportunities for future research. The current cognitive load assessment relies solely on HRV and GSR, which may not fully capture all aspects of cognitive strain. Future research will integrate additional physiological indicators, such as electroencephalography (EEG) and eye-tracking data, to enhance prediction accuracy and system adaptability. Additionally, while the LSTM-based model demonstrated strong predictive accuracy, its reliance on sequential dependencies may introduce latency in responding to sudden cognitive state changes, potentially compromising the real-time adaptability of the training system. Future research exploring hybrid architectures, such as integrating LSTM with attention mechanisms, could mitigate these challenges by enhancing responsiveness and robustness in highly dynamic construction training environments.

By integrating real-time physiological monitoring with adaptive learning algorithms, this study addresses critical gaps in existing training methodologies for drone operation in construction. The proposed system not only improves task performance and operational efficiency but also ensures that training is tailored to the cognitive capacities of individual workers. These advancements pave the way for more resilient and effective human-drone collaborations, ultimately contributing to safer and more productive construction practices.

Abstract -

This research explores an innovative AI-driven approach to optimizing construction processes with a focus on human-centered design, addressing key challenges in the construction industry, such as skilled labor shortages and ergonomic risks associated with work-related musculoskeletal disorders. By integrating process design with AI-based algorithms into simulation tools, various construction process layout variants including robot-assisted scenarios can be simulated and evaluated based on user-specific key performance indicators (e.g., ergonomic score, layouting parameters) to identify optimized solutions. A data processing algorithm automates the process, eliminating the need for manual simulation variations and resulting in increased operational productivity. The AI-based system evaluates and optimizes process layouts by adjusting control parameters. A case study on a brick laying process serves as an exemplary use case, highlighting the necessity and impact of adopting process optimization. The findings emphasize the transformative potential of automated process optimization within simulation environments to rethink existing construction practices, enhance worker well-being, and boost operational productivity.

1 Introduction

The construction industry is a crucial contributor to global economics [1]. However, it faces arising multifaceted challenges such as economic or demographic change, which worsens existing challenges [2]. In addition to inefficiencies and the slow adoption of digitalization and automation, the construction industry confronts an acute and growing shortage of skilled workers. The declining appeal of construction work as a field of employment exacerbates the physical demands on the existing workforce – who are essential to many construction processes – thereby significantly increasing the risk of work-related musculoskeletal disorders (WRMD) [3]. This widely prevalent health issue can result in premature retirement due to health reasons [4], thus aggravating the existing lack of skilled workers. To sustainably utilize human labor, construction processes must be optimized to minimize the risk of medium- and long-term health issues for workers. Hereby, Computer-Aided Process Planning (CAPP) offers a methodical option, combining a digital twin of the process containing the working tasks, which enables a realistic simulation [5]. The subsequent analysis of the simulated process gains insight to various predefined criteria. Advanced process simulations using the CAPP methodology can identify risks such as musculoskeletal disorders and serve as a foundation for human-centric optimization of construction processes. Human-centric optimized processes may represent a crucial element in addressing the aforementioned increasing shortage of skilled workers. This optimization efforts through simulation currently rely on manually iterations due to insufficient innovative approaches. Thus, each simulative change is implemented and evaluated individually, which involves a high time expenditure and complexity.

In addition to the human factors, a multitude of challenges exist in manual construction processes that can be described parametrically and, depending on the software solution, optimized in a suitable digital environment. With this premise, the number of practicable variants remains limited due to the manual processing of such simulations, which in many cases leads to suboptimal solutions and requires an innovative solution.

2 State of the Art

Process simulation is a digital tool currently implemented in various fields, such as the automotive industry [6]. This approach allows the digital production and process planning by creation of a digital process twin by the utilization of suitable CAPP software [5]. The ema Work Designer by imk Industrial Intelligence or Tecnomatix by Siemens for instance represent such a CAPP tool

including digital human models. Integrating human actions into the digital process enables the evaluation of process ergonomics based on various criteria that represent the physical load on the worker's body, whether caused by motion alone or by external forces acting on it. In the literature, several well-established evaluation criteria are widely recognized. These ergonomic evaluation criteria, which are particularly relevant in the context of this research, include:

- Ergonomic Assessment Worksheet (EAWS) score: Categorized into three groups, the EAWS score within a range of 0 to 25 represents a process without risk to get affected by WRMDs resulting in musculoskeletal damage. The range of 25 to 50 shows middle risk with recommendation to adapt these processes in a human-centered way, whereas values of more than 50 in EAWS score relate to high risk to suffer from WRMDs and therefore indicate the need for urgent process adaptation. Including the process duration, this commonly used criteria considers the posture combined with external loading [6].
- NIOSH: The NIOSH risk index represents a measure for the risk of adopting WRMDs caused by human lifting activities. This approach considers detailed parameters, such as weight of the object or vertical and horizontal location of object and target [7].
- RULA/REBA: The Rapid Upper Limb Assessment (RULA) and Rapid Entire Body Assessment (REBA) scores indicate the risk of getting affected by WRMDs analyzing body and segment angles, and repetitions of movements. RULA and REBA are based on assessment worksheets calculating an index considering single body part postures in addition to loading on the body resulting in a score from 1 (acceptable risk) to 7 in RULA respective 11 and more in REBA (high risk) [8]. In contrast to EAWS, RULA/REBA do not consider body postures and their duration [9].

As the topic of human-centered work process in construction is gaining relevance [10, 11], Kulkani and Devalkar investigated the ergonomic influence on construction workers in various construction tasks (granite cutting, brick work, shuttering, plastering and material transportation) by applying the RULA and REBA index [8]. Resulting in evaluation scores of 6 and 7 in RULA as well as 11 and more in REBA, the investigated construction processes indicate a high risk of the worker adopting WRMDs.

Schmailzl et al. proposed in prior work a framework for decision making regarding the degree of automation of an exemplary brick laying process [12]. To represent a process reproduction as close to reality as possible, motion capturing was used to record the construction worker's movements. Therefore, this approach evaluates the captured brick laying process regarding ergonomics of the worker incorporating the EAWS score as well as task duration within various initial layouts as well as the influence of integration of a robot as assistive technology. The results, showing an EAWS score of up to 154, clearly highlight the need to optimize certain construction processes with a focus on the human worker.

In contrary to standardized production lines, construction sites are characterized by dynamic changing conditions. However, recurring and standardized subprocesses, such as bricklaying, enable the implementation of CAPP software. Currently, even when these types of processes are planned and optimized, they are still manually developed and adjusted by layout designers. A comprehensive parametric design of layouts offers considerable advantages, as changes can be implemented quickly and effectively. Both in production factories and in the construction industry, the ability to make adaptive adjustments is becoming increasingly important, particularly due to the growing demand for customized production and buildings. Despite the great potential of artificial intelligence (AI) and algorithmic approaches in the field of process optimization, there are currently – due to the best knowledge of the authors – a lack of scientific studies that comprehensively address the forementioned process algorithmic approaches combined with ergonomic evaluation scores applied to the construction industry. Parametric design is frequently used in the construction industry, however, mainly in the context of building modelling and less in classical project management. As Abioye et al. showed in their literature review, AI-based optimization seems to be a promising approach for improving processes in the AEC industry [13]. The study by Bergmann shows how parameters simplify the control of an environment and which advantages result from this [14]. The use of generic approaches for optimization can improve the efficiency and performance of production systems significantly. Of particular interest are genetic algorithms (GAs), especially the NSGA-II variant, because they are able to handle numerous parameters and enable multi-objective optimization. Another example from the warehouse sector shows that alternative unconventional layout concepts, such as non-orthogonal shelving arrangements or v-shaped aisle systems, can offer considerable efficiency gains [15]. Investigating different layout options is currently a time-consuming manual task that limits the potential variance of the layout. A tailored algorithm could perform this task in a fraction of the time required by a designer while also identifying irrational but applicable solutions. The use of parametric algorithms in combination with detailed simulations enables the adjustment of critical layout parameters – such as the width of the aisles, the number of racking bays, or the capacities – which optimizes the flow of material and the use of storage space.

Building on the application of AI-driven optimization methods, such as those used in logistics, this research aims to transfer and adapt the concept of automated optimization to the construction industry, focusing on applications where fundamental principles, such as material transportation and storage, are analogous to those in other sectors.

Derivated from, i.a., the findings of Schmailzl et al. [12], this research aims for and proposes a concept for automated generation of process simulation variants, their evaluation as well as AI-based optimization in the field of construction in order to exceed a limited number of simulation cycles as in manual simulation. Additionally, the approach has the potential to reduce the risk of workers developing WRMDs, thereby promoting a more sustainable and attractive utilization of the workforce in the construction industry.

3 Methodology

Given the challenges faced by the construction industry, particularly the high health risks associated with construction work [3] and the limited adoption of digitalization, this research proposes a methodological approach for automated software pipeline encompassing an AI-driven optimization of construction processes with a focus on human-centered design. This section elaborates the concept of parametric process generation, the automation of simulation & evaluation and AI-based optimization.

The presented concept illustrates the intended functionality of a fully automated optimization loop; at this stage, intermediate manual data transfer steps are necessary due to current software capabilities regarding API connectivity, which currently restricts execution to a limited number of optimization cycles. Potential solutions to enable complete automation are discussed further in Section 5.

3.1 Concept

Figure 1 illustrates the proposed methodology. Taking a holistic perspective on construction processes, it presents a workflow comparison between traditional process optimization methods and the enhanced efficiency achievable through AI-based algorithms. With the ongoing digitalization of the construction sector, simulating models and components using advanced software has become a standard practice to optimize building designs prior to physical implementation. This approach extends to factory layout planning, where efficiency improvements are achieved through detailed simulations.

The concept shown in Figure 1 outlines how specific construction tasks, such as bricklaying or concrete pouring, can be integrated into CAPP software. The initial step involves the digital, parametric representation of tasks, incorporating parameters such as object positions and material information. This parametric control can be controlled by a software pipeline and enables a systematic as well as adaptable process. Process layout designers typically create an initial setup based on their expertise, but this manual approach often relies on subjective judgment. Analyzing key performance indicators (KPIs), such as ergonomic factors, material flow efficiency, or pathway criteria, offers a preliminary evaluation of the process. Without a defined baseline incorporating KPIs, comparative assessments regarding the process quality remain limited. The optimization loop in Figure 1 demonstrates two distinct approaches. The dashed line (1) illustrates the traditional method, which is characterized by the manual adjustment of parameters followed by manual repetition of simulations and the comparison of outcomes. Due to the time-intensive nature of this simulation scenario, this restricts the exploration of possible variants. Conversely, the second approach leverages AI-driven algorithms, which autonomously modify parameters and executes numerous simulations. The results are stored systematically and analyzed in relation to the chosen parameters.

By selecting appropriate algorithms, the optimization process achieves superior KPIs and significantly reduces manual work for achieving an optimized solution. AI-based methods are characterized by the recognition of correlations between parameter adjustments and their effects on the results, thus enabling more efficient and precise optimization.

Consequently, this advanced simulation framework provides a robust foundation for optimizing construction sites, enhancing process quality, and improving conditions based on specific KPIs and therefore serves as a basis to prevent the risk of getting affected by WRMDs delineating an approach to reduce the immense lack of skilled workers.

3.2 Structure of the parametric layout

To enable a layout to be fully controlled through parameters, an external structure must first be established that allows such control. This requires assigning unique parameter names to all values within the system, ensuring clear identification and reference. With this parametric structure in place, the entire layout can be adjusted flexibly by simply entering specific values. Moreover, the parametric system should allow the selection of different objects to enhance the realism of the scenario. The selection of specific process components was investigated in prior work [12]. Based on these outcomes, boolean operators must be incorporated to select the desired objects, with all objects existing in parallel within the system to maintain consistent parametric relations.

In case of manual adjustments, these are performed directly within the software and can be tailored to specific needs, offering flexibility, but often at the cost of time and

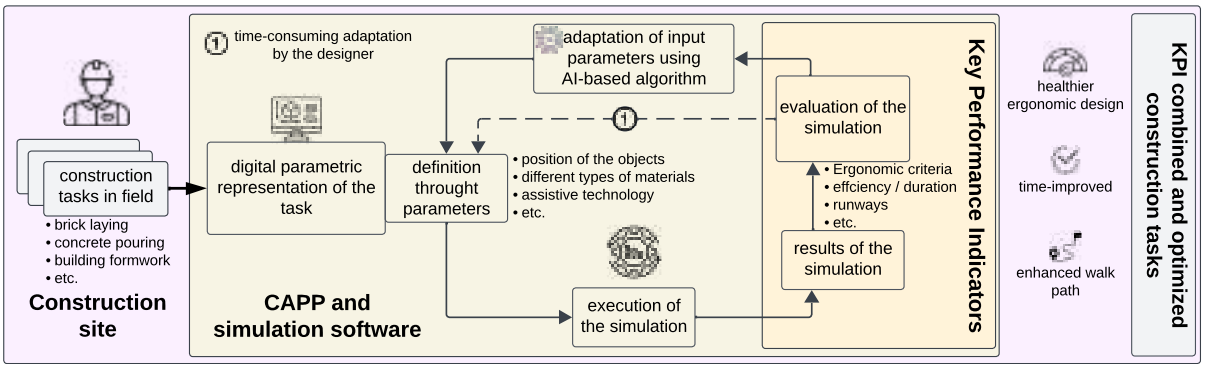

Figure 1. AI-based process optimization method: Is applied to construction tasks (left) optimized by predefined KPIs (right). The green CAPP box represents the automation of the manual workflow, with AI adapting parameters to generate and process multiple variants.

efficiency. To integrate algorithms into this process, an import and export interface for the parameters is essential.

Depending on the software, it may be necessary to export the entire setup or model and reimport it after structural modifications. More advanced software solutions allow the export of parameters alone, which can then be modified and reimported. This leaner approach significantly reduces time intense computational processes and enhances workflow efficiency.

Hereby, a well-developed API interface enables effective collaboration with algorithms and supports streamlined and time-efficient adjustments of parametric structures. Even rudimentary APIs often provide basic import and export functionalities, which are sufficient to implement algorithms into the workflow.

3.3 Validation of the simulation results

The validation is a critical step in process design, it gives value feedback to the planner to improve the setup. For every process, specific KPIs must be defined to serve as measurable benchmarks for future optimization. Efficiency remains a fundamental KPI, often including metrics such as cycle time, resource consumption, and material pathways. In manufacturing, this KPI play a central role in reducing costs and improving production rates. The ergonomic score is meanwhile gaining importance and is increasingly used, especially in manufacturing processes. In Germany, the Load Handling Ordinance requires risk assessments but does not consider details like weight limits or biomechanical impacts on the human [16]. In practice, a 25 kg limit is often used for manual lifting, but factors like carrying distance can greatly affect the biomechanical evaluations. In general, planners must evaluate trade-offs between competing KPIs, as optimizing one parameter may impact other parameters. Storing and documenting process results is essential for thorough validation. This includes capturing input parameters, such as material specifications or positions, alongside output metrics as discussed. Such data build the basis for advanced AI-driven optimization techniques. By analyzing data, AI algorithms can identify patterns and make targeted adjustments, leading to more efficient and streamlined processes.

3.4 Optimization of the results using AI

Optimization tasks require a careful selection of algorithms, each offering distinct advantages depending on the problem and context. For instance, gradient-based algorithms rapidly converge to a single optimal solution by iteratively improving from an initial guess, ideal for clearly defined, differentiable goals. However, for complex problems with conflicting objectives, genetic algorithms (GAs) are particularly effective in finding optimizations due to their inherent capability to manage multiple trade-offs simultaneously. The NSGA-II algorithm applied by Bergmann is a recognized method for multi-objective optimization [14], explicitly chosen in this study for its robust handling of multiple interdependent KPIs and its ability to maintain diverse, balanced solutions.

The NSGA-II algorithm refines a set of solutions step by step using evolutionary principles. Starting with random solutions, each computation repetition represents different combinations of parameters, resulting in specific outcomes. These outcomes are evaluated based on defined KPIs, such as efficiency or human ergonomics. The results are then ranked into groups, so-called Pareto fronts, with the best, non-dominated solutions placed in the first front. To ensure diversity, the algorithm calculates a crowding distance, spreading solutions evenly across the objective space.

The best solutions from the first front are selected and combined to create new combinations of input parameters by recombination. Additional mutations introduce

small variations of the parametric to explore new possibilities and avoid premature convergence. This process of evaluation, selection, recombination, and mutation recurs iteratively until a predefined stopping condition is met, such as reaching a set number of generations or achieving convergence.

The result is a Pareto front, a collection of high-quality solutions that balance conflicting objectives. Decision-makers can choose the most suitable solution from this set, depending on their specific priorities and constraints. This choice typically requires additional context-specific criteria or weighting of KPIs – such as prioritizing ergonomics over productivity. This makes the NSGA-II especially effective for problems involving multiple competing objectives. Additionally, the NSGA-II qualifies as an AI-based approach due to its use of evolutionary mechanisms and heuristic search strategies. Instead of exhaustively evaluating all possibilities, it focuses on exploring the most promising regions of the solution space efficiently.

Concluding, this flexibility and efficiency make the NSGA-II a highly promising choice for multi-objective optimization problems, especially in dynamic and constrained environments.

4 Application example: Brick laying process

The potential applications for this concept are diverse and can be implemented across various construction processes. In this section, we present a specific use case as an example of how the concept can be applied. As the initial scenario, we use a brick laying process that has been previously performed and analyzed in prior research.

Incorporating digital human models, the software is capable to consider human process behavior for a more realistic process representation. Besides the standard movements as provided by the algorithms of the software, human motion can be integrated from motion capturing. The motion data was recorded via an Inertial Measurement Unit (IMU) based Motion Capturing system as the orange sensor attachments in Figure 2 represent. The process was developed within the emaWD simulation software, a powerful tool capable of modeling complex setups and offering a range of advanced analytical functions. emaWD is widely utilized for factory layout simulations, providing comprehensive feedback to designers across multiple KPIs, including all those relevant and previously discussed in earlier sections. These sensor units combine an accelerometer, magnetometer and gyroscope to determine the human movements [17].

In manufacturing processes, robots often play a significant role. The software enables the integration of a vast selection of robot models, each with diverse functionalities and gripping mechanisms. Moreover, the software allows

customization and restrictions for robots, accommodating specific models that may not be natively included. The ability to incorporate and program these robots within the algorithm significantly broadens the scope of potential solutions, potentially leading to entirely novel configurations with drastically altered KPIs. While simply adding a robot to a process might seem to improve performance, it also introduces additional factors such as flexibility, feasibility, and cost, which must be carefully evaluated. These considerations are critical to ensure that the benefits of robot integration outweigh the associated challenges. Later in this section, the parametric integration of robots into the optimization process will be explored in greater detail. Although the software is not originally designed for construction tasks, designers can creatively adapt it to simulate various building processes, including the one described in

this study.

Besides the application of robotic devices, the earlier study highlights the significant impact of layout changes on key performance indicators (KPIs). In this process, depending on the four manually implemented layout options, the KPIs EAWS score, process duration and walk length were explored. The four layout variants differed as follows:

1. Original process: The original process describes a brick laying process done by a human worker, who transfers bricks from a pallet to a target position.
2. Repositioning of the pallet: Based on the original process, the pallet position was shifted 2 meters to opposite direction of the brick target position (see Figure 4).
3. Adaptation of brick material: Based on the original process, the brick type was changed resulting in a weight reduction from 4.5 kg to 2.8 kg for a same-sized brick.
4. Combined adaptation of brick material and pallet repositioning: This scenario represents both aforementioned repositioning of the pallet and adaptation of brick material.

Figure 4. Repositioning of brick storing pallet in a distance of 2.0 m to the original pallet position, depicted as gray copy.

The outcomes were systematically compared, with KPIs serving as the metrics to evaluate the performance of each variation.

Interestingly, the research revealed that certain irrational layout modifications resulted in better outcomes. All exemplary executed layout configurations were manually designed by planners and executed within the emaWD simulation software. The resulting processes exhibited varying KPI outcomes, highlighting the challenge of identifying the optimal layout. This case study demonstrates the complexity of achieving optimal solutions, even for a straightforward and repetitive process. When additional parameters and variables are introduced, finding layouts that improve all required KPIs simultaneously becomes nearly impossible without systematic optimization. This scenario emphasizes the necessity of integrating the proposed concept into the exemplary brick laying process to address these challenges effectively. The software already supports various export and import formats as essential basis for robust data transfer. An export method is provided by the emaWD Wizard, a data transfer assistant that generates an *xlsx*-file to represent the emaWD setup. This file has the capability to define all tasks, objects, and executing agents – whether human models or robots – completely with coordinate information. For the demonstration of the concept, the brick laying process was exported using the Wizard and described in a structured text format. At this stage, the *xlsx*-file can be accessed via a Python script, allowing extraction, manipulation, and adaptation of all relevant data. In this example, product information such as the weight and dimensions of the bricks was modified within the script and reflected in the *xlsx*-file. As noted earlier, every task and component can be adjusted within the spreadsheet. The algorithm modifies these layout parameters and updates the setup within the *xlsx*-file. Upon importing the updated spreadsheet into the emaWD software, a new simulation is executed. The results, expressed as KPIs, provide immediate feedback to the designer through various representations. These KPI outputs can also be exported in simpler formats, such as *csv*-files, given their reduced complexity compared to the process setup. This exported data is then integrated back into the Python script, supplying the algorithm with essential feedback from the results. The connection between input parameters and KPIs is pivotal, as it forms the foundation of the optimization loop. This single optimization cycle, with changed input parameters, is repeated multiple times to generate a diverse and extensive first dataset with different parametric, enabling the algorithm to identify non-dominated solutions across multiple Pareto fronts.

After the initial round of creating a broad dataset, the algorithm proceeds as outlined in subsection 3.4 selecting the most relevant data to further refine and improve the process. Currently, emaWD does not offer a public API interface, which limits its ability to fully support the intended operation of the optimization loop. The absence of an API interface prevents direct control over the software pipeline, hindering the algorithm's ability to efficiently optimize the parametric configurations and limiting its potential to enhance the parameters in a more effective and automated manner.

5 Discussion

This research explores the implementation of an automated AI-based approach for optimizing construction processes with a focus on the human worker.

The application of proposed research within an exemplary brick laying use case as demonstrated in section 4

Table 1. Overview of the simulation results and KPIs corresponding to the four considered design variants.

Design Variant	EAWS Posture Score	EAWS Load Score	**Sum EAWS Score**	Distance [m]	Duration [s]
1	19.5	140	**159.5**	4.7	47
2	8.5	140	**148.5**	16.5	55
3	37	110.5	**147.5**	4.7	47
4	27	110.5	**137.5**	16.5	50

primarily considers human-related KPIs as a measure to optimize construction processes. In particular, the EAWS score as measure for the worker's ergonomics is utilized in the application example. In general, according to the EAWS scores as depicted in Table 1 it seems that the human experiences lower risk of WRMDs when minimizing the load on the human body, as expected. Furthermore the EAWS increases when reducing the pathway as intuitive assumption would suggest. However, the subcategories load score and posture score of the EAWS cannot be explained by intuitive assumptions. Whereas the material handling score decreases from a value of 140 in the original process to a value of 110.5 in the brick weight reduced process as demonstrated in section 4, the relating posture scores show contradictory behavior. Consequently, the optimal resulting EAWS score can hardly be predicted by intuitive assumption of process design variants. Currently, the emaWD software only allows manual import and export of the KPIs and parametric, creating a bottleneck for efficient algorithm implementation. Integrating an automated AI-based process optimization is likely to enable the finding and application of unconventional and unintuitive parameters in design variants within simulation, which is an essential basis for effective process optimization in general.

The proposed algorithm represents an innovative approach to process optimization, enabling the simultaneous optimization of multiple KPIs. Particularly in optimization scenarios involving human factors alongside efficiency and other metrics, it is essential to identify balanced compromises that address all relevant aspects effectively. However, the effective application of AI-based tools relies on seamless data transfer and access through a robust API that allows algorithms to interface directly with simulation software. Despite the growing capabilities of AI-driven approaches, seemingly suitable simulation tools often lack the necessary API functionalities. This limitation significantly constricts the potential for automating and optimizing processes efficiently. Addressing this gap by developing powerful APIs would unlock new possibilities for improving existing workflows and overcoming current time-induced constraints through leveraging AI-based optimization.

Process simulation tools are already commonly used in various industrial fields, such as the automotive industry [18]. Given their ability to optimize production setups before realization, these simulation tools hold great promise for prefabrication processes within the construction sector. Specifically, the proposed optimization approach is particularly suited to prefabricated building components (e.g., wall elements, modular units) or standardized infrastructure elements (e.g., precast bridge segments, tunnel lining segments), where stable, predictable conditions prevail. Direct implementation on traditional, dynamic construction sites remains challenging due to variability; thus, prefabrication represents the primary and most effective context for applying the proposed simulation-driven optimization method.

This work emphasizes the critical role of the human worker, especially in mitigating issues related to health risks and improving working conditions. By automating process simulations, this approach has the potential to contribute to more efficient and effective human-oriented optimization methods.

While AI-driven optimization offers significant advantages, it also involves trade-offs. Implementation costs – such as computational resources and robotics integration – must be weighed against potential efficiency gains. Additionally, selecting appropriate hyperparameters is essential, as improper tuning can compromise algorithm stability and the quality of optimization results.

6 Conclusion

This research highlights the pressing need for automated, AI-based process optimization in the construction industry, emphasizing the importance of human-centered design. The proposed conceptional holistic approach demonstrates the potential to address critical challenges by identifying and analyzing complex parametric structures, simulating diverse scenarios, and evaluating specific construction tasks to achieve optimized process solutions. The ability of such systems to identify unconventional solutions opens up new possibilities for process improvement, alongside with an increase in simulation efficiency. Crucially, the development of robust APIs is identified as a foundational requirement to fully realize the benefits of this approach. When seamless integration via robust APIs becomes available, the proposed approach has the potential to unlock the full capabilities of AI-based optimization, driving a more efficient, adaptive, and sustainable construction sector while significantly improving human factors and fostering safer and more worker-centric con-

struction processes.

Abstract

The adoption of active exoskeleton systems in the construction industry shows potential for reducing work-related musculoskeletal disorders (WMSDs) by providing physical support to workers during labor-intensive tasks. However, concerns about the potential impact of exoskeletons on workers' vigilance and attention to hazards have not been fully explored. This study examines the effect of active exoskeletons on the vigilance levels of construction workers during common construction tasks. A high-fidelity, immersive virtual reality (VR) environment was developed to realistically simulate material handling tasks and collect eye-tracking data. Eighteen participants completed tasks under two conditions: with and without the use of an active back-support exoskeleton. Eye-tracking metrics, including fixation count and fixation duration on predefined Areas of Interest (AOI) of hazards in the simulated environment, were collected from the participants and analyzed to assess vigilance levels. The results showed no statistically significant difference in vigilance levels between participants, regardless of whether they used the exoskeleton. These findings suggest that the use of active exoskeletons does not negatively affect workers' vigilance or their ability to identify hazards. This study provides an empirical basis for supporting the wider adoption of active exoskeletons on construction sites.

Keywords –

Active Exoskeleton; Vigilance; Psychological Assessment; WMSDs

1 Introduction

The construction industry often requires workers to engage in repetitive, physically demanding tasks while maintaining uncomfortable postures for extended periods [1,2]. This biomechanical stress on the musculoskeletal system increases the likelihood of developing Work-Related Musculoskeletal Disorders (WMSDs) [3,4]. Data from the U.S. Bureau of Labor and Statistics reveals that WMSDs constitute approximately 37% of non-fatal injuries and illnesses among construction workers [5]. Furthermore, studies indicate that the construction industry faces annual workers' compensation costs exceeding $400 million due to WMSDs [6].

Prominent safety organizations like NIOSH and OSHA have advocated proper ergonomic practices to reduce WMSDs in construction [7]. However, the industry continues to be characterized by physically demanding tasks involving repetitive movements and awkward postures. The primary challenge stems from the dynamic and diverse nature of construction work, which resists the application of standardized ergonomic practices across all tasks and sites.

Exoskeletons, also known as wearable robotic systems, are gaining recognition as vital tools in the construction industry for mitigating WMSD risks. These devices are designed to assist workers by providing support during heavy lifting, distributing weight more evenly, and promoting proper posture, thus benefiting various construction tasks. Exoskeletons are generally categorized into two types: active and passive. Active exoskeletons are equipped with actuators, such as electric motors, hydraulics, or pneumatics, which actively amplify the wearer's physical strength [8]. On the other hand, passive exoskeletons do not have actuators; they rely on materials like springs or dampers to store energy from human movement and release it when needed to support the wearer [8]. While passive exoskeletons are often preferred due to their lower cost and ease of use, active exoskeletons offer greater potential for broader adoption in construction due to their capacity to provide more substantial physical assistance. However, as active exoskeletons become more prevalent in construction, new challenges and considerations are likely to arise.

Although powered exoskeletons offer considerable potential to mitigate WMSDs in construction, their

widespread adoption remains hampered by a limited understanding of their broader impacts on workers' psychophysiological state. While much of the current research focuses on understanding the physiological impact of exoskeletons [9–14]—such as muscular fatigue, metabolic cost and ergonomic risks, the psychological dimensions are often overlooked. The current body of knowledge fails to provide a comprehensive understanding of the psychological impacts of exoskeletons which may lead to decreased productivity and safety risks for workers wearing exoskeletons. The deployment of an exoskeleton on a job site may cause additional distractions, negatively impacting their vigilance (situational awareness) [15–18]. Wearing a powered exoskeleton may introduce new distractions for workers, such as the need to adjust the device, manage its operation, or adapt to the altered physical sensation it brings. These distractions can take attention away from the task at hand, reducing vigilance and potentially increasing the likelihood of accidents. For instance, if a worker is overly focused on the functioning of the exoskeleton—such as ensuring it is aligned correctly or adjusting to the support it provides—they may be less attentive to their immediate environment, including hazards or moving equipment. Wearing a powered exoskeleton may introduce new distractions for workers, such as the need to adjust the device, manage its operation, or adapt to the altered physical sensation it brings. These distractions can take attention away from the task at hand, reducing vigilance and potentially increasing the likelihood of accidents [19]. For instance, if a worker is overly focused on the functioning of the exoskeleton—such as ensuring it is aligned correctly or adjusting to the support it provides—they may be less attentive to their immediate environment, including hazards or moving equipment.

To that end, this research aims to investigate how active exoskeleton systems affect the vigilance levels of construction workers during routine tasks. To achieve this, a high-fidelity, immersive virtual reality (VR) environment was created to replicate common construction activities. This simulated environment served as a virtual testbed for gathering eye-tracking data, which was then analyzed to determine the impact of active exoskeleton use on workers' vigilance. The insights gained from this study contribute to understanding the psychological implications of implementing powered exoskeletons on construction sites, particularly regarding how they influence attention and focus during tasks.

2 Vigilance for Worker Safety in Technology-driven Construction Sector

In the construction industry, the integration of emerging technologies such as robotics heightens the need for psychophysiological well-being. Such technologies bring new complexities and learning curves, which can impact workers' psychophysiological well-being [20,21]. Ensuring psychophysiological well-being is essential for the construction workers in adapting to technology-driven workplaces, embracing innovation, and maintaining safe, productive work environment. The introduction of advanced technologies in construction can significantly alter cognitive demands on workers. As construction sites become more technologically advanced, maintaining vigilance about potential hazards is also increasingly and equally important [22]. Workers need to be continuously aware of both safety hazards and new risks introduced by technology. This involves staying vigilant to the operational aspects of technology, understanding its limitation, and being prepared for unexpected scenarios that might arise from technological integration. When safety hazards go unrecognized, workers are prone to engaging in unsafe behaviors, facing unexpected exposure to hazards, and potentially suffering severe injuries. Conversely, identifying safety hazards enables workers to evade such exposures, implement proper safety protocols, and prevent injuries at the workplace. Distracting technology can hinder the performance of construction tasks, impairing workers' ability to detect and address hazards effectively. Such technology not only affects their productivity but also compromises overall safety at the construction site.

3 Impact of Active Exoskeleton on Vigilance Level of Workers

While active exoskeletons in the workplace show great promise, they also introduce a range of new safety and usability concerns, from physical issues to psychological implications. The deployment of an exoskeleton on a job site can inevitably cause additional distractions, negatively impacting their vigilance (situational awareness) [15–18]. The additional sensory inputs from the device, such as vibrations or sounds, can lead to sensory overload, potentially overwhelming a worker's ability to process critical environmental cues. Moreover, the cognitive load required to operate the exoskeleton may divert attention away from the surrounding environment, reducing overall awareness. In addition, there is also a risk of overconfidence and complacency as workers become accustomed to the enhanced physical capabilities provided by exoskeletons. This could lead to a decreased perception of risk and, consequently, reduced vigilance. The altered sense of body awareness (proprioception) caused by exoskeleton use may affect spatial judgment, potentially leading to misjudgments of physical space and increased risk of accidents. Additionally, the pressure to perform with new

technology and anxiety about potential malfunctions can induce stress, further impacting a worker's ability to maintain optimal vigilance levels. Further, active exoskeletons may produce noise that interferes with important auditory cues in the workplace, and some designs might limit peripheral vision, potentially causing workers to miss visual warnings or approaching hazards.

4 Assessment of Active Exoskeletons on Workers' Vigilance Level

This research aims to explore how active exoskeleton systems influence the vigilance levels of construction workers during typical construction activities. Figure 1 outlines a two-phase research methodology.

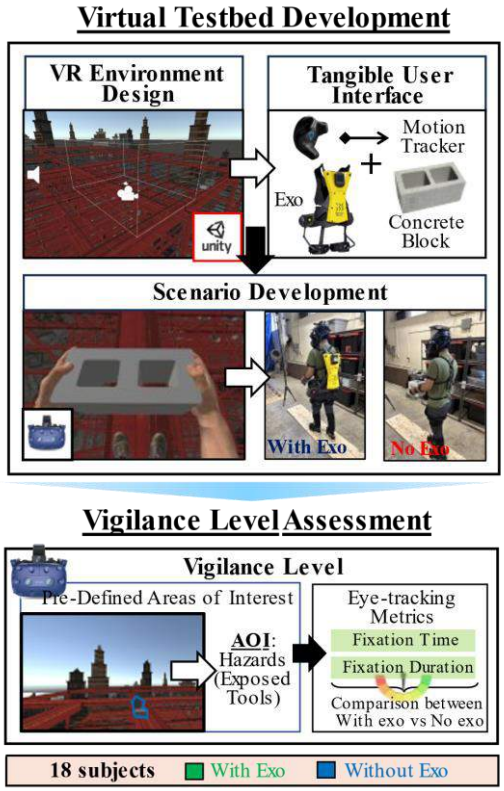

Figure 1. Research Methodology for Assessment of Active Exoskeleton on Workers' Vigilance Level

The study consists of two key phases: Virtual Testbed Development and the Assessment of Vigilance. In the first phase, an immersive and interactive virtual testbed was created to simulate realistic material handling tasks, under two conditions: with and without the use of an active exoskeleton. This environment allowed for the comparison of performance in both scenarios. In the second phase, workers' vigilance levels were assessed by analysing eye-tracking data collected from predefined areas of interest within the virtual environment, corresponding to both conditions. The following subsection will offer a detailed explanation of each step involved in these phases.

4.1 Virtual Testbed Development

In the first module of the proposed framework, a high-fidelity virtual testbed was developed to simulate typical construction tasks. This effort centered on designing a user-centered, simulated workspace to safely assess the impact of active exoskeletons on the vigilance level of workers during common construction tasks. The virtual job site was modeled using Building Information Modeling (BIM) software, specifically Autodesk Revit, and then imported into Unity, a game engine, to create a realistic construction environment, as seen in Figure 2-A. To enhance realism, the virtual space was populated with various elements, including construction machinery, automated systems like drones, personal protective equipment (PPE), and both static and dynamic virtual workers.

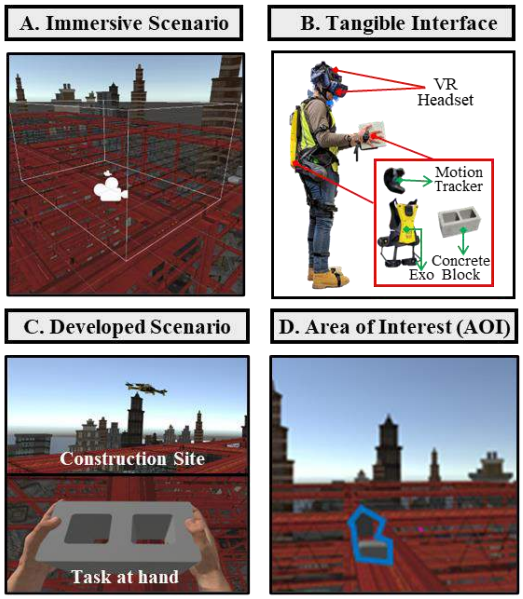

Figure 2. Development of the Virtual Testbed (A) Immersive Scenario Design; (B) Tangible User Interface; (C) Scenario of Material Handling Task at Height; (D) Area of Interest (AOI) in the virtual environment

A virtual representation of an active exoskeleton was integrated into the virtual environment as the primary tool for interaction. To make physical objects interactive in the immersive environment, a motion-tracking sensor was attached to each object, which was then rendered in

the VR setting, as seen in Figure 2-B. The core task simulated in this environment involved material handling, where participants lifted and carried concrete blocks to a designated area, all while working at heights by walking on an iron beam (Figure 2-C). By incorporating the working at height scenario into the simulated material handling tasks, the authors could comprehensively evaluate how the use of powered exoskeletons might influence the vigilance.

To analyze the impact of active exoskeletons on vigilance level of construction workers during common construction tasks, two scenarios were developed: one where participants performed the material handling tasks without an exoskeleton, and another where they used the exoskeleton. In both scenarios, participants interacted with real concrete blocks and an actual powered exoskeleton, presented as physical objects within the virtual environment. The tasks involved picking up the blocks, walking a 4-meter distance along a narrow 40 cm-wide wooden plank, designed to simulate an iron beam at height, and placing the blocks in a specified location. The immersive VR experience, including consistent sounds and visual effects, was the same for all participants, ensuring uniform conditions across both scenarios and eliminating potential biases. In the simulated environment, an Area of Interest (AOI) of hazards was predefined, which represented possible distraction within the virtual environment. Figure 2-D shows the AOI in the simulated environment. The AOIs in the virtual environment were intentionally placed within participants' peripheral vision and along their natural line of sight during task performance. This design ensured that hazards appeared within the operational workspace, mimicking real-world conditions where workers must remain vigilant to dynamic and spatially distributed risks. The immersive VR setting simulated realistic construction scenarios, where hazards typically appear within the operational workspace rather than at extreme angles requiring extensive head rotation.

4.2 Vigilance Level Assessment

Eighteen participants took part in the material-handling task as part of the study. The average age of the participants was 25.2 ± 4 years, with a mean height of 179 ± 5.5 cm, body mass of 74 ± 6.5 kg, and a body mass index (BMI) of 23.1 ± 2.5 kg/m². Before the experiment, all participants were given detailed informed consent forms that outlined the study's purpose, the data collection process, confidentiality measures, and their rights as participants. Written informed consent was obtained from each participant, in accordance with the guidelines approved by the Institutional Review Board (IRB) at the University of Illinois Urbana-Champaign. The researchers ensured that none of the participants had any medical conditions that could interfere with their performance in the immersive virtual environment, ensuring the integrity of the experiment and the safety of all participants.

After agreeing to participate and signing the consent form, the participants were randomly assigned to one of two virtual scenarios: performing the material handling with exoskeleton or without exoskeleton (Figure 3-A). Each participant was equipped with an HMD VR headset (HTC Vive Pro Eye), which included Tobii Pro eye-tracking technology, along with motion tracking sensors (Vive Trackers and Leap Motion), as seen in Figure 3-B. Once the VR system was properly set up, participants were instructed to carry out the material handling task at height within the immersive testbed. The task involved lifting, carrying, and lowering a 10-pound concrete block to replicate typical construction activities. To simulate real-world conditions, participants used an actual concrete block, which was integrated into the virtual environment via a tangible user interface. This setup allowed participants to experience a realistic material handling task at height, ensuring the task closely resembled those found on actual construction sites.

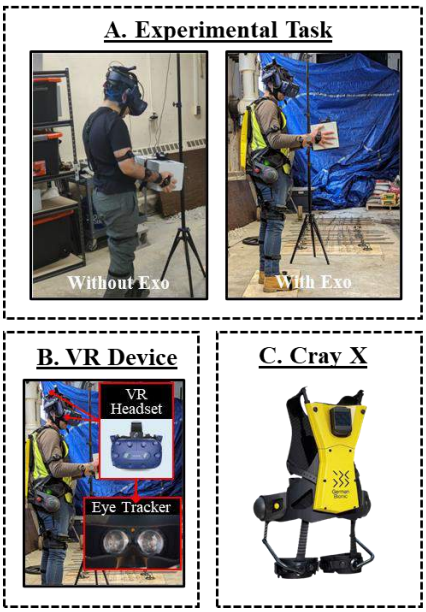

Figure 3. Vigilance Level Assessment Illustration (A) Experimental Task Setup (With and without active exoskeleton); (B) VR Device; and (C) Cray X exoskeleton

In addition, the actual active exoskeleton, Cray X, was integrated into the virtual testbed for the scenario involving material handling tasks with powered exoskeleton assistance. The study employed a crossover design, with participants randomly divided into two groups (nine participants in each group). In the first group, participants began by performing the material handling tasks without the use of the active exoskeleton. After

completing this phase, they crossed over to the second phase, where they repeated the tasks using the Cray X exoskeleton. Conversely, the second group started by using the active exoskeleton and then performed the tasks without it. The Cray X, an active exoskeleton manufactured by German Bionic, weighs approximately 8 kg and was used to provide support during the material handling tasks, as seen in Figure 3-C. The Cray X active exoskeleton, used in this study, is designed to support back and lower body movements without restricting neck mobility. Since the exoskeleton primarily assists with lifting and carrying tasks, its weight distribution does not impose significant constraints on head movements. For both scenarios, participants performed the tasks for 5 minutes, with a 5 -minute break in between sessions. Throughout the experiments, the Tobii eye tracker, integrated with the HMD VR headset, collected data on participants' gaze points, focusing on predefined AOI within the virtual environment. This data was crucial for analyzing the participants' vigilance during the tasks. During the experiment, participants did not report significant discomfort or difficulty in rotating their heads to observe hazards.

The metrics used to assess participants' vigilance while performing tasks in the VR environment include Fixation Count, which measured the number of times participants looked at a predefined AOI; and Fixation Duration, which calculated the total time each participant spent fixating on the AOI. The fixation duration was calculated by subtracting the timestamp when the participant shifted their gaze away from the hazard AOI from the initial timestamp when they first looked at it. A fixation was only recorded if it lasted longer than 100 milliseconds. Both fixation count and fixation duration serve as indicators of vigilance, providing insights into how often and for how long participants were distracted by the hazards in the virtual environment.

To assess the impact of active exoskeleton systems on the vigilance levels of construction workers during typical tasks, the extracted eye-tracking metrics were analyzed statistically. The normality of the data was evaluated using the Shapiro-Wilk test. In this test, a non-significant p-value (generally greater than 0.05) suggests that the data does not significantly deviate from a normal distribution. However, the test yielded a p-value of less than 0.05, indicating that the data significantly deviated from normality. Given that the data did not meet the assumptions of normality, a non-parametric test, specifically the Mann-Whitney U test, was employed to examine the effect of the active exoskeleton on the vigilance levels of the construction workers.

5 Results and Discussion

Table 1 presents the results for the calculated fixation count and fixation duration on AOI during the experiment. When using the active exoskeleton, participants exhibited an average fixation count of 59.85 ± 21.3 and spent an average of 43.8 ± 26.65 seconds fixating on the AOI. This suggests that while performing the material handling tasks, participants shifted their attention away from the task to focus on potential hazards in the environment at least 60 times, for a total of approximately 44 seconds during the 10-minute session in the immersive environment. In contrast, when the tasks were performed without the active exoskeleton, the mean fixation count on AOI was slightly lower at 54.35 ± 16.8, with participants spending an average of 39.85 ± 21.25 seconds focusing on the hazards. These findings indicate that, regardless of whether the exoskeleton was used, participants allocated a significant portion of their attention to environmental hazards, but the exoskeleton may have influenced the frequency and duration of these attentional shifts. The fixation count was slightly higher when participants used the exoskeleton. This suggests that participants may have been more aware of their surroundings or potential hazards while wearing the device. However, the difference is relatively small, and the high standard deviations indicate considerable variability among participants. Similarly, participants spent slightly more time fixating on the hazards when wearing the active exoskeleton. This could indicate that the active exoskeleton might have influenced participants to be more cautious or attentive to potential hazards. Again, the high standard deviations suggest significant individual differences.

Table 1 Results of eye-tracking metrics for AOI

Metrics	With exo	Without exo
Fixation Count	59.85 $\pm$ 21.3	54.35 $\pm$ 16.8
Fixation Duration	43.8 $\pm$ 26.65	39.85 $\pm$ 21.25

To further evaluate the statistical significance of the differences observed between the two conditions (with and without the active exoskeleton), a Mann-Whitney U test was conducted at a significance level of 0.05. The results indicated that the p-values for both the fixation count, and fixation duration metrics were greater than 0.05. This suggests that the differences in attentional allocation between the two conditions, in terms of how frequently participants fixated on the AOI and how long they spent focusing on it, were not statistically significant.

In both conditions, participants demonstrated a high level of attention to potential hazards, with approximately 54-60 fixations on hazards during the 10-minute session. This suggests that participants maintained a good level of safety awareness regardless of exoskeleton use. While the exoskeleton condition showed slightly higher fixation counts and durations, the

lack of statistical significance suggests that the device did not dramatically alter participants' visual attention patterns. The results indicate that the active exoskeleton doesn't significantly affect the vigilance level of construction workers during common construction tasks.

The slight increase in fixation counts and duration when using the exoskeleton could reflect a reallocation of cognitive resources, as suggested by Wickens' Multiple Resource Theory (MRT) [23,24]. According to MRT, cognitive resources are distributed across multiple modalities (visual, auditory) and processing stages (perception, cognition). The exoskeleton introduced additional sensory inputs, such as vibrations and altered proprioception, which could have competed for cognitive resources typically dedicated to visual processing and hazard detection. However, the lack of statistically significant differences in fixation metrics suggests that the exoskeleton's cognitive demands did not exceed participants' available resources, allowing them to maintain vigilance effectively. From the perspective of Endsley's Situation Awareness Model [25], which emphasizes perception, comprehension, and projection of environmental elements, participants demonstrated consistent attention to predefined AOIs representing hazards. This indicates that they effectively maintained all three levels of situation awareness—perceiving, comprehending, and anticipating hazards—despite the exoskeleton's sensory inputs. The slight increase in fixation metrics when using the exoskeleton may reflect heightened caution or attentiveness, but the high standard deviations suggest significant individual differences in how participants adapted to the device.

Despite the insightful findings, this study has several limitations that could be explored in future research endeavors. Firstly, the duration of the study (10 minutes) limits the ability to capture potential long-term effects of exoskeleton use on vigilance levels. Future studies should investigate whether prolonged use of exoskeleton leads to different outcomes in terms of hazard awareness and visual attention. Secondly, the sample size in this study may not accurately represent the full range of the construction workforce, which varies in age, gender, physical fitness, and experience. To improve the relevance of the findings, future research should include a larger and more diverse group of participants. This would help ensure the results are applicable to a broader segment of the construction industry. While the block-handling tasks used in this study are representative of common material handling activities in construction, they may not fully capture the characteristics of other construction tasks with different physical and cognitive demands. Future research should investigate the impact of exoskeleton use on vigilance during a broader range of construction tasks, including those requiring fine motor skills, spatial awareness, or dynamic hazard detection. Likewise, incorporating tasks with varying levels of complexity and collaboration (e.g., working with robotic systems or coordinating with other workers) would provide a more comprehensive understanding of how exoskeletons influence vigilance across different construction scenarios

Additionally, while this study focused on active exoskeletons, future research could compare the effects of active and passive exoskeletons on vigilance levels. Passive exoskeletons, which rely on mechanical components like springs or dampers rather than powered actuators, may introduce different cognitive and ergonomic challenges. A comparative analysis could provide deeper insights into how different types of exoskeletons influence workers' attention and safety awareness, ultimately informing the development of guidelines for their safe and effective use in construction settings. The 10-minute task duration in this study was chosen to establish a controlled and manageable experimental framework for assessing the immediate effects of active exoskeleton use on vigilance levels. While this duration allowed us to minimize participant fatigue and ensure consistency across trials, it lacks in reflecting the conditions of real construction work shifts, where vigilance effects may be cumulative over time due to prolonged exposure to physically and mentally demanding tasks. Future studies should investigate the effects of exoskeleton use over longer durations to provide a more comprehensive understanding of how vigilance evolves during extended work periods.

6 Conclusion

This study evaluated the impact of active exoskeleton systems on the vigilance levels of construction workers during common construction tasks. Eighteen subjects were required to complete material handling tasks under two conditions (with and without using an active back-support exoskeleton) in immersive virtual environments. Using eye-tracking metrics—specifically fixation count and fixation duration on AOI representing potential hazards in the simulated virtual environment, the results demonstrated that while participants showed slightly higher fixation counts and longer fixation durations when using the active exoskeleton, these differences were not statistically significant, as confirmed by the Mann-Whitney U test. Participants consistently maintained a strong level of attention to hazards, with approximately 54-60 fixations during the 10-minute task sessions, regardless of whether they used the exoskeleton. This suggests that the active exoskeleton did not distract workers or negatively impact their vigilance levels. Although there was a small increase in the number and duration of fixations when participants used the exoskeleton, the lack of statistical significance indicates

that the device did not substantially influence workers' vigilance. These findings provide important insights into the psychological effects of active exoskeletons, indicating that their use does not diminish workers' vigilance levels to potential safety risks on construction sites. The findings could help formulate standard guidelines for the adoption of active exoskeletons in construction sites. While this study was conducted with a relatively small sample size, future investigations could recruit a larger pool of subjects to further generalize results. Future studies should include a larger and more diverse group of participants to enhance the reliability of the results and provide more robust insights into the impact of exoskeletons on vigilance levels. Further research is necessary to examine long-term effects and ensure these devices support overall worker performance and safety. While the VR environment provided a controlled setting for studying vigilance, it cannot fully replicate the complexity of real-world construction sites, including factors such as site noise, terrain unevenness, unpredictable distractions, and multi-worker coordination. These variables could significantly affect vigilance levels in practice. Future studies could validate the findings in actual construction settings to provide a more comprehensive understanding of how exoskeletons impact vigilance in dynamic and unpredictable environments. While the VR environment provided a controlled setting for studying vigilance, it cannot fully replicate the complexity of real-world construction sites, including factors such as site noise, terrain unevenness, unpredictable distractions, and multi-worker coordination. These variables could significantly affect vigilance levels in practice. Even though the Mann-Whitney U test was appropriate for this study given the non-normal distribution of the data and the exploratory nature of the research, more sophisticated statistical methods, such as mixed-effects models, could provide deeper insights into the effects of exoskeleton use on vigilance levels.

Abstract –

Work-related musculoskeletal disorders (WMSDs) significantly impact worker health and productivity in construction. Physically coupled robotics, such as exoskeletons, offer a promising solution by augmenting human capabilities and reducing strain. However, their effective use requires precise human-robot synchronization, which can be challenging in dynamic construction environments. Traditional training methods often fail to address these complexities, leading to suboptimal performance, misuse, or increased injury risk. To overcome these challenges, this study develops a personalized Virtual Reality (VR) training platform incorporating an Individualized Bayesian Knowledge Tracing (iBKT) framework. The system continuously evaluates user performance in key body regions, waist, knee, and shoulder, using real-time metrics to dynamically adjust task difficulty, training frequency, and instructional feedback. This adaptive approach tailors training content to enhance motor coordination and postural control in exoskeleton-assisted tasks. Results indicate that ATG achieved greater reductions in postural errors across tasks, with total ER decreasing by 6, 3, and 5 points for walking, bending, and squatting, respectively, compared to 4, 2, and 5 points in TTG. These findings underscore the importance of adaptive, personalized training in enhancing human-robot interaction, safety, and productivity. By equipping workers with tailored skills, this study advances workforce-robot collaboration, fostering more resilient and efficient construction practices.

Physically coupled robots; Adaptive training; Virtual Reality

1 Introduction

Work-related musculoskeletal disorders (WMSDs) represent a significant health concern in the construction industry, where physically demanding tasks are routine. Over 20% of nonfatal injuries in construction result from WMSDs, highlighting the heightened physical strain and risks associated with construction work [1]. Research shows that over 43% of construction workers report chronic musculoskeletal pain, which has been directly linked to reduced productivity, higher rates of absenteeism, and escalating healthcare costs [2]. Furthermore, the physically intensive nature of construction tasks exacerbates the risk of cumulative trauma disorders, impacting not only the physical well-being of workers but also the efficiency and cost-effectiveness of construction operations [3]. Addressing these challenges with innovative technological solutions has thus become a priority to improve both worker health and productivity in this high-risk industry.

Physically coupled robotic systems, such as exoskeletons and collaborative lifting aids, offer promising solutions to mitigate the high incidence of WMSDs within construction[4]. By directly enhancing human strength and endurance, these systems support workers in performing physically demanding tasks, such as heavy lifting, repetitive movements, and sustained awkward postures, without the same level of physical strain [5]. Unlike traditional assistive devices, physically coupled robots operate in close synchronization with human operators, offering seamless support that adapts dynamically to the user's movements. Exoskeletons, for instance, designed for leg support can reduce muscular fatigue up to 71.5% [6], a benefit that has shown potential in experimental studies to improve workers' endurance in repetitive tasks. However, fully realizing their benefits depends on highly coordinated human-robot interactions, where human movement is synchronized with robotic support to optimize safety and productivity [7].

Unlike robots in controlled industrial settings, working with physically coupled robots on construction sites requires workers to adapt control to unpredictable, site-specific conditions [8]. Successful operation of these robots relies on seamless coordination between humans and machines, where workers need the skills to adjust movement patterns, manage force distribution, and

respond dynamically to real-time construction challenges. This complex, close-coupling demands specialized training to ensure workers are equipped to handle the nuanced control and adaptability needed to maximize the potential of these robots.

Traditional training programs are generally characterized by their formulaic and rigid structure, focusing on standardized methods and broad, theory-based instruction. These programs often emphasize repetition and adherence to fixed protocols, which can be effective for routine tasks but fall short in addressing the complexities of dynamic and evolving work environments. A key limitation of such approaches is their lack of flexibility and adaptability, making them ill-suited for preparing workers to navigate the nuanced demands of human-robot interaction in physically coupled systems. While theoretical robotic operations may be addressed, these programs often lack the targeted specificity and adaptability essential for real-world scenarios that demand precise, synchronized human-robot collaboration required by physically coupled robots in close-coupling applications. This gap highlights an urgent need for research-driven training solutions that go beyond traditional approaches, offering adaptable training methods tailored to worker's skills and progress.

In response, this paper presents an adaptive VR-based Human Robot Interaction (HRI) training platform specifically designed for physically coupled robots in construction. Utilizing an Individualized Bayesian Knowledge Tracing (iBKT) framework, the platform continuously evaluates each worker's performance on essential skills, dynamically adjusting the training content and pace in real-time. This adaptive approach creates a personalized learning experience that enables workers to develop a deeper understanding of the precise techniques required for effective close coupling with physically coupled robots. By simulating construction scenarios within a virtual environment, this adaptive training approach allows workers to build practical HRI skills and refine their interaction techniques with physically coupled robots, ultimately facilitating a safer and more efficient human-robot partnership on construction sites. Through this adaptive VR-based training platform, the study aims to demonstrate the effectiveness of personalized, adaptive training in reducing safety risks, and advancing the integration of physically coupled robots in construction.

2 The Emergence of Physically Coupled Robots in Construction: Amplifying Human Capability

Physically coupled robots are specifically engineered to operate in direct physical contact with human operators, enhancing human strength, endurance, and precision in ways that expand the range of tasks workers can perform [9]. Unlike traditional industrial robots, which function autonomously or semi-autonomously, physically coupled robots are deeply integrated with the user, forming a symbiotic relationship that merges human intuition with robotic power to increase productivity and efficiency [10]. Exoskeletons are a prominent and widely adopted example of physically coupled robots. These wearable devices are designed to augment human physical abilities by providing mechanical support during strenuous tasks [11]. Working in close coordination with the human body, exoskeletons function as an extension of the user's own movements, enhancing strength, endurance, and precision. This makes them particularly valuable in environments involving repetitive, heavy, or physically demanding tasks.

The construction industry is especially positioned to benefit from this form of human-robot collaboration. Given the labor-intensive and physically demanding nature of many construction tasks, physically coupled robots can significantly reduce physical strain, minimize injury risk, and improve operational efficiency. Tasks that require heavy lifting, repetitive actions, or prolonged exertion can be performed more safely and effectively with exoskeleton assistance [12]. These devices amplify the user's strength, stabilize posture, and reduce fatigue, ultimately enhancing task performance and reducing physical stress on workers.

However, the integration of physically coupled robotics, such as exoskeletons, into construction introduces challenges [13]. Unlike conventional assistive tools, these systems require active human engagement, demanding continuous adjustment and synchronization of worker movements with robotic assistance. Improper usage, such as misaligned movement patterns or incorrect force distribution, can result in inefficient task execution, discomfort, or heightened physical strain, ultimately diminishing the intended benefits of these technologies. Consequently, equipping workers with the requisite motor coordination, adaptive control strategies, and cognitive decision-making skills is crucial for the safe and effective deployment of these systems. To achieve this, structured training programs are indispensable, ensuring that workers receive personalized, responsive instruction that enhances their ability to integrate these robotic systems seamlessly into dynamic construction workflows. Traditional training programs, typically formulaic and rigid, lack the specificity needed for these dynamic environments [14]. This limitation highlights the need for adaptive training solutions that personalize the learning experience, equipping workers with the skills necessary for effective interaction with wearable robotic systems in real-world construction scenarios.

3 The Need for Adaptive Training in Physically Coupled Robotics

Adaptive training is defined as a method in which the problem, stimulus, or task adjusts dynamically based on the trainee's performance [15]. Unlike conventional, static approaches, adaptive training dynamically customizes adaptive variables through a defined adaptive logic that continuously monitors performance metrics. This real-time adjustment creates a highly personalized learning experience, enhancing both efficiency and effectiveness. Performance metrics are indicators of a trainee's current skill level and progress, such as movement accuracy, reaction times, task completion rates, and overall accuracy. These metrics are gathered either through ongoing assessments that provide immediate feedback or post-session evaluations to measure overall progress. These metrics feed into the adaptive logic, which determines how and when to adjust adaptive variables, such as simulation difficulty or feedback type, to keep training optimally aligned with the trainee's evolving needs [16].

Adaptive training methodologies have found widespread application in industries including construction, adaptive training has been employed to improve worker safety, skill development, and operational efficiency. Studies have developed personalized safety training programs that dynamically adjust hazard recognition tasks based on workers' prior performance and learning progress, leading to enhanced hazard identification and risk mitigation capabilities [17]. In labor-intensive construction tasks, adaptive methods have been utilized to modify task difficulty in real time based on ergonomic assessments, resulting in improved lifting techniques and a reduction in musculoskeletal strain [18]. Additionally, cognitive training frameworks in construction have employed adaptive approaches to tailor problem-solving complexity to individual proficiency levels, thereby enhancing situational awareness and decision-making in dynamic work environments.

Previous research has demonstrated that adaptive training enhances learning efficiency and y, knowledge retention, and task-specific skill acquisition by dynamically adjusting instruction based on user performance metrics. Given the specific demands of exoskeleton training, such as the need for precise movement synchronization, optimized force distribution, and adaptive cognitive control, workers could greatly benefit from adaptive training approaches that tailor instruction to their biomechanics and real-time interaction with robotic assistance. However, research specifically focusing on adaptive training for physically coupled exoskeleton systems remains limited.

This study aims to develop an adaptive training solution to enhance human-robot collaboration in physically coupled robotics for construction. Given the need for training that adapts to individual learning progress, dynamically modifies task complexity, and provides real-time feedback on movement synchronization and force distribution, Virtual Reality (VR) serves as an effective platform [19]. Its immersive and interactive environment enables controlled, data-driven adjustments to training parameters within diverse construction scenarios that enhance adaptability.

To achieve this, the research focuses on developing a framework that continuously monitors, evaluates, and adjusts training variables based on real-time performance metrics, including movement synchronization, force distribution, and task-specific coordination. By integrating adaptive logic with VR, this study seeks to replicate the dynamic conditions of construction sites, addressing a critical gap in training methodologies and facilitating the broader adoption of wearable robotics in the industry.

4 Method: Development of Adaptive Training Platform for Enhancing Human Physically Coupled Robot Interaction in Construction

The VR-based adaptive training system for worker-physically coupled robot interaction is a data-driven approach to improve learning efficiency and optimize task mastery. The system relies on performance metrics to capture real-time motion data from user movements, which are processed by the iBKT-based adaptive logic to analyze the user's task mastery probabilities (Figure 1). When these probabilities exceed a predefined threshold, the system dynamically adjusts adaptive variables, such as task difficulty and task frequency, within the VR training environment. These adjustments are tailored to challenge the user appropriately while preventing skill stagnation, ensuring that users can master the required skills effectively and efficiently.

4.1 Performance Metrics

Key performance metrics were established to evaluate workers' capabilities in worker-physically coupled robot interaction, with a focus on movement accuracy as indicators of effective collaboration. Body angles were selected as the primary indicator of movement accuracy, measured through motion tracking sensors from Inertial Measurement Units (IMUs) and Lighthouse Tracking system (LTS) placed on key body segments, including the waist, knee and shoulder. These IMU sensors continuously monitor, enabling real-time analysis of worker posture and alignment within the robotic system. To mitigate drift errors commonly associated with IMUs, a sensor fusion approach

integrating LTS data was employed to provide periodic corrections, ensuring long-term accuracy. Additionally, drift compensation algorithms, including zero-velocity updates and complementary filtering, were applied to correct accumulated errors over time. To accurately assess movement accuracy, joint angles at critical body points are calculated using vector-based computations derived from IMU data. For each body segment $\vec{u}$, it's calculated by determining the difference between the three-dimensional coordinates of the segment's endpoints $\overrightarrow{P_1}$ and $\overrightarrow{P_2}$ as $\vec{u} = \overrightarrow{P_1} - \overrightarrow{P_2}$. With segment vectors established for adjacent body parts, the joint angle θ between two connected segments $\vec{u}$ and $\vec{v}$ is then computed using the cosine rule $\theta = arccos(\frac{\vec{u}\cdot\vec{v}}{|\vec{u}||\vec{v}|})$.

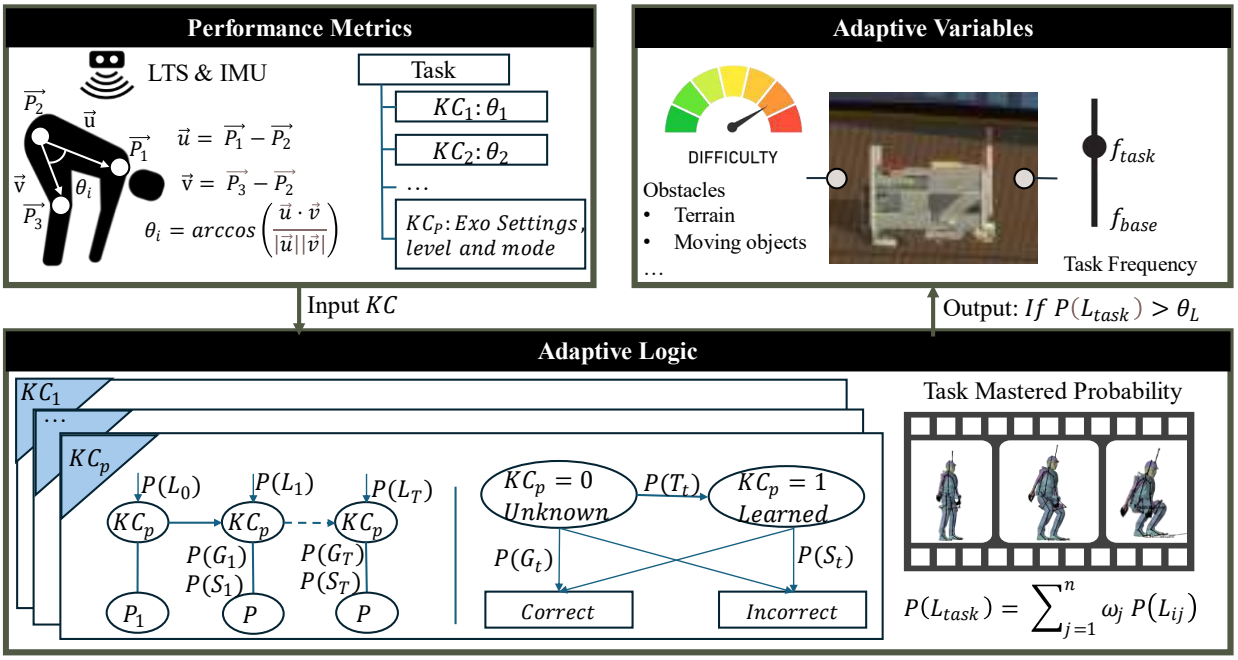

Figure 1. Overview of the developed VR-based adaptive training syste

4.2 Adaptive Logic

Effective adaptive training for physically coupled robotics requires a framework that continuously monitors user performance, dynamically adjusts training parameters, and personalizes learning trajectories. Bayesian Knowledge Tracing (BKT) is well-suited for this application as it models skill acquisition by estimating a learner's mastery probability and updating it based on observed performance. However, standard BKT assumes fixed learning and error probabilities, limiting its responsiveness to real-time changes in human-robot interaction. To address this, we propose an individualized BKT (iBKT) model, which dynamically updates learning probabilities based on real-time performance metrics, refining adaptation to individual learning curves and optimizing skill acquisition in exoskeleton training

The proposed iBKT model extends the traditional BKT framework by enabling real-time adaptation of key parameters based on observed learner performance, thus catering to individual characteristics. The training content is divided into knowledge components (KCs), where each KC represents key body angles extracted from the performance matrix, with a value of KC=1 indicating mastery and KC=0 indicating non-mastery. These components are selected according to ergonomic and task-specific requirements.

A preliminary test is administered in which participants complete a set of baseline tasks designed to evaluate their prior knowledge and motor coordination relevant to exoskeleton operation. This test is used to initialize four critical parameters within the iBKT model for each KC, including the initial probability that user i knows KC j $P(L_{0_{ij}})$; the likelihood of transitioning from a state of non-mastery to mastery of learning KC j after an interaction $P(T_{ij})$; the guess probability $P(G_{ij})$, which is the probability of a correct response to a KC j-related question despite lack of mastery; and slip probability, $P(S_{ij})$, which is the probability of an incorrect response despite mastery of the KC j. Due to the inherent uncertainty in the guessing and slipping behaviors, $P(G_{ij})$ and $P(S_{ij})$ are assumed to follow Beta distributions, allowing for flexible and continuous adjustment based on learner performance.

After initialization, these parameters are continually updated based on the learner's real-time performance to individualize the training process. The guess and slip probabilities, $P(G_{ij})$ and $P(S_{\text{ij}})$, are updated via Bayesian inference, refining these parameters based on learner performance over time. For $P(S_{\text{ij}})$, if the learner has mastered the knowledge but makes an incorrect response (indicating a slip), the posterior distribution is updated as

$$S|data \sim Beta(\alpha_S + f, \beta_S + m - f) \quad (1)$$

where m represents the total number of responses in the mastered state, and f is the number of incorrect responses. Similarly, $P(G_{\text{ij}})$ is updated when the learner is in an unmastered state and correctly guesses the answer, with the posterior distribution.

$$G|data \sim Beta(\alpha_G + g, \beta_s + n - g) \quad (2)$$

where n is the total number of responses in the unmastered state, and g represents correct responses within that state.

The learning probability is $P(T_{ij})$ dynamically adjusted based on recent task performance. If the learner's recent accuracy R meets or exceeds a predefined target accuracy R_{target}, $P(T_{ij})$ is incremented by a set step size ΔT. Conversely, if R falls below R_{target}, $P(T_{ij})$ is reduced by ΔT. $P(T_{ij})$ is updated as

$$P(T_{ij}) = \min(0, \max(1, P(T_{ij}) + \Delta T \cdot sign(R - R_{target}))) \quad (3)$$

Finally, the mastery probability $P(L_{0_{ij}})$ is updated at each time step t through the forward algorithm. Given a learner's response at time t, the probability of correctly answering a question related to KC j, denoted as $P\left(C_{t_{ij}}\right)$, is calculated by

$$P\left(C_{t_{ij}}\right) = P\left(L_{t_{ij}}\right) \times \left(1 - P(S_{ij})\right) + \left(1 - P\left(L_{t_{ij}}\right)\right) \times P(G_{ij}). \quad (4)$$

Following each response, $P\left(L_{t+1_{ij}}\right)$ is updated based on whether the answer was correct or incorrect. For a correct response, the updated mastery probability is $P\left(L_{t+1_{ij}} \middle| observation = C_{t_{ij}}\right) = \frac{P\left(L_{t_{ij}}\right) \times \left(1 - P(S_{ij})\right)}{P\left(C_{t_{ij}}\right)}$. Conversely, if the response is incorrect, the update is given by $P\left(L_{t+1_{ij}} \middle| obs = \neg C_{t_{ij}}\right) = \frac{P\left(L_{t_{ij}}\right) \times P(S_{ij})}{P\left(\neg C_{t_{ij}}\right)}$. The final mastery probability $P\left(L_{t+1_{ij}}\right)$ after time t is calculated as

$$P\left(L_{t+1_{ij}}\right) = P\left(L_{t+1_{ij}} \middle| obs\right) + P(T_{ij}) \times \left(1 - P\left(L_{t+1_{ij}} \middle| obs\right)\right) \quad (5)$$

For a specific human-robot interaction task, the overall task mastery probability $P(L_{task})$ is computed by aggregating the mastery probabilities across all relevant KCs required for the task as $P(L_{task}) = \sum_{j=1}^{n} \omega_j P\left(L_{ij}\right)$, where ω_j is the weight of KC j, satisfying the condition $\sum_{j=1}^{n} \omega_j = 1$.

4.3 Adaptive Variables

The training platform dynamically adjusts certain human-physically coupled robot interaction task difficulty and frequency based on the user's performance on certain task, optimizing the training experience to support mastery in human-robot interaction under realistic conditions. When the learner's mastery probability $P(L_{task})$ for a specific task reaches or exceeds a predefined threshold θ_T, indicating sufficient proficiency, the model increases task difficulty by introducing additional construction-related obstacles, such as uneven terrain or moving objects, to simulate the dynamic and unpredictable nature of a real-world construction environment. This adjustment helps further challenge the learner and prevent skill stagnation. To ensure task diversity and avoid overexposure to a single task, the model employs a rotation mechanism that varies task frequency f_{task} based on mastery levels. Task frequency f_{task} is adjusted according to the function.

$$f_{task} = f_{base} \cdot (1 - \alpha \cdot \frac{P(L_{task}) - \theta}{1 - \theta}) \quad (6)$$

where f_{base} is the base frequency of task rotation, and α is a scaling factor that controls how rapidly the task frequency decreases as $P(L_{task})$ approaches 1. This rotation mechanism ensures a balanced distribution of tasks across all relevant KCs, while placing greater emphasis on those areas that require further development, thus promoting well-rounded proficiency.

5 Case Study: Evaluating the Effectiveness of Adaptive HRI Training Platform

The adaptive training platform was developed in a virtual reality (VR) environment using Unity [20] and deployed on the VIVE PRO 2 [21] system. To enable real-time tracking of body movements, SteamVR motion trackers were attached to each participant, allowing the platform to dynamically adjust training variables based on real-time body position data.

To evaluate the effectiveness of the adaptive training

platform for exoskeleton operation, a case study was conducted with a diverse group of 30 participants with varying backgrounds and skill levels. Participants ranged from novice users with no prior exoskeleton experience to experienced operators. To control prior knowledge, participants were evenly divided into two groups based on their experience: the Adaptive Training Group (ATG), which received training through the iBKT-based adaptive platform, and the Traditional Training Group (TTG), which underwent standard, non-adaptive training. To ensure an accurate assessment of each participant's skill improvement, all participants first completed a pre-assessment to establish baseline task score in exoskeleton operation. The tasks include walking, bending, and squatting. During the process, each participant was instructed to perform the designated tasks while motion tracking sensors recorded joint angles and movement trajectories. The collected data was processed to calculate error rate (ER) metrics, which quantified deviations in posture and movement accuracy based on REBA scoring criteria [22], which assesses postural risks by assigning scores to different body regions. ER is calculated by quantifying deviations in key body joints, including shoulders, waist, and knees, and mapping these deviations to corresponding REBA risk levels. Following the pre-assessment, participants engaged in training according to their group assignment. Upon completing the training, participants were evaluated using the same ER metrics as in the pre-assessment.

6 Results

The effectiveness of the adaptive VR training platform was evaluated by comparing the mastery probability $P(L_{task})$ progression and error rates (ER) between the ATG and TTG across the training period.

6.1 Task Mastery Probability Progression

Figure 2 illustrates the progression of mastery probabilities over the training sessions for a randomly selected participant from the ATG. Three commonly encountered tasks in construction and main body joint mastery probabilities in each task are recorded. The upper panel of the figure (3 × 13 grid) depicts the evolution of the proficiencies of three KCs, $P(L_j)$, and the lower panel (3 × 13 grid) illustrates the progression of trained task proficiencies, $P(L_{Task_i})$, across 13 training sessions. From the figure, tasks with fewer correct attempts appear more frequently in the training sequence, ensuring the participant receives sufficient practice opportunities to reinforce weaker areas. The proficiencies in both panels reveal a clear upward trend, reflecting the gradual improvement in mastery levels for both knowledge components and tasks, driven by the adaptive nature of the training system.

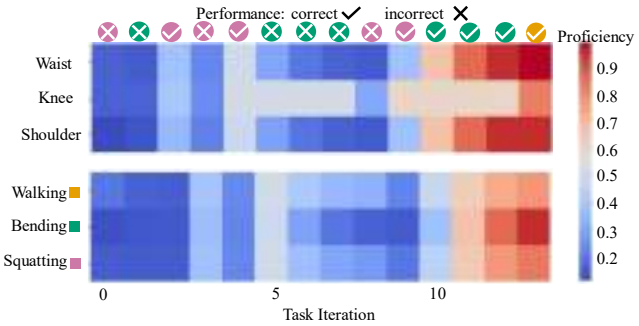

Figure 2. An example of the iBKT-based adaptive training process

6.2 Task Score Comparison

Figure 3 illustrates the pre- and post-training error rates (ER) for the targeted tasks—walking, bending, and squatting, broken down by body parts for the Adaptive Training Group (ATG) and the Traditional Training Group (TTG). For walking, the total ER for ATG decreased from 9 (waist: 7, knee: 2) to 3 (waist: 1, knee: 2), showing a reduction of 6 points. TTG also improved, with total ER decreasing from 8 (waist: 7, knee: 1) to 4 (waist: 3, knee: 1), a reduction of 4 points.

For bending, ATG's total ER decreased from 7 (waist: 2, shoulder: 5) to 4 (waist: 2, shoulder: 2), reflecting a 3-point improvement. TTG also showed a 2-point reduction, with total ER decreasing from 7 (waist: 3, shoulder: 4) to 5 (waist: 3, shoulder: 2). For squatting, ATG's total ER improved significantly, decreasing from 8 (waist: 4, knee: 3, shoulder: 1) to 3 (waist: 1, knee: 1, shoulder: 1), a reduction of 5 points. TTG's total ER decreased from 10 (waist: 4, knee: 4, shoulder: 2) to 5 (waist: 2, knee: 2, shoulder: 1), showing a reduction of 5 points. These results indicate that ATG exhibited greater reductions in postural errors across tasks, particularly in waist and shoulder alignment, with higher total score reductions compared to TTG. This suggests that the adaptive nature of the training platform contributed to more substantial improvements in movement accuracy and postural control. The observed enhancements in waist and shoulder positioning are particularly relevant, as these areas are critical for exoskeleton operation, influencing overall balance and load distribution. The ability of the system to dynamically modify task difficulty and provide real-time feedback likely played a key role in refining postural strategies and improving motor coordination.

Furthermore, paired t-tests indicate that ATG participants exhibited significantly greater improvements in knee ($p=0.0004$), shoulder ($p<0.0001$), and waist ($p=0.0001$) error rates across walking, bending, and squatting tasks, respectively. Independent t-tests further confirm that post-training ER values were significantly lower in ATG than TTG ($p<0.05$), demonstrating the

superior effectiveness of adaptive training in refining movement accuracy and postural stability in exoskeleton operation.

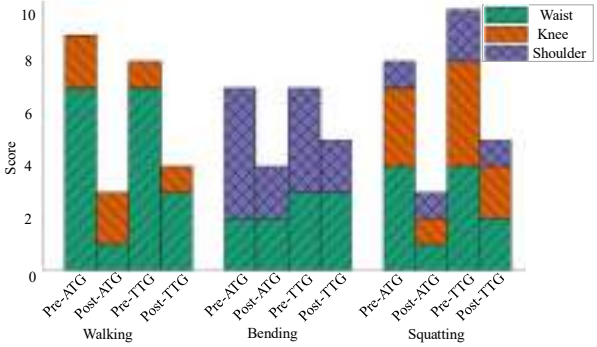

Figure 3. Pre- and Post-Training Task Scores for ATG and TTG

7 Conclusion

This research developed an adaptive training platform using the Individualized Bayesian Knowledge Tracing (iBKT) framework to enhance HRI skills for construction workers operating physically coupled robots, such as exoskeletons. The platform provided personalized, real-time adjustments to training content, effectively addressing individual performance gaps and ensuring efficient skill acquisition. Results demonstrated that the adaptive training led to steady improvement in task mastery and showed significant advantages compared to traditional training. This study underscores the importance of adaptive training in optimizing human-robot collaboration, particularly in dynamic and demanding construction environments.

However, several limitations remain. The current study was conducted in a simulated VR environment without real-world validation using physical exoskeletons, necessitating future studies to assess its practical applicability. Additionally, the system was designed for individual training, and its effectiveness in multi-user collaborative settings has yet to be explored. Long-term retention studies are also required to evaluate whether skills acquired through adaptive VR training persist over time or require.

By integrating real-time feedback and immersive VR simulations, the platform allowed workers to build essential skills safely and effectively. Future research could expand on this approach by exploring other adaptive algorithms and broader applications across different types of physically coupled robots. Ultimately, this adaptive training model represents a promising direction for facilitating the integration of advanced robotics in construction.

Abstract

Off-site construction (OSC) is a well-established paradigm for achieving productivity, safety, and sustainability in construction. The key factor in its success is the efficiency of the workforce transforming blueprints into actual buildings and building elements. This has driven efforts to improve working conditions at the production facility, paving the way towards human-centric construction manufacturing. Achieving a safe and healthy indoor environmental quality (IEQ) is among the most critical aspects of this endeavor. Given the dynamic nature of IEQ in OSC facilities, there is a need for real-time performance monitoring as a means of identifying any deviations from IEQ standards and regulations. As such, the objective of this study is to develop a digital twin-based system for real-time monitoring of the IEQ of OSC facilities with continuous management and alerting features. The proposed *O-IEQ Alert System* encompasses four phases: (1) IEQ metrics identification, (2) data acquisition, (3) digital modelling, and (4) development of the IEQ alerting component. The system is successfully applied in a case study of a wall-production manufacturing facility. A web-based alert system is developed that presents real-time monitoring of the IEQ indices, including Air Quality Index, thermal comfort Predicted Mean Vote Index, and the Sound Level Index for each workstation along with the time-series trends. In case any of the indices does not fall within the defined threshold, an alert is issued to management to take the necessary corrective and preventive measures. The ultimate aim is to provide a safe, healthy, and productive working environment in OSC facilities.

Indoor Environmental Quality; Digital Twin; Alert System; Off-site Construction; Human-centricity

1 Introduction and Literature Review

The off-site construction (OSC) method has emerged as an alternative to conventional construction approaches in an effort to industrialize the construction industry. In OSC, building elements are fabricated in off-site production facility and then shipped to the construction site for installation and assembly [1]. It is well-established as a successful approach to achieving a faster, more productive, safer, and more sustainable construction as compared to conventional methods [1].

Typically, an individual spends about a third of their life at the workplace [2] emphasizing the need to create safe and healthy working environments, especially that employees tend to carry their workplace experiences into their personal lives [3]. In OSC, the production facility acts as the workers' workplace as they undertake different activities of the building fabrication process. The setup in a controlled factory environment has paved the way into human-centric construction manufacturing which requires placing the well-being of workers at the center of production [4]. Well-being covers the physical, emotional, social, financial, vocational, and environmental aspects [5]. Human centric research in OSC has been evolving in several directions, such as ensuring safety [6], assessing and improving ergonomics[7], enhancing productivity [8], etc.

Achieving a safe and healthy indoor environmental quality (IEQ) is among the most critical human-centric factors. IEQ is impacted by several dimensions: air quality, thermal comfort, acoustic comfort, and lighting quality. Studies showed that there is a direct and strong correlation between IEQ and productivity. Individuals tend to perform their tasks more efficiently when they feel comfortable within the environment [9]. It is a core element in human-centric construction manufacturing as workers in these facilities can be prone to uncomfortable sound levels, indoor air pollution, and uncomfortable thermal state. These can be due to several factors such as the heavy use of machinery, construction material cutting and processing, the use of specific personal protective equipment (PPEs), the installed heating and ventilation systems, available natural lighting, visual comfort, etc. However, IEQ studies in OSC are limited to the acoustic comfort through identifying the noise sources in an OSC facility [10] as well as the workers' exposure level in an effort to identify safe and high-risk working areas [11].

Monitoring the IEQ is the first step into achieving a safe and comfortable indoor environment that meets the required IEQ standards and regulations set by different organizations such as ASHRAE [12], the World Health Organization (WHO) [13], the Environmental Protection Agency (EPA) [14], etc. However, monitoring on its own is not sufficient, and must be accompanied by an information interaction system that can be leveraged by management to make timely decisions. This can be achieved by developing a real-time monitoring and alert system to detect deviations from acceptable ranges. Once a deviation is detected, management is alerted to take the necessary measures. Digital twins (DT) can be used in this case as an integrated system to monitor and control the indoor environment [15]. DT systems are composed of three main components including physical space, virtual space and the information connection and processing between the two layers [16]. They have been successfully implemented for IEQ applications in the built environment. For example, Arsiwala et al. [17] created a DT-based solution to monitor the indoor air quality of existing building assets to enable data-driven decision making for retrofitting strategies. This ultimately helps achieve net zero carbon emission targets. In another study, Shahinmoghadam et al. [18] proposed a DT model in order to monitor thermal comfort in buildings in a virtual reality environment. The model also allows modifications to modify certain parameters that impact thermal comfort to study what-if scenarios based on the real-time thermal comfort data feed.

A review of the relevant literature showed that although the OSC industry is shifting more towards human-centric approaches, the IEQ applications remain limited. Moreover, IEQ directly correlates to the health, safety, and productivity of the individuals in the workplace, and therefore must be addressed in the context of OSC. Monitoring IEQ enables the detection of deviations from the established IEQ standards and regulations. In this regard, DTs have been successfully incorporated into IEQ real-time monitoring. However, IEQ applications in OSC have been relatively limited. As such, the objective of the present study is to develop a DT-based system for real-time monitoring of the IEQ of OSC facilities with continuous management and alerting features. The contribution of the system is bifold, 1) it provides a real-time assessment of the IEQ and 2) it can assist management to take the necessary corrective and preventive measures to ensure a safe, healthy, and productive environment.

2 Methodology

This study adopts the Design Science Research (DSR) method for developing the proposed IEQ monitoring system. DSR is a structured approach to developing artifacts that address an identified problem, and to demonstrate the artifact's effectiveness [19]. The method consists of the following four steps: (1) identifying the problem, (2) defining the objective, (3) developing the artifact, and (4) demonstrating the artifact [20].

In the present study, the first step is a thorough review of the literature to obtain a solid understanding of the current human-centric research in OSC, IEQ in OSC workplaces, and the potential of DTs in the built environment. The literature review reveals the importance of IEQ as a core element in the workplace. While the controlled indoor environment of OSC provides an opportunity to apply IEQ standards and improvements, applications of these standards in OSC are limited. The problem—in the present case, the gap in the literature regarding IEQ applications in OSC—having been identified, the system's objective is articulated in the second step of "Defining the objective." In the present case, the objective is defined as the development of a structured approach for real-time IEQ monitoring and alerting in OSC capitalizing on DT technology. With real-time monitoring of IEQ parameters, any deviations between the actual conditions at the factory and the identified thresholds can be detected. In the case of a deviation, management will be alerted, and the necessary measures can be taken. Ultimately, such a system helps to ensure the health, safety, and productivity of workers at the production facility. The third step is the development of the proposed system, and this comprises four phases: (1) IEQ metric identification, (2) data acquisition, (3) digital modelling, and (4) development of the IEQ alerting component of the system. The system employs DT-based tools that have been validated in the built environment, tailoring them to IEQ real-time monitoring in OSC. Several tools are leveraged, including sensor technologies, laser scanning, 3D modelling, Unity game engine, and web-based functions. Details on the development of the system are presented in section 3. The fourth step is to present an illustrative application, a case study of an OSC facility prefabricated components for residential projects—to demonstrate the system's applicability.

3 Proposed *O-IEQ Alert System*

The aim underlying the development of the *O-IEQ Alert System* (i.e., Step 3) is to provide a DT-based system for real-time IEQ monitoring and alerting in OSC facilities to promote the health, safety, and productivity of workers. As noted above, its development is composed of four phases: (1) IEQ metric identification, (2) data acquisition, (3) digital modelling, and (4) development of IEQ alerting component of the system. The following sub-sections outline the developed system (see Figure 1). It should be noted that the proposed system can be

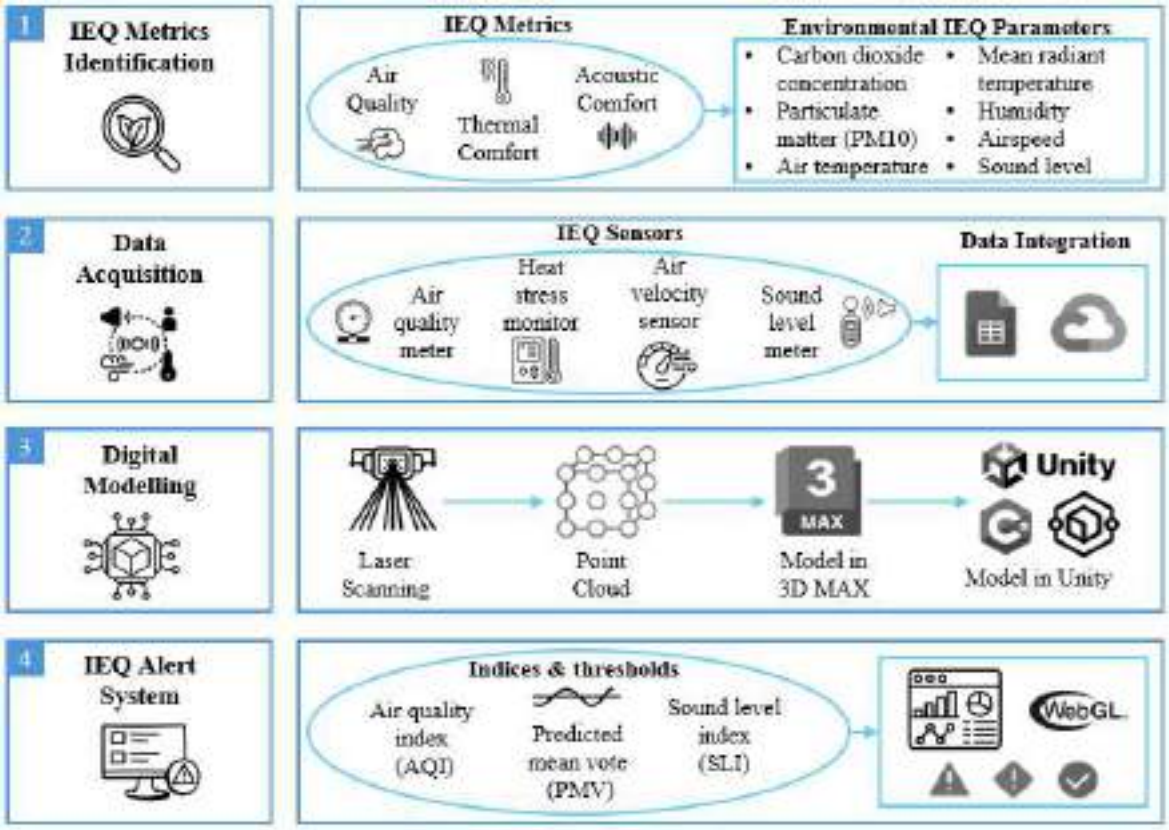

Figure 1. Proposed framework for the O-IEQ monitoring and alert system

customized as per the production operations as well as the IEQ needs and expectations of the production facility of interest.

3.1 IEQ Metric Identification

The proposed *O-IEQ ALERT System* encompasses three IEQ metrics: air quality, thermal comfort, and acoustic comfort. (Lighting quality may also be incorporated in future work.)

Indoor air quality is influenced by several parameters. In the present study, the system monitors levels of carbon dioxide (CO_2) and particulate matter (PM10). CO_2 is indicative of the freshness of indoor air, while PM10 measures the presence of coarse, harmful particles [21]

According to Fanger [22] a person's thermal comfort depends on six environmental and personal parameters: air temperature, mean radiant air temperature, relative humidity, air speed, metabolic rate, and clothing insulation. Air temperature refers to the temperature of the air surrounding the human body, while mean radiant air temperature refers to the heat radiated from a warm object. Air speed is the speed at which air circulates around humans. Relative humidity is the present state of humidity relative to the maximum humidity given at a certain temperature, and the metabolic rate refers to the physical effort required to perform tasks. Clothing insulation, finally, refers to the worker's ability to adapt their clothing to feel comfortable, while also considering the necessary personal protective equipment [22].

Acoustic comfort, meanwhile, has to do with the sound pressure levels perceived by the worker while performing tasks at the factory. Sound levels are influenced by the combined noise generated from different activities at the factory, whether manual or machine-based activities [11].

3.2 Data Acquisition

The parameters that affect the factory's IEQ having been identified, the next step is to develop a data acquisition system for collecting real-time data from each workstation. This is achieved by implementing various types of sensors at locations throughout the production facility. There are many types of sensors available for automated monitoring of IEQ parameters [23]. The selection of the sensors is typically case-specific and depends on sensor availability, range, accuracy, ease of use, ease of installation, cost, data transmission, and interoperability with other software.

Regarding the acquisition of IEQ data, an air quality meter can be used to measure the CO_2 and PM10 levels [24]. Personal parameters of thermal comfort are often assumed to be constant, whereas environmental factors—i.e., air temperature, mean radiant temperature, relative humidity, and air speed—are dynamic and must be monitored over time. Air temperature, mean radiant temperature, and relative humidity can be collected using a heat stress monitor, while air speed data can be collected using an air velocity meter [25]. To measure sound levels, a sound level meter can be employed [10]. Following the selection of commercially available sensors, sensing equipment is installed at the factory in accordance with the associated manufacturing guidelines.

The sensors, having been installed, data can be collected in real time at select intervals, such as one, five, or 10 minutes. The intervals are selected based on the criticality of the IEQ in the factory, as well as the variability of operations. Once the data on the different parameters is collected, it will undergo a process of data cleaning, processing, and structuring into the proper format so that it can be used as an input to the digital model. The specific steps depend on the selected sensors, the integration between the sensors, and the case study.

The cleaned and structured sensor data is then integrated with the digital model of the production facility (as discussed in the description of Phase 3 below) to ensure the link between the physical and virtual environments of the DT [26]. This integration is achieved by storing the sensor data in Google Sheets, with each row representing a single time stamp and each column representing a different IEQ parameter. These Google Sheets are hosted on a Google Cloud platform, which allows for separate sheets to be created for each workstation. An application programming interface (API) is then created in Google Cloud to integrate data from the sensors via the created Google Sheets. A URL link is then generated to present the data in JSON format. This allows for the data to be retrieved in the Unity modelling software. It should be noted that the APIs are restricted so that only employees of the case company and members of the research team can access the sensor data.

3.3 Digital Modelling

A 3D model that is reflective of actual production line operations in the facility and that represents the information flow of the IEQ indices and parameters in real time is critical, as it improves the user experience. In developing the 3D model, laser scanning is used to automatically measure and locate thousands of datapoints at the factory based on the selected positions of the laser scanners. This results in a spherical point cloud that maps to the factory. The point cloud, in turn, is imported to 3Ds Max for model development [26]. Finally, the model is imported to Unity software, which provides an interactive environment for the real-time monitoring and alert system.

3.4 IEQ Alert System

The purpose of the IEQ alert system is to provide a means of monitoring the quality of the indoor factory environment in real time. The system issues warnings if IEQ levels are not within the acceptable ranges set by the standards and regulations. Management can then take the necessary corrective or preventive measures to ensure a healthy, satisfactory, and productive environment for workers. For the alert system, three indices are selected corresponding with the three IEQ metrics of interest. The three indices are the Air Quality Index (AQI), Predicted Mean Vote index (PMV), and Sound Level Index (SLI). Each of these indices considers the influencing parameters identified in Phase 1 (see above). The indices having been identified, the next step is to determine the acceptable thresholds based on the relevant standards, guides, and regulations. A three-level warning system (good, fair, or poor) is introduced accordingly. Further details on the influencing parameters, index establishment, thresholds, and warning levels for each index are described as follows.

The AQI index is dependent on the CO_2 and PM10 concentration levels [21]. Since there is no universal index to measure the indoor air quality, the AQI was developed based on the thresholds of its dependent parameters. Table 1 shows the good, fair and poor ranges for the indoor CO_2 and PM10 concentration levels as per the ASHRAE 62.12 for CO2 [12]as well as the WHO [13] and the EPA [14] for PM10.

Table 1. CO_2 and PM10 levels

	Good	Fair	Poor
CO_2 concentration (ppm)	< 1,000	1,001–2,000	> 4,000
PM10 Level (ug/m³)	< 50	51–150	> 150

The next step identifies the 9 combinations of the CO_2 and PM10 levels to provide a qualitative indoor air quality index. If both CO_2 and PM10 are at acceptable levels, then the AQI is also acceptable with an index of 1. If either one is fair and the other is good, the AQI is moderate with an index of 2. If both are fair, the index will increase to 3. The index will be considered unhealthy at 4, if one is good and the other is poor. The index changes to 5 and becomes very unhealthy if either one becomes poor. Finally, the AQI index increases to 6 and becomes hazardous in case both parameters are in a poor state. Table 2 represents the developed AQI and its concern levels with a range from 1 to 6, with 1 being in good condition and 6 being in a hazardous state.

Table 2. AQI development

CO_2 Level	PM10 Level	AQI (index)	Level of Concern
good	good	1	Good
good	fair	2	Moderate
fair	good	2	Moderate
fair	fair	3	Moderate
good	poor	4	Unhealthy
poor	good	4	Unhealthy
fair	poor	5	Very unhealthy
poor	fair	5	Very unhealthy
poor	poor	6	Hazardous

Thermal comfort is dependent on 6 parameters, including personal and environmental parameters as per Fanger's model [22]. The metabolic rate and the clothing insulation are assumed to be constant values in the model. These can be selected based on the activity being performed by the worker and the clothing characterises respectively as per the ASHRAE Standard 55[27]. It should be noted that these values typically remain constant for a certain period and require an update upon major changes such as allocating a new worker to a certain task, entering a new season (winter and summer), or a change in the tasks of the production process, etc. As such, the manual selection of these values is feasible [28]. The environmental parameters include the air temperature, mean radiant air temperature, humidity, and air speed [22]. Based on these 6 parameters, thermal comfort can be quantified by calculating the Predicted Mean Vote (PMV) index as per the mathematical model developed by Fanger [22]. The PMV varies on a 7-class scale as follows: hot (−3), warm (−2), slightly warm (−1), neutral (0), slightly cool (−1), cool (−2), and cold (−4). Typically, a PMV between −0.5 and +0.5 reflects a comfortable indoor thermal environment.

The sound level index is developed based on the corresponding measured sound levels [11]. Table 3 presents the ranges of the noise levels, the level of concern, and the SLI. The SLI ranges from 1 to 6, with 1 being safe and 6 being extremely high risk.

Table 3. SLI development

Sound level dBA	Level of concern	Sound level index (SLI)
<66	Safe	1
66–71	Tolerable	2
71–76	Low risk	3
76–81	Moderate risk	4
81–85	High risk	5
85	Extremely high risk	6

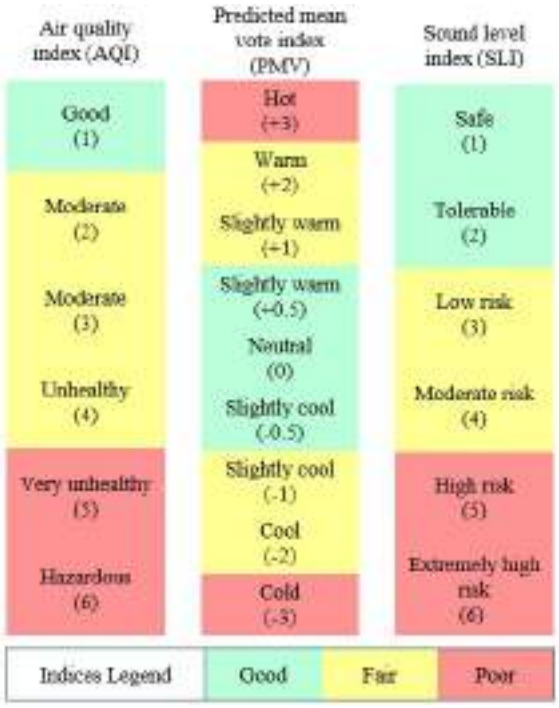

Figure 2. IEQ indices warning levels

Once the three IEQ indices are defined and established, the warning and alerting levels are introduced, as shown in Figure 2.

Once the indices, their thresholds, and warning levels are established, they are reflected in the Google Sheets on Google Cloud and thus are reflected in the APIs that feed data into the Unity model of the factory. A Canvas is created in Unity that shows two monitoring and alerting stages across two developed scenes. The first stage, Layout Scene, represents the layout of the production facility. This includes the sensors' location and status of the three IEQ indices for each workstation (good, fair, or poor). The second stage, Station Scene, shows the three indices' values, warning levels, and time series trends for each of the seven IEQ parameters for the station of interest. It should be noted that all indices, trends, and warning levels are updated in real time in Unity, given that the real time sensor data is fed via the API data integration.

The last step in the IEQ monitoring and alert system is to enable users (i.e., management at the production facility) to monitor the facility's IEQ remotely through a web-based decentralized network that can be accessed from any compatible browser [29]. Such solutions have been successfully applied in the planning of OSC projects [30] and are provided in Unity through the WebGL function as a JavaScript API [31].

4 Illustrative Application of the *O-IEQ Alert System*

The proposed *O-IEQ Alert System* is part of a larger study that aims to assess the quality of the indoor environment in OSC facilities to ensure a human-centric healthy, safe, and productive environment. A case study of a wall production line in an OSC facility is introduced to showcase an illustrative application of the proposed system. The application covers four stages of the process, including framing, sheathing, multi-function bridge, and the installation of windows and doors.

As discussed in the "Proposed O-IEQ Alert System" section, the three IEQ indices, including the AQI, PMV, and SLI, can be monitored by the *O-IEQ Alert System*, as well as the parameters of CO_2, PM10, air temperature, mean radiant air temperature, humidity, air speed, and sound level. Given that the data acquisition phase is under development, and the sensor installation and data collection steps are in progress, the authors used synthetic sample data to showcase the applicability of the system. This is a preliminary step that will help validate the system prior to real data acquisition and integration.

Although the authors relied on simulating data points to mimic the sensor data, the system is updating in real-time based on its acquired data. As such, the authors created a sample dataset with 200 data point stamps at 10-second intervals for each of the 7 parameters of interest. Then, the indices and the warning levels were accordingly calculated. The synthetic sensor data, along with the corresponding IEQ indices and warning levels, were uploaded to Google Sheets on Google Cloud, where the corresponding APIs were created. As such, the authors were able to replicate real-time data feed into the digital model for real time updating.

The digital model development of the production facility was achieved through laser scanning, whereby point cloud data was generated. The data was used to develop the model in 3Ds MAX, and the model was then transferred to Unity. The Unity model was uploaded to the web using the WebGL function to allow for online and remote access to the system. As such, the model can be accessed through a URL, as shown in Figure 3. Figure 3 also introduces the aim of the system and its main outcomes.

Figure 3. Web-based O-IEQ Alert System overview

Once the user runs the model, they will be taken to the Layout Scene, as shown in Figure 4. This scene presents the layout of the wall framing production line and the 4 stations understudy. Each of these stations is associated with a unique warning level, with coloured indices representing the IEQ index of interest. The user can select any of the 3 indices, and the warning levels will be updated accordingly.

Figure 4. Layout scene of O-IEQ Alert System

Once the user clicks on any of the stations, they will be taken to the Station Scene, as shown in Figure 5, providing more detailed insights regarding the IEQ. The user can view how the 3 indices are being updated and can select a certain index to view the time series of its corresponding parameters. Figure 5 shows the status of the framing station, where AQI is in a fair condition, and the PMV and SLI are in good condition. The user can select the other 2 indices to monitor the trends of the relevant parameters. It should be noted that the Layout Scene and the Station Scene are fed real time synthetic data using the aforementioned data integration workflow, and the indices, the warning levels, and the parameters trends are updated accordingly in real-time.

5 Conclusion and Future Work

In summary, this study proposed a digital twin-based system to monitor the IEQ of off-site construction facilities in real time with continuous management and alerting features. The developed *ALERT O-IEQ System* was developed in reference to the DSR method through identifying the need for the system, defining its objectives, developing and evaluating it. The system is composed of four phases including (1) IEQ metric identification, (2) data acquisition, (3) digital modelling, and (4) development of the IEQ alerting component of the system. An illustrative application was presented in a

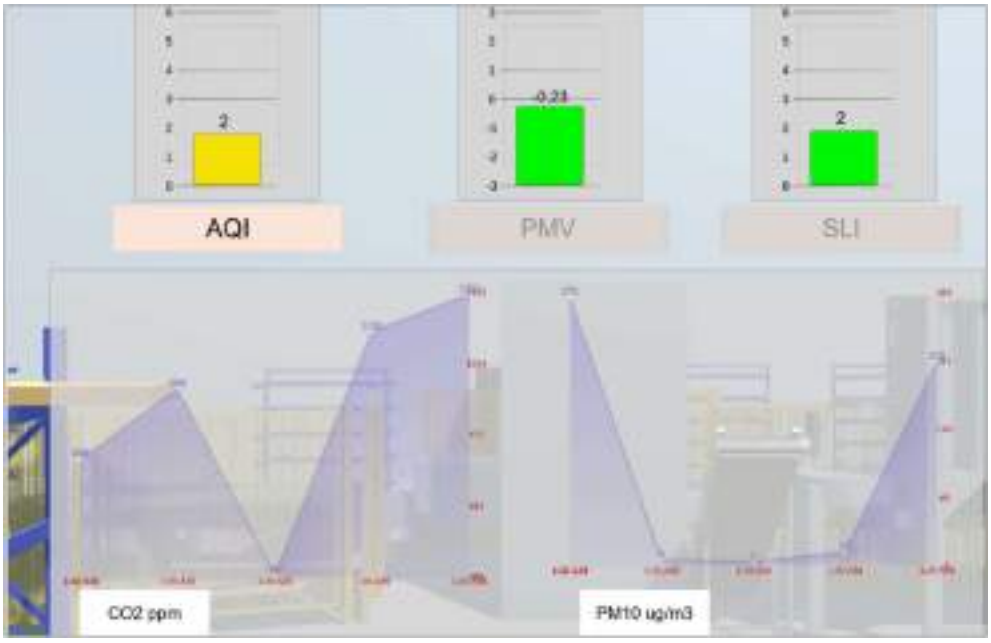

Figure 5. Framing station scene of the O-IEQ Alert System

wall-production manufacturing facility. A web-based Canvas in a 3D environment was developed to monitor the IEQ in real-time including the Air Quality Index, thermal comfort Predicted Mean Vote Index, and the Sound Level Index for each workstation. It also shows detailed insights into each workstation, including real-time time-series trends of the IEQ parameters (i.e. PM10 level, noise level, etc.). In case the IEQ is not within the acceptable thresholds, an alert is issued to the management in order to take the necessary measures. Certain limitations exist in the study that should be addressed. Firstly, the AQI index integrated in the developed system only considers two parameters, the CO2 and PM10 levels, while other parameters can impact the air quality. In the future, the AQI will be further developed to include the ground-level ozone, PM2.5, PM10, carbon monoxide, sulfur dioxide, and nitrogen dioxide as per EPA's U.S AQI to ensure more comprehensive and reliable air quality monitoring. Secondly, the system requires further validation to ensure its reliability in practice. As such, the system will be implemented on an actual case study of an OSC facility to test its effectiveness in the future.

Abstract

Public participation is crucial for designing livable cities and accelerating planning procedures. A key challenge is the complexity of planning documents, which are often difficult for non-experts to understand. Digital participation and techniques like 3D visualizations and Building Information Modeling (BIM) offer promising solutions to enhance the comprehensibility and acceptance of construction projects.

This study aims to develop an assessment matrix for participation procedures that enables the quality and effectiveness of such processes to be comprehensively evaluated. A systematic literature analysis is first used to identify success factors and challenges of public participation as well as specific success factors and challenges for digital forms of participation (e-participation). These success factors are divided into the categories of resources, communication and process-related aspects, while challenges are categorized into stakeholder-specific and overarching aspects.

Based on these findings, an assessment matrix is created to evaluate public participation in the context of planning and approval procedures. The assessment matrix includes parameters such as background information, the participation process, planning documents, and responses and their respective impacts. This matrix will be applied in the BIM4People research project, funded by the Ministry of Digital and Transport (BMDV), to identify improvements in current participation processes and explore how BIM models can optimize them.

Keywords

Building Information Modeling (BIM), e-participation, evaluation matrix for public participation, success factors and challenges of public and e-participation

1 Introduction

"*A good city is like a good party — people stay longer than really necessary because they are enjoying themselves*" - Jan Gehl [1]

Public participation plays a central role in the design of livable cities and infrastructures. Nevertheless, such participation processes regularly lead to conflicts, particularly in the case of complex infrastructure projects. Protests, resistance and legal disputes on the part of citizens are often the consequences, which can have a negative impact on the progress and success of such processes [2].

One of the major factors contributing to these conflicts are planning documents, which are often complex and difficult to understand, especially for people who are not familiar with technical drawings. The traditional presentation of planning documents is often in the form of textual elaborations and two-dimensional drawings that are difficult for the non-expert to access [3]. This barrier can make participation in planning processes considerably more difficult, as those affected often find it difficult to grasp and understand the full dimensions of the planned projects.

In this context, new possibilities for participation and visualization of construction projects, such as 3D visualizations and Building Information Modelling (BIM) models, offer promising approaches for improving public participation [4]. These technologies promise to provide more vivid and intuitive representations, making planning documents more comprehensible and potentially increasing transparency and public acceptance. To systematically evaluate the effectiveness of participation processes, various approaches and guidelines have been developed in the past [5–7]. However, these primarily focus on traditional, non-digital formats or specific types of participation. A comprehensive framework that incorporates both traditional and digital participation formats—while

enabling a comparative analysis of text-based, two-dimensional, and three-dimensional planning documents—has not yet been established.

With this background, an assessment matrix for planning and approval procedures is developed that makes it possible to systematically evaluate the quality of such public participation processes. It provides a structured method for evaluating various aspects and parameters that play an important role in such processes. The matrix is used to systematically identify weaknesses and potential for improvement in order to make the entire process both more efficient and more citizen friendly.

In order to develop this assessment matrix, a comprehensive overview of the success factors and challenges of public participation and digital participation opportunities, so-called e-participation measures [8], is first required. Analyzing these factors makes it possible to determine the relevant parameters that are important for the evaluation of the planning documents. Once the success factors and challenges have been analyzed, the specific assessment parameters can be derived and integrated into the assessment matrix.

The detailed methodological procedure for developing the assessment matrix is described in the following chapter. The identified success factors and challenges are then highlighted, and the developed assessment matrix is presented. Finally, the key results are discussed and summarized. This section also contains an outlook that shows the context in which the assessment matrix is to be used as an example.

2 Methodology

To develop the assessment matrix, a systematic literature analysis was carried out based on the approach of Webster and Watson (2002) [9] and Vom Brocke et al. (2009) [10].

According to Webster and Watson, a literature search essentially involves searching scientific databases using keywords. The authors recommend using a backward and forward search to find relevant literature. A forward search looks for literature that cites the literature already found. In a backward search, on the other hand, the literature found is searched for cited literature in order to include it after checking its suitability [9].

Vom Brocke et al. (2009) take up these approaches and at the same time note that only a few detailed methods and standardized procedures exist for literature research. They emphasize the difficulty of searching for literature at a time when more and more sources and literature are being published every year. In their explanations, the authors emphasize the importance of a careful literature review. Strict documentation and presentation of the research processes is required in order to make the procedure comprehensible and reproducible [10]. Therefore, the systematic literature analysis of this study is based on three phases.

In the **first phase** of this study, search criteria and search parameters are defined. The databases SpringerLink, ScienceDirect, and Scopus were selected as the foundation for the literature search. Scopus and ScienceDirect, as predominantly English-language databases, were used exclusively for English-language literature. In contrast, SpringerLink was specifically chosen to cover German-language sources. Google Scholar was included as it is considered to cover German-language literature more efficiently than comparable databases [11]. Moreover, its inclusion ensured that relevant insights from non-academic sources, such as municipal master plans and governmental reports, were also captured, as these can provide valuable findings for the research context. However, Google Scholar does not provide literature directly but refers to other databases [12].

The literature search is based on predefined keywords to systematically identify relevant sources. Keywords related to public participation, including ‘public participation’ and ‘citizen participation,’ as well as their German equivalents, were selected. Additionally, terms associated with e-participation, such as ‘e-participation,’ its German translation, and ‘digital participation,’ were included. This targeted selection ensures a comprehensive review of relevant literature in both English and German.

To refine the search scope, only open-access sources classified under the subject area *Engineering* were considered. In Scopus, the presence of the respective keyword was required, while in ScienceDirect, the term *participation* had to appear in the title. Additionally, the search was limited to the last 15 years (2008–2023) to ensure relevance, as scientific findings are continuously updated. Given the rapid innovation cycles in e-participation technologies, a more recent timeframe is particularly relevant. [13]. Furthermore, by 2008, over three-quarters of German households had broadband access, establishing the foundation for digital participation.[14]. This approach resulted in 979 identified sources.

In the **second phase**, duplicates were first removed. The remaining sources then underwent an abstract screening to assess their relevance. After this process, 169 sources met the criteria and were selected for detailed analysis.

In the **third phase**, the success factors and challenges for both public participation and e-participation were analyzed. Based on the respective success factors and challenges, 23 evaluation parameters were then derived.

The entire procedure, including each phase from initial literature search to the development of the assessment matrix, is summarized in the following figure.

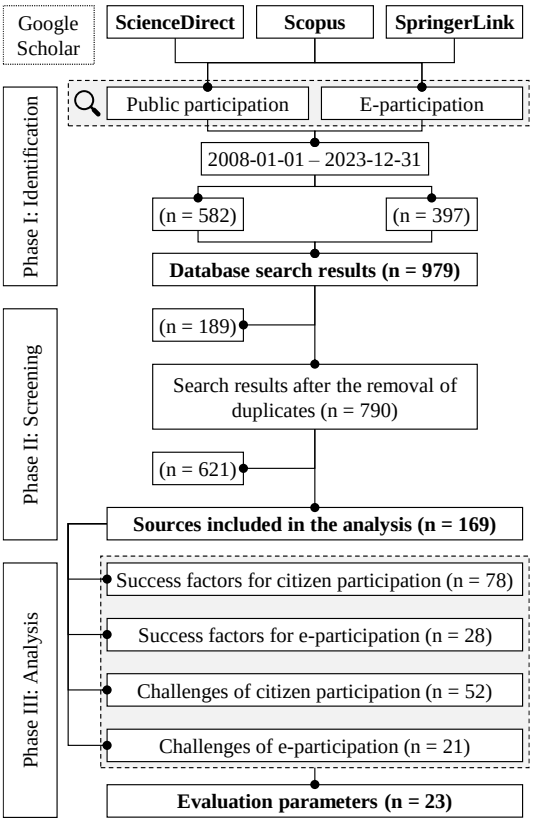

Figure 1. Methodology Findings

The first step is to define the terms 'success factor' and 'challenge' for a shared understanding in evaluating public participation processes. Success can be perceived subjectively by different actors, with citizens viewing success as the assertion of their interests, while organizers may see functional participation as successful [15]. In 1988, Lutz Hildebrandt defined the 'success factor' as a key variable linking performance indicators and planning units [16].

The following definition can be derived from this regarding the success of public and e-participation:

Success factors in public participation and e-participation measures are those variables that help to make the participation process as pleasant and simple as possible for all those involved, as well as creating a feeling of satisfaction and promoting and strengthening user behavior.

According to the Oxford English Dictionary, challenges are defined as demanding situations or tasks designed to test one's abilities or character. Lazarus and Folkmann, on the other hand, write that the evaluation of challenges focuses on the winning or growth potential of an encounter (and is characterized by pleasurable emotions such as eagerness, excitement and enthusiasm) [17]. The focus/stimulus of challenges is therefore to achieve the desired goal by completing the demanding task. However, there is always the risk of failing at the task or that the desired goal is not achieved. Challenges in the context of public and e-participation measures can therefore be defined as follows:

Challenges in public participation and e-participation measures are all matters that could lead to more successful participation but involve a lot of effort and are not guaranteed to have a positive impact.

2.1 Success factors for public participation and e-participation

The study identified 78 success factors for public participation and 28 specifically for e-participation measures. Following an inductive categorization method as outlined by Mayring [18], these success factors can be grouped into three main categories: "Resources," "Communication," and "Process-related Aspects." Each main category further divides into several subcategories (see Figure 2 and 3).

	Success factors for public participation		
	Resources	Communication	Process-related aspects
	1	2	3
a	Personnel n = 6	Real participation n = 8	Traceability in the process n = 4
b	Organisational n = 17	At eye level n = 10	Preparation and follow-up n = 10
c	Range n = 7	Create clarity n = 9	Quality and continuity in the process n = 7

Figure 2. Success factors for public participation

	Success factors for e-participation		
	Resources	Communication	Process-related aspects
	1	2	3
a	Personnel n = 3	Avoiding frustration n = 3	Preparation and follow-up n = 2
b	Organisational n = 2	Exchange medium n = 12	Quality and continuity in the process n = 5
c	Range n = 1		

Figure 3. Success factors for e-participation

In the area of public participation, **resources** are crucial to the success of participation processes. Resources are understood as 'certain means that are necessary to achieve a goal' [19]. Human resources, such as the stakeholders involved, play a key role. Social competence from authorities is a crucial success factor, as it facilitates communication and interaction with citizens, improving the process's effectiveness [20]. Another example is the involvement of external, neutral moderators. These help to promote the acceptance of procedures and minimize barriers to participation, as they act as impartial mediators [21]. The availability of technical support plays a decisive role in the area of e-participation measures. Technical support ensures that all participants receive the necessary assistance with digital matters [22]. This makes a significant contribution to ensuring that sufficient support is provided when giving feedback, which is an important assessment parameter in the evaluation of participation processes.

Organizational success factors include the general willingness of the authority to carry out participation [23]. This willingness is reflected in the openness of the authorities to actively involve citizens in decision-making processes. Other factors are the existence of a harmonious relationship between the costs and benefits of participation [20] and the general accessibility of information [24]. In the context of e-participation measures, it is also necessary to ensure barrier-free online access [23].

Outreach is another aspect of successful participation processes. The success factors in this sub-category include the use of various media to disseminate information [20] and widespread publicity for the implementation of a participation process [25]. Another success factor for e-participation measures is the awareness of and attention generated by digital participation opportunities [26].

The **communication** category refers to the direct exchange between the participants and the participating institutions. Both verbal and non-verbal exchange is crucial here.

In this context, various success factors can be identified that ensure genuine participation. Key success factors include avoiding the impression of a fictitious participation [27] and a recognizable prospect of success through the investment [24]. This knowledge motivates active participation and increases the willingness to get involved in the process. A concrete evaluation parameter that captures this aspect of communication is the consideration of feedback in further planning. This shows the participants that their contributions are taken seriously and are actually incorporated into the decision-making processes.

Furthermore, success factors that build trust are crucial, including openness to communication, willingness to discuss, and avoiding specialized terminology [20].

Clear communication is also conducive to extensive participation and a process that is perceived as fair. Unclear statements and feedback can lead to false expectations, which should be avoided [28]. A key evaluation parameter that ensures this clarity is the thematic response to feedback from the public. If the authority's feedback specifically addresses the points raised, misunderstandings can be avoided and the satisfaction of those involved can be increased.

In the area of e-participation measures, there are additional factors to consider that help to avoid frustration when using digital technologies. One decisive factor is a user-friendly interface that makes it easier for users to find their way around digital platforms [29]. In addition, it is important to provide visual and auditory content to cater for different learning and communication styles and to facilitate access for all user groups [26].

The category of **process-related aspects** includes factors that influence 'traceability in the process', 'preparation and follow-up' and 'quality and continuity in the process'.

Transparent procedures and the provision of background information are necessary for traceability in the process [21]. Transparent procedures enable those involved to clearly understand the progress and decisions within the process. This evaluation parameter increases the confidence of those involved in the process and ensures that they feel they are taken seriously. To achieve this goal, the planning documents themselves must also be relevant, comprehensible and transparent.

Preparation and follow-up include early activation and mobilization of the public [15] and the start of participation before irreversible decisions are made [24]. This enables a well-founded opinion to be formed and promotes the quality of the contributions. In this context, the procedure and the key points of participation must be known [30].

In order to ensure high quality and continuity in the process, it is of central importance that comprehensive information on participation is provided [21]. In addition, proactively taking up feedback during the planning phase is a key success factor. This ensures that the feedback from those involved is taken into account and integrated into further planning, which increases the effectiveness and acceptance of the entire participation process.

E-participation also benefits from limiting anonymity for accountability and conducting objective fact-checks to maintain accurate and current information [31].

2.2 Challenges of public participation and e-participation

Using Mayring's inductive categorization method [18], the study identified 52 challenges in public

participation and 21 specific to e-participation. These are categorized as "Stakeholder-specific" and "Overarching challenges" (see Figure 4).

	Challenges of public participation and *e-participation	
	Stakeholder-specific challenges	Overarching challenges
	1	2
a	On the authority side n = 12 *n = 7	Representation n = 7 *n = 1
b	Interaction with the citizen side n = 13 * n = 7	Framework conditions n = 12 *n = 4
c	Citizen side n = 8 *n = 2	

Figure 4. Challenges of public participation and e-participation

Stakeholder-specific challenges in public participation are categorized into three sub-categories: public authorities, citizens, and their interactions.

Public authority challenges mainly involve internal structures and processes, including resource shortages that hinder effective participation implementation in terms of staff and finances [32]. Additional challenges arise in the area of e-participation measures. E-participation introduces technical and organizational challenges, requiring authorities to develop and maintain digital platforms. [33]. Managing large volumes of digital data also demands effective systems for collection, analysis, and interpretation. [26].

There are numerous challenges on the citizens' side, with a central problem being insufficient information about participation opportunities and the underlying procedures [20]. In addition, there is often a lack of trust in the authorities based on previous experience of insufficient consideration of citizens' opinions [29]. In this context, it is essential to ensure the credibility of the planning documents. Consistent and complete planning documents are crucial for this. In addition, the fulfilment of technical requirements for e-participation measures poses a challenge. Many citizens do not have the necessary digital skills or access to suitable technology to participate in online participation procedures [26].

The interaction between authorities and citizens also harbors specific challenges. A frequent problem is dealing with different interest groups [34] and the scope of information provision [29]. These difficulties can lead to time and financial burdens on the one hand and make it difficult to satisfy individual concerns on the other. With regard to e-participation measures, there are additional challenges, particularly in terms of ensuring the credibility of these measures. The credibility of e-participation processes is often questioned as there are concerns regarding the manipulability of online surveys and polls [35].

Overarching challenges include representation and framework conditions, which are crucial for the effectiveness and legitimacy of participation processes.

A common issue is the dominance of well-organized, vocal groups, which can overshadow diverse perspectives [21]. Additionally, proponents of a project are often underrepresented, with participation processes frequently attracting more opponents, leading to an imbalanced discourse [21].

The framework conditions of public participation processes are also of crucial importance. A frequent challenge is the lack of clarity about the influence of citizens' opinions on the actual decisions [28]. In addition, the high complexity of construction projects poses a further challenge [29]. Construction projects often involve complex technical, legal and economic aspects that can be difficult for laypeople to understand. Consequently, more vibrant, clear and understandable documentation and feedback are crucial and consequently represent concrete evaluation parameters.

E-participation faces challenges like software dependency [26], where functionality and usability are crucial, and resistance to change from both citizens and authorities unfamiliar with digital tools [36].

3 Assessment matrix

The assessment matrix includes aspects, parameters, descriptions, and a scale from 1 to 6. Aspects are broad categories, with parameters serving as specific criteria. The scale evaluates the degree of fulfillment, from 1 (not fulfilled) to 6 (fully fulfilled), allowing for a detailed assessment of strengths and weaknesses.

The assessment matrix includes four aspects: (i) background information, (ii) participation process, (iii) planning documents, and (iv) response and impact. These were derived from the identified success factors and challenges. Since evaluation parameters often influence multiple factors, a direct one-to-one mapping was not possible. The matrix focuses on evaluating public participation and e-participation from the citizens' perspective to help identify strengths and weaknesses for the initiators.

The 'background information' aspect ensures citizens understand the process, deadlines, and project details. The 'participation process' evaluates citizen involvement and support. The 'planning documents' aspect assesses the quality and review challenges of the provided information. The 'response and impact' aspect examines how authorities respond to citizen input and its impact.

Aspect	Assessment parameter	Description	Ranking					
			1	2	3	4	5	6
Background-information	Familiarity with the procedure	Assesses whether the course of the procedure is known.						
	Awareness of dates and deadlines for participation	Evaluates whether the relevant deadlines and dates for participation have been clearly communicated.						
	Sufficient information on the project	Measures whether sufficient information has been provided about the project.						
	Feeling of sufficient participation present	Assesses whether the feeling of having been given sufficient opportunities to participate.						
Participation process	Sufficient information for providing feedback	Checks whether the provision of information on participation was adequate.						
	Sufficient support for providing feedback	Measures the extent to which support measures were available for the submission of feedback.						
Planning documents	Accessibility of the planning documents	Evaluates the accessibility of the planning documents.						
	Completeness of the planning documents	Checks whether the planning documents contain all the necessary information.						
	Comprehensibility of the planning documents	Checks the comprehensibility of the planning documents.						
	Attractive visual presentation of the planning documents	Evaluates the clear presentation of the planned impacts in the planning documents.						
	Clarity of the planning documents	Evaluates the clarity of the planning documents.						
	Relevance of the planning documents	Evaluated whether all relevant information was easy to find in the planning documents						
	Consistency of the planning documents	Measures the consistency within the planning documents provided.						
	Credibility of the planning documents	Assesses the credibility of the planning documents.						
	Comprehensibility of the planning documents	Checks whether the presentation of the impacts in the planning documents is comprehensible.						
	Transparency of the planning documents	Evaluates the transparent presentation of decisions in the planning documents.						
	Appropriate timeframe for reviewing the planning documents	Measures whether the time available for reviewing the planning documents was sufficient.						
	Financially unproblematic inspection of the planning documents	Evaluates whether access to the planning documents was associated with financial barriers.						
Response and impact	Comprehensibility of the feedback	Measures the comprehensibility of the feedback received.						
	Thematic response to the feedback	Evaluates whether the feedback has been answered thematically.						
	Satisfaction with the feedback received	Checks whether the feedback could satisfy the individual concerns.						
	Discussion of the feedback	Checks to what extent the submitted feedback has been discussed.						
	Feeling of integration of feedback into the planning process	Evaluates whether there is a feeling that the feedback has been taken into account in further planning.						

1 = Not achieved 2 = Barely achieved 3 = Partially achieved 4 = Well achieved 5 = Almost fully achieved 6 = Fully achieved

Table 1. Assessment matrix for evaluating public participation procedures in planning and approval procedures

4 Discussion and Conclusion

Public participation is a crucial factor in accelerating planning and approval processes, significantly contributing to the success of complex infrastructure projects. Despite its importance, dissatisfaction and complaints remain common. Digital participation formats offer new opportunities to improve the comprehensibility and acceptance of these processes. However, existing evaluation approaches often focus on traditional, non-digital participation methods or specific participation types, lacking a comprehensive framework that equally considers both conventional and digital formats. A holistic evaluation approach is essential to systematically assess the transition to digital participation and analyze its potential and challenges in a structured manner.

This study aimed to develop an assessment matrix that systematically evaluates the quality and effectiveness of public participation processes in the context of planning and approval procedure, identifying weaknesses and potential areas for improvement, particularly regarding digital visualization techniques. A systematic literature review was conducted to identify relevant success factors and challenges, which were categorized into four dimensions: 'resources,' 'communication,' 'process-related aspects,' and 'stakeholder-specific and overarching challenges.' The resulting assessment parameters were incorporated into the matrix, which consists of four core aspects: background information, participation process, planning documents, and response and impact.

The developed assessment matrix serves as a structured tool for objectively evaluating public participation processes. It enables a systematic comparison of different planning document formats—whether text-based, 2D, or 3D visualizations—contributing to a deeper understanding of their effectiveness in participation processes. Since the matrix is designed for use in both analog and digital participation formats, it offers a flexible means of identifying and addressing shortcomings. If certain aspects—such as comprehensibility or accessibility—receive low scores, particularly in relation to the format of planning documents, alternative representations (e.g., replacing text-based or 2D plans with 3D visualizations) can be tested. The matrix then facilitates a systematic evaluation of whether these adjustments lead to improvements in specific assessment parameters, ensuring that participation strategies can be iteratively refined based on empirical findings.

This structured evaluation fosters dialogue between citizens and decision-makers, ensuring that participation processes not only meet formal requirements but also align with the needs and expectations of stakeholders. By applying the matrix, targeted recommendations for improvement can be developed to enhance the quality and acceptance of public participation processes. Additionally, incorporating free-text input allows for capturing qualitative feedback that extends beyond predefined assessment parameters, further refining the evaluation and optimization of participation strategies.

Abstract -

Robots hold great potential for enhancing efficiency, quality, and safety in construction, yet the unstructured and dynamic nature of construction sites limits the feasibility of full automation. Human-robot collaboration (HRC) offers a solution by integrating human expertise with robotic precision to improve adaptability. However, there remains a significant gap in understanding the systematic integration of human and robotic intelligence, particularly in dynamic control sharing. This study addresses this gap through a systematic review of shared control in HRC within unstructured environments, reflecting on its application to construction. A two-layer classification framework is proposed, encompassing "human-in-the-loop" (HITL) and "human-on-the-loop" (HOTL) systems, further divided into five subcategories. Key challenges and future research directions are also identified, providing actionable insights for designing and optimizing HRC systems in complex construction scenarios.

Keywords -

Robotic construction; Human-robot collaboration; Control sharing; Unstructured construction environment

1 Introduction

The construction industry, which contributes approximately 13% of global GDP, continues to face persistent challenges related to safety and labor shortages. In the UK, construction sector accounted for 51 worker fatalities in 2023, representing 37% of all workplace deaths [1], alongside a shortfall of over 150,000 skilled workers jeopardizing housing plans [2]. Robotics presents a promising avenue for mitigating workforce deficits and undertaking hazardous tasks. However, the inherently unstructured and dynamic nature of construction sites—characterized by irregular components and unpredictable environmental conditions—demands a high degree of adaptability. This complexity underscores the difficulty of achieving fully autonomous robotic operations in construction, highlighting the need for intelligent systems capable of navigating uncertainties and adjusting dynamically [3].

Humans' agility and expertise are crucial for managing uncertainties in unstructured environments, making human-robot collaboration (HRC) a viable approach for deploying construction robots. Although originally developed for industrial settings, HRC has expanded into fields such as surgery and military operations, while its application in construction remains in an early stage. Recent reviews have examined HRC in construction, focusing on robot autonomy [3], worker skill transfer methods [4], multidimensional taxonomy frameworks [5], and applications scenarios [6], laying the foundation for advancements in this field. Nevertheless, it remains unclear how the integration of human operators' intelligence and robotic autonomy is achieved in unstructured construction environments. In this study, we focus primarily on human-robot collaboration systems under teleoperation scenarios. Within this context, as the robot is the primary entity executing tasks, human-robot collaboration can also be referred to as shared control of the robot. A limited understanding of shared control constrains HRC system design, restricts autonomy, heightens risks, reduces efficiency, and undermines user trust—ultimately impeding adoption in complex construction settings.

To fill the aforementioned knowledge gaps, this study investigates shared control mechanisms of human-robot collaboration systems in an unstructured construction environment. A systematic literature review methodology is employed, involving comprehensive retrieval and rigorous screening to ensure the scientific rigor and reliability. The findings aim to provide theoretical support for the design and optimization of HRC systems in such complex settings. The research questions are formulated as following: (1) What shared control methods have been developed in existing human-robot collaboration systems in unstructured environment? And how can they be systematically classified? (2) What are the key challenges in implementing shared control systems for construction

robots operating in unstructured environments? (3) What are the emerging research trends for the advancement of shared control systems in construction robotics?

2 Methodology

This study conducted a systematic literature review following the PRISMA guideline [7]. As instructed in PRISMA flow diagram, there are two steps in PRISMA i.e. studies identification and screening each of which will be introduced in details in this section.

2.1 Identification

In PRISMA, relevant records need to be systematically identified first and then initially filtered out of duplicates and ineligible records using automated tools. To ensure the comprehensiveness of the literature review, we carefully selected search terms as shown in the Figure 1. Specifically, we incorporated a broad range of terms capable of reflecting various human-robot collaboration paradigms that combine human expertise with robot autonomy. It is important to note that these terms do not have standardized definitions, and in some cases they are cross-used. In addition, we selected "robot" and "uav" to cover common types of robots. For built environments, the search strategy included terms describing unstructured environments similar to buildings, ensuring coverage of a wide range of dynamic and changing built environments, including "building", "architecture", "infrastructure ", "unstructured environments", "changing environments", "dynamic environments", and "clutter ".

Through this systematic search, 656 records were initially retrieved. Automated filters were then applied to refine the dataset, restricting it to English publications from 2010 to September 2023 within the engineering and computer science fields to ensure a comprehensive and up-to-date literature review. Finally, 521 records remained after removing duplicates.

2.2 Screening

In this subsection, the screening criteria and rigorously assessment process will be introduced. This study focused on the remotely collaboration between human and real robots within unstructured construction environment. Thus, studies in which only systems with partial shared control and physical robots were included, excluding review papers, fully human-controlled or fully autonomous systems, soft robots, and miniature robots. Additionally, selected studies focused on applications in unstructured, dynamic, and cluttered environments typical of construction engineering, ensuring relevance to complex construction scenarios.

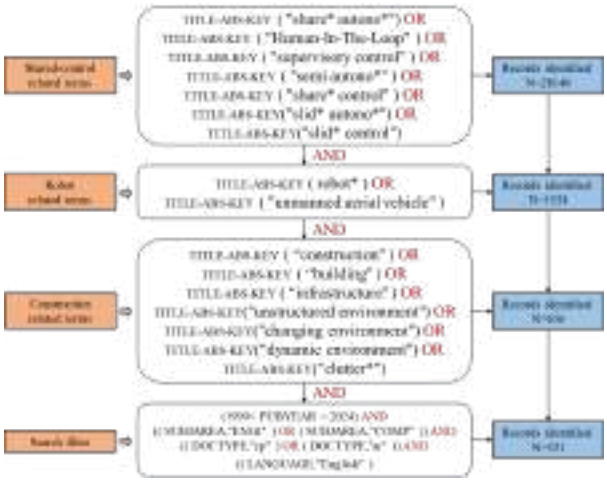

Figure 1. Combination of searching terms

To ensure rigor in the screening process and reduce subjective bias, a literature assessment team consisting of three PhD students was formed. The assessment process consists of three steps: (1) independent assessment of titles, abstracts, and keywords to identify relevant or uncertain studies; (2) independent full-text review of selected articles; and (3) consensus among raters, requiring at least two agreements for inclusion. Before final consensus, each rater followed the above screening criteria without any interference from others. By following the above criteria and process, a total of 65 relevant articles were finally included for detailed review.

3 Bibliometric Analysis

This section analyzes publications on human-robot collaboration based on shared control in unstructured environments, highlighting trends, robot types, and key venues.

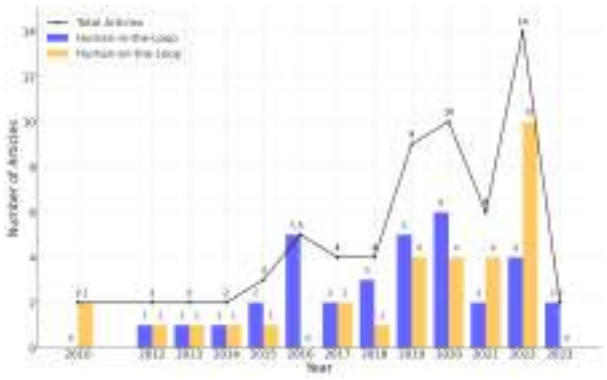

Figure 2. Numbers of publications of each shared control category by year

As shown in Figure 2, the annual publication count of

shared control systems has steadily increased, with significant growth since 2016 and a peak in 2022 (14 articles). The trends of "Human-in-the-Loop" (HITL) and "Human-on-the-Loop" (HOTL) indicate a shift towards supervisory roles, as HITL research peaked in 2020 while HOTL rapidly expanded in 2022, driven by advancements in AI and the demand for balancing automation and human oversight.

Figure 3. Distribution of robot types

Figure 3 shows that robot arms dominate the field (48.4%), with 90% being single-arm systems, reflecting their maturity in industry. Mobile robots (29.7%), led by UAVs (42%) and UGVs (58%), highlight their versatility, while mobile manipulators (21.9%) showcase rising interest in dynamic environments. Humanoids (4.3%) and excavators (5.7%) remain niche areas.

4 Classification of shared control based human-robot collaboration systems

Based on retrieved studies, a two-layer classification framework of human-robot collaboration systems is proposed in this section based on control sharing mechanisms. Table 1 shows a summary of the classification framework.

4.1 Human-in-the-loop system (HITLs)

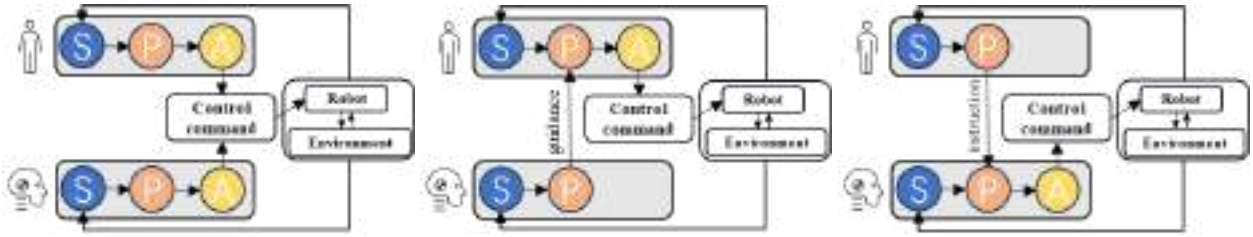
Human-in-the-loop (HITL) systems involve the active participation of human operators within the robot's control loop, where human input is essential to ensure task execution. Depending on the mechanism by which human and robotic control are integrated, HITL systems can be categorized into three subtypes as shown in Figure 4: semi-autonomous human-in-the-loop systems, robot-guided human-in-the-loop systems, and human-instructed human-in-the-loop systems.

4.1.1 Semi-autonomous human-in-the-loop system (SA-HITLs)

SA-HITL refers to a shared control system capable of fusing motion commands from both human operators and autonomous controllers, which are then executed by the robot. In SA-HITL, the operator provides low-level motion commands in a human-in-the-loop manner, while the autonomous controller simultaneously generates motion commands to assist the operator in performing tasks such as obstacle avoidance in unstructured environments. To fuse the commands from both the operator and the autonomous controller, existing studies primarily adopt two methods: (1) degrees of freedom (DOF) allocation and (2) command fusion. In the DOF allocation method, the operator and the autonomous controller independently control different components or DOF of the robotic system. For example, [8] developed a shared control system for motor graders, where human commands control steering and autonomous commands control blade motion. Such studies typically assign certain robot DOFs, often those challenging to automate, to human control, enhancing the system's adaptability in uncertain environments.

In another type of SA-HITL, operator and robot commands act on the same DOFs and are fused, typically using linear, probabilistic or constraint optimization methods, to generate the final execution command. Adjusting fusion strategies, such as the weights in linear fusion, allows the system to better align with human intentions or objectives of autonomous controller. For example, a linear command fusion strategy was proposed [9] to utilize robot-generated obstacle avoidance commands to mitigate collision risks caused by reduced situational awareness during human teleoperation of robots in cluttered and unknown environments.

4.1.2 Robot-guided human-in-the-loop system (RG-HITLs)



RG-HITL systems enable shared control by guiding, prompting, or constraining the operator's inputs, without the autonomous controller directly generating commands for the robot's actuators. This approach allows operators to effectively control the robot while leveraging the autonomous system's planning and situational awareness. RG-HITL systems can be classified into sensation-based and virtual fixture-based systems.

Sensation-based systems enhance operators' situational awareness by conveying environmental information to them through multimodal feedback, such as visual [10], auditory [11], or haptic cues [12]. For instance, a UAV haptic interface guided operators in navigating obstacle-laden environments, where tactile feedback not only reduced collision risks but also improved performance in scenarios with limited visibility [13].

Table 1. Classification of shared control based human-robot collaboration systems

Class	Subclass	Human Role	Robot Role	Techniques	Potential HRC applications in construction
HITL	SA-HITL [8, 9]	Provide control commands	Generates control commands, fuses operator commands, and executes.	DOF allocation [8]; Commands fusion [9]	Tasks with redundant robot's DOFs such as grading and rolling
	RG-HITL [10, 11, 12] [13, 14, 15]	Provide control commands with robot's guidance	Provide guidance to operator and executes operator's commands.	Visual[10], auditory [11], and haptic cues[12]; Virtual fixtures [14, 15]	Dynamic tasks requiring accurate control such as Welding or drilling
	HI-HITL [16, 17, 18] [19, 20]	Provide high-level planning instructions	Convert operator's high-level instructions into low-level planning, generate executable control commands, and execute them.	Geometric [16], template-based [19], and demonstration-based motion planning [17]	Tasks requiring high-complexity planning such as grasping structural demolition components
HOTL	HI-HOTL [21, 22, 23]	Supervise robot performance and intervene when necessary	Execute tasks autonomously and await human intervention when needed.	Gesture, haptic[21], or voice-based "take over" mechanisms [22]	Tasks with conditional robot autonomy such as drone-based construction site safety monitoring
	RI-HOTL [24, 25, 26]	Intervene when triggered by robot based on external information	Execute tasks autonomously, monitor system/environment state, and adjust autonomy.	Task failure risk prediction [25, 26], system gain prediction [24]	Tasks with high robot autonomy: drone-based 3D reconstruction of the exterior of buildings

Note: Due to page limitations, identified works for each shared control category cannot be fully indexed. The full list is provided in the appendix A.

(a) SA-HITL (b) RG-HITL (c) HI-HITL

Figure 4. Schematic diagram of three HITL shared control systems

The second type of RG-HITLs is virtual fixture-based, which employs attractors or repulsors to guide or constrain operator inputs. Attractor fixtures create a converging force field, directing the operator's control toward a desired trajectory or target, enhancing precision and simplifying tasks. For example, Adjigble et al. [14] applied attractor-based fixtures in robotic telemanipulation for industrial assembly, enabling stable and accurate peg-in-hole operations even in unstructured environments. Conversely, repulsor fixtures generate a diverging force field to prevent the operator from moving the robot into restricted or unsafe areas. For instance, Gottardi et al. [15] utilized repulsor fixtures in a teleoperated UAV for search-and-rescue missions, helping operators navigate around collapsed structures and debris, thereby reducing collision risks and enhancing safety in disaster response scenarios.

4.1.3 Human-instructed human-in-the-loop system (HI-HITLs)

Human-instructed human-in-the-Loop (HI-HITL) systems are characterized by a distinct interaction model where the operator provides high-level instructions rather than low-level motion commands. These high-level instructions are integrated by the robot's autonomous planner to generate detailed, low-level control commands. By eliminating the need for real-time low-level robot control, with HI-HITLs operators can focus on higher-level planning.

Components on construction sites tend to be irregular in shape and material compared to parts in manufacturing. To achieve robust autonomous gripping requires tedious computation, yet this is a subconscious action for humans. The HI-HITL system can effectively utilize human dexterity and tacit knowledge in grasping irregular objects to compensate for deficiencies in robotic reasoning. For example, existing studies have proposed that operators could instruct robots through (1) setting a target grasping pose [19], (2) selecting from a set of grasping candidates generated by the robot [20], or (3) defining geometric constraints for grasping [16, 17]. In addition to grasping assistance, another type of application for HI-HITL is in guiding mobile robots through complex environments. For example,

Jia et al. [18] used a graphical interface enabling operators to modify the robot's cost map by marking non-traversable obstacles that are difficult for the robot to perceive, improving path planning in cluttered environments.

4.2 Human-on-the-loop system (HOTLs)

Unlike the HITL system, the HOTL system places more emphasis on robot autonomy, i.e., the robot has the ability to perform tasks autonomously under ideal circumstances, but retains the authority of the human operator to intervene. Thus HOTL systems have the capability of control authority switching, which is also referred to as sliding control or supervisory autonomy in some contexts. Depending on how control authority switching is triggered, HOTL can be categorized into human-initiated HOTLs and robot-initiated HOTLs. These systems reduce operator workload, ensure reliability and safety, and balance efficiency with adaptability in complex environments by limiting intervention to critical situations.

4.2.1 Human-initiated human-on-the-loop system (HI-HOTLs)

HI-HOTL systems enable operators to "take over" control as needed, often through emergency stop buttons or GUI-based triggers in teleoperation scenarios. Other that these, haptic devices also play a role, allowing intuitive takeovers by detecting operator actions, such as moving the device, as demonstrated by Brosque et al. [21] in collaborative welding tasks. Additionally, systems can transition to operator control based on confidence in predicting the operator's intent, ensuring alignment with human goals.

While the reliability of the HI-HOTL system is ensured by human supervision, it relies on the operator's ability to understand the robot's state, environment and condition accurately and in a timely manner. Traditional approaches typically require operators to continuously monitor sensor data, plans, and environmental information, which can be unintuitive and cognitively demanding. To address this, Song et al. [22] introduced a system using visual-language models to present the robot's perception and motion planning in natural language, enhancing intuitiveness. Additionally, research aims to enable robots to learn from operator interventions, improving autonomy and reducing the need for future takeovers [23].

4.2.2 Robot-initiated human-on-the-loop system (RI-HOTLs)

RI-HOTL systems enable robots to operate autonomously while involving human operators only when necessary. By monitoring their state and environment, robots identify situations requiring intervention, relieving operators from constant monitoring. This further reduces operators' cognitive load and allows them to manage other tasks, improving efficiency and multitasking capabilities.

In existing RI-HOTL systems, the decision to involve human assistance is fundamentally rooted in predictions concerning the environment or task execution. This decision-making process primarily revolves around two key aspects:

1. **Estimating System Gains from Human Assistance:** For instance, hierarchical reinforcement learning has been utilized to predict the potential gains of human intervention, such as improving rescue efficiency and safety in cluttered environments. Here, the robot learns to decide when to involve the human operator to maximize task performance and ensure safety [24].

2. **Assessing Task Failure Risks:** Another approach involves evaluating the risks associated with task failures. For example, in [25], a 3D environmental uncertainities estimation model-based, risk identification and management framework was presented in which the failure probabilities of various type of mobile manipulator's task such as collisions and missed grasping were estimated. Except for utilizing task information, environmental information such as environmental accessibility [26] can also be used to regulate the autonomy of the system.

5 Challenges of deploying shared-control system in unstructured construction environment

In this section, we identify three key challenges associated with the deployment of shared control HRC in an unstructured construction environment.

5.1 Low latency bidirectional communication systems

A stable and low-latency bidirectional communication system is essential for shared control systems. Communication delays can cause command mismatches and feedback distortion, undermining operator control and robot performance [27]. This is particularly critical for SA-HITL, RG-HITL, and HI-HOTL frameworks. In SA-HITL and RG-HITL, operators provide real-time low-level control commands, and latency disrupts synchronization between operator inputs and robot actions. For instance, hydraulic excavators experience efficiency drops to 40–60% of manned operation levels due to communication delays [28]. Similarly, in HI-HOTL systems, where operators monitor and intervene, delays impair situational awareness, as seen in crane operations, which face increased task difficulty and extended completion times [29].

5.2 Intuitive human-robot interaction interface

An intuitive human-robot interaction interface is essential for shared control in construction, as it determines whether a construction worker, without robotics expertise, can accurately interpret the robot's state and remote environment, make appropriate decisions, and efficiently issue control commands with minimal errors. While most existing research on shared control focuses on the fusion mechanisms of human and robot commands, the impact of interaction interface design has received significantly less attention.

HRI interfaces can be categorized into feedback and control interfaces. Feedback interfaces are used to communicate information about the robot, the mission and the environment to the remote operator, and are therefore critical in SA-HITL, RG-HITL and HI-HOTL systems that require real-time operator feedback or supervision. Existing studies have shown that the addition of sensory dimensions such as vision, auditory and haptic can help improve situational awareness under teleoperation [30]. However, other studies have found that providing too much information to operators increases their cognitive load and, in turn, decreases their productivity. For example, relying only on visual modal information when teleoperating an excavator can overload the operator, cause fatigue and poor decisions to operators, and even damage underground utility facilities such as pipes and wires [31]. Therefore, what and how information is presented to the remote operator for different construction tasks and environments still needs a lot of human subject validation. Unlike feedback interfaces, the core challenge of control interfaces for human-robot collaboration in the field of construction engineering lies in the mismatch between limited robotic degrees of freedom and highly flexible human movement. Construction workers often require extensive training to overcome mismatches with field robots during teleoperation, thereby raising the barrier to widespread adoption.

5.3 Building trust between human and robots

Trust between humans and robots reflects the confidence and willingness of humans to rely on or cooperate with robots to accomplish tasks. Without some level of trust, it is difficult to apply any shared control method to a real construction site. Typically, the more autonomous a robot is, the more it needs human trust. For example, the HOTL system has the ability to operate fully autonomously compared to HITL, and therefore also requires more trust from the human supervisor.

To foster trust between humans and construction robots, key questions include: (1) Trust in Specific Autonomy Levels: Which shared control framework is most trusted for a given task and environment? (2) Transparency and Explainability: How can robotic systems improve transparency to enhance operator trust? (3) Impact of Training: Does continuous training increase operator trust and acceptance of higher autonomy?

6 Future trends

In this section, two future research trends identified from related works are introduced which helps to tackle with the above challenges as shown in Figure 5.

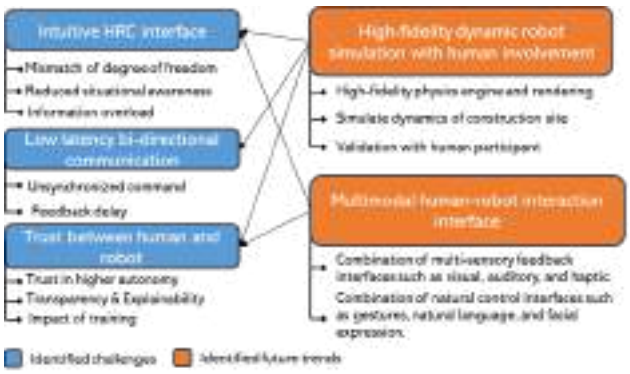


Figure 5. Mapping between identified challenges and future trends

6.1 High-fidelity dynamic robot simulation with human involvement

Compared to traditional static, low-fidelity robot simulations, shared control systems in unstructured construction environments require high-fidelity simulations to reflect the dynamics of the site and the operator's perception of the environment. High-fidelity means that the simulated environment accurately replicates the physical conditions affecting the robot and operator. For example, simulating a drone in a tunnel must account for lighting and airflow, while a robotic crane needs to model the dynamics of a pendulum in a wind or rush-stop situation to address payload swing. Similarly, simulations of inspection robots navigating incomplete structures should include uneven surfaces, temporary scaffolding, and obstacles such as materials or moving people to ensure effective robot adaptation. Future research should prioritize high-precision physics engines and advanced graphics rendering for realistic simulations. Digital twin technology can be used to capture the dynamics of the construction site and integrate real-time data to effectively simulate the ever-changing construction environment.

6.2 Multimodal human-robot interaction interface

Current research on shared control is primarily based on GUI to convey signals to operators in a visual format.

In recent years, auditory and haptic modalities have been shown to enhance remote operator situational awareness [30]. Thus, future research could focus on the integration of multiple sensory modalities, such as vision, auditory, and haptic, to provide remote operators with an immersive experience. For example, by leveraging vision-language models, robots can explain their understanding of the environment and their own actions to operators in natural language [22], while operators can also issue commands to the robots using natural language.

7 Conclusion

This paper reviews shared-control human-robot collaboration systems, focusing on their application in unstructured construction environments. A two-layer classification framework was proposed that categorizes these systems into "Human-in-the-Loop" (HITL) and "Human-on-the-Loop" (HOTL), highlighting varying autonomy levels and human involvement. Bibliometric analysis reveals significant growth, with a shift toward supervisory HOTL roles enabled by advances in autonomy. However, challenges persist, including limited focus on usability, and insufficient exploration of real-world deployment, particularly regarding trust-building, training, and adaptability. Future research should prioritize standardized frameworks, user-centered design, high-fidelity simulations, and multi-modal interaction interface to bridge the gap between theory and practice, accelerating adoption and improving safety, efficiency, and collaboration in construction robotics.

Abstract –

Visual fidelity affects the user experience and performance in virtual environments. While past studies have explored its effects, most have relied on qualitative measures, and few quantitative studies have specified visual quality standards. This study examined the influence of visual fidelity on task performance and mental workload in immersive virtual environments (IVEs). Two environmental models were tested in virtual reality (VR) and mixed reality (MR): a high-visual quality model featuring detailed materials, realistic lighting, and outdoor scenery, and a low-fidelity research model with basic colors, dimensional lighting, and no external views. Sixty participants completed cognitive tasks (digit span, spatial working memory updating, go/no-go), while the EEG measured mental workload. The results showed that high-fidelity increased the cognitive load in complex tasks, whereas MR environments supported better performance. These findings emphasize the need to balance realism and cognitive demands to optimize virtual experiences.

Keywords –

Immersive Virtual Environments; Visual Fidelity; Task Performance; Mental Workload

1 Introduction

Immersive Virtual Environments (IVEs) are increasingly being used in research and industry for training, simulation, and entertainment. Advancements in head-mounted display (HMD) hardware and software have enhanced visual fidelity by incorporating detailed textures, realistic lighting, and function-focused representations [1]. Visual fidelity, defined as the level of realism and detail in rendered virtual environments (VEs), is widely assumed to enhance the user's sense of presence (SoP), the subjective perception of "being there" [2].

However, previous studies have primarily focused on qualitative methods, such as surveys and interviews [3], leaving the impact of visual fidelity on objective measures of task performance and mental workload less explored. Task performance is a critical factor in indoor behavior and influences business and educational outcomes [4,5]. Mental workload, which represents cognitive effort during work or study, is influenced by complexity and environmental outcomes [6,7]. While high-fidelity elements enhance realism and immersion, they may also increase the cognitive load by demanding greater processing resources, particularly in scenarios requiring complex decision-making or problem-solving within Virtual (VR) and Mixed Reality (MR) [8,9].

This study aimed to investigate the influence of high and low visual fidelity on task performance and mental workload in IVEs. By comparing VR and MR settings, we provide insights into leveraging visual presentation to balance performance and cognitive demands.

2 Literature Reviews

Visual fidelity is often correlated with user engagement, presence, and satisfaction with a VEs [10]. Previous studies have suggested that realistic lighting and detailed textures significantly enhance SoP [11,12]. However, high-fidelity elements also require greater computational resource and may inadvertently increase the cognitive load [13]. Experimental investigations on IVEs have shown that variations in environmental realism can significantly affect user experience [14,15]. Beyond a certain threshold, further enhancements in graphical detail may yield diminishing returns on engagement and fail to substantially improve task performance [16].

Milgram and Kishino [17] described the Reality-Virtuality Continuum, bridging the gap between fully virtual and real environments. Whereas VR places the user in a completely simulated space, whereas MR overlays digital objects in the real-world. This dual

processing may lead to different cognitive demands than those in the VE. Supporting this notion, Hong et al. [18] demonstrated that users' subjective evaluations of an urban soundscape did not significantly differ between real and IVEs, suggesting a certain level of equivalence in the perceived experience.

Physical environmental factors, such as ceiling height, nature elements, and window size, are well known to influence work performance [19–22]. The translation of these insights into IVEs, particularly those designed with varying degrees of visual fidelity, is an area of ongoing research. High visual fidelity can enhance the user's SoP and realism in virtual experiences. However, they may also increase the cognitive load, especially during complex decision-making or problem-solving tasks. For instance, a study on visuospatial problem-solving in MR environments found that although high-fidelity visuals improved task accuracy, they also led to longer completion times, indicating increased cognitive effort [23]. Similarly, research on the cognitive load in 3D Ves suggests that higher visual complexity can elevate the cognitive load, potentially affecting user performance [9].

This gap in understanding, explains how visual fidelity in immersive environments influences task performance, mental workload. By systematically examining user performance and mental workload across varying levels of visual realism, we aimed to clarify whether increased visual fidelity truly benefits VE users. While previous research has highlighted the potential of high-fidelity environments to enhance SoP and immersion, their impact on practical outcomes, such as cognitive efficiency and task performance, remains underexplored.

3 Methods

3.1 Experimental Settings

3.1.1 Physical Space

An L-shaped classroom was selected as the experimental setting for this study, because its layout is particularly relevant for examining the cognitive load and occupant engagement while reducing distractions [24]. The physical space used was 15.5 m^2 L-shaped educational facility in Seoul, Republic of Korea. Thes room was furnished with basic furniture, including four tables and chairs, a television, two pendent lights, bar tables and chairs, and air conditioners. In addition, the wall interior was painted using a green diagonal design and punched plate finishing. The features of this room, along with general images, are shown in Figure 1.

3.1.2 Virtual Spaces

Two distinct VEs were created in this study. First, the virtual setting was modelled in Unity 3D using a 3D model developed from the original CAD floor plan in Revit software. Second, the 3D modelling file was exported as an fbx file and imported into the Unity 3D environment. Finally, detailed virtual settings were designed in the Unity 3D engine such as texture, lighting, and outdoor scenery. This design process was performed based on different visual fidelity levels, with high and low quality implemented in each VR and MR devices.

3.1.3 Visual Quality Levels in VEs

Each virtual environment was presented at two visual quality levels, following the framework outlined by Graham et al. [25]. The authors classified visual fidelity into two levels of detail (LOD 1 and LOD 2) in VR environments, using identical base modelling files. In LOD 1, textures were applied to 3D models using a generic texture library available on software platforms

Figure 1. Floor plan and cross-section photos of the physical space

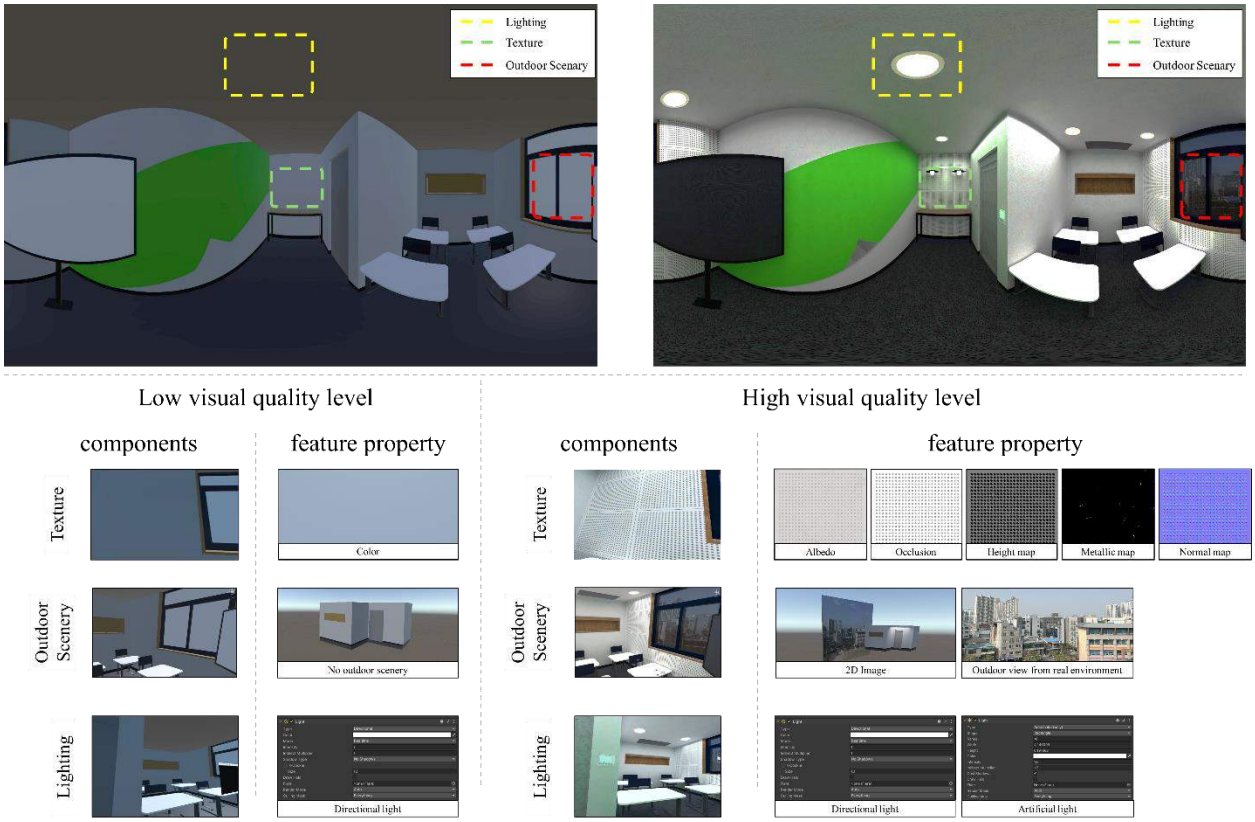

Figure 2. Description of LQ and HQ visual fidelity features in VEs

such as Autodesk Revit, Rhinoceros, or Unity 3D. Conversely, LOD 2 incorporates highly detailed texture features, leveraging advanced techniques such as detail maps (including normal, height, and adobe maps) or data derived from laser scanning and photogrammetry.

In this study, the High-Quality (HQ) visual fidelity level includes realistic artificial indoor lighting that enhanced the immersive quality of the environment. In addition, the outdoor scenery visible through windows was modelled using real photographs, further contributing to the realism of the virtual environment. However, the Low-Quality (LQ) visual fidelity level relies solely on directional lighting provided by Unity 3D, which simplifies the lighting setup. Unlike the HQ, the LQ does not include outdoor scenery, which results in a less immersive virtual experience.

3.2 Subjects

A one-way analysis of variance (ANOVA) was conducted. Based on the central limit theorem and assumption of normality in the distribution for statistical analysis, a sample size of 30 participants was used [26]. The specific sample size was calculated using G*power 3.1 software. We used an ANOVA: fixed effects, omnibus, one-way function with an effect size of 0.60 as the middle scale, an alpha error probability of 0.05, and a power level of 0.80 with three groups.

As the experimental groups were conducted using VR, MR, and real-world settings, a total of 50 participants was calculated, and 60 subjects were recruited, considering a dropout rate of 20%. All the study procedures were approved by the Institutional Review Board and Ethics Committee of Hanyang University (HYUIRB-202406-014). In total, 60 subjects participated in this study, none of whom had a history of mental or physical health problems. Among the 60 collected data points, three were excluded because of poor data quality, two from the HQ group and one from the LQ group.

The study sample consisted of 60 participants aged 20 – 32 years, reflecting the target demographics of university students. Among the participants, 42 were male, and 18 were female. The average age for male participants is 25.43 years, and the average age for female participants is 24.06 years. The overall average age of the sample is 25.02 years. The decision to recruit participants primarily in their twenties aligns with the study's focus on classroom environments, as university students represent the primary users

3.3 Measurements

3.3.1 Task Performance

Cognitive tests are widely used to assess domains such as executive function, attention, memory, intelligence, language ability, and reasoning [27]. These cognitive domains are regarded as key indicators of concentration and predictors of future job performance [28]. While specific cognitive requirements may vary depending on job demands, executive function, attention, and memory are fundamental to general work performance [29].

To evaluate productivity across different spatial environments, three cognitive tests were conducted, the 2-back test, spatial working memory updating, and go/no-go test. In an MR environment, where holographic information is overlaid onto the real world, the use of a traditional keyboard can be challenging for users. To address this limitation, cognitive tests that rely on simple button interactions, such as pressing a space bar or number keypads, were adopted.

The 2-back test presents sequential visual stimuli to the users, requiring them to memorize and respond correct time [30]. In the 2-back test, participants must identify when the current stimulus matches the one presented two steps earlier, necessitating continuous updating of information.

Spatial working memory updating was utilized to assess memory ability. The original test uses a 2x2 matrix displayed on the screen, in which a color-filled square briefly appeared in one spot before disappearing [31]. In the updated version of the test, a 3x3 blank square matrix was used to further assess participants' memory abilities.

The go/no-go test is an intuitive measure of participants' attention ability [32]. In this test, a green or checkerboard pattern sphere appeared on the screen to evaluate the response time and accuracy. This test effectively gauges participants' ability to focus, process stimuli, and exercise inhibitory control.

To quantify learning performance, accuracy and response time were recorded for all cognitive tests. The learning performance was calculated using Equation (1) and employed as the primary indicator [3].

3.3.2 Mental Workload

The experiments imposed a cognitive load on participants, making it necessary to quantify and measure this load. The cognitive load experienced by participants during the task increased as they completed the given assignments, with workload and stress being the primary factors involved in the process. To assess this, we used the EPOC X+ device to collect raw EEG data. Brainwave data were extracted from the frontal (AF3, F7, F3, FC5, FC6, F4, F8, and AF4), parietal (T7, P7, P8, and T8), and occipital lobes (O1 and O2 through 14 electrodes, capturing frequencies within the range of 0.16 to 43 Hz.

Raw data often contain noise, such as eye blinks, head movements, and muscle activity, which necessitates a noise removal process. A finite-impulse response (FIR) filter was applied to eliminate these artifacts, and data outside the 4-40 Hz range were discarded. Next, an independent component analysis (ICA) was performed to remove impractical features from the filtered EEG data. Finally, the collected EEG data were classified into theta, alpha, beta, and gamma wave categories using fast Fourier transform (FFT). This method, which is widely validated in neuroscience, allows for the differentiation of brainwave activity. In simple term, theta waves are typically active during states of relaxation [34], alpha waves during calmness [35], beta waves during thinking or when experiencing tension [36], and gamma waves during heightened focus and concentration [37].

To conduct an in-depth analysis of the cognitive load during tasks, the mental workload was calculated and used as indicators. The methods for measuring each indicator follow Equations (2) [38].

3.4 Research Procedure

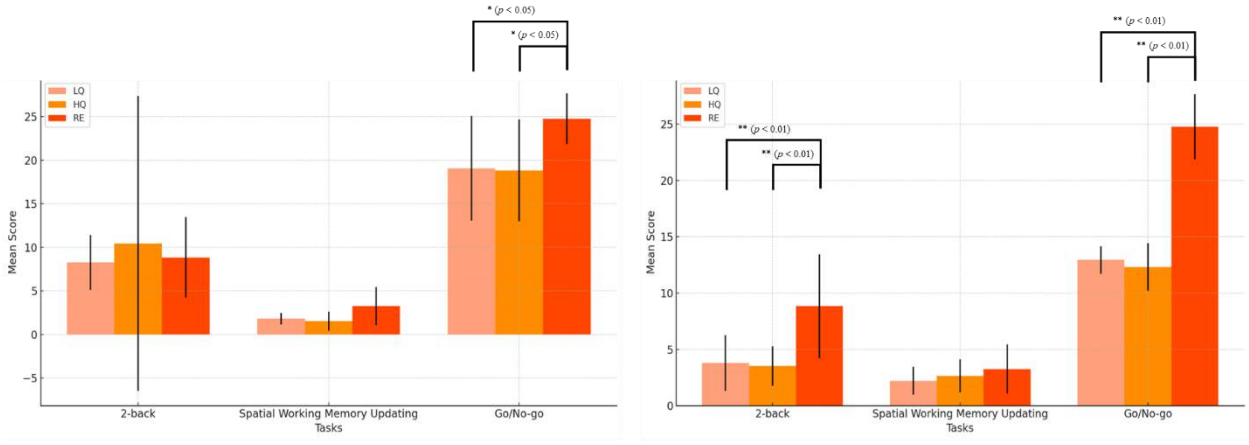
Each experiment was conducted in the same classroom with a modelled environment to prevent misunderstandings regarding the spatial layout. Participants underwent a preparation phase that consisted of an explanation of
the experiment, a Short Portable Mental Status Questionnaires (SPMSQ), and a short training of VR and MR to familiarize themselves with the navigation and interaction features in VE. The SPMSQ was used to check whether the participants had cognitive impairment [39]. Including the preparation phase, all VE experiences using the HMD device were limited to two minutes to prevent motion sickness, cyber-sickness, and dizziness. To measure brainwaves, the participants wore an EEG device on the MR HMD. After the preparation phase, the subjects performed three cognitive tests in each experimental environment, and the accuracy rate, response time, and brain wave data were collected. Cognitive tests were conducted in random order to prevent ordering effects [28].

$$Learning\ Performance = \left[(Accuracy, \%)^{0.5} \times \frac{1}{(Response\ Time,\ ms)^{0.5}}\right]^2 \times 100 \quad (1)$$

$$Mental\ workload = \frac{(Relative\ Beta)_{Frontal}}{(Relative\ Theta)_{Frontal} + (Relative\ Alpha)_{Frontal}} \quad (2)$$

4 Results

4.1 Task Performance Result



For the 2-back task, no significant differences in performance were observed among LQ, HQ, and RE in VR ($p = 0.350$). However, in MR, a significant difference was observed ($p < 0.001$), with RE outperforming HQ and LQ ($p < 0.01$). The performance advantage of MR may stem from the added realism of the real environment, which likely reduces the cognitive load.

In the Spatial Working Memory Updating Task (SWM), performance remained consistent across LQ, HQ, and RE in both VR ($p = 0.077$) and MR ($p = 0.356$). This indicates that visual fidelity does not have a strong impact on working memory tasks, regardless of the medium.

For the go/no-go task, RE significantly outperformed HQ and LQ across both VR ($p < 0.05$) and MR ($p < 0.001$). In both environments, RE outperformed HQ and LQ, with a post-hoc analysis showing that RE was significantly better than both HQ and LQ. This highlights the advantage of intuitive familiarity of the real environment in tasks requiring rapid decision-making and response inhibition.

(a) VR Environment (b) MR Environment

Figure 4. Comparison of mental workload across visual fidelity in VR and MR environments

4.2 Mental Workload Result

In terms of mental workload, no significant differences were observed for the 2-back task across the environments in VR (p = 0.061) and MR (p = 0.271). This indicated that the cognitive load associated with the 2-back task was not significantly affected by the environment or visual fidelity levels.

For SWM, VR showed a significant difference in mental workload (p = 0.048), with post hoc analysis indicating a higher cognitive load in HQ than in RE. In contrast, no significant differences were observed in MR (p = 0.525), suggesting that visual fidelity did not affect the mental workload for this task in MR

The go/no-go task exhibited no significant differences in the mental workload across environments or media, as indicated by the results for both VR (p = 0.055) and MR (p = 0.800). This suggests that the visual fidelity levels did not significantly influence the cognitive load in this task.

5 Conclusion

This study examined the nuanced relationships among visual fidelity, task performance, and mental workload in VR and MR environments. For the 2-back task, the significant difference observed in MR but not in VR underscores the importance of considering specific medium when designing IVEs. In MR, the presence of real-world elements or cues may enhance task performance by providing familiar and intuitive spatial references that can reduce the cognitive demands. However, SWM showed consistent performance across all environments in both VR and MR, suggesting that

visual fidelity had minimal effect on tasks involving working memory. By contrast, excessive visual detail in the HQ can burden cognitive resources without contributing to performance improvements. For the go/no-go task, the real environment consistently outperformed the VEs in both the VR and MR tasks, emphasizing the role of familiarity and intuitive interactions in optimizing task efficiency. The mental workload did not vary significantly for this task, indicating that the cognitive demands of response inhibition were stable regardless of environmental realism.

While this study was conducted in a L-shaped classroom setting, the cognitive process examined, such as executive function, memory, attention, are fundamental to human performance and can have implications beyond this specific environment. In real-world construction settings, particularly in open-plan sites and industrial environments, workers often navigate complex and unpredictable surroundings that require continuous cognitive adaptation. Given these considerations, our findings may provide valuable insights for applications in virtual construction environments, such as hazard perception training, safety simulation, and the understanding of complex procedural sequences. By integrating these cognitive insights into virtual construction platforms, training programs can replicate real-world conditions precisely, allowing for improved spatial awareness.

To enhance the generalizability of this study, future research should explore the way in which cognitive mechanisms influence decision-making and situational awareness in active construction environments. Expanding this research into dynamic, real-world settings could further validate its applicability in construction safety management.

Abstract –

Manufacturing is a critical stage in modular construction, as it directly affects cost, schedule, and quality. Human-robot collaboration (HRC) has the potential to enhance modular construction manufacturing (MCM) productivity while preserving essential flexibility. Despite these benefits, previous studies on designing HRC workplaces for MCM have primarily focused on efficiency, often overlooking ergonomics and human factors. This oversight can negatively affect workers' occupational safety and health (OSH) and overall well-being. Therefore, this research aims to promote the concept of ergonomic HRC (EHRC) and inform the EHRC design for MCM. Three cases are further presented to demonstrate the design of EHRC under different variables and considerations. This study encourages researchers and practitioners to place human well-being at the center of the production system.

Keywords –

Human-robot collaboration (HRC); modular construction; ergonomics; human-centric HRC; workplace design

1 Introduction

Modular construction is a process where building modules are manufactured offsite and then transported to the construction sites for the final assembly [1]. Various terms are used in the literature to describe this manufacturing-oriented construction approach, including offsite construction [2], prefabricated construction [3], or industrialized construction [4]. To clarify, this study uses the term "modules" to encompass all prefabricated components, including 1D elements, 2D panelized systems, and 3D volumetric units [5]. Modular construction has been considered a viable alternative to traditional construction methods due to its improved productivity, quality, safety, and sustainability [6]. With its controlled manufacturing environment, robots can play a significant role in modular construction manufacturing (MCM) processes by alleviating workers' fatigue, improving quality, and boosting productivity [7, 8].

Despite the increasing use of automation in producing standardized building modules, significant challenges persist in MCM. First, MCM must accommodate diverse design styles to meet varying demands and adapt to economic fluctuations, resulting in considerable variability in manufacturing workflows [9]. This customization presents a challenge for standard automation, as conventional robotic systems lack the flexibility needed to handle frequent production changes. Second, fully automating MCM processes requires substantial upfront investments, such as the cost of equipment and factory reconfiguration [10]. This can be a barrier for small and medium-sized manufacturers with limited tolerance for financial risks [11]. Third, many MCM tasks require human involvement for the dexterous use of construction tools and the improvisational skills to adapt to material variations [12], while robots struggle to cope with these complexities.

To address these challenges, combining human expertise with robotic systems in MCM processes presents a promising solution through efficient human-robot collaboration (HRC) [13]. HRC capitalizes on the complementary strengths of humans and robots: humans excel at flexibility and adaptability for creative and ill-defined tasks, while robots offer unparalleled precision and consistency. Consequently, HRC offers significant potential for achieving the trade-off between MCM productivity and flexibility.

HRC workplace designs require careful consideration of various factors. Existing studies on HRC for MCM often prioritize productivity, efficiency, and flexibility by developing innovative workflows. For example, Tavares, Costa [14] presented a collaborative welding system where both a robot and a human share part of the physical welding task. Lee and Han [15] designed a novel robot system for welding, with an interactive interface for human fine-tuning. However, these studies paid limited attention to ergonomics and human factors, which may adversely affect workers' occupational safety and health

(OSH) and well-being [16]. With the advance of Industry 5.0, there is an increasing focus on human-centric HRC, where human well-being is prioritized in production processes [17]. Safety and ergonomics are central to this human-centric paradigm, yet current studies often fail to integrate ergonomic factors into HRC designs for MCM [18]. Besides, little research has been conducted in exploring HRC design considerations for MCM.

To bridge the gap, this paper aims to explore different HRC schemes in MCM and discuss critical considerations in designing ergonomic HRC (EHRC) workplaces. This study adopts an exploratory research approach, combining a literature review with case study analysis. First, we synthesize existing research to define EHRC and identify its design considerations in MCM. Second, we illustrate these considerations through three case studies derived from prior work, representing diverse MCM tasks, human roles, and robot types. By shifting the focus from productivity to human well-being, this study contributes to the development of human-centric and ergonomically optimized HRC applications in MCM.

2 Preliminary concepts for EHRC

HRC is gaining prominence to achieve the trade-off between flexibility and efficiency in production [19]. Its main goal is to reduce the physical and repetitive workload on human workers by enabling robots to assist in labor-intensive tasks. In the manufacturing industry, HRC typically involves humans and robots collaborating in a shared workplace towards a common goal. While similarities between MCM and traditional product manufacturing have been indicated [20], the make-to-order and elaborate nature of MCM presents unique challenges for implementing industrial HRC solutions effectively. Therefore, this paper adopts a broad definition of "collaboration" emphasizing joint efforts between individuals, especially in intellectual or creative pursuits [21].

To address worker well-being in such systems, ergonomics offers a critical foundation. The International Ergonomics Association (IEA) defines ergonomics as, "*the scientific discipline concerned with the understanding of interactions among humans and other elements of a system, and the profession that applies theory, principles, data, and methods to design in order to optimize human well-being and overall system performance.*" [22]. Although the terms "ergonomics" and "human factors" are sometimes distinguished - ergonomics being linked to physical aspects and human factors to psychological and cognitive aspects - they are often used interchangeably [22-24]. For clarity, this study adopts the IEA definition of ergonomics, encompassing both the physical and cognitive/psychological dimensions of human interaction. Furthermore, this study narrows its focus to the individual worker level, aligning with the scope of micro-ergonomics, which addresses both physical and cognitive factors [25] that directly impact worker well-being. Building on this, the study defines ergonomic human-robot collaboration (EHRC) as "using ergonomics principles to design a workplace where humans and robots collaborate safely, efficiently, and in support of worker well-being".

The EHRC further draws on the industrial human needs pyramid [17], which consists of five levels: (1) safety, the foundational level, which ensures physical protection and legal rights; (2) health, the next level, which focuses on creating a healthy work environment to support physical, cognitive, and psychological well-being; (3) belonging, which meets social needs of workers and to promote connections and trust between human-machine team; (4) esteem, which enhances workers' confidence, self-belief, and respect from peers; and (5) self-actualization, the highest level, which enables personal growth, fulfillment, and sense of purpose through meaningful work. This pyramid highlights that human health is founded on physical safety while facilitating higher levels of well-being. Mapping to the HRC domain, safe HRC primarily fulfills the safety level by mitigating physical hazards, while EHRC extends this to the health level by addressing physical, cognitive, and psychological factors to promote long-term well-being. Figure 1 illustrates this relationship, highlighting how EHRC builds upon safe HRC within the industrial human needs pyramid to enhance workplace design.

Figure 1. Role of EHRC in the industrial human needs pyramid (adapted from [17])

3 Design considerations of EHRC for MCM

3.1 HRC variables in MCM

Different HRC variables involve different requirements. Workers collaborating with robots on MCM tasks face specific ergonomic challenges that differ from the standardized and lightweight tasks in conventional manufacturing. This paper summarizes three critical HRC variables in MCM, i.e., MCM tasks, human roles, and robot types.

MCM tasks can be generally summarized into three types, i.e., small-size component production, 1D and 2D prefabricated component production, and 3D volumetric module production:

- Small-size component production: This involves manufacturing smaller components (e.g., windows and plumbing elements) that are later assembled on larger modules or buildings. In MCM, tasks to produce small components are less repetitive since size and specification needs vary in different projects. Intermittent and varied tasks require workers to make frequent postural or tool adjustments, increasing physical strain and cognitive burden.
- 1D and 2D prefabricated component production: This involves manufacturing structural elements such as steel beams (1D) and timber panels (2D) that bear the loads and stresses of the building. These components can be produced in assembly lines or fixed-position setups. Assembly-line workers face shoulder and back strain from repetitive lifting (e.g., aligning beams for robotic welding), while fixed-position tasks require prolonged leaning or twisting, increasing musculoskeletal risks.
- 3D volumetric module production: This refers to the manufacture of 3D volumetric housing prefabricated units. These volumetric modules can be prefabricated, pre-finished, and even pre-furnished, representing different levels of completion in modular construction. The large size and weight of these modules often confine workers and robots to fixed-position workstations. When working on the interior of a module, workers must collaborate with robots in tight spaces, which increases safety hazards while potentially further restricting workers' movement and forcing them to maintain awkward postures. As for exterior work such as cladding or window sealing, workers have more room to maneuver but face the challenges of working from heights or extending their arms.

Human roles can be categorized into four types: supervisor, teammate, operator, and bystander [13]:

- Supervisor: Supervisors are responsible for monitoring the robot and instructing the robot to perform the task. This role requires sustained attention to one or more robots performing diverse tasks in a cluttered MCM environment. As a result, this role requires constant vigilance, with increased cognitive load and mental fatigue.
- Teammate: Teammates are responsible for completing physical activities beyond the capabilities of the robot to achieve a common goal. As teammates are required to share physical tasks, they cannot avoid the postural risks associated with lifting, pushing, or adjusting materials. Collaborating in close proximity to the robot also increases the mental workload of the worker.
- Operator: Operators take direct control of the actions of the robot during the execution of the task. The control can be either in close proximity (e.g., guiding a gantry robot installing a window) or remotely (e.g., guiding a robot with VR controllers). Proximity control requires repetitive body postures, while telecontrol increases eyestrain and cognitive load.
- Bystander: Bystanders work in the same space as robots without direct interaction, but should be concerned with issues related to safety and situation awareness. Bystanders must be distracted from the robot's movements while focusing on the MCM task at hand, which causes additional mental stress and cognitive burden.

Robots commonly adopted in MCM can be classified into three categories, i.e., stationary, mobile, and wearable robots [26]:

- Stationary robot: Stationary robots are fixed in the workplace, have a limited working range, and cannot move freely. The most common stationary robot is robot arms that are bolted in the workstation. Due to their large payloads and high power, safety protocols prioritize isolation over proximity HRC. This physical isolation shifts the ergonomic challenge to remote monitoring.
- Mobile robot: Mobile robots provide enough flexibility to create an adaptive workplace. Automated guided vehicles (AGVs) are commonly used to transport materials around the factories. Robot arms (e.g., collaborative robots) mounted on AGVs or gantries are also considered mobile as they can reconfigure their location freely in the factory. Since these robots offer flexibility to work around workers, they are either with lower payload and power, or are less automated and require workers' direct control to ensure safety. Collaboration with these robots can be physically

demanding and cognitively taxing.

- Wearable robot: Wearable robots, commonly known as exoskeletons, are designed to boost human physical strength and endurance. These robots not only enable individuals to handle heavier loads but also help improve body posture during tasks, reducing the risk of strain and injury. Due to the complexity of controls and fewer applications, they can be an added cognitive burden for workers.

3.2 Design considerations for EHRC

Designing EHRC workplaces in MCM requires careful attention to safety strategies, physical ergonomic design, and cognitive ergonomic design.

3.2.1 Safety strategies

Safety strategies in HRC include a blender of separation protection, passive protection, and proactive protection. These strategies should be carefully selected in the EHRC design.

- Separation protection: Separation protection ensures safety by keeping humans and robots physically separated. This protection method is typically achieved through safeguards such as guards (e.g., fences, barriers, and light curtains). When collaborating with heavy industrial robots, maintaining a strict separation between humans and robots is essential.
- Passive protection: Passive protection ensures safety with robots' built-in design features without requiring active monitoring and prediction of human state. Collaborative robots typically have passive protection mechanisms such as limited payload and end-effector state detection, since they are designed to allow closed collaboration in a shared workplace.
- Proactive protection: Proactive protection perceives and predicts the human state and adapts robot behavior in real time to avoid safety risks. This method integrates advanced sensors such as depth cameras and wearable devices to monitor humans and adopt actions before an unsafe event occurs.

3.2.2 Ergonomic design considerations

In addition to keeping workers away from safety hazards, EHRC prioritizes worker health and well-being through ergonomic design, consisting of both physical and cognitive aspects [17]. Physical ergonomics examines human postures and behaviors that could cause musculoskeletal injuries [27], assessed through tools such as rapid upper limb assessment (RULA) [28] and rapid entire body assessment (REBA) [29], which evaluate posture risks, and biomechanics analysis (e.g., OpenSim), which measures muscle tension and joint loads. Cognitive ergonomics focuses on reducing the mental stress and psychological challenges faced by workers sharing the workplace with robots [30], evaluated using self-report scales such as NASA task load index (NASA-TLX) [31], supplemented by physiological data (e.g., electrodermal activity, heart activity, electroencephalography, electromyogram, eye activity) from wearable sensors. These physical and cognitive ergonomic principles are integrated into three design considerations tailored to MCM:

- Ergonomic task design: This balances task demands to reduce physical and cognitive strain. By optimizing task sequences, repetitive actions are delegated to robots, while workers engage in varied movements to lower musculoskeletal injury risks in assembly-line or fixed-position setups. Dynamic task adaptation allows robots to sense human states (e.g., physical fatigue and cognitive overload) in order to react by taking over demanding tasks or adjusting the speed of work, ensuring the well-being of workers in a custom-driven workflow. Real-time task feedback can help workers make informed decisions with a high level of trust and low cognitive workload.
- Ergonomic workstation design: This optimizes the physical workspace to minimize strain and environmental stress. Adjustable workstations allow workers to maintain natural postures minimizing the need for excessive bending or overextension during tasks. Additionally, mitigating adverse environmental factors such as noise and vibration generated by robots can preserve worker well-being and minimize ergonomic stress.
- Ergonomic interaction design: This enhances the usability and cognitive comfort of human-robot interaction. Intuitive interfaces allow workers to interact seamlessly with the robot, improving usability while reducing frustration and cognitive effort. Predictable robot motion can enhance worker trust and situational awareness and reduce stress when interacting with robots. Personalized interface settings cater to a diverse workforce in MCM, avoiding information overload for experienced operators while ensuring sufficient guidance for novices.

Although EHRC is a human-centric paradigm prioritizing human well-being, the system's efficiency cannot be ignored. However, the efficiency is not deeply examined in the paper, but its impact is presented in the discussion.

4 Case study

Three case studies under MCM scenarios are presented based on different EHRC requirements.

4.1 Case 1: Window installation on 3D modules

The first case is from our previous work [18], where a material-handling robot is applied to install a window component in an opening of a building module, as shown in Figure 2(a). Since 3D volumetric module production typically involves fixed-position workplace layouts that require workers and robots to work around the module, robot mobility is critical, which can be achieved with gantry cranes specialized for factory environments. The case has developed a 5-degree-of-freedom (DOF) gantry robot with 3 translational and 2 rotational servo-controlled axes. It is used to handle heavy window glasses; thus, the end-effector consists of a gripper with four vacuum cups. The worker is required to physically operate the robot to secure the window and haul the robot to its final location. Specifically, the worker first operates the two-handed handle with sensors, by moving it downward until it makes contact with the window glass. Once in position, the worker activates the gripping mechanism to secure the glass, enabling easy manipulation. Subsequently, the forward rotation button is engaged to orient the window to an upright position. The worker then guides the robot, along with the secured glass, to align it with the designated opening in the building module. After carefully adjusting the window to fit the opening, the worker releases the glass by pressing the release button. Finally, the robot is guided back to its initial position, and the gripper's rotation is reset, thereby completing one task cycle.

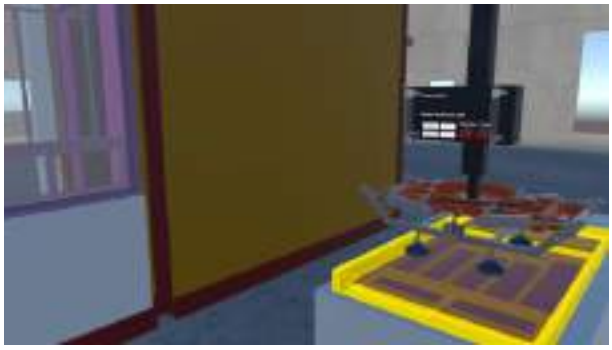

Figure 2. VR-based iterative EHRC design in case 1 [18]

The design of this collaborative robot allows humans to operate in close proximity, and the method of ensuring safety relies on its built-in mechanism design. The end-effector releases the part only after all the weight has been removed. If any problem occurs, the emergency stop button can be pressed.

The design of the HRC workstation meets ergonomics requirements from both physical and cognitive aspects. To improve physical ergonomics, the height of the worktable and the width between the two handles on the collaborative robot have been carefully designed, and both RULA and REBA tools show low risk. In terms of cognitive ergonomics, the cognitive workload and trust in the robot can be kept at an acceptable level due to the simplicity of the operation process and the intuitive human-robot interface. It is worth noting that the ergonomic assessment of this case was conducted in a virtual reality (VR) environment [Figure 2(b)], which offers a cost-efficient and iterative platform for designers to evaluate and refine ergonomic parameters with minimal resource expenditure.

4.2 Case 2: 2D timber panel production

The case 2 [11] adopts the TIM platform [32], which incorporates two KUKA KR-500 industrial robots and a swiveling table. Figure 3(a) shows the configuration of case 2. The industrial robots utilized have a scope of 2830 mm, including the end effector, a payload capacity of 500 kg, excluding the end effector, and maintain a pose repeatability accuracy of +- 0.08 mm. The robots are equipped with different end effectors each, namely a mechanical gripper, pneumatic gripper, and 3D-Camera for the PINP robot, and a nail gun, spindle and glue gun for the GNM robot, thus defining their respective skills. In this case study, the PINP robot uses the mechanical gripper for picking up the slat, placing and securing it, whereas the GNM robot employs the nail gun to fasten it. The swiveling table facilitates an extended reach for the robots by repositioning the workpieces.

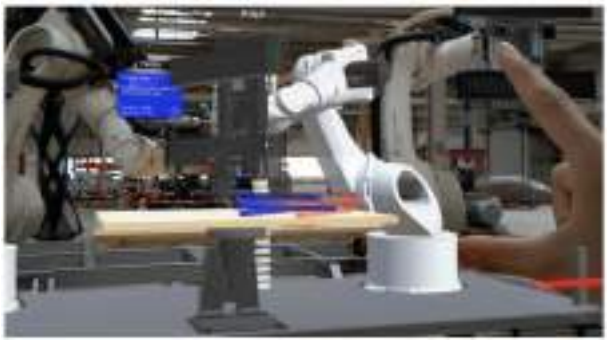

Figure 3. AR-based EHRC in case 2 [11]

This case adopts industrial robots to handle large-scale materials, which are too dangerous for physical collaboration. Therefore, separation protection is used to ensure human safety. By getting away from robots, human supervisors can avoid hazards from potential

crashes. When humans need to enter the range of the high-payload industrial robots to conduct tasks such as material supply, confirming that the robots are inactive is crucial to prevent accidents.

As supervisors, humans are required high-level cognitive capacities. This case provides an intuitive and smooth augmented reality (AR) interface for humans to improve their cognitive ergonomics, as shown in Figure 3(b). Although improper use of HRC systems could affect physical ergonomics, the motion introduced by AR (e.g., shoulder uplift motion associated with gesture recognition used in human-robot interaction) is neglectable from a biomechanical loading perspective.

4.3 Case 3: Window frame processing

The last case is from [33], which adopts a collaborative robot, UR5e robot arm, for holding the workpiece (i.e., a window frame), and a human conducts processing tasks on the workpiece. Specifically, the human is required to hold a power drill to punch four holes in each corner of the window frame, while the robot is responsible for adapting the workpiece's position and orientation to provide an ergonomic work condition. The configuration of case 3 is shown in Figure 4.

Figure 4. Proactive EHRC in case 3 [33]

This EHRC workstation ensures safety through proactive protection. On the one hand, the built-in safety mechanisms of the UR5e are designed in compliance with EN ISO 13849-1 and EN ISO 10218-1. On the other hand, the RealSense camera is used to perceive the safety condition of humans so as to prevent hazards proactively.

The robot can improve physical ergonomics by monitoring the 3D skeleton of the human, evaluating posture-related risks based on RULA tools, and adapting its motion accordingly to reduce the risks. In addition, the human wears AR glasses, which provide task-related information and hands-on instruction. The worker awareness and trust in robots can also improve through robot digital twins.

4.4 Discussion

Table 1 summarizes the three EHRC cases under study. These MCM cases illustrate differences in MCM tasks, human roles and robot types. Additionally, they involve different design considerations, offering insights for EHRC design in MCM:

- For 3D volumetric module production (Case 1), the fixed-position workplace layout confines workers and robots to work around the module, exposing workers to both physical and cognitive ergonomic risks. The case assigns heavy lifting to the robot, while the worker is only responsible for precise positioning, thus greatly reducing the burden on muscles. To design an ergonomic workstation, this case carefully designs a mobile gantry robot with adjustable gripper height, reducing awkward postures during window installation. The intuitive interface supports ergonomic interaction by simplifying operation, minimizing cognitive effort in this task. By adopting an ergonomic design, this case remains ergonomic risks to an acceptable level both physically (i.e., RULA and REBA) and cognitively (i.e., cognitive workload and trust).
- In 2D timber panel production (Case 2), heavy-duty industrial robots require separation protection, shifting human roles to supervisors focused on monitoring. The case assigns almost all of the physical work to the robot, with the worker needing only supervision and guidance. Ergonomic workstation design plays a minimal role here due to physical isolation. The AR interface enhances ergonomic interaction by providing seamless and intuitive task oversight, improving comprehension and reducing mental fatigue. This case does not directly demonstrate ergonomic design improvements for workers from physical and cognitive perspectives, but the intuitiveness, task support, and skill enhancement provided by AR technology are highly aligned with cognitive ergonomics principles.
- For small-size component tasks like window frame processing (Case 3), this case leaves the dexterity task to the worker, while the robot is responsible for helping to adjust the position of the workpiece, thus allowing the worker to reduce postural risks. The workstation senses human states (e.g., improper posture) in real time through sensors and adjusts the robot's pose to provide ergonomic working conditions that ensure worker health. An AR-driven interface enhances ergonomic interactions by providing ergonomic warnings, task guidance, and robot trajectory prediction, thereby improving situational awareness and cognitive capacity. The ergonomic design of this case keeps the RULA risk scores of the workers' arms and wrists at a low-risk level and improves their cognitive understanding of the HRC task and their trust in the robot.

Table 1. Summary of EHRC cases under study

Variables	Case 1	Case 2	Case 3
Task	Window installation on 3D modules	2D timber panel production	Window frame processing
Robot type	Mobile robot (Gantry robot)	Stationary robot (Industrial robots)	Mobile robot (collaborative robots)
Human role	Operator	Supervisor	Teammate
Safety strategy	Passive	Separation	Proactive
Ergonomic task design	Aligning robots for heavy lifting	Aligning robots for primary work	Aligning robots for workpiece adjustment
Ergonomic workstation design	Adjustable design	-	Adjustable design
Ergonomic interaction design	Intuitive controls	Intuitive AR, predictable robot motion	Intuitive AR, predictable robot motion

5 Conclusion

This paper establishes a rigorous definition of EHRC, emphasizing the design of workplaces where humans and robots work together safely, comfortably, and efficiently. It further delineates design considerations under MCM scenarios, considering HRC variables and specific challenges in MCM. Through the analysis of three case studies, this paper elucidates practical insights into the development of EHRC systems tailored to MCM. Theoretically, this study advances this field by identifying current HRC ergonomic challenges in MCM and proposing tailored design solutions that prioritize human-centric systems. It also provides a roadmap for practitioners to enhance worker safety and comfort, while mitigating expenditures on workers' compensation claims.

This paper serves as an initial blueprint for EHRC. Three future directions are proposed:

- *Multidisciplinary integration in EHRC design*. The complexity of EHRC requires a multidisciplinary approach, bridging ergonomics with robotics, medicine, psychology, human resources, and end-user perspectives. To achieve this, interoperability between these diverse fields is crucial [34]. A collaborative team of experts from these disciplines must work together to ensure that their insights and solutions are not only comprehensive but also seamlessly integrated.
- *Customized interaction interfaces.* Customized human-robot interaction interfaces are essential for achieving effective EHRC. Future efforts should focus on developing diverse interfaces for users to choose from, complemented by empirical user studies. Such studies are critical to assessing the impact of varying interface designs on different workers, optimizing information load, presentation modalities, and input mechanisms for enhanced usability and performance.
- *Dynamic adaptation in real-time systems*. Static and offline methodologies fail to account for the variability in human actions and states during real-time operations. Future systems must incorporate dynamic task allocation within human-robot teams [35] and adaptive robotic responses contingent on real-time human states. This requires perceiving and responding to human conditions, such as improper postures or elevated cognitive loads, ensuring safe and ergonomic collaboration.

Abstract

An unsupervised multimodal learning scheme based on autoencoder (AE) is proposed and developed for fault detection of building heating, ventilation, and air conditioning (HVAC) systems, applicable across multiple types of fan coil units (FCUs), i.e., cooling, heating, cooling & heating FCUs. Building automation system data of these three types of FCUs are used in developing, training and evaluating the proposed models and algorithms. The main contributions of this work include: (i) a methodology for developing a generalized AE model through multimodal and transfer learning; (ii) generalizing the AE model across three specific types of FCUs through cross-testing and transfer learning, which enables fault detection at the device-level (a specific FCU type), and system-level (across different FCU types).

Keywords–Unsupervised learning; multimodal learning; autoencoder; fan coil units; fault detection, building HVAC

1 Introduction

According to Intergovernmental Panel on Climate Change (IPCC) report [1], buildings account for 37% of global carbon emissions and 34% of energy demand worldwide. In particular, a building's heating, ventilation, and air conditioning (HVAC) system accounts for half of its total energy use, making them a primary focus for energy optimization [2]. Due to existing design flaws, operational variances, and system faults [3] [4], any undetected faults can cause an additional 103 to 500 TWh of energy consumption annually in the U.S. [5]. To mitigate these issues, fault detection and diagnosis (FDD) has been employed as a cost-effective solution for identifying potential system failure or deficiencies, and addressing these faults [6].

A fan coil unit (FCU) is the "last mile" in many building HVAC systems, providing zone-level heating and cooling. FCUs typically consist of a heating and/or cooling coil, fan, and filter, and are controlled with local thermostats to achieve desired space conditions. Large buildings may contain dozens – even hundreds – of FCUs installed in a building, thus ineffective or faulty FCUs operation can result in occupant discomfort and energy waste. Limited research has explored FDD for FCUs and the majority rely on simulation-based methods using simulated data [7, 8], or unsupervised [9] [10] methods. Further, existing FDD solutions are mostly developed specifically for particular, limited fault categories (e.g. valve stuck, fan failure) [10] or a particular FCU type. There is still a lack of generalized solutions for characterizing FCU operation and FDD for the FCUs, in lieu of designing different FDD solutions for different types of FCUs for cooling or heating. Even if machine learning or neural network-based solutions were to be implemented, they require retraining for at least three different types of FCUs (one for each type), which incurs significant additional resources.

In this paper, we propose an unsupervised multimodal learning approach for developing and designing novel algorithms for fault detection of the FCUs. A methodology for developing a generalized autoencoder (AE) model through multimodal and transfer learning is first presented. This methodology facilitates unsupervised learning for fault detection at the equipment-level (for a specific FCU type), and system-level (across different FCU types). Then, a global model and specific models are developed for fault detection of multiple FCU types. Fault detection performance of the global model and specific models are evaluated to demonstrate the generalizability of the AE across different FCU types. These are achieved through cross-testing and transfer learning based on real building automation system data. In a nutshell, based on unsupervised multimodal learning, only a single global AE model is required for fault detection through unsupervised learning from historical data of cooling-only, heating-only, cooling & heating FCUs.

2 Background

Figure 1 shows a schematic of an FCU, consisting of a heating coil (H/C), a cooling coil (C/C), and a fan. It is

part of an HVAC system and is widely used in multi-unit residential, commercial, and industrial buildings.

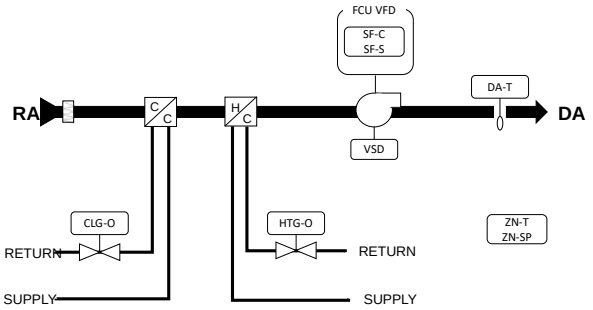

Figure 1: Schematic diagram of a FCU; VSD denotes variable speed drive.

Each component of a FCU and their functionalities are described in Table 1.

Table 1. FCU components and functionalities.

Component	Description
Cooling coil command (CLG-O)	The cooling coil is controlled by a valve controlled by a command CLG-O (of continuous value between 0 and 1), which indicates the percentage the valve is open. The valve is for controlling the flow of chilled water to regulate the coil's cooling capacity as needed.
Heating coil command (HTG-O)	The heating coil is controlled by a valve controlled by a command HTG-O (of continuous value between 0 and 1), which indicates the percentage the valve is open for supplying hot water from the building's central heating plant. When heating is needed, this coil introduces warmth to the air drawing into it, effectively raising the temperature. The flow of hot water through the heating coil is regulated by a valve for controlling the amount of heat to the air.
Supply air (DA)	Conditioned air to the space. The temperature of the supply air is indicated by the DA-T sensor.
Zone sensors (ZN-T, ZN-SP)	Sensors placed within the conditioned zone. ZN-T is the zone temperature; ZN-SP is the set-point of the temperature.
Fan sensors (SF-C, SF-S)	The fan draws air through the coils and then discharges it into the room. Supply Fan Command (SF-C) is a control output which commands the operation of the supply fan. Supply Fan Status (SF-S) indicates the supply fan's on/off status.
Occupancy schedule (OCC-SCHEDULE)	The system will operate based on a time of day schedule adjustable by the user.
Unit enable signal (UNITEN-MODE)	A network unit enable signal (UNITEN-MODE) will control the mode of the unit.

In this work, real building automation system datasets of cooling-only, heating-only, and cooling & heating FCUs in a building HVAC system are adopted. The data information covers the room temperature (ZN-T), supply air temperature (DA-T), as well as command data such as cooling valve output (CLG-O), heating valve output (HTG-O), and temperature set point (ZN-SP), etc., as summarized in Table 1.

2.1 Principle of an Autoencoder

AEs are a type of neural network model that enable unsupervised features extraction [11], due to their strong representation learning capabilities, simple structure, and ease of training. As illustrated in Figure 2, the architecture is formed by an encoder and a decoder.

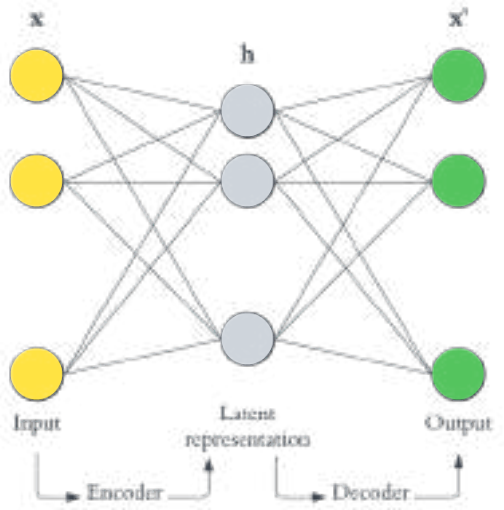

Figure 2: Neural network architecture of an AE.

The mathematical formulation of the AE architecture is as follows:

$$\boldsymbol{h} = f(\boldsymbol{W}_e\boldsymbol{x} + \boldsymbol{b}_e) \quad (1)$$

$$\boldsymbol{x}' = g(\boldsymbol{W}_d\boldsymbol{h} + \boldsymbol{b}_d) \quad (2)$$

where $\boldsymbol{x}$ and $\boldsymbol{x}'$ denote the input and reconstructed output, respectively, $\boldsymbol{h}$ denotes the latent space; $\boldsymbol{W}_e$ and $\boldsymbol{b}_e$ denotes the encoder's weights and bias respectively, while $\boldsymbol{W}_d$ and $\boldsymbol{b}_d$ denote the decoder's weights and bias respectively; $f()$ and $g()$ denote each of their respective activation functions.

In an AE, the encoder section first compresses high-dimensional input data into a compact latent representation. This compact latent representation is then used by its decoder section to reconstruct the original data.

During training phase, the AE's objective is to minimize the error between the original input data and

its reconstructed data. Given a training data set of size N, the neural network weights of an AE are optimized by minimizing a loss function $\mathcal{L}$ using gradient descent algorithm. The loss function $\mathcal{L}$ quantifies the reconstruction error as,

$$\mathcal{L} = \frac{1}{N}\sum_{i=1}^{N}\left|x^{(i)} - x'^{(i)}\right|^2 \quad (3)$$

After successful training, the latent space $\boldsymbol{h}$ can be adopted as the feature representation for any given input $\boldsymbol{x}$.

This training process facilitates the neural network to learn and capture essential relationships among input variables, while filtering out any anomalies and noise, enabling the latent space to characterize any hidden patterns in the original input data. In general, the above encoder-decoder framework also facilitates integration of other deep learning networks like recurrent neural networks and convolutional neural networks for more complex representation learning [12].

A larger latent space that is close to the input size could lead to overfitting, as the AE model merely copies the input data without extracting essential patterns or features from the original input data. Conversely, a latent space that is too small, such as one dimension could cause underfitting and poor reconstruction of input data, as the AE model fails to extract any features or features from the original input data.

3 Multimodal AE for Fault Detection

The primary goal of this work is to design a generalized AE that captures the dynamics and interaction of unimodal (cooling-only, heating-only) and bimodal (heating & cooling) operations of three different FCU types, while also models each of them separately. Previous works in multimodal research has proposed feature concatenation and tensor fusion approaches for multimodal learning. In this work, the tensor fusion approach is adopted for multimodal modeling and learning of three types FCUs, by first defining the following vector field using a 2-fold Cartesian product:

$$\{(\boldsymbol{z}_c, \boldsymbol{z}_h) | \boldsymbol{z}_c \in \begin{bmatrix} CLG_0 \\ 1 \end{bmatrix}, \boldsymbol{z}_h \in \begin{bmatrix} HTG_0 \\ 1 \end{bmatrix}\} \quad (4)$$

where the subscripts $_c$ and $_h$ denote, respectively, cooling and heating; CLG-O denotes the cooling valve output command to a FCU for cooling; HTG-O denotes the heating valve output command to a FCU for heating. Note that the extra constant dimension with value 1 is for generating the three distinct input feature variables that capture, respectively, the dynamics and interaction unimodal (cooling-only, heating-only) and bimodal (heating & cooling) operations. As a result, for the designed AE neural network, each coordinate $(\boldsymbol{z}_c; \boldsymbol{z}_h)$ can be seen as a 2-D point in the 2-fold Cartesian space defined by the embedding vector $\begin{bmatrix} CLG_0 \\ 1 \end{bmatrix}$ for cooling, and the embedding vector $\begin{bmatrix} HTG_0 \\ 1 \end{bmatrix}$ for heating. Mathematically, this is equivalent to an outer product between the representation for cooling, $\boldsymbol{z}_c$, and the representation for heating, $\boldsymbol{z}_h$,

$$\boldsymbol{z}_m = \begin{bmatrix} CLG_0 \\ 1 \end{bmatrix} \otimes \begin{bmatrix} HTG_0 \\ 1 \end{bmatrix} \quad (5)$$

where $\otimes$ denotes the outer product between two vectors.

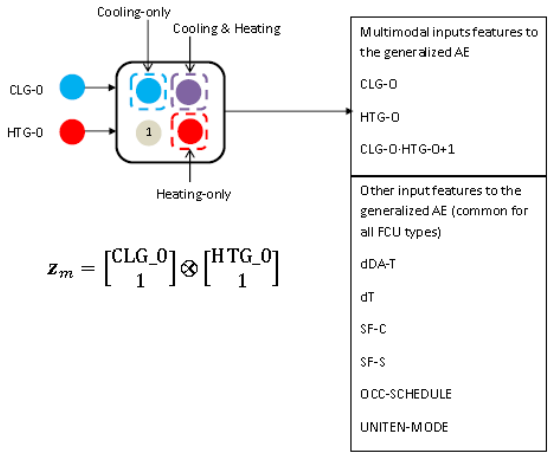

Figure 3: Proposed fusion approach with unimodal (cooling-only, heating-only) and bimodal (heating & cooling) features as additional inputs to the multimodal AE

As illustrated in Figure 3, the resulting matrix $\boldsymbol{z}_m$ can be viewed as a 2D surface that can be divided into 3 sub-regions, corresponding to three combinations of the data variables CLG-O, HTG-O and 1. In a nutshell, these three sub-regions characterize unimodal and bimodal dynamics, as well as interactions between three operational modes (cooling-only, heating-only, heating & cooling) of these three different FCU types.

3.1 Multimodal Learning for Fault Detection

Based on the design in Figure 3, the new input feature variable, G = CLG-O · HTG-O+1, is created, where CLG-O · HTG-O denotes the element-wise product of command points of cooling valve output command (CLG-O) and heating valve output command (HTG-O). Essentially, this variable is created for modeling the multimodal AE's behavior in learning and capturing the overall dynamics and interaction across the cooling-only, heating-only, heating & cooling FCUs as follows:

- For cooling-only FCUs, CLG-O ≠ 0 and HTG-O = 0; G = 1. HTG-O does not contribute to the error for fault detection.
- For heating-only FCUs, CLG-O = 0 and HTG-O ≠ 0; G = 1. CLG-O does not contribute to the error

for fault detection.

- For heating & cooling FCUs, CLG-O ≠ 0 and HTG-O ≠ 0; $G > 1$. Both CLG-O and HTG-O contribute to the error for fault detection.

The value of G also provides an indication to the multimodal AE that the FCU is operating for any of the cooling-only, heating-only, or heating & cooling purpose. In particular, the G enables the AE to capture the instances with hot water flowing through the heating coil, while chilled water flowing through the cooling coil (simultaneously), which is likely a fault event. On top of the above, all input variables are standardized using a min/max scaler to ensure uniform scaling across the dataset.

In addition, at the HVAC controllers, the temperature difference between the observed temperature and the set point is used for regulating the heating and cooling. Due to the temperature set-points are adjusted by different users and according to different cooling/heating requirements at different rooms in the building, there is a lack of consistency (rule) across different FCUs for set-point setting. It is challenging for a small neural network to capture this dynamic due to such inconsistency in setting set-points. To address this limitation, new feature variables are created [13]: (i) dT (room temperature ZN-T minus its set-point ZN-SP); (ii) dDA-T (discharge air temperature DA-T minus the room temperature set-point ZN-SP) and used as input to the AE models. These new variables emulate the controller's behavior, by taking account only the difference relative to the temperature set-point.

The other input feature variables to the AE, including CLG-O, HTG-O, SF-C, SF-S, etc., are points on the building automation system sensors, which are evaluated to identify unusual behavior, which could indicate an equipment fault. Based on the encoder and decoder outputs of each of the AE model for FCUs, the mean absolute error (MAE), which quantifies the error between each model's predictions and the actual observations, can be computed. The MAE is used for evaluation of both global model and specific models for FCUs, as to be explained in Section 3.3.

3.1.1 Effects of Faults on AE Input Variables

Potential fault examples of the FCUs are summarized in Figure 4. In Table 2, we present potential fault examples and their effects on the input variables to the AE. Note that these cover a subset of potential faults that can be inferred from existing sensors and not all possible fault combinations.

Note how these potential faults affect the input feature variables to the AE models. As an example, for fault CV1 (cooling valve stuck open), the valve command signal CLG-O could be at 0% (or any low value), while the room temperature (ZN-T) and supply air temperature (DA-T) are low due to full cooling conditions

Figure 4: Classification of FCU faults [13].

Table 2: Potential faults examples [13] and their effects on the input feature variables to the AE.

Fault codes	Condition	Effects of fault
CC1, CC2, CC3, CV2	CLG-O = 100%	High DA-T
HC2, HV2, HC1, HC3	HTG-O = 100%	Low ZN-T & DA-T
CV1	CLG-O = 0%	Low ZN-T & DA-T
HV1	HTG-O = 0%	High ZN-T & DA-T
SF2, SF4	CLG-O = 100%	High ZN-T

3.2 Development of Generalized AE Models

Two generalized AE models are developed and proposed: (i) Specific models (cooling-only, or heating-only, or heating & cooling); (ii) A global model that characterizes all three types of FCUs.

Proposed unsupervised multimodal AE for FCUs: The created feature G is adopted as a new input to the multimodal AE model. The proposed multimodal AE model that covers all cooling-only, heating-only, heating & cooling FCUs is illustrated in Figure 5. Following the abovementioned fusion design approach, the multimodal AE characterizes dynamics of these three FCU-types for fault detection.

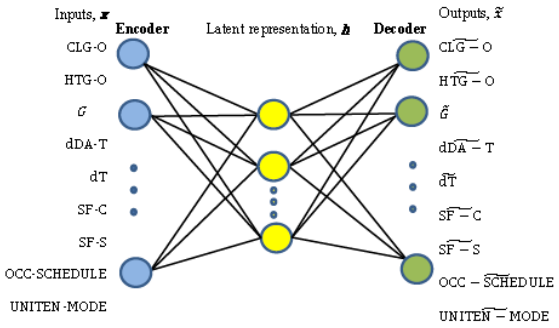

Figure 5: Proposed multimodal AE model

3.2.1 Global Model and Specific Models for FCUs

In this subsection, training steps for the multimodal AE to develop a global model and specific models for fault detection of FCUs are presented.

Specific models: The multimodal AE model in Figure 5 is trained to be ('specifically') applicable for fault detection for a specific FCU type (e.g., cooling-specific FCU). To that end, each specific model for a given FCU is trained with two-third of its own (or type) data. For example, the specific model of cooling-only FCU-C1 can be trained by its own historical data. By extension, we can also develop models for each type of FCUs, for e.g., cooling-only FCU, using data from multiple cooling-only FCUs. The specific model of any FCU is trained and used for fault detection of that particular FCU. Consequently, a specific model is expected to learn and characterize specific operational patterns which are limited to each type of FCU (as it is trained for), with a tradeoff for limited generalization capability.

Global model: The multimodal AE model in Figure 5 is trained to be (globally) applicable for fault detection across all three types of FCUs (cooling-only, heating-only, or heating & cooling). To that end, the (single) global model is trained with two-third of the data from a combination of all three types of FCUs. This global model is developed through a combination of training data from cooling-only FCUs (labeled as FCU-C1, FCU-C2, FCU-C3), heating-only FCUs (FCU-H1, FCU-H2, FCU-H3) as well as heating & cooling FCUs (FCU-HC1, FCU-HC2, FCU-HC3).

The single global model is trained for fault detection of three types of FCUs. Consequently, the global model is expected to learn and characterize more general operational patterns across all three types of FCUs due to its generalization capability, with a tradeoff for less accurate prediction of finer details.

As an example, consider a cooling-only FCU conditioning a server room. Due to constant heat emission from servers, this FCU is likely to operate according to more extreme cooling requirements. The specific (AE) model that is trained (using its cooling-only FCU data) is better at detecting anomalies during the FCU's normal or usual operational setting, but risks false alarms in new operational setting, such as during server maintenance shutdowns.

Alternatively, the above specific model can be substituted with the global AE model that has been trained with data from all three types of FCUs. Due to the global (AE) model's generalization capability, we expect that the global model's is less likely to give false alarms in new operational setting, while it may miss certain finer pattern shifts in the data information.

3.3 Quantifying Reconstruction Error

After learning a latent representation, the AE can be used to predict expected values for all variables at the output of its decoder section. To quantify the reconstruction error, individual MAEs are first evaluated by calculating the difference between the input values and outputs values of each feature variable. The average of all individual MAEs is called the global MAE. Then, fault detection is performed by comparing the global MAE against a predetermined threshold. This threshold can be prescribed through observing deviations of data, for example, by setting it as 10% variation in normalized data. During normal operation of any FCU, the MAE (or reconstruction error) is low. In the presence of any faults or anomalies, a significant deviation of any inputs from their normal values results in a larger MAE for the affected variables. A global MAE exceeding the prescribed threshold indicates that a potential fault occurs, as the FCUs operation is likely deviating from its normal operation. The input feature variable(s) associated with the highest individual MAE(s) are typically implicated as the cause of the fault.

Moreover, the MAE can also be used as a relative performance score for: (i) monitoring and comparing performance across different or same types of FCUs; (ii) tracking the operational health of a single FCU over time. The latter is due to the increasing MAE values could provide indication for potential deteriorating operation and system health of any FCUs.

4 Results and Discussion

In Figure 6 and Figure 7, fault detection results are presented for a heating & cooling FCU using the global model and its specific model with both real and predicted data. As shown in Fig. 6, both the global model and specific model detect similar anomalies patterns of CLG-O·HTG-O > 0, while hot water was flowing through the heating coil, and chilled water was flowing through the cooling coil simultaneously, which are likely fault events.

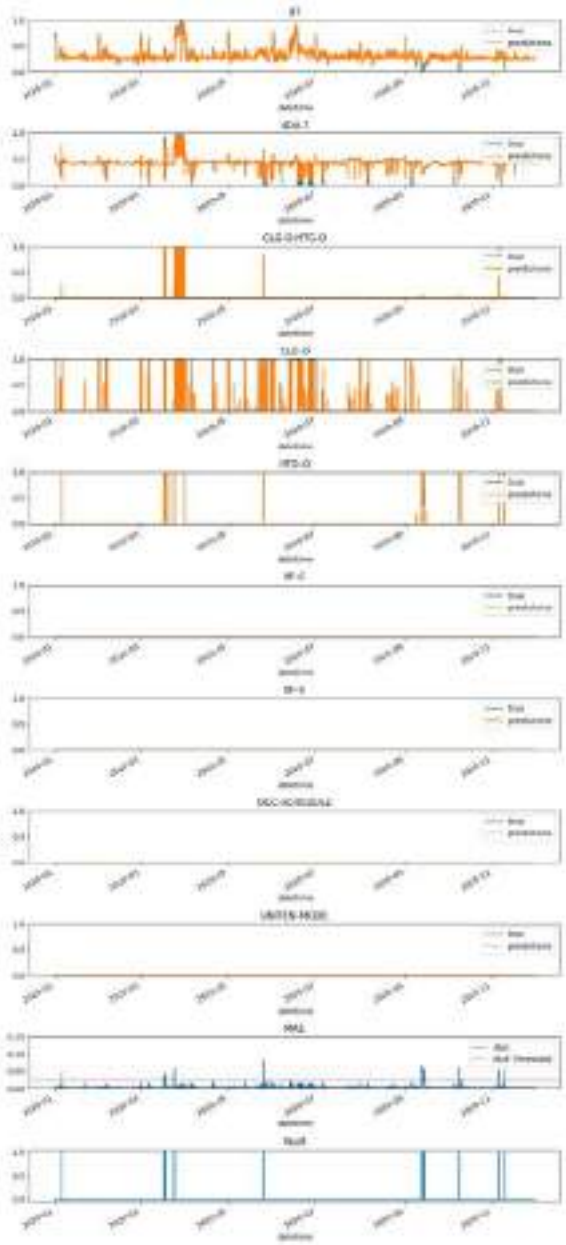

Figure 6: Prediction by the developed specific model for the heating & cooling FCU-HC1.

In particular, in April 2020, as both the supply air temperature (DA-T) and the room temperature (ZN-T) were increasing and causing spikes in dDA-T (= DA-T minus ZN-SP) and dT (= ZN-T minus ZN-SP), the FCU continued to supply hot water through the heating coil (HTG-O $\neq$ 0). Similarly, in Fig. 7, the global and specific models each detect the instance of CLG-O$\cdot$HTG-O > 0, which contribute to the peak of the overall MAE for fault detection. The threshold for MAE is calibrated such that that 0.5% of faults of data points is faulty. As expected, the global model predicts finer fluctuations less accurately than the specific model.

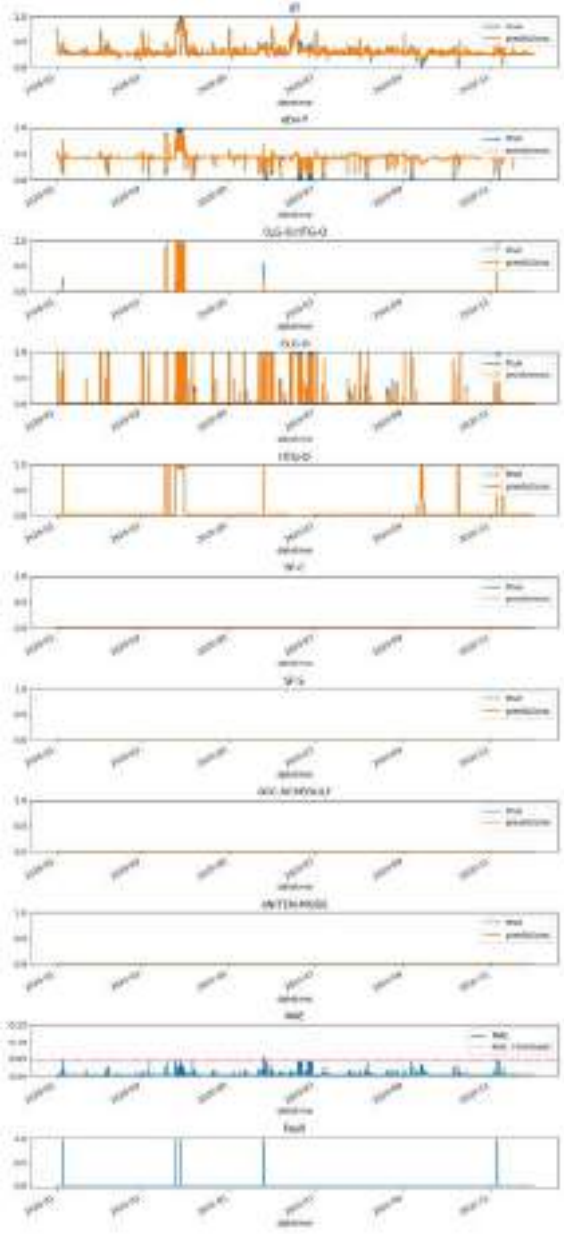

Figure 7: Prediction for the heating & cooling FCU-HC1 by the developed global model.

In Figure 8, fault detection results of the global model are presented for a heating-only FCU using real data and prediction. During the winter period of January to April 2020 in Canada, both the supply air temperature (DA-T) and the room temperature (ZN-T) regularly dropped below the setpoint, likely due to envelope heat loss. The heating valve output command (HTG-O) was regularly activated to supply hot water to the FCU's heating coil. Both the global model and the specific model (not shown) detect similar anomalies patterns of the FCU operation as faulty events, which lead to increasing total MAE above the detection threshold.

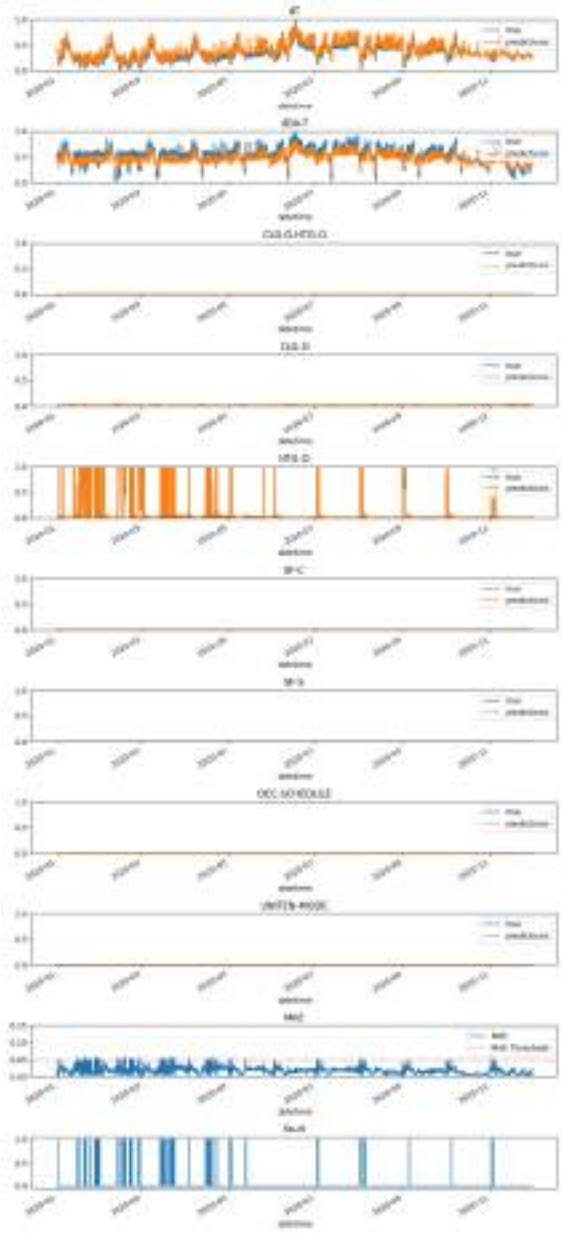

Figure 8: Prediction by the global model for the heating-only FCU-H2.

Data instances of normal operation as well as faulty ones are required for testing the developed models and evaluating the MAE for fault detection. Due to their scarcity, faulty data have been emulated by incorporating expected changes in appropriate sensor measurement data points for each FCU type [13].

In the left column of Figure 9, test results of the global model are presented for the heating-only FCU-H1 in detecting an emulated fault. The test dataset consists of 200 samples of normal data followed by 200 samples of emulated fault data of the heating valve being stuck open, despite not being commanded on (HTG-O = 0).

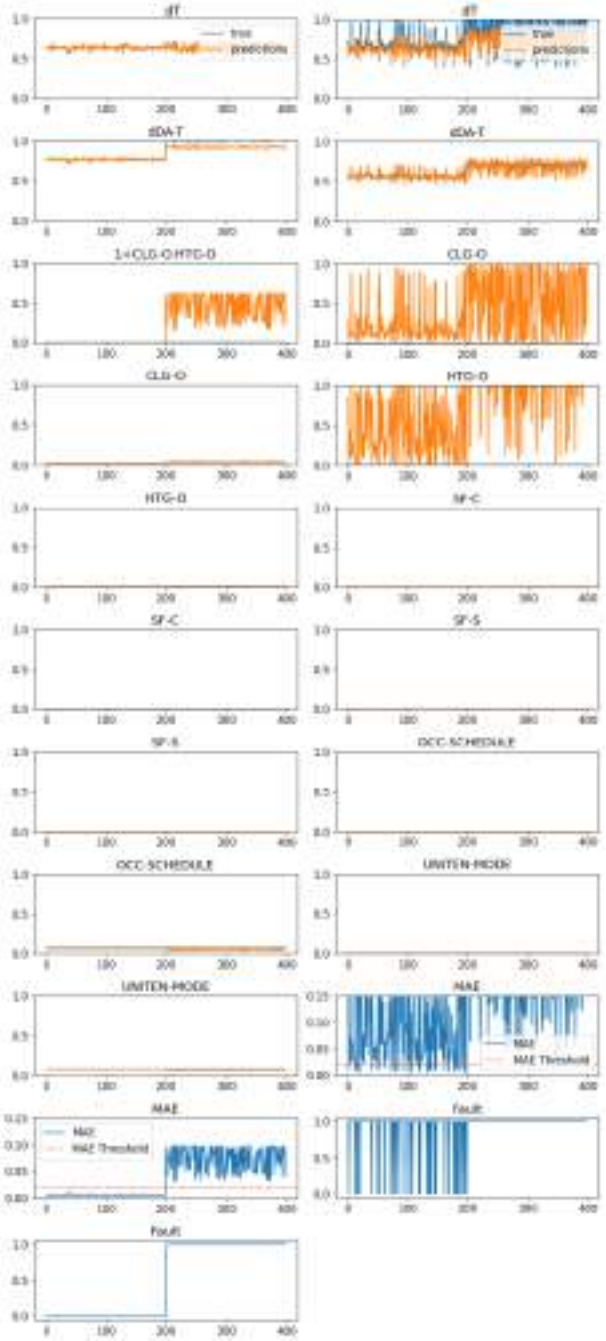

Figure 9: Detection of emulated fault by the: (left) global model with unsupervised multimodal learning, and (right) AE model without multimodal learning [13] for the heating-only FCU-H1.

The room temperature (ZN-T) and supply air temperature (DA-T) were modified accordingly to emulated full heating conditions, exhibiting higher supply air temperature (DA-T) values for the 200th to 400th samples, which the global model correctly identifies as faulty events, with *G* (= CLG-O·HTG-O+1)

and dDA-T (= DA-T minus ZN-SP) being the variables that lead to increasing total MAE above the detection threshold.

In the right column of Figure 9, fault detection results are presented for a recently published AE model in [13] without multimodal learning capability, after training it using historical data of 6 FCUs of the heating & cooling type. Without loss of generality, in-slab heating is omitted. In stark contrast, the AE model in [13] predicts that both the heating and cooling valve output commands (HTG-O and CLG-O) are to be activated throughout the normal and emulated fault intervals, in spite of FCU-H1 being a heating-only FCU. Due to lacking of multimodal learning capability, it fails to identify the actual emulated fault event, as the error between its predicted values and true values of dT, CLG-O and HTG-O significantly increase the total MAE above the detection threshold for all samples.

5 Conclusion

A multimodal AE is proposed for developing the global model and specific models for different types of FCUs through unsupervised multimodal learning: (i) the specific models are trained using data of a specific (or type) of FCU(s); (ii) the global model is trained using a combination of data from three types of FCUs. The applicability of unsupervised multimodal AE for fault detection across different types of FCUs is achieved through multimodal learning and transfer learning.

Abstract –

In Korea, research initiatives have commenced to digitize engineering and construction codes, and automate their compliance using BIM models for mandatory submission in public projects. The initiatives require employing IFC, a neutral and standard data format, to associate individual codes with relevant BIM elements. However, the IFC does not provide explicit extensions to represent the varied codes, which include the Korean Design Standards (KDS) and the Korean Construction Specifications (KCS).

To address this limitation, this study developed an extended IFC schema called 'IFC-KR', focusing initially on bridges. The extensions define subtypes to represent various types of bridges, structures, and elements, along with property sets that capture the relevant attributes and properties of 1,437 KDS codes. Moreover, a specialized extension module named 'IFC-KR Toolkit' has been developed to automate the addition of KDS data relevant to each element within the IFC Physical File.

To validate the functionality of the module, KDS items were applied to an Extradosed (ED) cable-stayed bridge model. The results confirmed that all data were accurately integrated, and the extended data was consistently verified using a third-party IFC viewer, demonstrating its accuracy and interoperability.

1 Introduction

In Korea, engineering and design submittals for all public projects must be checked for their conformance to Korean Design Standards (KDS) and Construction Specifications (KCS) [8]. However, the current code checking process remains highly inefficient as it relies on engineers manually verifying KDS presented in textual format. Moreover, this manual process significantly hinders the ability to promptly respond to design changes or updates of these codes [17].

The Korean Ministry of Land, Infrastructure, and Transport (MOLIT) is making significant efforts to overcome these limitations by developing a framework for BIM-based automated code checking (ACC) [12]. At the core of these initiatives is the digitalization of KDS, which involves the conversion of individual provisions into digital rules and parameters that can be seamlessly integrated with BIM model data, thereby enable the ACC process.

Associating BIM models with KDS data requires employing the Industry Foundation Classes (IFC), the international standard data format, which allows customized extensions of its schema for local or regional data sharing requirements [11]. However, the standard IFC schema lacks formal definitions for the entities and property sets (Psets) required to integrate KDS tailored to Korea.

The Building and Construction Authority (BCA) in Singapore developed an extended IFC schema, known as 'IFC-SG[1]'. IFC-SG defines custom entities and Psets to ensure that data within IFC models aligns with Singapore's information mandates of BIM models, and is used as the medium for information exchange in CORENET-X [2] [3]. However, IFC-SG is designed exclusively for the building permit domain and is not suitable for accommodating KDS related data that relates to infrastructure assets and engineering specifications.

This study aimed to develop an extended IFC schema, termed 'IFC-KR', specifically tailored to accommodate data related to Korea's design standards while integrating

[2] https://www1.bca.gov.sg/regulatory-info/building-control/corenet-x

specialized engineering knowledge pertinent to the infrastructure domain. To enhance practical applicability, the study also developed 'IFC-KR Toolkit', a module that enables the insertion of required data into the IFC Physical File (IPF) in accordance with the IFC-KR schema.

This study focuses on bridges, a representative infrastructure facility type, and is structured as follows: Section 2 reviews the development status and limitations of the standard IFC schema and previous studies on IFC schema extensions. Section 3 presents the research methodology. Section 4 details the development process of the IFC-KR schema, and Section 5 outlines the methodology for developing the IFC-KR Toolkit. Section 6 validates the extension results in IFC-KR Toolkit.
