buildingSMART International (bSI) developed the IFC, a neutral standard model, to enable seamless data exchange between BIM applications. The standard IFC schema provided by bSI encompasses the specification of objects, attributes, and relationships within BIM models and undergoes continuous updates to ensure its adaptability and relevance [10].

The initial IFC schema was primarily designed to represent the architectural domain [9]. However, the release of IFC4 in 2013 introduced support for infrastructure-related objects, focusing primarily on bridge facilities. In particular, bridge-related elements were formally integrated, with the addition of the *IfcBridge* and *IfcBridgePart* entities, geometric representations for horizontal structures and structural connectivity, and data attributes for load conditions. This was further expanded with IFC4.3 in 2021, which added entities and attributes to accommodate a broader range of infrastructure facilities, including railways, and roads [4].

Despite the continuous updates to the IFC schema, several factors still hinder its practical application. The main challenges include: 1) limited scope of application, 2) difficulties in adopting national and regional requirements, and 3) incomplete representation of domain-specific data requirements. The detailed issues for each challenge are as follows:

1) Limited scope of application

While the IFC schema has been updated to include new entities, its initial development was heavily focused on the architectural domain. Consequently, other domains, such as infrastructure, often had to adopt architectural entities to represent their specific objects. This limitation has been identified as a major barrier to achieving interoperability in non-architectural domains [14, 18]. In particular, Korean infrastructure projects frequently include tunnels, yet the IFC schema does not provide explicit definitions for tunnel-related entities. As a result, architectural entities must still be adopted to represent tunnels, which limits their practical application and interoperability.

2) Difficulties in adopting national and regional requirements

Although the IFC schema is designed as a standardized data structure, it has limitations in adopting the diverse requirements of various nations and regions. Furthermore, updates to the schema must undergo a rigorous review process by the bSI Standards Committee, which is time-consuming and makes it challenging to promptly incorporate necessary data into the schema [2]. This limitation is particularly evident in Korean infrastructure projects, where the KDS require detailed structural analysis and geometric attributes. However, the current IFC schema lacks predefined entity types and attributes for these requirements, making it difficult to directly integrate KDS compliance into BIM-based workflows.

3) Incomplete representation of domain-specific data requirements

bSI has continuously expanded the scope of IFC to address the evolving requirements of the construction industry. Initially, structural elements and analysis domains were introduced, followed by MEP domains, and more recently, infrastructure domains such as roads and railways. However, throughout this process, many newly defined entities have failed to fully capture the semantic representations and attributes required by their respective domains. Such limitations in representing essential information hinder the full utility of IFC, posing significant constraints on its applicability. For instance, while IFC4 introduced bridge-related entities, essential elements widely used in Korean bridge projects, such as joints and approach slabs, are still missing. This absence limits the accuracy and completeness of bridge models within the IFC schema, necessitating extensive customization to meet Korean infrastructure project requirements. Additionally, gaps in representation, interoperability, and compliance with engineering standards were identified based on practical application cases [13]. These limitations highlight the need for extensions such as IFC-KR to enhance adaptability while maintaining compatibility with the existing IFC framework.

2.2 Approaches for IFC Schema Extension

To address the limitations of the standard IFC, many studies have proposed to extend its schema. These

extensions are broadly classified into two methods: Entity Extension, which involves the definition of new entities, and Property Extension, which focuses on integrating and associating additional data with existing entities.

2.2.1 Entity Extension

This method involves defining new entities within the existing schema to represent previously unsupported elements and processes. By enabling the detailed representation of domains and entities that were not previously addressed, it provides the advantage of supporting tailored and highly precise data modeling [6]. However, the outcomes of this method are often not officially incorporated into the standard IFC schema. As a result, the added entities can only be utilized in BIM authoring tools and IFC viewers specifically modified to recognize these custom entities, presenting a significant limitation.

2.2.2 Property Extension

This method involves adding new properties, attributes, or subtypes to existing entities, primarily utilizing Type entities (e.g., *IfcBuiltElementType*) or Property sets (Psets). For example, the *IfcColumn* entity can be further specified using *IfcColumnType* entity, a subtype of *IfcBuiltElementType* entity. Additionally, when further detailed classifications are required, new types can be added using the USERDEFINED type.

Psets are employed to define general attributes, such as dimensions or materials, and are linked with *IfcObject* entities using *IfcRelDefinesByProperties* entity. This method preserves the original IFC schema while allowing new data to be added, minimizing compatibility issues across BIM authoring tools and IFC viewers.

Recently, the 'Linked Data Approach' has emerged as a method to effectively connect external data to the IFC schema while maintaining data integrity. This method links external data stored in the buildingSMART Data Dictionary (bSDD) and Object-Type Libraries (OTLs) to the IFC schema, enabling connectivity between IFC models and various data sources [16].

bSI does not recommend creating new entities that may be limited to specific use cases. Rather, it prioritizes the use of property extensions by using predefined classifications, types, and Psets within the standard IFC schema [1].

3 Research Methodology

This study aims to develop an extended IFC schema and extension module to facilitate BIM-based automated code checking in the bridge domain. As illustrated in Figure 1, the research is structured into three phases: 1) development of an extended IFC schema, 'IFC-KR', 2) development of a module for creating IFC-KR extensions, and 3) validation of the extended IFC using the extension module.

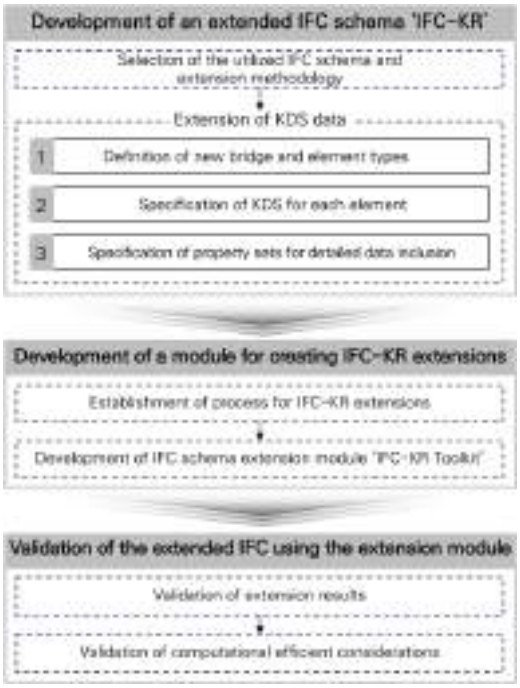

Figure 1. Research process

4 Development of 'IFC-KR'

4.1 Selection of the Utilized IFC Schema and Extension Methodology

IFC-KR is an extended IFC schema specialized for incorporating data related to the KDS. We developed the optimal IFC schema and extension method based on the extension approaches discussed in Section 2. Additionally, appropriate software was selected to implement the IFC-KR Toolkit, a module designed to extend the IFC schema and incorporate KDS data for individual elements into the IPF.

The standard IFC schema targeted for extension was selected as IFC4.3, which effectively represents bridge structures and infrastructural characteristics. IFC4.3 includes the *IfcBridge* entity for representing bridges, and bridge types such as Arch, Truss, and Girder bridges can be defined using the *IfcBridgeTypeEnum* entity. Additionally, structural elements of bridges, such as Abutments, Piers, and Superstructures, can be defined using the *IfcBridgePartTypeEnum* entity.

The property extension approach was adopted to incorporate the KDS data. Individual properties served as the basic units of data for this extension, while Pset was

utilized to organize and extend the schema when multiple KDS data items needed to be included.

This approach allows additional data to be incorporated without altering the standard IFC schema, ensuring that IFC-KR remains compatible with existing IFC-supported applications. Since the extensions are structured as additional Psets rather than modifications to core schema entities, software that supports the base IFC schema can still process IFC-KR schema without interoperability issues.

In the process of applying the Property Extension methodology, the Data Linkage Approach, inspired by the Linked Data Approach, was utilized. Similar to conventional methods, this approach connects external data to Psets. However, instead of relying on bSDD or OTLs, it is specifically designed to directly link to external files (e.g., .xml, .csv) containing digitized KDS. For this study, Autodesk Revit 2025, equipped with an IFC Exporter capable of extracting in the IFC4.3 format, was utilized as the BIM authoring tool. For the IFC viewer, KBim Assess-Lite[3], an open-source application with a proprietary parser enabling fast data exchange, was employed. The IFC-KR Toolkit, the module developed specifically for this study, was developed as an add-in in KBim Assess-Lite.

4.2 Extension of KDS Data

4.2.1 Definition of New Bridge and Element Types

This study focused on three bridge types most commonly utilized in Korea: PSC girder bridges, Steel girder bridges, and Extradosed (ED) cable-stayed bridges. In IFC4.3, the *IfcBridge* entity defines bridge types using the predefined type, *IfcBridgeTypeEnum* entity. However, the aforementioned three bridge types are not included within the predefined options. Thus, these bridge types were newly defined under the USERDEFINED type in *IfcBridgeTypeEnum* entity.

For elements, the *IfcElement* entity was used, with detailed subtypes defined by the enumeration type of the *IfcElementType* entity. For this study, 16 subtypes already defined in the standard IFC schema and applicable to the three bridge types were utilized without modification. For the nine element types not covered by the standard IFC schema, new subtypes were introduced as USERDEFINED types (Table 1).

Table 1. Subtypes by Elements in IFC-KR

Element (IFC4.3 entity)	Subtypes (*=USERDEFINED)
Anchor (*IfcTendonAnchor*)	TENSIONING_END
Approach slab (*IfcSlab*)	*APPROACH_SLAB
Base plate (*IfcPlate*)	BASE_PLATE
Bearing (*IfcBearing*)	ELASTOMERIC
Bracing (*IfcMember*)	BRACE
Bracing wall (*IfcWall*)	*BRACING_WALL
Cable (*IfcMechanicalFastener*)	*CABLE
Cast in place pile (*IfcPile*)	BORED
Column (*IfcColumn*)	PIERSTEM
Continuous slab (*IfcSlab*)	*CONTINUOUS_SLAB
Covering (*IfcCovering*)	COPING
Cross beam (*IfcBeam*)	*CROSSBEAM
Deck plate (*IfcPlate*)	BASE_PLATE
Diaphragm (*IfcBeam*)	DIAPHRAGM
Girder (*IfcBeam*)	GIRDER_SEGMENT
Parapet wall (*IfcWall*)	PARAPET
Pile foundation (*IfcPile*)	SUPPORT
Pylon (*IfcElementAssembly*)	PYLON
Steel pipe pile (*IfcPile*)	*STEEL_PIPE
Wall (*IfcWall*)	STANDARD
Wing wall (*IfcWall*)	RETAININGWALL
Joint (*IfcMember*)	*JOINT
Shear connector (*IfcMechanicalFastener*)	SHEARCONNECTOR
K-braced Diaphragm (*IfcBeam*)	*KBRACED_DAPHRAGM
PC_HOUSE (*IfcBuildingElementProxy*)	*PCHOUSE

4.2.2 Specification of KDS for Each Element

[15] developed a ‘standards map’ based on bridge design and construction processes that visualizes the code checking sequence and conditions for each element, and links them to the applicable KDS. This study utilized these standards maps to identify the required KDS for each element type and categorized KDS items by considering both element units and code checking procedures (Table 2).

Table 2. Classification of KDS items by elements and code checking procedures

Bridge type	Element type	Code checking procedure	KDS item
PSC girder bridge	Cross beam	Selection of design conditions	KDS 24 14 21_ 4.2.1.2_Table 4.2-1
			KDS 24 14 21_ 4.2.1.2_Table 4.2-2
		Load calculation and combination	KDS 24 12 21
			KDS 24 12 11
		Review of cross beam cross-section	KDS 24 17 11_ 4.6.3.3
			KDS 24 14 21_ 4.2.3.3
ED cable-stayed bridge	Pylon	Selection of design conditions	KDS 24 14 21_ 4.4.4.2_Table 4.4-3
			KDS 24 14 21_ 4.4.1_Table 4.4-1
		Load calculation and combination	KDS 24 12 22
			KDS 24 12 12
		Design of pylon cross-section	KDS 24 14 21_ 4.1.2.1
			KDS 24 14 21_ 4.6.2.6 (5)

4.2.3 Specification of Psets for Detailed Data Inclusion

[5, 7] classified the specific KDS codes for bridge

[3] Open-source IFC viewer developed by the national research project (https://www.inno-lab.co.kr/Home/kr/product-KBim_Assess- Lite.html)

structures based on quantitative and qualitative characteristics. They identified the input variables necessary for performing code checking for each item and the output variables required to represent the results.

KDS items were categorized as: 1) quantitative items requiring formula-based calculations and 2) qualitative items requiring engineering decisions (Table 3). Ultimately, only the quantitative items suitable for digitalization were selected, resulting in 1,437 KDS items being utilized.

Table 3. Examples of quantitative/qualitative classification items

Category	Contents of KDS
Quantitative	KDS 11 50 15_4.1.1.1 (2) [Allowable axial displacement of pile foundation] : The allowable axial displacement of the pile foundation shall be within the allowable displacement of the superstructure.
Qualitative	KDS 11 50 15_4.2.3.4 (4) [Consolidation settlement] : Other consolidation settlement can be calculated through appropriate numerical analysis methods such as finite element analysis.

4.3 Detailed Schema of IFC-KR

The IFC-KR schema, designed to incorporate the newly defined items, was developed with a three-tier structure comprising 'Object taxonomy, KDS mapping, and Psets'. The schema was further divided into separate sub-schemas to align specifically with KDS requirements.

1) Object taxonomy tier

The object taxonomy tier defines the IFC entities required to represent the different types of bridge, structural composition, and element. It specifies the structures and elements associated with each bridge type. Specifically, it consists of (1) bridge type (*IfcBridge*), (2) structural composition (*IfcBridgePart*), (3) element name, (4) IFC4.3 entity (*IfcElement*), and (5) subtypes of each element (*IfcElementType*).

The taxonomy was developed to include the three bridge types and nine element types defined in Section 4.2.1. An excerpt of the KDS object taxonomy tier is provided in Figure 2. For example, 'PSC Girder Bridge' is defined using the *IfcBridge* entity, while one of its sub-elements 'ABUTMENT' is defined using the *IfcBridgePart* entity. The specific element 'Wall' is assigned using IFC4.3 entity *IfcWall*, while its subtypes such as the 'STANDARD' and 'RETAININGWALL' are defined using the enumeration type of the *IfcElementType* entity.

Figure 2. Example of object taxonomy tier (KDS)

2) KDS mapping tier

The KDS mapping tier defines the KDS items that need to be checked for individual elements previously specified through the object taxonomy tier. For example, the Abutment wall needs to be checked for its load calculation and combinations. These correspond to 'KDS 24 14 21_4.6.6.2 (1)' and 'KDS 24 14 21_4.6.6.2 (2)'. A sample of the KDS mapping tier is shown in Figure 3.

Figure 3. Example of KDS mapping tier

3) Psets tier

The Psets tier define the data required for the quantitative code checking of the 1,437 KDS items. Each Pset contains the following items: (1) Pset name (KRPset Name), (2) KDS code, (3) BIM design values, and (4) Results. The detailed structure of the Pset tier for the 'Load calculation and combination' item (KDS 24 14 21_4.6.6.2 (2)) related to the wall element of a PSC girder bridge is given in Table 4, with an example input shown in Figure 4.

In Table 4, 'KRPset name' indicates the name of the design code associated with the element, while 'Property name' indicates the names of the input/output variables. 'Property value' represents the detailed values of these variables, and 'Property type' indicates the specific data type. Data types are expressed as *IfcLabel* for strings, *IfcReal* for real numbers, and *IfcBoolean* for boolean values. Finally, the 'Property unit' defines the unit of the detailed values.

Figure 4. Example of Psets tier (KDS)

Table 4. Example of Pset for 'KDS 24 14 21_4.6.6.2 (2)'

KRPset name	Property name	Property value	Property type	Property unit
KRPset_ KDS 24 14 21_ 4.6.6.2 (2)	KDS code	24 14 21_ 4.6.6.2 (2)	*IfcLabel*	-
	Axial reinforcing bar cross-sectional area in normal section, not at lap joint		*IfcReal*	mm^2
	Cross-sectional area of a column		*IfcReal*	mm^2
	Cross-sectional area of prestressing steel		*IfcReal*	mm^2
	Design tensile strength of prestressing steel		*IfcReal*	Mpa
	Design basis yield strength of axial reinforcing bar		*IfcReal*	Mpa
	Specified compressive strength of concrete		*IfcReal*	Mpa
	Results		*IfcBoolean*	-

5 Development of Module for creating IFC-KR extensions

5.1 Process of creating IFC-KR extensions

A four-step process for inserting KDS data into individual elements within an IPF using the extended IFC structure, IFC-KR, is presented in Figure 5.

The first step involves specifying the bridge type and individual structure types for the IFC4.3 model extracted from a BIM authoring tool. The second step determines the appropriate entity and subtype according to the specified element type. The third step selects the design checking procedures applicable to the specified element type and displays the relevant KDS items. Finally, detailed data is displayed for each checking item, including 'KDS code, BIM design values, and results' with the option to manually enter detailed BIM design values if necessary.

5.2 IFC Schema Extension Module 'IFC-KR Toolkit'

The process was implemented by developing the 'IFC-KR Toolkit'. This module was integrated as an add-in within KBim Assess-Lite. The User Interface (UI) was designed to display appropriate KDS provisions for the selected element by allowing users to specify consecutively, the Object taxonomy, KDS mapping, and Psets tier of IFC-KR. The module operates on IPFs extracted from BIM authoring tools (e.g., Autodesk Revit) which need to be extracted using version IFC4.3 and Reference View. The module also allows for the modification of incorrectly entered element types and enables the selection of unmapped additional items from the complete KDS list.

6 Validation of Results

6.1 Validation of extension results

To verify the effectiveness of the developed module, the validation process was conducted in three stages: 1) data integration accuracy, 2) property set consistency, and 3) IFC standard compliance.

1) Data integration accuracy

The IFC-KR was applied to an ED cable-stayed bridge model, where five KDS items were mapped to three key elements (pylon, girder, and pier). The IFC-KR Toolkit was used to insert the required KDS properties into the IPF (.ifc). The extended IPF file was then inspected to confirm that the correct KDS properties were assigned to each corresponding element.

2) Property set consistency

To ensure the accuracy of the inserted data, the generated IFC file was loaded into KBim Assess-Lite, where the extended KDS properties were checked within the 'Property Set' tab. Each property was manually verified to confirm that its naming, data types (e.g., *IfcReal*, *IfcBoolean*), and data structure matched the intended KDS format (Figure 6).

3) IFC standard compliance

Finally, the extended IFC-KR model was exported and tested using BIMvision, a commercial IFC viewer supporting IFC4.3. This step ensured that the inserted KDS properties were correctly interpreted and displayed without loss of data or formatting inconsistencies. Additionally, interoperability with third-party IFC viewers was assessed by verifying that the modified IFC schema maintained compatibility with existing BIM workflows.

The results of this validation confirmed that all KDS data was successfully embedded into the IFC model and could be accurately visualized and interpreted in external IFC software (Figure 7).

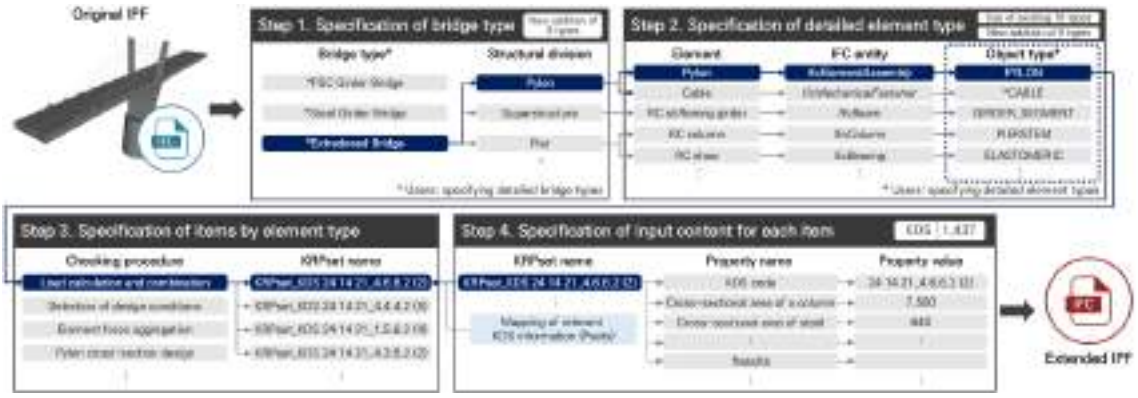

Figure 5. Process of extending KDS data using IFC-KR

This study primarily focused on the validation of an ED cable-stayed bridge as an example because ED bridges have a more complex structural configuration compared to PSC girder bridges and steel girder bridges. Given the higher complexity of ED bridges, it serves as a more rigorous test case for validating the IFC-KR schema. Additionally, the same validation process was applied to PSC girder bridges and steel girder bridges, and the results confirmed that the IFC-KR schema was equally effective for these bridge types as well.

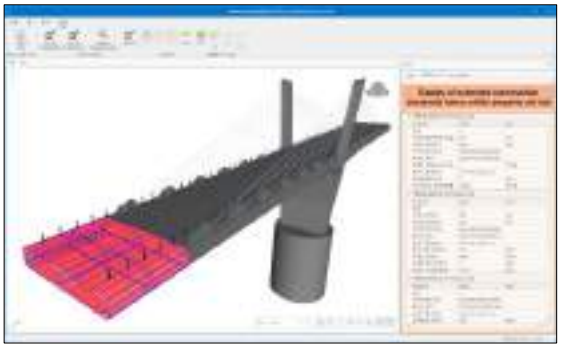

Figure 6. Extension results in IFC-KR Toolkit

Figure 7. Validation of extension results in BIMvision

6.2 Computational Efficiency Considerations

The IFC model used in this validation had a file size of 80MB, and the extension process using the IFC-KR Toolkit took approximately 15 seconds. However, it is important to note that the validated IFC model contained only a limited number of reinforcing bars. For high-LOD models with a significant number of reinforcing bars, the processing time may increase substantially. As such, further research will focus on evaluating computational efficiency under different model complexities and exploring potential optimization strategies to enhance performance.

7 Conclusion

This study introduced the extended IFC schema, 'IFC-KR', and 'IFC-KR Toolkit', a module dedicated to creating IFC-KR extensions, to support BIM-based ACC for Korean design standards.

IFC-KR was built on the IFC4.3 standard, with three bridge types and nine detailed element types newly defined as USERDEFINED types. Additionally, 1,437 KDS items were mapped, and the required data for each item, including input/output variables and BIM design values, was extended in the form of Psets.

The IFC-KR Toolkit was developed as a tool that enables the creation of IFC-KR compliant IPF's. The module allows the input and display of KDS items and Pset data for each element during the extension process.

To validate the module, KDS items were extended for the pylon, girder, and pier elements of an ED cable-stayed bridge model. The results confirmed that all KDS data was successfully populated, which was further verified by inspecting the data exported to a commercial IFC viewer, BIMvision.

This study formalized a framework for incorporating KDS data into IFC, and thereby enabled extended BIM-based ACC to include engineering specification checking for the infrastructure domain. This work is regarded as an important step in establishing a foundational framework for future BIM-based ACC implementation.

The stability of the IFC-KR schema in relation to future IFC standard updates was also considered during

development. Since IFC-KR does not directly modify the core IFC schema but extends it through additional property sets, it remains stable within the same IFC version (IFC4.3). Significant changes within the same version are unlikely, ensuring that the proposed extensions remain functional in the foreseeable future. However, future iterations of the IFC standard may introduce updates to infrastructure-related entities, which could affect certain extensions. Therefore, continuous monitoring and adaptation will be necessary to ensure long-term compatibility and maintain interoperability across evolving BIM standards.

A Mixed Reality Dataset and Benchmarking of Deep Learning Models for MEP Classification

Boan Tao[1], Jiajun Li[1] and Frédéric Bosché [1]

[1]School of Engineering, University of Edinburgh, Edinburgh, Scotland, UK

boan.tao@ed.ac.uk, Jiajun.Li@ed.ac.uk, f.bosche@ed.ac.uk,

Abstract -

This paper introduces a Mixed Reality (MR)-captured dataset and a benchmark evaluation of deep learning models for Mechanical, Electrical, and Plumbing (MEP) component classification. The dataset, collected using Microsoft HoloLens 2, comprises eight distinct building environments containing pipes and ducts, presenting unique challenges characteristic of MR-captured data, including lower point density and increased noise compared to laser scans. In addition to presenting the dataset, this study provides a comparative evaluation of nine state-of-the-art deep learning architectures, assessing their performance and computational efficiency through rigorous cross-validation. Our analysis reveals that PointNN, a non-parametric approach, achieves superior classification accuracy (90.21%) while maintaining minimal computational requirements (1.34 GFLOPs). This dual contribution of this paper aims to advance automated MEP inspection systems and provide insights for developing efficient deep learning models for construction applications.

Keywords -

1 Introduction

Mechanical, Electrical, and Plumbing (MEP) systems form intricate networks essential for providing services such as heating, ventilation, air conditioning (HVAC), water distribution, and waste management. The inherent complexity of these systems introduces significant challenges in their design, installation, and maintenance, which result in inefficiencies, conflicts, and costly rework during construction [1]. Recent advancements in digital technologies have offered promising solutions to address these challenges. Notably, the integration of Mixed Reality (MR) and Artificial Intelligence (AI) can contribute to improving MEP system construction, monitoring and management.

Mixed Reality (MR) devices, such as the Microsoft HoloLens 2, provide unprecedented capabilities to overlay digital information onto the physical world, enabling real-time visualisation and interaction with virtual MEP components in their actual context [2]. These visualisation capabilities can be enhanced by deep learning algorithms that efficiently process and analyse complex three-dimensional data, including point clouds representing MEP systems [3]. For example, mobile scanning solutions like Apple's RoomPlan API [4] integrate device sensors with machine learning to create parametric 3D models of interior spaces. Such systems leverage camera feeds and LiDAR sensors to automatically detect and classify structural elements like walls, windows, and openings, while simultaneously recognising room features and fixtures, providing a comprehensive digital representation of the built environment. However, while such tools exist for capturing and modelling architectural elements, there is currently no comparable automated solution for MEP system mapping. Even with high-quality laser scanning data, the automated detection and classification of MEP components remains a significant technical challenge. This is due to several factors, including the inherent complexity and diversity of MEP systems, as well as occlusions commonly encountered in densely packed service areas.

This paper presents two key contributions:

1. It introduces a novel MR-captured dataset for MEP component classification, detailing its acquisition, preprocessing, and characteristics.
2. It benchmarks multiple 3D deep learning architectures on this dataset, providing insights into their classification performance and computational efficiency.

The remainder of this paper is organised as follows: Section 2 provides a comprehensive review of existing 3D datasets in construction, challenges in MR-based data capture, and recent advances in point cloud classification methods. Section 3 presents our dataset acquisition and preparation methodology, including detailed scanning protocols, dataset statistics, and cross-validation strategies. Section 4 introduces the selected deep learning models and evaluation metrics, along with implementation specifications. In Section 5, we present a detailed analysis of model performance and computational efficiency, accompanied by insights into the relative strengths and limitations of different architectural approaches. Within this section, we also discuss the implications of our findings for practical deployment and outline future research directions.

Finally, Section 6 summarises our key contributions and their significance for advancing MR-based MEP inspection in the Architecture, Engineering, and Construction (AEC) industry.

2 Literature Review

2.1 3D Datasets in Construction

Many point cloud datasets used in research are not fully representative of the challenges faced in construction environments. For instance, the ModelNet dataset [5] is a popular benchmark for 3D shape classification and segmentation, but it consists of CAD models converted to point clouds, lacking the noise and incompleteness typical of real-world scans. Similarly, ShapeNet [6] is a large-scale dataset of 3D shapes, but it also consists of clean, complete 3D models rather than actual scanned point clouds. These datasets are valuable for developing and testing algorithms, but they don't capture the complexity, imperfections and overall challenges of real-world construction scenes.

Recognising this limitation, Uy et al. [7] introduced ScanObjectNN, a real-world point cloud dataset for object classification. ScanObjectNN includes point clouds extracted from scanned indoor scenes, preserving real-world characteristics like background, occlusion, and missing parts. While more realistic than synthetic datasets, ScanObjectNN focuses on common indoor objects (e.g., chairs, tables, beds, cabinets, displays) rather than construction-specific or MEP components.

For construction-specific applications, several datasets have been developed to address the unique challenges of the built environment. The S3DIS dataset [8] provides large-scale, real-world point clouds of indoor spaces, including structural elements and some building components (e.g., doors, windows, columns, beams). The Paris-Lille-3D dataset [9] offers large-scale outdoor point clouds of urban environments, which can be relevant for certain construction tasks.

In more direct relation to MEP components (the focus of our paper), Yin et al. [10] established a benchmark industrial LiDAR dataset containing approximately 80 million data points from four industrial scenes. Their dataset, captured using a Leica BLK360 scanner, achieved accuracies of 4 mm to 7 mm and included five categories of MEP components: pipes, pumps, tanks, I-shape, and rectangular beams. Agapaki and Brilakis [11] also introduce construction and MEP point cloud datasets: CLOI (Channels, L-shapes, circular sections, I-shapes). It is a large-scale repository of labelled point clusters specifically designed for industrial and MEP components. It contains over 140 million hand-labelled points from five industrial facilities, covering ten classes of the most frequent construction and MEP shapes. The dataset was collected using static terrestrial laser scanners, capturing the real-world noise and occlusions typical in complex industrial environments.

2.2 Challenges in MR-based Data Capture

Despite the potential of MR devices for on-site data capture, several challenges remain. Hübner et al. [12] evaluated the HoloLens (version 1) for indoor mapping applications, providing insights into its depth sensing capabilities and limitations. They found that the device's accuracy was highly dependent on distance and surface inclination, with optimal performance at distances less than 2.5 m and inclinations below 20 degrees. Beyond these limits, the sensor's accuracy deteriorated significantly, with noise exceeding 2 cm at greater distances or inclinations.

MR devices like the HoloLens produce point clouds that are significantly less dense and more prone to noise compared to traditional LiDAR scans. This is particularly problematic in MEP environments, where occlusions, reflective surfaces, and hard-to-reach installation locations can further degrade data quality.

The accuracy of MR-captured point clouds decreases with distance, which poses challenges for capturing tall or expansive spaces often encountered in industrial and commercial buildings. These limitations have implications for the applicability of existing deep learning models, which are typically trained on high-quality LiDAR datasets, as discussed in Section 2.1.

2.3 Point cloud Classification

Point cloud classification has advanced significantly with deep learning techniques. PointNet [13] pioneered direct processing of unordered point sets using MLPs but struggled with capturing local features. PointNet++ [14] improved upon this by introducing hierarchical feature learning to model local geometric structures and handle noise.

Recent works have built on this foundation with various improvements. PointNeXt [15] modernises PointNet++ with better training strategies, while PointMetaBase [16] introduces a modular meta-architecture to optimize computational efficiency. PointVector [17] enhances local feature learning through vector-based representations.

Graph-based models like DGCNN [18] apply dynamic edge convolutions to capture local relationships and adapt to structural changes, which is especially useful for noisy MR data. DeepGCNs [19] extend this concept with deeper architectures and residual connections for more complex feature hierarchies.

Attention mechanisms, such as those used in Point Transformer [20], help models focus on the most informative regions of sparse or noisy point clouds, improving robustness.

Further, PointMLP [21] simplifies the architecture using residual MLPs while achieving strong performance on real-world datasets like ScanObjectNN, making it suitable

for MR data.

Finally, Point-NN [22] introduces a non-parametric approach using simple operations (FPS, k-NN, pooling) with trigonometric spatial encoding. This method excels in MR environments due to its inherent robustness to varying point densities and distributions without requiring trainable parameters.

2.4 Gap in Existing Research

While there has been significant progress in both point cloud analysis and the application of MR in construction, there remains a critical gap in datasets with characteristics representative of data acquisition using typical MR-mounted sensing solutions, in particular to support applications related to MEP mapping. Existing datasets predominantly focus on high-precision LiDAR scans, which do not adequately capture the unique challenges posed by MR-based data collection. The sparse, noisy, and gap-prone nature of MR-captured meshes is not represented in these datasets. There is a need for datasets that reflect the real-world conditions encountered in MR-based inspections, including lower point density, increased noise, and more frequent occlusions due to the limitations of MR devices and the challenging nature of MEP environments.

3 Dataset Acquisition and Preparation

3.1 Research Framework

To clearly present the overall workflow of this research, we summarise the main steps, objectives, methods, and equipment involved:

- **1. MR Data Acquisition**
  Objective: Capture raw 3D spatial meshes of real-world MEP systems (pipes and ducts) under realistic MR conditions, while managing challenges such as noise and sparsity.
  Device: Microsoft HoloLens 2
  Method: On-site scanning of building environments with multi-angle coverage and careful motion control. The operator tilted the device upwards to capture ceiling-mounted MEP components, ensuring maximum possible coverage.

- **2. Dataset Preparation**
  Objective: Generate a structured and labelled MR point cloud dataset (MR-MEP) suitable for training and evaluating deep learning models.
  Process: Convert raw spatial meshes to point clouds, clean the data (removing large architectural elements and noise), segment MEP components using BIM-derived Oriented Bounding Boxes (OBBs), label points as 'pipe' or 'duct', and apply data augmentation to balance class distribution.

- **3. Model Benchmarking**
  Objective: Assess and compare the classification performance and computational demands of state-of-the-art models on MR-captured MEP data.
  Models: Nine deep learning architectures, including PointNet, PointNet++, DGCNN, PointMLP, PointNeXt, PointTransformer, PointMetaBase, PointVector, and PointNN.
  Method: Perform 6-fold cross-validation with scene-based splits, applying pre-training on ScanObjectNN where applicable and balancing training data with augmented samples.
  Evaluation Metrics: Overall Accuracy (OA), Mean Class Accuracy (mAcc), class-specific accuracy (pipes and ducts), and computational efficiency (parameters, FLOPs, throughput).

- **4. Performance Analysis**
  Objective: Determine the optimal model for practical MR-based MEP classification, balancing high accuracy with computational efficiency for real-world deployment, including potential on-device processing.
  Process: Analyse cross-validation results, evaluate accuracy and stability, and compare computational efficiency. Identify models most suitable for MR data constraints, such as sparsity and noise.

3.2 Scanning Procedure and Protocols

The Microsoft HoloLens 2 MR headset was selected as the primary data collection device for this study, owing to its sophisticated sensing and processing capabilities [23]. This advanced device incorporates a comprehensive sensor array specifically designed for spatial mapping. Hübner et al. [12] conducted an extensive evaluation of the HoloLens 2 for indoor mapping tasks, revealing a correlation between sensor-to-object distance and measurement accuracy. Their findings indicate that as the distance between the sensor and the object increases, the associated measurement noise also tends to rise. Specifically, for distances under 2.5 m, the noise level remains below 5 mm. However, beyond this threshold, the error exhibits a rapid escalation, with noise levels reaching 2 cm or more at greater distances.

In our study reported here, the scene mapping functionality of the HoloLens 2 (HL2) was utilised to capture the environment as a triangle mesh. The mesh resolution was set to the finest level, and a comprehensive scan of the environment was conducted. Given that the HL2's capture sensors are front-facing, it was necessary to tilt the device upwards to scan certain areas. Additionally, since some Mechanical, Electrical, and Plumbing (MEP) components were located on the ceiling, which exceeded a height of 2.5 m, at times the device had to be handheld at arm's length above the operator's head, with both hands gripping the sides of the headset for stability. The camera was oriented upward to directly face the MEP components,

and the operator maintained a steady, controlled motion with movement speed kept below approximately 0.3 meters per second to ensure complete coverage.

Data acquisition was conducted across 8 distinct building environments to ensure a diverse and representative dataset. A standardised scanning protocol was implemented to maintain consistency and data quality across all sites. This protocol comprised a preliminary site walkthrough to identify and delineate key MEP areas of interest, followed by systematic and comprehensive scanning of the identified MEP areas. Particular attention was given to capturing each component thoroughly from multiple angles to optimise coverage. The duration of each scanning session was approximately 15-20 minutes, with variations depending on the complexity and scale of the individual construction site.

3.3 Dataset Overview and Statistics

The dataset primarily focuses on MEP components like pipes and ducts, featuring both mixed reality captured environments and their corresponding BIM models. Data were collected from eight distinct scenes, six of which are classified as mixed environments containing both pipes and ducts: bike parking, apartment room, Garage 1, Garage 2, Garage 5, and Garage 6. The remaining two scenes, Garage 3 and Garage 4, are pipe-only environments.

To establish the ground truth, BIM was employed to generate precise digital representations from laser scan data acquisition of those environments.

3.4 Dataset Preparation for Point Cloud Classification Use Case

In the context of scan-vs-BIM comparison for automated construction progress monitoring, we developed a component-wise detection strategy utilising oriented bounding boxes (OBBs) derived from the corresponding BIM elements. Similarly to [24, 25], the idea is to explore whether the point cloud in the vicinity of each BIM object confirms the presence of that element. This systematic decomposition approach resulted in 382 distinct OBB regions across all environments, where each OBB region encompasses point cloud data that potentially corresponds to a specific MEP component segment.

Table 1 presents the key characteristics of the eight scenes in our dataset, detailing the number of vertices, segmented pipes, segmented ducts, and the dimensions of OBB enclosing each MEP component in each scene.

3.5 Class Balancing Strategy

Analysis of the dataset composition reveals a significant class imbalance between ducts and pipes. Of the total 382 elements, 44 (11.5%) represent ducts, while the remaining 338 (88.5%) correspond to pipes. This imbalance is arguably representative of the reality of building environments [26], where piping networks often dominate due to their essential role in various building services including water supply, drainage, heating, cooling, and fire protection systems.

To mitigate the issue of class imbalance, a data augmentation pipeline consisting of rotation, scaling, and mirroring was applied to the duct class within the mixed scenes. This augmentation process was repeated until a 1:1 ratio between duct and pipe samples was achieved, ensuring a balanced dataset for model training.

3.6 Cross-Validation Strategy

A 6-fold cross-validation strategy was employed to robustly evaluate the performance of the selected and deployed classification models. Each fold ensures that every mixed scene serves as the test set once, while the model is evaluated on a combination of pipes and ducts. During training, the model is exposed to both mixed scenes and pipe-only scenes.

The cross-validation folds were structured such that in each iteration, one scene was held out for testing while all others were used for training. The test scenes for the six folds were: Bike Parking, Apartment Room, Garage 1, Garage 2, Garage 5, and Garage 6, respectively.

4 Methods and Implementation

4.1 Selected Deep Learning Models

We select a diverse set of classification models, including traditional deep learning architectures, graph-based methods, transformer-inspired models, and a non-parametric method. This range enables an assessment of trade-offs between model complexity, computational efficiency, and performance, particularly for point cloud processing tasks involving noisy or sparse data captured by MR devices. These models have been pre-trained on ScanObjectNN, which closely resembles Mixed Reality captured data as discussed in Section section 2.1, making them particularly suitable for real-world MR applications. The selected architectures include:

- **PointNet** [13] serves as a fundamental architecture for point cloud classification and segmentation tasks.
- **PointNet++** [14] builds on PointNet and introduces hierarchical feature learning through Set Abstraction modules, enhancing the model's capability to capture local structures.
- **DGCNN** [18] takes a graph-based approach, implementing dynamic edge convolution to address noise and sparsity challenges by effectively leveraging local neighborhood structures.
- **PointMLP** [21] advances the field by implementing a sophisticated residual MLP framework designed for robust performance.

Scene	Vertices	Pipes	Ducts	Size (m^2)
Bike Parking	32,962	51	3	10.4 × 8.6
Apartment Room	82,139	96	11	12.5 × 10.8
Garage 1	95,416	24	7	18.6 × 14.8
Garage 2	85,814	40	4	20.9 × 10.9
Garage 3	47,177	67	0	12.2 × 4.3
Garage 4	14,029	24	0	13.2 × 8.0
Garage 5	35,967	3	5	12.7 × 3.9
Garage 6	39,447	33	14	30.5 × 15.9
Total	432,951	338	44	131.0 × 77.2

Table 1. Scene-level characteristics of the captured environments

- **PointNeXt** [15] revisits the PointNet++ architecture, incorporating enhanced training strategies and introducing a more scalable model design.
- **PointMetaBase** [16] offers a unified analysis framework that enables efficient point cloud processing.
- **PointVector** [17], which employs vector-based processing techniques to capture spatial relationships within point clouds;
- **PointTransformer** [20], which adapts transformer principles to emphasise spatial relationships in point cloud data;
- **Point-NN** [22] takes a unique approach as a non-parametric, training-free method that utilises a point-memory bank for similarity matching.

4.2 Evaluation Metrics

We employ a diverse set of metrics across six-fold validation to rigorously assess model performance and efficiency.

The evaluation of classification accuracy encompasses three distinct metrics:

- **Class-specific Accuracy (Acc)** quantifying the classification accuracy for pipe and ducts independently, enabling granular performance assessment and identification of potential classification biases.
- **Overall Accuracy (OA)** quantifies the proportion of correctly classified samples across the entire dataset, providing a global performance indicator.
- **Mean Class Accuracy (mAcc)** averages individual class accuracies, thereby ensuring equitable evaluation across all categories, regardless of class imbalance issues.

The evaluation of computational efficiency also comprises three fundamental metrics:

- **M, the total number of trainable parameters** quantifying the model complexity and expressed in millions.
- **G, the FLOPs** quantifying the computational demand during inference and expressed in billions of floating-point operations.
- **Throughput measurements** quantifying the system's processing speed by measuring the number of complete inference requests the model can process per second under realistic deployment conditions.

For statistical robustness, we report the mean and standard deviation of each accuracy and efficiency metrics across all six folds, thereby providing comprehensive insights into both performance magnitude and consistency.

4.3 Hardware and Software Specifications

The experiments were conducted on a system equipped with an NVIDIA GeForce RTX 3090 GPU and an AMD Ryzen 9 3900X 12-core processor. The software environment included Ubuntu 20.04.6 LTS as the operating system. The deep learning framework used was PyTorch 2.0.0, which was integrated with CUDA 11.8 for GPU acceleration. Python version 3.9.0 was used as the programming language to run the experiments.

5 Results and Discussion

The experimental results are presented in table 2 and table 3 that provide a comprehensive evaluation of the selected models across both accuracy and computational efficiency metrics. Table 2 summarises the cross-validation accruacy results.Among all models, PointNN demonstrates clear superior performance, achieving by far the highest scores across all accuracy metrics (90.21% overall accuracy), and with lower standard deviations, indicating more stable performance across different test scenes. Table 3 presents the computational efficiency metrics.The results show that PointNN achieves optimal efficiency with minimal parameters (~0.0M[1]) and highest processing speed (11,932.60 instances per second), while PointMetaBase requires the least computational operations at 0.55G FLOPs, demonstrating its theoretical computational efficiency.

To visualise the trade-off between model performance and computational demands, fig. 1 plots the Overall Accuracy against FLOPs for all evaluated models. The figure clearly demonstrates that PointNN (marked with a star) achieves an optimal balance, reaching the highest accuracy

[1]because it is a non-parametric method

Model	Overall Accuracy (%)	Mean Class Accuracy (%)	Pipe (%)	Duct (%)
PointNN	**90.21 ± 2.12**	**89.45 ± 2.34**	**91.33 ± 2.45**	**85.67 ± 3.56**
PointMLP	81.55 ± 8.23	74.00 ± 12.45	67.76 ± 37.91	80.23 ± 21.54
PointNet++	80.85 ± 13.21	78.22 ± 13.45	77.42 ± 23.45	79.02 ± 24.12
PointTransformer	80.52 ± 13.45	77.49 ± 14.56	89.20 ± 11.23	75.78 ± 17.89
PointNext	80.45 ± 14.23	75.37 ± 17.34	80.53 ± 34.56	70.22 ± 31.23
DGCNN	78.57 ± 7.89	72.36 ± 9.21	70.44 ± 31.82	74.28 ± 25.85
PointNet	78.43 ± 8.56	70.24 ± 9.78	62.80 ± 33.45	77.68 ± 24.56
PointMetaBase	78.35 ± 13.65	74.79 ± 11.83	81.80 ± 18.32	67.78 ± 32.41
PointVector	68.79 ± 15.67	63.79 ± 12.45	71.85 ± 27.89	55.74 ± 37.89

Table 2. Cross-validation Results (Mean ± Std)

Model	Parameters (M)	FLOPs (G)	Throughput (ins./sec)
PointNN	**~0.0**	1.34	**11,932.60**
PointMetaBase	1.417	**0.55**	2,313.80
PointNext	1.364	1.64	2,776.64
PointNet++	1.463	1.71	2,373.52
PointVector	1.544	1.68	1,069.91
DGCNN	1.800	4.82	802.59
PointNet	3.470	0.91	5,620.63
PointMLP	13.228	31.35	199.37
PointTransforme	22.647	29.16	432.74

Table 3. Computational Efficiency Metrics

while maintaining moderate computational complexity. Most deep learning models cluster in the middle range of both metrics, with FLOPs between 0.5G and 5G and accuracies between 75% and 85%. Notably, more complex models like PointMLP and PointTransformer, despite their substantially higher computational demands (>25G FLOPs), do not yield proportional improvements in accuracy.

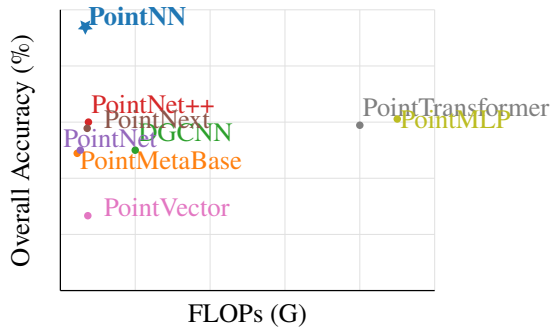

Figure 1. Model accuracy versus computational complexity (FLOPs). PointNN (marked with a star) achieves the best accuracy while maintaining minimal computational requirements.

5.1 Performance Analysis

PointNN achieves superior performance across all accuracy metrics, with an overall accuracy of 90.21% (±2.12%) and mean class accuracy of 89.45% (±2.34%). PointNN's consistently low standard deviations (±2.12% to ±3.56% across different metrics) strongly suggest superior generalization capability and resistance to overfitting, particularly valuable for MR applications where data distributions can vary significantly between deployments. Most notably, it maintains remarkably consistent performance across both Pipe (91.33% ±2.45%) and Duct (85.67% ±3.56%) classes, indicating stable learning across different geometric features.

The second tier of performers exhibits concerning signs of potential overfitting, as evidenced by their high cross-validation standard deviations. PointMLP (±8.23%), PointNet++ (±13.21%), PointTransformer (±13.45%), and PointNext (±14.23%) show comparable mean accuracy but their high variances across different folds suggest that these models may be overspecialising to training set characteristics rather than learning generalisable features, with their class-specific performance showing dramatic variations (up to ±37.91% for PointMLP's pipe classification) indicating inconsistent feature learning.

More traditional architectures like DGCNN (78.57% ±7.89%) and the original PointNet (78.43% ±8.56%) demonstrate moderate performance with relatively lower cross-validation standard deviations compared to the second tier. While their balanced standard deviations suggest more stable learning, their lower overall accuracy makes them less suitable for precision-critical MR applications. These models' moderate standard deviations indicate better generalisation than more complex models but still fall short of PointNN's stability.

From a computational perspective, PointNN's perfor-

mance is particularly noteworthy for MR applications, given its minimal parameter count (~0.0M) and high throughput (11,932.60 instances/second). The absence of learnable parameters inherently prevents traditional overfitting, as reflected in the consistent cross-validation results. This stands in stark contrast to more complex models like Point-Transformer and PointMLP, which require substantially more parameters (22.647M and 13.228M respectively) and show signs of overfitting in their high standard deviations despite achieving reasonable mean accuracy.

Overall, the non-parametric approach of PointNN provides several key advantages for MR point cloud processing: First, the trigonometric encoding effectively captures high-frequency geometric patterns, which remain stable even when surface details are inconsistently captured by MR devices. Second, the point-memory bank's similarity-based classification provides flexible matching rather than rigid decision boundaries, crucial for handling varying point densities and object appearances. Third, PointNN shows remarkable immunity to common MR data challenges including partial occlusions and sensor noise through its local geometry aggregation mechanism. Combined with its computational efficiency and inherent regularization from the non-parametric design, these characteristics make PointNN especially valuable for real-world MR deployments where robustness, consistency, and real-time processing are critical requirements.

6 Conclusion

This work presented a new dataset MR-MEP and an investigation into the performance of point cloud classification deep learning models on that type of data. Specifically, we present MR-MEP, a specialised dataset that pairs mixed reality captured point clouds with corresponding BIM models for MEP components in building environments. The dataset was collected using Microsoft HL2 across 8 diverse building scenes, containing 432, 951 vertices spanning a total area of 131.0×77.2 m^2. What distinguishes MR-MEP is its dual-source nature - combining precisely captured mixed reality point cloud data with corresponding BIM models - making it valuable for multiple point cloud understanding tasks including classification, object detection, and semantic/instance segmentation. For our specific investigation into MEP component classification, the dataset is split into 382 annotated MEP components (338 pipes and 44 ducts), segmented using BIM-derived oriented bounding boxes (OBBs). To ensure robust evaluation, we implemented a 6-fold cross-validation strategy and addressed the natural class imbalance through careful data augmentation.

Our experimental analysis of the different point cloud classification models demonstrates that the recently proposed non-parametric approach, PointNN, achieves state-of-the-art performance with 90.21% classification accuracy while maintaining minimal computational overhead of 1.34 GFLOPs. The model's ability to maintain high accuracy despite the quality limitations of MR-captured data suggests potential for robust deployment in real-world construction scenarios. Moreover, the minimal computational requirements make it particularly suitable for on-device processing in MR devices, addressing a critical need in mobile construction inspection applications.

Although the proposed approach demonstrates promising results in MEP component classification from MR-acquired point cloud data, several critical areas merit further investigation. The current implementation, while effective, has been primarily evaluated on a binary classification task distinguishing between pipes and ducts. This should be extended to support multi-class classification capabilities, in order to accommodate the diverse range of MEP components encountered in real-world construction environments. Additionally, while our work focuses on classification, further evaluation across other crucial point cloud understanding tasks is needed. For instance, in real construction scenarios, MEP components need to be precisely localized through object detection and semantically segmented for detailed analysis. For such tasks, while Point-NN's non-parametric approach demonstrates strong performance in classification, its effectiveness in more complex scenarios like instance or semantic segmentation remains to be thoroughly investigated. It is possible that other architectures with learned parameters (including the *Point-PN* approach proposed by the same authors [22]) might prove more suitable for tasks requiring fine-grained spatial understanding or complex feature hierarchies, as these tasks may benefit from learned, task-specific feature representations. To bridge the gap between theoretical advances and practical implementation, future work should focus on integrating deep learning-based detection and classification models like those into comprehensive MEP construction monitoring frameworks such as the one proposed by [24]. Such integration presents several technical challenges that warrant investigation, including: the optimisation of real-time processing capabilities within MR-based progress monitoring systems, and the development of robust verification mechanisms for construction geometry inspection.

Abstract -

The issue of renovating a significant number of buildings has emerged as a prominent concern within the architecture field in recent years. The renovation of existing buildings represents a significant opportunity for reducing energy consumption and greenhouse gas emissions at minimal economic cost. However, achieving effective renovation outcomes can be challenging, particularly for customers who lack technical expertise. To address this gap, this paper presents an online data acquisition platform designed to streamline the integration of building information through a standardized process. Furthermore, this paper presents the optimization of algorithms to address common challenges such as fragmentation, an over-reliance on manual input, and the utilization of disconnected tools in the renovation process. Finally, the feasibility and effectiveness of the platform are demonstrated through case studies featuring 3D building models processed through the platform. These case studies highlight the potential of the platform as a valuable tool for building renovation.

Keywords -

Data acquisition; renovation; energy saving; modeling.

1 Introduction

Since the intensification of extreme weather and climate events resulting from global climate change represents an escalating risk to human society [1][2][3]. Over the past two decades, greenhouse gas emissions have emerged as a primary driver of the climate crisis [4]. The construction industry, in particular, has emerged as a significant contributor to both greenhouse gas emissions and energy consumption [5], thereby exacerbating environmental concerns. As the urgency to mitigate these issues grows, the need for innovative solutions that enhance energy efficiency in the built environment becomes increasingly evident.

In response to this pressing need, this study proposes an online platform aimed at improving energy efficiency and standardizing renovation practices in the construction industry. The prevailing renovation methodologies are characterized by fragmentation, an over-reliance on manual input, and the utilization of disconnected tools. This results in inefficiencies and suboptimal energy assessments. To address these challenges, the proposed platform implements a semi-automated, structured workflow to ensure consistency and accuracy throughout the renovation process.

The platform operates by guiding users through a systematic process, beginning with the input of basic building data, which generates an initial model devoid of openings. Subsequent processing and integration of existing openings generates a comprehensive and normalized model. This structured approach not only eliminates errors but also streamlines energy assessments, improving the efficiency and reliability of renovation projects.

This paper commences with an overview of the prevailing circumstances of the renovation of buildings. Thereafter, the functionality of the online platform is elucidated, whereby all processes are rendered uniform. The processes include the user input of existing basic building information, the creation of an initial simple model based on the user input (without any openings on the walls), the pre-processing of the existing openings information, the combination of the simple model with the existing information, and the generation of the final model, normalization process of the obtained model. Subsequently, the optimization section, which encompasses several technically challenging elements, is addressed. This study presents a series of case studies based on the developed platform. Concurrently, a set of criteria is provided to complete the evaluation of the platform. The findings indicate that the online platform is both effective and straightforward to operate, thereby potentially streamlining the process of building renovation.

2 Related work

2.1 Existing platforms for building renovation

As previously stated in the introduction, the integral functional data acquisition platform designed in this

project is not based on any other existing platforms. However, there are some existing renovation systems proposed by other researchers.

For instance, the RINNO project [6] provides a comprehensive solution for the full-lifecycle management of renovations, encompassing the entire project from initial planning and design to the end-of-life phases. The platform incorporates advanced analytical capabilities, interoperability with BIM [7], and a repository for renovation resources, thereby optimizing time, costs, and energy efficiency while enhancing stakeholder collaboration.

The SUNShine platform [8] is an innovative digital tool designed to enhance efficiency, transparency, and standardization in the deep renovation of multi-family buildings. By facilitating effective communication among diverse stakeholders throughout the renovation process, the platform streamlines project management and reduces costs through digitalized and standardized documentation.

It is evident that the majority of contemporary research endeavors are oriented towards the development of a comprehensive renovation platform. However, there is a notable absence of a standardized platform for data acquisition.

2.2 Challenges in building renovation

A substantial body of evidence [9] indicates that the rate of building renovation in the Europe Union (EU) is relatively low, falling far short of the EU's stated targets [10][11][12][13] for such work. Nevertheless, the research [14] indicates that accelerating the renovation of buildings in the near term is a formidable challenge. In addition to identifying the optimal channels for reaching both the demand and supply sides of renovation technology, it is crucial to assess the user-friendliness and efficiency of these channels.

The challenge mentioned above was also proposed by other researchers [15]. In order to achieve the implementation of Nearly Zero-Energy Buildings (NZEB) [16] renovation packages in Europe, it is necessary to shift building renovation strategies towards solutions that incorporate a multitude of passive and active components. This will inevitably result in an increase in the complexity and costs associated with the execution of such strategies.

Besides, in comparison to new construction projects, renovations of existing buildings present a number of challenges, including high design difficulty, demanding quality and safety management, complex construction processes, poor site conditions, and dynamic project management requirements. The design phase of existing building renovation projects is often lengthy and inefficient [17].

Based on these existing challenges, a fully functional online data acquisition platform is required in order to effectively increase the renovation rate of buildings and reduce energy loss.

3 Methodology

3.1 The stepwise data acquisition platform

The data acquisition process comprises several regularized phases. During this process,

1. the user is required to input the relevant information pertaining to the target building, as illustrated in Figure 1.
2. the creation of an initial simple model based on the user input, which does not include any openings (windows, balconies, doors...) on the facades.
3. the pre-processing of the existing openings information. The openings information here can be generated by another platform, which is the culmination of our research group's efforts [18]. Its primary objective is to facilitate the selection of openings on a facade from images captured from disparate viewpoints, subsequently storing them in a normalized `.json` file.
4. the combination of the model with the processed existing openings information.
5. the generation of the final model in the form of a formatted `.json` file, which can be utilized to visualize the comprehensive model with all the openings clearly delineated. This format is particularly well-suited for 3D modeling and BIM applications, offering a streamlined process for architects and designers [19][20][21][22][23][24].
6. the normalization of the obtained final model for being transferred into an `.ifc` file.

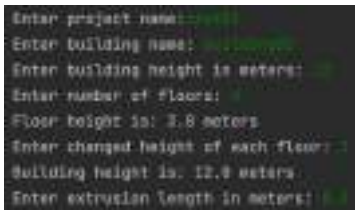

Figure 1. The illustration of user input

3.2 The illustration of the data acquisition process

The provided flowchart illustrated in Figure 2 presents a comprehensive overview of the data acquisition platform, delineating the sequence of operations and offering a more intuitive representation of its efficacy.

4 Optimization

As previously stated in the section on related work, the current challenges make the renovation process a signifi-

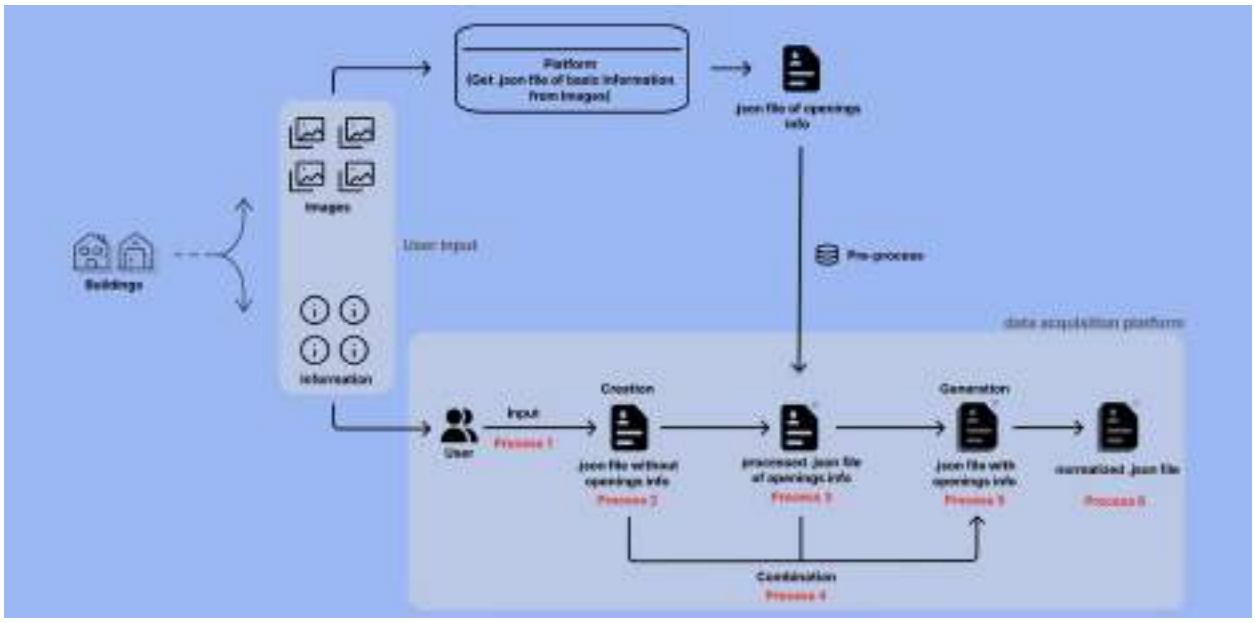

Figure 2. The flowchart of the designed platform

cant undertaking. To surmount these obstacles, it is imperative to augment the efficacy and sophistication of the data acquisition methodology, thereby paving the way for the comprehensive automation of the operational procedure. It is of paramount importance to ensure that the generated model is as close as possible to the actual building in the real world. In light of the aforementioned considerations, a number of optimizations can be implemented with a view to enhancing the platform's automation capabilities, the precision and reliability of the model simulation.

4.1 Roof implementation

The majority of contemporary algorithms fail to consider the impact of a building's roof on its renovation. This is an important shortcoming, as it results in the generation of buildings that bear little resemblance to those found in the real world. The data acquisition platform proposed in this paper addresses this issue by allowing the addition of a variety of roof styles to buildings.

In order to guarantee that the roof appears as an organic extension of the building, it is essential to ensure that there are no gaps between the facades and roof elements. The roof is therefore treated as an additional layer, seamlessly integrated with the rest of the building's geometry. And the structure of the model should be like the structure shown in Figure 3.

4.2 Data filtering

The filtering function was developed with the objective of filtering and processing building data from an external

Figure 3. The structure of the building with a roof

`.json` file, incorporating user input for the targeted model. The process commences with the loading of data from a `.json` file, followed by the handling of any potential errors that may arise.

For example, in the majority of cases, only a single building will be processed; however, the `.json` file will contain a series of buildings. The user is prompted to select a specific building by its unique identifier, which is assumed to be an integer. This allows the program to filter the `.json` file and retain only the relevant building data. In the event that no matching building is identified, the script will notify the user and terminate without implementing any changes to the file.

To illustrate, if a `.json` file contains information about multiple buildings, but the user only wishes to process one (e.g., the building with ID= 3), the only thing required to do is to enter the ID of the desired building (3) in the user input field. The platform will then automatically filter out all other buildings with IDs other than 3. This

feature also facilitates greater automation of the platform. The illustration of this optimization is shown below in the Figure 4.

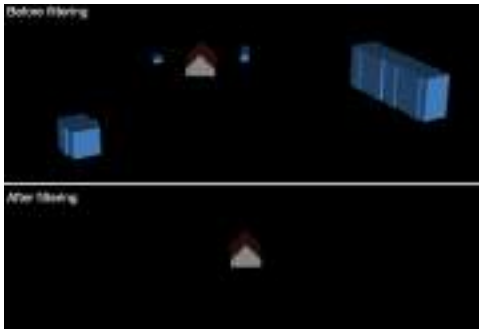

Figure 4. Before and after using the filter function

4.3 Data combination

As previously stated in the `Methodology` section, the file generated externally and the file obtained by user input must be combined. However, since the fundamental data regarding openings is not always consistent, the algorithm is optimized by loading the building data from two sources and identifying the pertinent facade objects (openings) and their geometries.

Subsequently, the data regarding the openings within the aforementioned facades is extracted and stored for subsequent utilization. By iterating through the building structures and their components, the script effectively isolates key data related to facades and their openings, which is essential for accurate building modeling and analysis.

In addition, this phase of the process entails the processing of facade names, whereby they are extracted from the building data and modified to ensure uniformity in format. This guarantees that walls from both data sources can be readily identified and matched, despite minor discrepancies in their nomenclature. And in the event of slight discrepancies in nomenclature between the two files, such as differences in case and initial count, it is imperative to normalize the naming conventions in order to ensure consistency. It plays a pivotal role in aligning the data between the two sources, thereby facilitating a seamless merging process.

4.4 Height estimation

In light of the fact that users are not always able to provide precise building heights, the height estimation was incorporated into the design of the platform as an additional feature. This results in a more precise final model, which the user can then utilise for the renovation of the building with the objective of reducing energy consumption.

The optimized algorithm based on [25] for estimating building height in the absence of external data, specifically addressing the scenario where the camera is angled relative to the building facade. The diagonal distance (D'), defined as the straight-line distance from the camera to the building base, serves as a preliminary reference point. However, it necessitates correction to account for perspective distortions induced by the camera's angle of observation. This is accomplished through the application of the formula:

$$D = D' \cdot \cos(\theta), \tag{1}$$

wherein θ represents the angle between the camera's line of sight and the perpendicular to the facade. The angle θ can be determined through image analysis or by reference to the camera setup data. The correction of D' to D ensures an accurate representation of the horizontal distance between the camera and the building base. With the corrected horizontal distance (D), the real-world height of the building (H_{building}) is calculated using the principles of projective geometry.

$$H_{\text{building}} = \frac{H_{\text{image}} \cdot D \cdot H_{\text{sensor}}}{f \cdot R_h}, \tag{2}$$

where:

- H_{building}: Real-world height of the building (in meters).
- H_{image}: Building height in the image (in pixels).
- D: Corrected horizontal distance from the camera to the building base.
- H_{sensor}: Physical height of the camera sensor (in millimeters).
- f: Camera focal length (in millimeters).
- R_h: Image resolution (vertical pixel count).

In light of the aforementioned details, the user is only obliged to input the letter D; the remainder of the information will be automatically detected and extracted by the platform. This has the potential to markedly enhance the precision and efficacy of our modelling procedures.

5 Case study - Pilot buildings

A number of pilot buildings have been selected for the purpose of evaluating the designed online data acquisition platform. The designed platform was subjected to an examination of its functionality on over 20 different buildings in various locations across Europe. In this section, two models, one relatively simple and the other more complex, have been presented for the purpose of demonstrating the feasibility of the data acquisition platform.

To be mentioned, the input of this platform should be from users as shown in Figure 1 and the output should be the final normalized .json file which can be transferred into the .ifc file for the visualization.

5.1 Pilot building 1 (6 facades)

Initiating the process, the first pilot building presented here is comprised of six facades, each exhibiting a limited number of openings. Subsequent to the data acquisition platform's processing, the resulting model, illustrated in Figure 5, was generated. And the approximate external shape of the model and the address information (Munich, Germany) are provided in the attachment to Figure 6.

Figure 5. Example of the simple building

Figure 6. Basic information of the simple building

5.2 Pilot building 2 (22 facades)

To illustrate the capacity of the designed platform to address the complexities inherent in more sophisticated buildings, an additional pilot building is presented here for evaluation. Given the 22 facades comprising this pilot building, a comprehensive comparison for each facade is not feasible. For purposes of reference, the images of this building can be accessed via this URL: `https://www.ensnare.eu/#pilotsites`. The illustration of this pilot building is shown below in Figure 7.

Figure 7. Example of the complicated building

6 Future work

6.1 More roof types

A significant area for future research is the expansion of the methodology to accommodate a broader range of roof types in building height estimation. Although the existing methodology is effective in handling standard roof designs, real-world applications frequently entail more intricate geometries, such as gable, hip, mansard, or even curved roofs. This improvement will facilitate the system's ability to process a more expansive range of building types, thereby enhancing its robustness and versatility in real-world scenarios.

For example, there are a number of different configurations as shown in Figure 8, including flat (or shed), gabled, hipped, arched, and domed. Additionally, there is a wide variety of other configurations. Copyright information can be found at this URL: `https://commons.wikimedia.org/wiki/File:Roof_diagram.jpg`

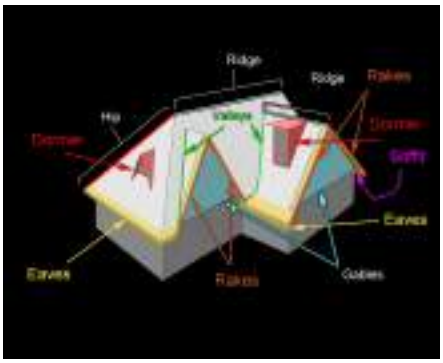

Figure 8. An illustration of different types of roofs

6.2 Multi-Platform Integration

Another crucial objective is the integration of the proposed platform with existing platform [18], with the aim of creating a comprehensive and unified system. Many platforms are currently designed for specific tasks in building renovation, such as initial modeling, data acquisition or simulation. However, they often operate independently. This integration will entail the harmonization of data formats, the optimization of interoperability between modules, and the implementation of automated workflows with the objective of minimizing manual intervention. Such a unified system will not only enhance usability for non-expert users but also provide a seamless end-to-end solution for building renovation projects, aligning with the prevailing industry trends toward automation and digitization.

7 Conclusion

The designed data acquisition and building modeling platform represents a substantial advancement in the ability to address the complexities inherent to building renovation projects. The platform's modular design incorporates features such as standardized data input, pre-processing of structural details, the generation of detailed 3D models and so on, thereby ensuring accuracy and efficiency across renovation workflows. Furthermore, the optimization of key algorithms addresses common technical challenges, thereby enhancing the platform's performance and reliability.

Besides, the feasibility and effectiveness of the platform are demonstrated by the generation of accurate three-dimensional pilot building models, which validate its capability to facilitate complex renovation tasks. The platform not only simplifies data workflows but also enhances the quality of decision-making and project outcomes. Its innovative approach provides a robust foundation for future enhancements, including the incorporation of advanced modeling for diverse building types and integration with comprehensive renovation management systems. In conclusion, the platform represents a crucial instrument for modernizing and simplifying the building renovation process, in accordance with the increasing demand for digital transformation in the fields of architecture and construction.

Abstract

Integrating computer vision technologies into the construction industry has the potential to revolutionize site monitoring, safety management, and quality control. However, a critical gap remains in the availability of specialized datasets tailored to construction sites' distinct conditions and complexities while including sufficient classes representing most items in construction sites. Existing Computer Vision (CV) models often rely on generic training datasets, which limit their effectiveness for specific construction-monitoring-related tasks. Consequently, there is a pressing need for comprehensive domain-specific datasets that can capture the full spectrum of construction-related objects and activities.

This study addresses this gap by developing a foundational training dataset called the Construction Industry Vision Alberta Dataset (CIVAD), specifically designed for CV applications in the construction sector. Our dataset included over 50 classes with more than 86,905 images of different objects, such as tools, machinery, safety equipment, and construction materials, to support diverse CV tasks. It utilizes a combination of web scraping, inclusion of existing open-source datasets, and direct data captured from construction sites.

A set of novel methods, such as semiauto-labeling with advanced models, such as Grounded SAM and Grounding DINO, were used with our custom algorithms. These models were utilized to process parts of the dataset imagery with humans in the loop. This approach facilitated an efficient and accurate dataset creation process. The CIVAD dataset and methods employed in this study represent a significant step forward in integrating CV technologies across various construction-related applications.

1 Introduction

The construction industry is one of the largest and most complex sectors in the world and has a significant impact on the global economy [1]. It builds and maintains physical infrastructure, including roads, bridges, buildings, and other critical structures that support modern society. It remains a highly diverse and dynamic sector characterized by inherent challenges, including constantly evolving project environments, diverse stakeholder requirements, and the interplay of numerous variables and uncertainties that directly impact project outcomes [2]. These complexities require innovative solutions to enhance efficiency, ensure safety, and maintain quality standards under ever-changing conditions.

Although digital technologies have gradually penetrated the construction industry, they are yet to catalyze a fundamental transformation in their practices. The industry remains manual and fragmented, grappling with longstanding inefficiencies and challenges that underscore the nascent stage of it is digital evolution and highlight the gap in integrating Industry 4.0 [3]. However, in recent years, the construction industry has experienced several changes, primarily fueled by the growing implementation of artificial intelligence technologies, particularly in subfields such as computer vision.

CV has the potential to revolutionize various aspects of construction [4], including site monitoring, progress tracking, and safety compliance monitoring. CV technologies use cameras and other sensors to capture and analyze visual data, thereby providing valuable insights and information that can be used to improve construction processes and outcomes [12]. Despite the potential of CV technologies, their adoption in the construction industry has been limited. One of the most notable barriers is the lack of standardized datasets. Developing field-applicable computer vision models entails datasets tailored to the unique and dynamic conditions of construction sites, including diverse construction-related objects and environmental variability [13].

However, creating these datasets is challenging. First, collecting and annotating large amounts of visual data is labor-intensive and costly, and requires specialized knowledge of construction processes and CV techniques. In addition, the fragmented nature of the construction industry, in which projects often vary widely in scale, location, and standards, makes it difficult to develop universal datasets that replicate the complex environments of construction sites [4].

2 Related Work

Computer vision technologies are increasingly applied in the construction industry to help perform specific tasks [5], such as monitoring and tracking construction equipment at construction sites. This cannot be achieved without proper training datasets to train the CV models on these activities, which is essential for building any CV model. The training datasets help the model to understand it as a deployment environment, which in this case is a construction site. To support these efforts, researchers have developed several domain-specific datasets that can be used to train and evaluate CV models in construction-related applications. This study examines four widely utilized and cited publicly available construction datasets: MOCS [6], SODA [7], ACID [8], and CIS [9], highlighting their contributions and limitations and demonstrating how these shortcomings highlight the need for the development of more comprehensive and versatile datasets.

The MOCS (Moving Objects in Construction Sites) dataset contains roughly 41,668 images sourced from 174 construction sites. It consists of 13 classes of moving objects commonly found in construction environments, including workers, various types of cranes, vehicles, and machinery. Although MOCS has proven valuable for safety analysis, activity recognition, and productivity monitoring, the limited number of object classes restricts it is applicability to a narrow range of elements commonly encountered in traditional construction settings. In addition, it focuses on dynamic entities and overlooks the material, environmental, and structural aspects, making the trained models less adaptable to complex or unconventional construction scenarios.

Although MOCS has broader coverage, the Site Object Detection Dataset (SODA) features 19,846 images across 15 classes, offering a more balanced approach to object selection. However, the overall scale and scope of the dataset remain limited because of the relatively small number of classes and limited extent of scene variability. Models trained merely on SODA are not sufficiently generalizable to cover many items found within the construction environment, such as different types of construction equipment tools and materials, because of the limited scope of the SODA dataset in terms of the number of classes. A significant limitation of both the MOCS and SODA datasets is their geographic bias, as most of the annotated data were collected exclusively from construction sites in Asian countries. This narrow scope restricts the dataset's ability to generalize to North American or European contexts, where differences in color schemes, signage, safety banner languages, and weather conditions, such as snow, can significantly affect the performance and accuracy of the trained models. Another existing dataset is the Alberta Construction Image Dataset (ACID), which consists of 10,000 images across 10 classes with instance segmentation and image captioning. It primarily focuses on heavy construction equipment. Despite it is usefulness in machinery identification and detection, ACID is narrow and has only a few categories, limiting it is applicability to more integrated applications in construction [23].

Another important dataset is the Construction Instance Segmentation (CIS) dataset, which has many unique features that differentiate it from other construction-specific datasets. The dataset contained 50,000 images with over 100,000 instances annotated across 10 different classes. One of the most notable aspects is the inclusion of Prefabricated Building Construction (PBC) objects such as precast components (PCs) and PC delivery trucks, which are required for computer vision-based studies on PBC management. Moreover, the dataset distinguishes between workers who wore safety helmets and those who did not, making helmet-wearing detection more efficient than separately detecting helmets and workers. The CIS dataset spans a large set of construction sites, viewpoints, and weather, providing a variety of construction-specific object segmentation, helmet detection, and large instance segmentation data, thereby addressing gaps in the current PBC-related object segmentation research. However, the CIS dataset still suffers from the same limitations that exist in all the previously discussed datasets, which is the limited number of classes included in these datasets, which makes them only cover a specific portion of machinery, tools, workers, and materials existing in traditional construction sites.

These limitations make it challenging to build and train accurate CV models that are capable of handling the diverse needs of traditional construction sites. These sites typically involve multiple vehicle types, various tools, numerous workers, and assorted materials that must be tracked and classified. Consequently, tasks beyond equipment-related recognition, such as integrated site monitoring, schedule compliance checks, and resource allocation, are incredibly challenging without broader scene coverage.

Although merging existing datasets to mitigate their individual gaps could be considered, in practice, combining them with CV models such as YOLO is difficult because of potential issues such as data misalignment, differing annotation formats, inconsistent image resolutions, varied augmentation strategies, and ensuring that all datasets use the same classes [10].

3 Addressing Shortcomings in Construction Datasets: Why CIVAD Is Necessary

Although pioneering datasets, such as MOCS, SODA, ACID, and CIS, have advanced CV research in construction, they share limitations that hinder broader industry adoption, highlighting the need for a new dataset. This dataset captures the unique complexities of construction sites, including variable lighting, occlusions, and diverse camera viewpoints. Unlike static environments, construction sites often face unpredictable conditions [11]. Additional factors, such as local safety regulations and specialized machinery in places such as Canada, further underscore the need for more comprehensive construction-specific datasets.

In response to these limitations, we created a new dataset called the Construction Industry Vision Alberta Dataset (CIVAD), which offers a more versatile training option for researchers looking into training computer vision models to implement in different types of applications within the construction industry. These applications can include productivity estimations, vehicle tracking and monitoring, safety monitoring of construction individuals, and identification of potential bottlenecks in different construction processes. The CIVAD contains more than 86,905 images across 50 classes, and Figure 1 shows a sample of the dataset. In terms of class numbers, diversity, and the general number of annotated images, CIVAD covers much more than any other available computer vision dataset, specifically for construction applications, as listed in Table 1.

Figure 1- a sample of the CIVAD Dataset shows different classes

Table 1. A comparison between CIVAD and other datasets

	Dataset name				
Feature/Metric	**MOCS**	**SODA**	**ACID**	**CIS**	**CIVAD**
Total Images	41,668	19,846	10,000	50,000	86,905
Number of Classes	13	15	10	10	50
Annotation Types	Bounding Boxes, Masks	Bounding Boxes	Bounding Boxes, Limited Segmentation	Bounding Boxes, Masks	Bounding Boxes, Multiple Formats
Regional Scope	Asia	Asia	Canada	Asia	Worldwide
Objects Covered	Moving Objects	Site Objects	Heavy Machinery	PBC Objects, Helmet Detection	Workers, Tools, Machinery, Materials, Safety Equipment
Specialized Classes	Vehicles, Workers	Equipment, Tools	Machinery	Workers (Helmet Detection), PBC	Machinery, Workers, Safety Equipment, Tools, Materials
Format ready to Fintune Vision-Language Models	No	No	No	No	Yes
Application Areas	Safety Analysis, Activity Recognition	Object Detection	Machinery Identification	PBC Management, Safety Compliance	Safety Monitoring, Productivity Analysis, Resource Management
Unique Features	Focus on dynamic objects	Balance between object types	Heavy machinery emphasis	Helmet detection, PBC-specific data	Comprehensive data diversity
Data Collection Method	Site Collection	Site Collection	Open-source, Site Collection	Site Collection	Web Scraping, Site Collection, Augmented

CIVAD is unique because it is data diverse, which includes machinery, tools, workers, safety equipment, materials, and infrastructure components; therefore, it broadly represents the construction environment. To improve the robustness of the trained CV model on CIVAD, the dataset covers a wide range of weather conditions, lighting conditions, and different camera angles, with different types of augmentations applied to the dataset to expand it is size and versatility. It is also important to mention that our dataset offers training data in more than five different formats, ranging from JSON, TFRecord, and Pascal VOC to the YOLO format in TXT. This diversity is particularly advantageous for fine-tuning Vision-Language Models (VLMs) and vision foundation models, such as Microsoft's Florence-2 [15], which rely on large and variable datasets to learn robust representations.

By incorporating multiple object types under different environmental scenarios, CIVAD helps these models capture subtle visual cues that generic datasets may overlook, such as the unique features of construction equipment or the contextual interplay of workers, machinery, and materials. VLMs demonstrate notable zero-shot detection abilities and can detect and classify objects without explicit training data [16]. CIVAD enables researchers and practitioners to continuously refine the accuracy and generalization of VLM in construction environments, allowing the development of real-world applications. CIVAD fills a gap in the literature by providing a standardized and comprehensive dataset that bridges the gap between academic research and practical implementation.

This can accelerate innovation in computer vision technology and encourage the development of resilient AI models that can reshape construction safety, productivity, and efficiency.

4 CIVAD Dataset Creation Process

The CIVAD dataset was created using a well-defined process with different steps and techniques to efficiently and accurately develop this large dataset. This includes new approaches for making this dataset as efficient as possible, as shown in Figure 2, which shows all steps from data collection to the final dataset composition.

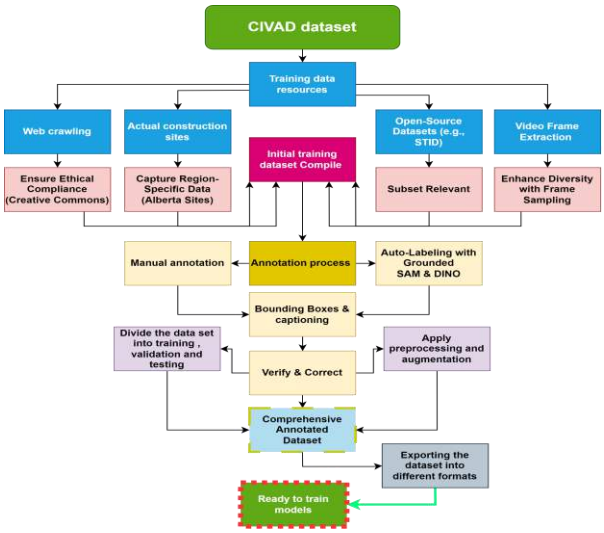

Figure 2. CIVAD dataset creation steps

4.1 included classes

CIVAD currently includes 50 object classes organized into five major categories, as shown in Table 2.

Table 2. CIVAD classes according to their categories

Categories	Classes names				
Machinery	Articulated Haulers	Bulldozer	Concrete Mixer	Concrete Pump	Dump Truck
	Excavator	Forklift	Mobile Crane	Motor Graders	Pile Boring Machine
	Scissor Lift	Sheepsfoot Roller	Skid Steer Loader	Smooth Roller	Static Crane
	Tower Crane	Wheel Loader			
Workers	White Hat Engineers	Red Hat Firefighter	Yellow Hat Worker	Green Hat Safety Officer	-
Tools	Bolts	Wrench	Trowel	Bucket	Cutter
	Drill	Grinder	Hammer	Knife	Saw
	Shovel	Spanner	Tacker		
Safety Equipment	Safety Barrier	Safety Cone	Safety Helmet	Safety Shoes	Safety Sign
	Safety Vest	Traffic Barrel	Welding Helmets	Safety Goggles	
Materials	Wood Plank	Concrete Block	-	-	-

4.2 Image Collection

The process of collecting images for the CIVAD dataset was carefully designed to strike a balance between scale, diversity, and realism, all of which have been recognized as critical factors in developing strong and generalizable computer vision models [27]. For example, large and varied datasets, such as COCO [14], have demonstrated that increasing both the quantity and variety of training samples can significantly improve a model's ability to generalize to real-world scenarios. Additionally, realism ensures that data capture authentic conditions and further refines model performance when transitioning from laboratory to field applications [28].
The CIVAD dataset creation methodology utilizes a combination of approaches, including web scraping, subsetting open-source datasets, and manual data capture to assemble a large, varied, and contextually relevant dataset that aligns with the requirements of the construction industry.

By encompassing a wide range of conditions and subjects, CIVAD aims to mirror the complexity and unpredictability inherent in real construction sites, thereby enhancing the robustness and transferability of the trained models. All images and video sources used were ethically compliant (i.e., open access or licensed under Creative Commons). During scraping, specific criteria were used to ensure that the retrieved images contained relevant construction activity, machinery, workers, tools, and materials. The systematic analysis of many online archives, such as Pixabay [26], has enabled the collection of a large pool of high-resolution visuals that represent real-world construction environments. Frame extraction from videos was used to increase the size and diversity of the dataset.

Individual frames were extracted from high-resolution videos at regular intervals during construction activities. This technique increases the total number of images and brings about natural variations in lighting, angles, and viewpoints, as well as worker/machine interaction, making the photos more realistic and providing rich supervision [29]. Frame extraction ensures that the dataset contains the dynamic and ever-changing nature of construction environments while replicating real-world scenarios better than static imagery alone [30]. We also included a subset of 3,600 pictures from an existing open-source dataset called the Small Tool Image Database (STID), which is under Creative Commons license 4.0 [17]. The STID dataset consists of 12 classes of small tools used in the construction industry, which we used as a base to include these types of tools in our dataset and then expanded it with more images for each class.

This inclusion was motivated by the need to represent small, handheld tools that are critical to everyday construction tasks yet are often underrepresented in general-purpose image datasets. Incorporating STID data helped ensure that these tools, which can significantly influence safety, productivity, and site operations, were adequately covered in the CIVAD. Also, incorporating a pre-annotated subset of 3,600 images from the STID (Small Tool Image Database) significantly reduced the time and effort needed to include 12 classes of small tools in our dataset, sparing us from annotating all such data from scratch. However, many publicly available construction image datasets originate from or predominantly replicate Asian construction environments, which can differ markedly from those found in Canada, the U.S., and Europe; for instance, in the types of equipment used, signage design, and specific safety protocols.

Therefore, we conducted manual data capture at construction sites in Alberta, Canada, where we captured approximately 3,158 pictures representing approximately 10% of the CIVAD without augmentation, to address these regional discrepancies and enhance the applicability of the dataset in Canadian contexts. This approach ensures that our dataset reflects region-specific factors such as environmental conditions and safety standards, which may not be adequately represented in datasets with predominantly Asian or non-Canadian content. Researchers obtain permission from project managers at active construction sites, ranging from commercial developments to infrastructure projects, and adhere to strict guidelines to respect property rights and protect sensitive information. As a result, the collected images more accurately represented the construction machinery, materials, and safety measures typical of North American settings. This emphasis on North American conditions, combined with the diverse set of tools, weather conditions, and site layouts in the dataset, boosts the overall realism and transferability of computer vision applications across regions, with construction practices similar to those in Canada, the U.S., and potentially even parts of Europe.

The final dataset comprised 86,905 images, which were expanded from 32,380 images using different augmentation techniques and strategically split into training, validation, and test sets to support model development and evaluation: a training set of 81,849 images (94%), a validation set of 3,632 images (4%), and a test set of 1,424 images (2%) of the total dataset.

4.3 The Annotation Process

To annotate the CIVAD dataset, the Roboflow platform [18] was utilized to perform accurate and efficient construction image labeling. Because of the large size of the CIVAD dataset (over 32,380 images without augmentation), a semiautomatic annotation approach was used to ensure accuracy and efficiency. Manual annotation and integration of cutting-edge automated tools were used in a process that combined these approaches. Manual annotation was performed to ensure that key objects, such as machinery, tools, workers, and safety equipment, were adequately identified and labeled by applying bounding boxes to the objects of interest in the images to achieve accuracy in object localization. For annotation acceleration and dataset scale management, semi-automatic labeling techniques have used state-of-the-art foundational computer vision models such as Grounded SAM [19] and Grounding DINO [20], which generate automatic predictions of bounding box coordinates.

These models proved helpful for adding annotations to identifiable object classes based on their training data; however, not all objects were correctly identified. Therefore, a thorough manual review was performed to ensure that all the relevant classes were properly labeled in each image. This hybrid approach reduced the annotation time as much as possible without sacrificing the accuracy across the entire dataset. The result was a comprehensive dataset of 32,380 images annotated with over 58,789 instances representing 50 object classes. On average, there are 2.8 annotations per image, demonstrating the complexity and variety of construction site visuals. It's worth noting that the resolution of the images in the dataset ranged from 4 megapixels to 1 megapixel, and the median image ratio for the dataset was 1280x900 pixels, with an average of 1.08 megapixels throughout the whole dataset. Figure 3 shows the number of individual annotation count distributions for images in the CIVAD dataset.

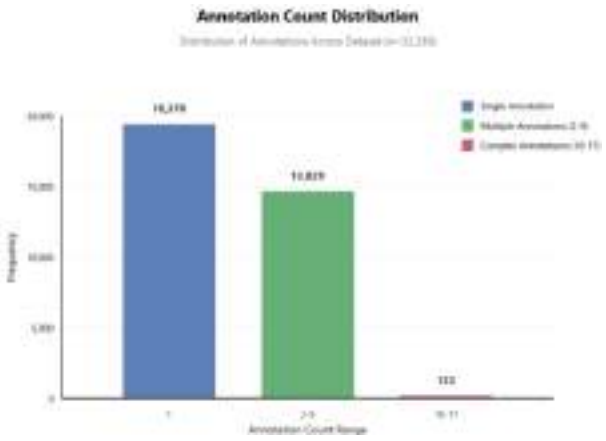

Figure 3. Annotation count distributions for images in the CIVAD dataset.

The attributes of this dataset, such as high-resolution images, diverse object classes, and realistic coverage, make it ready to train robust CV models for object detection and tracking tasks. Higher-resolution images in CIVAD capture subtle details, such as tool features and safety gear, thereby improving accuracy in complex environments. A variety of machinery, tools, and contexts help models learn richer features and generalize more effectively. The combination of manual precision with automated tools leads to annotations with a sufficient scale and the required quality accuracy to serve a range of computer vision applications in the construction industry, as proven by the high accuracy of the trained models on the dataset, which will be discussed in the next section.

4.4 The Applied Preprocessing and Augmentations Process on CIVAD

A series of preprocessing techniques was applied to standardize the images and enhance their usability in preparing the dataset for use in computer vision tasks. We began by performing an auto-orientation step to correct the image alignment by ensuring a consistent orientation based on the EXIF metadata, thereby preventing annotation mismatches caused by misaligned pixel coordinates. This preprocessing step eliminates common issues in computer vision pipelines, such as misrotation, ensuring that the images in the CIVAD dataset are uniformly oriented, have accurate annotations, and are ready for training [25]. All images were then resized to 640 × 640 pixels, which is a standard input size requirement for YOLO-based models [21], to ensure compatibility with state-of-the-art object detection frameworks and reduce computational overhead. Various augmentation techniques have been used to create camera augmentations for simulating conditions commonly seen in real-world construction sites, further diversifying the dataset and improving the model's generalization ability.

The following augmentations were applied:

- Crop: Variations in the scale and focal point of the objects were achieved by cropping the images with 0% minimum zoom and 20% maximum zoom, which gave us good results in our tests.
- Rotation: To simulate tilted or angled camera views, random rotations between -15° and +15° were performed.
- Exposure: Changes in lighting conditions were applied, by changing lighting conditions within a range of -15% to +15%, reflecting the effects of natural and artificial lighting on construction sites.

Augmentation was strategically applied to expand CIVAD from 32,380 original images to 86,905 images, significantly enhancing the dataset diversity without incurring additional annotation costs. The rationale for this augmentation is to simulate real-world variations, such as lighting changes, camera angles, and object perspectives, which are crucial for training robust and generalizable computer vision models, thus reflecting realistic construction site scenarios more accurately.

5 Trained Model Performance Evaluation

In this section, we discuss the training of a YOLOv11-M model [24] on CIVAD's 50 classes to confirm the dataset's quality and alignment with our research goals. The dataset was divided into training (81,849 images), validation (3,632 images), and test (1, 424 images) sets. Training was performed over 300 epochs with a batch size of 16, an initial learning rate of 0.001, and stochastic gradient descent optimization on an NVIDIA GeForce RTX 4090 GPU with 24 GB of VRAM [22], which required approximately 44 hours to complete. By applying preprocessing and strategic augmentation, we increased the dataset from the original size of 32,380 images to 86,905 images. The rationale behind this augmentation was to simulate real-world variability, such as changes in lighting, camera angles, and environmental conditions, thus enhancing the robustness and generalization capability of the trained computer vision models. To comprehensively evaluate the model's performance, we utilized the mean Average Precision (mAP), Precision, and Recall, which are recognized metrics for evaluating object detection model performance [31]. These metrics reflect the accuracy of the model and can be generalized across diverse construction scenarios, validating both the dataset size and appropriateness of augmentation techniques for simulating real-world variations.

These metrics demonstrate that the model is capable of accurately detecting and classifying objects from the 50 object classes of workers, machinery, tools, materials, and safety equipment across the dataset, as shown in Figure 4, which shows the trained model's performance across some of the CIVAD classes.

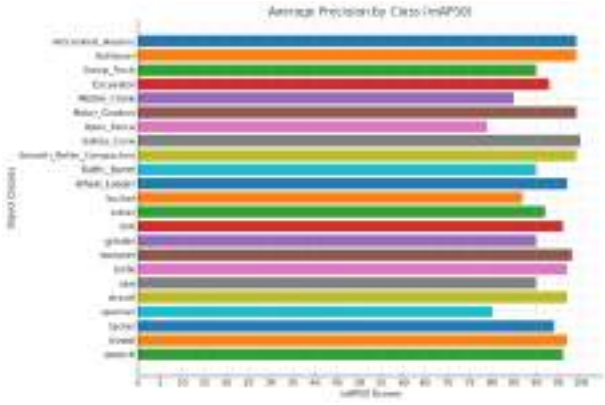

Figure 4. YOLOv11-M training results on common classes from the CIVAD dataset

6 Conclusion

To support the digital transformation of the construction industry, this study introduces some promising annotation techniques along with the CIVAD dataset, which comprises more than 86,905 images across 50 classes, capturing only a subset of the existing items in traditional construction sites. However, this dataset bridges critical gaps in existing datasets and provides vast diversity and applicability. It offers great flexibility through multiple annotation file formats and compatibility with various deep-learning frameworks, including YOLO and Vision-Language Models. CIVAD has great potential for use in safety monitoring, productivity analysis, and automated resource management, which can help improve the efficiency and safety of construction sites. We anticipate that these advancements will foster new opportunities for construction automation and that CIVAD will continue to catalyze innovation in computer vision applications related to the construction industry for many years.

7 Future Work

The CIVAD dataset provides a robust foundation for increasing the number of existing computer vision applications in construction. However, the evolution of the dataset is necessary to meet changing requirements and extend it is scope.

Future plans include:

- Expansion of Dataset Scope: We will increase the number of object classes from 50 to over 100 and the dataset size to more than 120,000 images. The dataset will include more sophisticated tools, machinery, materials, and safety equipment to better represent the different environments at construction sites. This is important for extending the generalization capabilities of the dataset.
- Enhancing Dataset Diversity: Introducing rare and region-specific scenarios of construction, such as nighttime activities, extreme weather, and geographic diversity, to enhance model robustness and generalization.
- Support for Vision-Language Models (VLMs): We will introduce additional captioning, metadata, and annotations tailored for VLM development. This multimodal focus will enable automated documentation, semantic scene understanding, and other tasks that require synergy between textual and visual data.

These points will expand the CIVAD dataset as a valuable tool to help researchers overcome barriers that hinder the integration of modern technologies, such as computer vision, into traditional industries, including the construction industry. This will enable researchers to build more reliable computer vision models in the construction industry.

Disclaimer: Specific portions of this dataset will be available upon request. Please contact Dr. Vicente Gonzalez at vagonzal@ualberta.ca to submit any requests.

Abstract

This research presents a two-phase AI-driven approach to enhance automated construction planning and scheduling, addressing common challenges such as project delays and budget overruns in the Architecture, Engineering, and Construction (AEC) industry, often caused by inefficient project management. Traditional AI methods rely heavily on static programming and manually annotated datasets, leading to inefficiencies. The proposed methodology uses prompt engineering to systematically extract and structure information from historical project schedules, creating datasets for training domain-specific Small Language Models (SLMs). In the first phase, fine-tuning SLMs, particularly mistral-7B, achieved 83.69% accuracy, outperforming traditional approaches. In the second phase, another fine-tuned SLM identified activity patterns, optimized sequencing, and predicted missing tasks, achieving a mean similarity score of 81.43%. The results demonstrate that structured prompt engineering significantly improves model accuracy and efficiency, reduces manual efforts, and addresses computational inefficiencies. This scalable, secure, and efficient approach sets a new standard in automated construction planning.

Keywords

Prompt Engineering; Domain-Specific Instruct Fine-Tuning; Small Language Models; Construction Planning and Scheduling; Activity Sequencing

1 Introduction

Construction delays and cost overruns are pervasive challenges in the AEC industry, significantly impacting the successful completion of projects [5]. Planning and scheduling are at the core of these issues and pivotal in determining project timelines and budgets. A deficiency in planning and scheduling processes can lead to delays, misallocated resources, and, ultimately, increased costs [7]. Inaccurate estimations, inadequate risk assessments, and failure to account for the complexities and interdependencies of construction activities often result in unrealistic and unachievable schedules. This lack of detailed and precise planning leads to inefficiencies in resource utilization, conflicts in task scheduling, and disruptions in the workflow, all of which contribute to extended project durations and escalated costs.

1.1 Challenges in AEC Project Planning and Scheduling

In the AEC industry, project planning and scheduling face significant challenges, notably in learning from documents, leveraging historical schedules, addressing fragmentation and interoperability issues, mitigating human errors in plan generation and updates, and implementing automation [4]. The intricate process of extracting actionable insights (key construction information and activity sequences) from extensive project documentation and past schedules is compounded by the diverse formats and standards, leading to fragmentation that hinders seamless data integration and interoperability across different project management tools. Furthermore, the reliance on manual input for generating and updating project plans introduces a high potential for human error, affecting the accuracy and reliability of schedules. These challenges highlight the need for advanced solutions to automate processes, improving efficiency and accuracy in project planning. Using sophisticated algorithms and machine learning to analyze historical data and automate schedule generation can greatly reduce these issues, leading to more streamlined and error-resistant project management in the AEC sector.

1.2 Need for Automated Planning and Scheduling

Automation in AEC project planning and scheduling is vital for optimizing project management practices [8].

Over the past three decades, researchers have explored various methods to reduce manual work and improve precision, including case-based reasoning, knowledge-based systems, model-based approaches, meta-heuristic algorithms, expert systems, and learning-based techniques [4]. However, challenges in data integration, platform interoperability, and adapting automation to project-specific needs persist. The complex and dynamic nature of construction projects demands more flexible solutions. Generative AI, with advanced Natural Language Understanding (NLU) and Natural Language Generation (NLG), presents a promising alternative [6], enhancing efficiency by interpreting complex documents and generating detailed schedules from large datasets. This marks a significant improvement in AEC automation in planning and scheduling.

2 Related Works

In the AEC industry, Building Information Modeling (BIM) and Natural Language Processing (NLP) have significantly enhanced project management by improving communication and information efficiency [11]. BIM revolutionizes the industry with digital building representations, facilitating automatic schedule generation and optimization, thereby reducing reliance on planners' expertise and using various data types like spatial and material information. Meanwhile, NLP, a sub-field of AI, focuses on computer interactions with human language through syntactic, semantic, and ontological analysis, accelerating information extraction from documents and interpreting construction processes. NLP's applications in the AEC sector include extracting data from BIM for safety compliance, analyzing contract documents, and automating Construction Schedule Management (CSM) [11], thereby improving schedule generation, validation, and accuracy.

2.1 Current Practices in Construction Planning and Scheduling

Recent efforts to automate construction scheduling have focused on leveraging BIM, with early methods combining BIM data with genetic algorithms [8] and incorporating graph-based indexing and AI for task scheduling [12], though BIM models often lack the granularity to capture project management aspects such as design approvals and procurement. More recent approaches employ NLP and deep learning to extract construction knowledge from historical schedules. Amer and Golparvar-Fard [2] introduced dynamic templates by learning from past schedules, while subsequent studies applied deep-learning-based NLP for sequence evaluation. Hong et al. [9] explored Graph Convolutional Networks to identify activity types and sequences.

2.2 Role of Language Models in the AEC Industry

LMs are revolutionizing planning and scheduling in the AEC industry by analyzing complex project data and identifying critical patterns for effective management [3]. They extract essential task details from project documents and past schedules [10], improving accuracy and reducing human error. Domain-specific training is essential [14], enabling LMs to handle construction-specific terminology and enhance project management applications. This training helps LMs identify tasks, understand resource needs, and predict challenges effectively. Integrating LMs into AEC workflows supports data-driven decisions, resource optimization, and delay reduction through historical data and predictive analytics [2][9]. Their performance improves with continued learning from real-world projects, promoting efficient project delivery.

This study addresses critical challenges in construction planning, particularly the extraction of structured information from historical project schedules and the generation of optimized activity sequences, including the prediction of missing tasks. To tackle these challenges, this research proposes a two-phase AI-driven framework integrating prompt engineering techniques with domain-specific fine-tuned SLMs. The paper is systematically organized, beginning with an introduction that outlines current industry challenges and emphasizes the need for automation in planning practices. It then reviews relevant literature, details the proposed methodology, presents experimental validations and analyses, and concludes by summarizing key findings with recommendations for future research directions.

3 Methodology

Figure 1 illustrates the framework proposed in this study for construction project planning using Generative AI. The approach leverages historical project schedules as the primary input. At its core is the extraction of key information, including detailed descriptions of the work breakdown structure, specific activities, tasks, and the network of predecessor-successor relationships. It captures the complex interplay of critical dependencies in construction planning. This study adopts a two-phase methodology that applies Generative AI and fine-tuned SLMs to enhance construction project planning and scheduling.

In Phase 1, prompt engineering is applied to extract and organize key information from existing and historical project schedules, resulting in a structured dataset. This dataset is then used to fine-tune an SLM for domain-specific information extraction in construction planning.

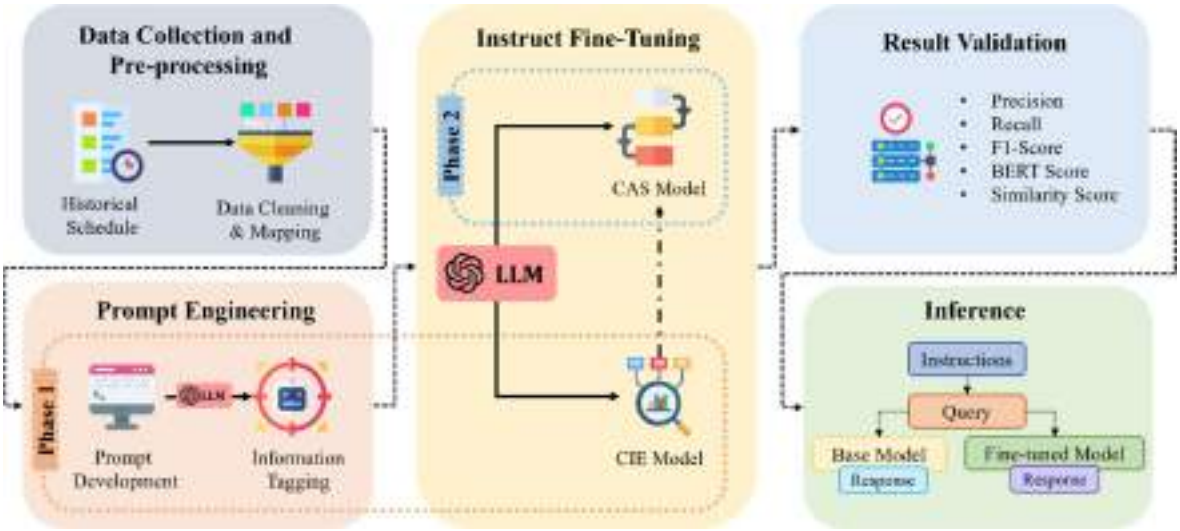

Figure 1. Overview of Proposed Methodology

In Phase 2, a separate SLM is trained on the organized data to learn activity patterns, enabling it to generate optimized activity sequences and identify missing tasks. The fine-tuned SLMs performance is evaluated against a benchmark model to assess its accuracy and reliability. Additionally, local deployment of the model ensures enhanced data privacy and security. This two-phase approach effectively reduces manual errors, accelerates processing, and improves the efficiency and accuracy of construction planning and scheduling.

3.1 Construction Activity Formalization for Data Preparation

In real-world construction projects, planning and scheduling have unique characteristics but share common structures, formats, and dependencies due to similar construction elements. Extracting information from historical schedules is challenging due to individualized approaches by schedulers, who use distinct terminologies based on specific project requirements [1]. For example, terms like "formwork" and "shuttering" serve the same function but differ in terminology. Work breakdown structures also vary; a cast-in-situ project may describe a superstructure task as "Construction-Super Structure-First Floor-Column-Reinforcement" under labels like "EPC Type-Work Item-Location-Object-Task," while a firefighting task may be labeled as "Construction-MEPF (Fire Fighting work)-Firefighting pipes-Fix or Installation-First Floor" under "EPC Type-Work Item-Object-Task-Location." This variation underscores the lack of uniformity in construction labels.

This study presents a structured approach to formalize construction activity definitions to improve data preparation for downstream processing. It consolidates details from diverse work breakdown structures and maps them to standardized labels "EPC Type, Work Items, Location, Object, and Task," emphasizing Location, Object, and Task. By harmonizing inconsistent terminologies and structures, this method improves the uniformity and usability of construction schedule data, enhancing the efficiency and accuracy of data analysis and model training.

3.2 Prompt Engineering and Key Construction Information Extraction

Prompt engineering is a vital technique for advanced models like GPT, involving the crafting of specific queries to guide the model in generating relevant outputs. It enhances precision and fine-tuning capabilities, enabling refined interaction and alignment with specific objectives. In the AEC industry, prompt engineering is a powerful tool for streamlining data retrieval [14], particularly when processing historical scheduling data. It automates the extraction and tagging of construction labels from past schedules, transforming a labor-intensive task into an efficient process. Effective prompt design requires understanding both model mechanics and domain-specific knowledge. In this study, prompts are strategically designed to capture relevant data and the complexities of construction project management. Prompt engineering, by targeting tasks, objects, and locations, ensures precise data extraction and categorization, forming a core part of our methodology.

3.3 Instruct Fine-Tuning SLMs for Construction Planning

In this study, we apply instruct fine-tuning to SLMs, tailoring these advanced AI systems to meet the

unique requirements of the construction industry. Although LMs are inherently powerful, their generalist training needs more depth for specialized tasks [13]. Our methodology strategically guides these models with carefully crafted prompts from prompt engineering data, enabling them to produce outputs that accurately align with the nuanced demands of construction management. This fine-tuning enhances the LMs proficiency in interpreting task-specific data [6], significantly improving their performance in complex construction tasks. The models are trained to parse detailed construction data, providing insights directly applicable to various aspects of construction management, such as extracting key information, generating activity sequences, and identifying missing activities. By refining these models to understand and process the unique aspects of construction scheduling and task interrelations, we transform SLMs into essential tools for delivering targeted, domain-specific solutions. This approach positions instruct fine-tuning at the core of our methodology, leveraging SLMs capabilities to advance construction project management.

4 Experimental Setup

4.1 Data Collection

In our approach to tagging construction constituents within comprehensive activities, we collected structured historical schedule data from two residential building projects, selecting 1500 activities for thorough analysis. To understand activity dependencies and sequences, we also compiled 1375 pairs of predecessor and successor activities, covering structural work, finishing, MEP (Mechanical, Electrical, and Plumbing), and commissioning domains. Using Python libraries, we efficiently extracted and parsed information from .xer files, the metadata files of Primavera, a widely used project management software in construction. This systematic organization prepared the data for subsequent analysis and model training in our study.

4.2 Materials and Methods

In this research, dataset preparation and model fine-tuning were conducted using Large Language Models (LLMs) via the OpenAI API and high-performance computational resources. Models were chosen for their domain-specific fine-tuning suitability, computational efficiency, and open-source availability. Initial evaluations were performed using the OpenAI API, while fine-tuning was done on Mistral-7B, Gemma-2-9B, and LLaMA-3.1-8B. Training utilized an NVIDIA RTX A6000 GPU with 48 GB VRAM, 50 GB RAM, and 8 virtual CPUs.

4.3 Prompt Template Preparation

Prompt templates are essential for effectively guiding and fine-tuning pre-trained models. In our approach, we use OpenAI's structured response prompt template with various instruction formats—zero-shot, one-shot, few-shot, chain-of-thought (CoT), and CoT with few-shot prompting. These formats help the model interpret and respond accurately by providing varying levels of contextual guidance. For fine-tuning, we adopt the Alpaca dataset format, illustrated in Figure 2, which standardizes instruction, user input, and assistant response. This ensures model outputs align with intended objectives. Fine-tuning is performed using open-source SLMs, allowing customization for domain-specific tasks. Combining OpenAI's prompt templates with the Alpaca format enhances the performance and adaptability of pre-trained models. This structured, context-rich data preparation enables the model to handle complex, domain-specific tasks with improved precision and efficiency.

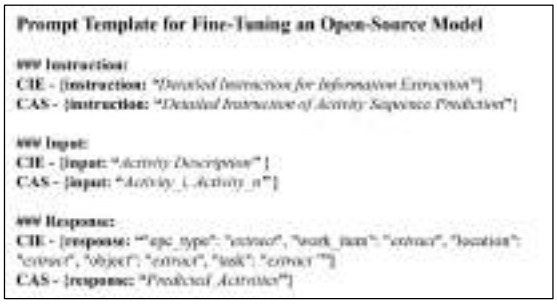

Figure 2. Overview of Prompt Template

4.4 Prompt Template for Key Construction Information Extraction (CIE)

This template is intricately designed to facilitate the extraction of construction constituents from activities. It includes explicit instructions that detail the specific constituents needed for each activity, like EPC Type, Work Item, Location, Object, and Task. Structured input is provided to ensure that all aspects of a construction activity are precisely captured and categorized. This categorized data is then used to fine-tune the Key Construction Information Extraction model. Initially, the template provides clear instructions for the information extraction task. Following this, the user input section allows for entering specific details regarding the construction activity. The model then processes this input and generates responses in specified categories. This structured interaction ensures the models accurate understanding and categorization of essential construction information, thereby enhancing information extraction accuracy.

4.5 Prompt Template for Construction Activity Sequencing (CAS)

For sequencing construction activities, the instruction section clearly outlines the sequencing task, guiding users to input detailed descriptions of construction activities. Users then provide specific sequences. The model processes this information and responds with a logically organized sequence of activities, capturing the necessary progressions and dependencies. This template is pivotal in accurately forecasting construction activity flows, which is crucial for effective project planning and execution.

Building upon the dataset preparation and fine-tuning processes described, the subsequent section presents a comprehensive evaluation of the selected language models. The results highlight their effectiveness in domain-specific tasks, particularly in information extraction and activity sequence generation, demonstrating their applicability and performance within the context of automated construction planning and scheduling.

5 Results and Discussion

In this research, LLM was first used to extract activity constituents for dataset preparation. The model's performance was evaluated using various instruction formats with a base LLM to identify the most effective strategy. The best-performing format was then used to prepare the dataset for fine-tuning, requiring only minor manual corrections to ensure accuracy and quality. The finalized dataset was split into 80% for training and 20% for testing. This structured approach ensured effective model learning and reliable performance evaluation on unseen test data.

5.1 Phase 1: Performance of Key Construction Information Extraction (CIE)

Figure 3 shows the impact of different prompting strategies on the GPT-4o-mini-base model's performance in extracting activity constituent information. The CoT Few-shot approach achieved the highest accuracy, proving that combining step-by-step reasoning with examples greatly enhances the model's predictive ability. Similarly, the CoT and Few-shot methods also improved accuracy, highlighting the importance of structured reasoning. In contrast, the Zero-shot strategy led to more non-predictions and hallucinations, indicating that lacking contextual guidance reduces the model's effectiveness. Overall, Figure 3 underscores that structured prompting with reasoning and examples are key to improving model performance in specialized tasks.

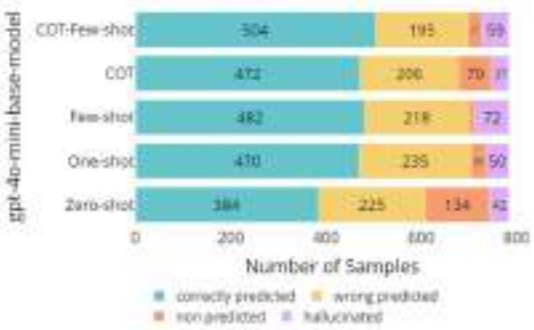

Figure 3. Performance Analysis of the CIE Model by Structured Prompt Techniques

The performance of fine-tuned SLMs, including mistral 7B, gemma 2 9B, and llama 3 8B, was evaluated for information extraction tasks. As shown in Figure 4, the mistral 7B model achieved the highest accuracy with the most correct predictions, followed closely by gemma 2 9B. In contrast, llama 3 8B exhibited lower accuracy with a higher number of non-predictions and hallucinated outputs. These models were fine-tuned using a consistent configuration across all models to ensure a fair comparison.

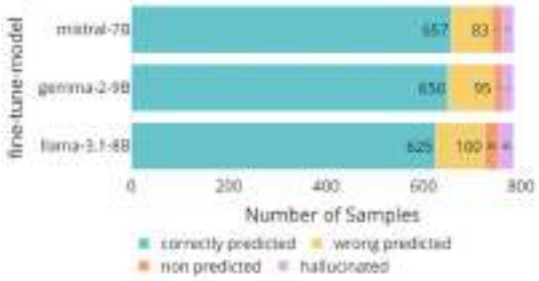

Figure 4. Performance Analysis of the CIE Model by Fine-tune model

Specifically, Low-Rank Adaptation (LoRA) adaptation was applied with a rank of 16, targeting key projection layers (e.g., q_proj, k_proj, v_proj) and optimized settings such as lora_alpha of 16 and lora_dropout set to 0. Training was conducted with a batch size of 2, gradient accumulation steps of 4, a learning rate of 2e-4.

To quantify model performance, all models were tested using these identical parameters, ensuring consistent evaluation. However, these parameters can be adjusted in future experiments to further enhance model performance.

Table 2 presents a performance comparison between fine-tuned open-source models and closed-source base models for information extraction tasks. Among the fine-tuned models, mistral 7B achieved the highest accuracy with 83.69% correct prediction, followed closely by

Table 2: Performance Comparison of Fine-Tuned Open-Source Models and Closed-Source Base Models for Information Extraction

Model Type	Model/Approach	Performance Gap to Best (%)	Correctly Predicted (%)
Fine Tune Model (Open Source)	mistral-7B	0.00	83.69
	gemma-2-9B	-0.89	82.80
	llama-3.1-8B	-4.07	79.61
Base Model (Closed Source)	gpt-4o-mini (CoT-Few-shot)	-19.49	64.20
	gpt-4o-mini (Few-shot)	-22.29	61.40
	gpt-4o-mini (CoT)	-23.56	60.12
	gpt-4o-mini (One-shot)	-23.82	59.87
	gpt-4o-mini (Zero-shot)	-34.77	48.91

gemma 2 9B and llama 3 1 8B, with slight performance gaps. In contrast, the closed-source gpt-4o-mini model, evaluated across various prompting strategies, showed noticeably lower performance. The CoT Few-shot approach led the closed-source models with 64.20% accuracy, while the Zero-shot strategy had the lowest accuracy at 48.91%. The performance gap to the best-performing model was smallest for mistral 7B and significantly larger for the base gpt-4o-mini models, especially with simpler prompting methods. These results highlight the superior performance of fine-tuned open-source models over closed-source base models in information extraction tasks.

5.2 Phase 2: Performance of Construction Activity Sequences (CAS)

As shown in Figure 5, the evaluation of construction activity sequence generation using BERTScores metrics Precision, Recall, and F1-score primarily focused on the performance of fine-tuned SLMs, specifically mistral-7B, gemma-2-9B, and llama-3.1-8B. Among these models, mistral-7B demonstrated the most balanced and consistent performance across all evaluation metrics, indicating its relative effectiveness in accurately generating and predicting construction activity sequences. In comparison, gemma-2-9B and llama-3.1-8B exhibited lower performance, suggesting that these models require further fine-tuning and optimization to improve their sequence generation capabilities. To provide a benchmark, the gpt-4o-mini model was included in the evaluation and achieved the highest scores across all metrics, with a precision of 0.89, recall of 0.87, and an F1-score of 0.88. While these results highlight the strong performance of larger models in complex sequence generations, this study primarily focused on assessing and improving fine-tuned SLMs for their computational efficiency and scalability.

The similarity scores of generated construction activity sequences were evaluated to compare the performance of fine-tuned SLMs and the larger gpt-4o-mini model. As shown in Figure 6, the gpt-4o-mini model achieved the highest mean similarity score of 91.59%, highlighting its superior ability to generate sequences closely aligned with the reference data. Among the fine-tuned models, mistral-7B performed the best with a mean similarity of 81.43%, while llama-3.1-8B and gemma-2-9B recorded mean similarity scores of 78.20% and 77.68%, respectively.

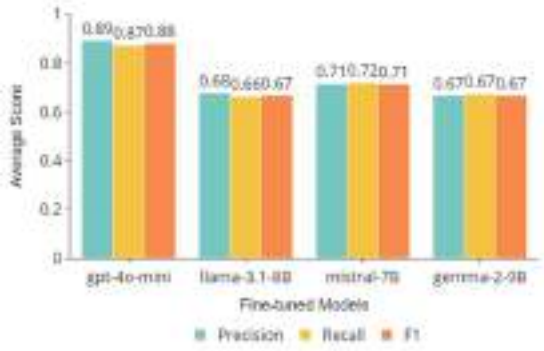

Figure 5. Evaluation of CAS Model: BERTScores (Precision, Recall, and F1) Analysis

These results demonstrate that while the fine-tuned SLMs performed reasonably well, they still lag the gpt-4o-mini in generating accurate and coherent construction activity sequences. However, the performance of the fine-tuned models, particularly mistral-7B, suggests that SLMs have strong potential for improvement.

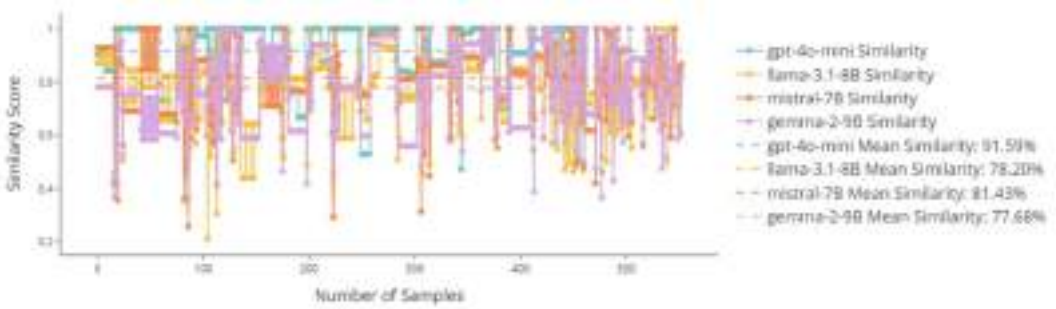

Figure 6. Evaluation of CAS Model: BERT Similarity Scores

5.3 Key Findings and Lesson Learned

In comparison to previous studies [1][9], which heavily rely on human-labeled schedule data and models such as LSTM, GNN, or BERT for learning activity patterns [9][2][3], this research adopts a more scalable and efficient approach using Small Language Models (SLMs) fine-tuned on minimally labeled data. Although pre-trained LLMs such as gpt-4o-mini were fine-tuned independently within this study and used as performance benchmarks, the primary emphasis remains on open-source SLMs. Among these, mistral-7B exhibited strong adaptability and effectiveness in handling construction planning tasks, offering a domain-aligned and practical alternative.

A key lesson learned is that targeted improvements in fine-tuning strategies such as advanced hyperparameter optimization and task-specific adaptation significantly enhance SLM performance. Emphasizing object and task identification during training allowed the models to infer contextual elements like location, improving the accuracy and relevance of generated sequences. The iterative process of hyperparameter tuning and model refinement proved crucial in balancing performance and computational efficiency.

These findings highlight the value of domain-specific data preparation, continuous model enhancement, and the combined potential of large and small models. With further optimization, fine-tuned SLMs can serve as effective, resource-efficient solutions for large-scale construction activity sequence generation.

5.4 Inferences of CIE and CAS model

Figure 7 showcases the optimal fine-tuned CIE model, mistral-7B, illustrating the differences in responses to user queries between the base model assistant and the fine-tuned model. Similarly, Figure 8 highlights the superior CAS fine-tuned model, mistral-7B, emphasizing the discrepancies in responses between the base and fine-tuned models. In both figures, errors are marked in red, while correct and newly identified sequences previously missed by the base model assistant are indicated in green. This comparison demonstrates the enhanced accuracy and predictive capabilities of the fine-tuned mistral-7B model.

System:
<Instruction_predicting_comprehensive_construction_activity_constituents>

User: "First Floor Column Shuttering Work"
Base Model Assistant: "EPC Type: Not specified, Work Item Domain: Construction, Location: First Floor, Object: Column, Task: Shuttering Work"
Fine-Tuned Model Assistant: first floor: location, column: object, shuttering: task, construction: epc type, structural: work item domain

Figure 7. Inference Outcomes Demonstrated by the CIE Model

System:
<Instruction_predicting_sequence_and_missing_activity>

Example: Same construction work item domain structural

Base Model Assistant: "first floor column reinforcement, first floor column pouring, first floor beam reinforcement, first floor beam pouring, first floor slab formwork"
Fine-Tuned Model Assistant: first floor column reinforcement, first floor column formwork, first floor column pouring, first floor slab formwork

Example: Different construction work item domain finishing to mep
User: User: "Ceiling Plastering,..., HVAC testing"
Base Model: Based on the typical order of construction activities, ...could include:....."Ceiling Plastering, Wiring installation, Insulation installation, Drywall installation, Painting, Trim installation, Flooring installation, HVAC testing"
Fine-Tuned Model Assistant: Ceiling Plastering, Ceiling Priming, Ceiling Sanding, Ceiling Painting, HVAC Duct Installation, HVAC Duct Insulation, HVAC Duct Testing, HVAC Testing

Figure 8. Inference Outcomes Demonstrated by the CAS Model

6 Conclusion

This research presents a two-phase AI-driven approach to enhance automated construction project planning using SLMs for activity sequencing and missing task prediction. In the first phase, prompt engineering extracts and organizes key information from historical project schedules to produce structured outputs. Due to inconsistencies and lower accuracy, an SLM was fine-tuned with domain-specific data to improve extraction. In the second phase, another SLM, trained on the refined dataset, learns activity patterns to generate optimized sequences and identify missing tasks. The gpt-4o-mini model served as a benchmark and achieved the highest accuracy. However, fine-tuned models like mistral-7B delivered promising results with notable advantages in efficiency, scalability, and security.

A key advantage of SLMs is their enhanced data privacy and security. Once fine-tuned, these models can be deployed and used locally without relying on external servers or cloud-based services, ensuring sensitive construction data remain secure and protected. This makes SLMs particularly suitable for industries like construction, where data confidentiality is critical.

Future work will address unstandardized schedule data, generate synthetic data for diverse projects, and enhance reasoning in models for better understanding of scheduling logic. Expanding datasets, adopting open-source models, and integrating with BIM will further improve performance and efficiency in AEC project management.

Abstract

In petrochemical plant construction, pipe installation critically the affects overall progress and costs, making accurate on-site pipe quantification essential. However, the wide range of pipe diameters, high-density layouts, and complex site conditions poses significant challenges for automated counting methods. To address these issues, this study constructs the "PetroPipe" dataset, comprising 2,380 images (340 originals and 2,040 augmented) with pipes ranging from 0.75 to 60 inches in diameter under various resolutions. Multiple data augmentation strategies and a multi-stage training process enhance robustness under dynamic construction conditions. Building on this dataset, a pipe counting method is proposed that integrates instance segmentation with a counting head and a transformer encoder. Based on the Mask R-CNN framework, the model applies a discrete-bin classification approach to achieve accurate global quantity predictions, while maintaining high-quality instance-level detection and segmentation. The experimental results demonstrate that the developed model outperforms the standard Mask R-CNN model on the test set, increasing the counting accuracy from 65.55% without a counting head to 85.50%. When evaluated on an unlabelled 18-second video captured in a real-world scenario, it attained an accuracy of approximately 98.1%, demonstrating its capacity to adapt to practical industrial conditions. These results indicate that the proposed approach effectively accommodates varying pipe diameters, dense layouts, and complex backgrounds. Consequently, it provides a scalable, efficient pipe counting, progress monitoring, and resource optimization in petrochemical construction environments.

Keywords –

Petrochemical plant pipe; Instance Segmentation; Counting; Transformer

1 Introduction

During construction of petrochemical plants, pipe installation is a crucial element of the overall construction schedule. It is a prominent component of workload and cost distribution [1]. Statistical evidence suggests that pipe installation often dictates the overall project timeline, with materials and labor accounting for approximately 71% of the total pipeline construction costs [2]. Given the large volumes and varied specifications of piping materials, this key stage significantly influences project outcomes. To ensure smooth progress, project managers must accurately and efficiently record and verify the on-site quantities, types, specifications, and manufacturers of these materials [3].

However, the widely used material management approaches, including barcodes, radio frequency identification (RFID) tags, and manual counting, frequently face significant challenges in practice. On the one hand, manual verification and data entry are time-consuming and labour-intensive, and they are easily affected by human errors and environmental interferences. In addition, RFID and barcode systems require special hardware and pre-applied labels, conditions that cannot always be satisfiedin complex and rapidly changing construction environments [4]. Real-time tracking and frequent updates of material information are often required. Under these conditions, traditional methods fail to provide the speed and flexibility required for modern detail-oriented project management [3].

In this context, rapid advances in computer vision and image processing technologies have provided new opportunities for digitalization and intelligent management of construction sites. Previous studies have successfully applied deep learning-based visual analysis methods to tasks such as crack detection, structural damage assessment, and construction quality control [5,

6], indicating that using image data for automated construction material counting is both feasible and competitive. Compared with conventional labelling methods, image processing requires no additional hardware markers and can extract information in real time from video streams, thereby significantly improving operational efficiency and data accuracy [5]. Nevertheless, the direct application of image processing techniques to pipe counting in petrochemical plants remains challenging. Piping materials are frequently stacked in high densities, differ in size and shape, and are often partially obscured [3]. Consequently, traditional detection methods that rely solely on bounding boxes struggle to delineate pipe boundaries accurately in dense scenes, leading to counting errors [7]. Moreover, the complexity of the environment and variability in data distributions highlight the urgent need to enhance model robustness and generalization.

To address these challenges, instance segmentation provides a more direct technical pathway for improving counting accuracy and detection reliability. Among these, Mask R-CNN, as a classic and widely used deep-learning method, has been extensively explored and validated in counting tasks for plants, vehicles, and animals. However, it exhibits insufficient accuracy and limited generalization when handling complex scenarios characterized by high target density, significant scale variations, and severe occlusions [8–10]. By contrast, transformers have demonstrated initial success in capturing global context, integrating multi-scale information, and enhancing feature representations in other counting tasks [11, 12]. Incorporating a transformer into the instance segmentation and counting framework may improve the adaptability and generalization of the model in petrochemical plant settings characterized by diverse pipe diameters, high densities, and significant scale variations. This study addresses the current gaps in the literature related to these aspects.

This study extends the classical Mask R-CNN instance segmentation model by integrating a Transformer-based counting head into the existing framework. This integration enables precise multi-object instance segmentation while directly estimating the overall number of targets. Using a multi-task joint training strategy, the model achieves coordinated optimization of detection, segmentation, and counting at the feature level, thereby improving its robustness and generalization in complex construction scenarios. Moreover, the proposed approach adapted for other types of densely distributed construction materials and can be seamlessly integrated into on-site digital information management systems, ultimately providing more efficient, accurate, and intelligent support for project scheduling, resource allocation, and cost optimization.

2 Related Work

Over the past decade, traditional computer vision techniques based on image processing have progressed in counting construction materials. Thammasorn et al. (2013) proposed a template matching method for counting rectangular and circular steel pipes, achieving high accuracy when the camera angle is relatively fixed and the main targets occupy most of the image [13]. Ghazali et al. (2017) combined the Hough transform with post-processing and morphological operations to detect and count circular and rectangular steel materials, thereby demonstrating initial practical outcomes [14]. Liu et al. (2019) employed the Prewitt operator to extract oriented gradient features and used support vector machine (SVM) to locate and count bundled rebars, achieving an average accuracy of approximately91% in their experiments [15].

However, traditional image processing and feature engineering methods are sensitive to environmental conditions. Factors such as the camera angle, illumination changes, steel material size, cross-sectional shape, and background clutter, can cause significant performance fluctuations [3]. In actual construction sites, uneven lighting, weather variations, and increasingly complex background textures further compromise the stability and generalizability of such methods [5]. This highlights the difficulty of designing sufficiently robust features that can handle the diversity and uncertainty of on-site environments using traditional approaches.

In recent years, deep learning methods, including convolutional neural networks (CNNs), have gained wide acceptance and validation in the visual analysis of construction engineering [16]. Compared with traditional image processing techniques, these approaches can handle complex scenes more effectively while improving both accuracy and robustness, thereby offering strong technical support for construction informatization and intelligent decision-making [5, 17]. Motivated by these advances, researchers have started exploring deep learning techniques for automated counting of construction materials. For example, Fan et al. (2019) reframed the task of counting rebars as an image classification problem by classifying local patches within an image [17]. However, this approach requires the examination of each patch individually, which prolongs the inference time. In addition, its reliance on parameters such as target radius restricts its applicability in dynamic and ever-changing construction environments. In efforts to improve practical performance, Wang et al. (2023) integrated UAV imagery with Faster R-CNN and trained 384 model variants on both original and augmented datasets collected under real construction conditions [5]. Their best model achieved an accuracy of 94.16% at AP50. Similarly, Li et al. (2022) developed a precise counting model using YOLOv3 and released a large-

scale steel pipe dataset covering diverse on-site conditions, thereby providing abundant resources for research [3].

To achieve deeper feature representation and stronger global context capture, Bai et al. (2023) introduced the CounTr model, which uses a pure Transformer architecture with multi-head self-attention. By using a hierarchical self-attention decoder to fuse multi-scale and global information, CounTr delivered significantly better performance than traditional CNN-based approaches on both the UCF_CC_50 high-density crowd dataset and the FDST diversified dataset [11]. Feng et al. (2023) presented a pig counting and localization method based on density maps. Their approach employs a lightweight hybrid network that integrates selective convolution and a Vision Transformer to generate density maps and then uses an improved K-means algorithm to locate individual targets on these maps. The experimental results showed a low counting error (MAE=0.726), along with precision and recall rates of 88.22% and 86.02%, respectively, making it suitable for large-scale and crowded scenarios [12]. However, in the context of pipe counting, the current research remains largely confined to object detection and classification, with insufficient in-depth exploration of the integration of instance segmentation and Transformer-based techniques. Instance segmentation provides independent, pixel-level masks and precise boundary information for each pipe, thereby effectively enhancing the counting accuracy and stability in complex backgrounds [7]. It also provides a solid foundation for subsequent pipe layout planning and optimization. Incorporating Transformers into this framework is expected to strengthen the capture of the global context and integration of multi-scale features. These improvements facilitate better adaptation and generalization to the challenging conditions present in petrochemical plants, including a wide range of pipe diameters, high densities, and significant scale variations.

In summary, applying a counting method based on instance segmentation and Transformers for pipe counting in petrochemical plants is both a logical and potentially valuable. This approach not only compensates for the shortcomings of existing research under complex industrial conditions, but can also provide more comprehensive and robust technical support for achieving more accurate counting and spatial layout optimization in future industrial applications.

3 Material and Methods

3.1 Data collection

The effective training of deep learning models often relies on large and diverse image datasets. However, research on counting construction materials, particularly pipes, has been limited by the lack of large-scale data resources.

To address this shortcoming, this study constructed a comprehensive dataset designed for a petrochemical plant environment, referred to as the “PetroPipe” dataset. This dataset is publicly available on Kaggle and comprises 340 images with 14,855 pipe instances [18]. All images were captured with an iPhone 14 Pro under various conditions and from multiple angles, increasing the data diversity and improving the adaptability of the model. As shown in Figure 1, the pipes cover diameters ranging from 0.75 60 inches, ensuring that the trained models will be more robust in real-world scenarios. The dataset includes images of three different resolutions (3061×3024, 3024×4032, and 4032×3024), reflecting the variety of image sizes encountered in industrial environments. The inclusion of multiple resolutions helps the model maintain strong generalization performance under varying imaging conditions.

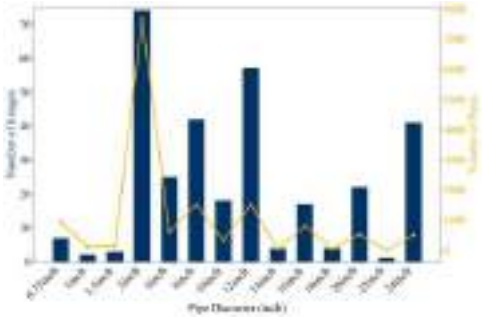

Figure 1. Distribution in the PetroPipe dataset

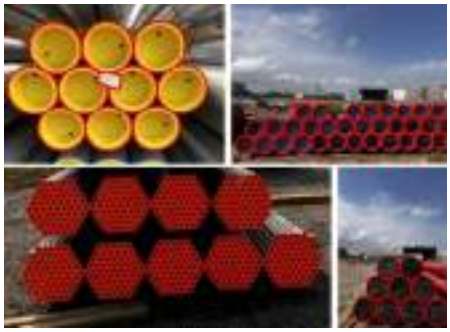

Figure 2. Example of polygon-based annotations

For data annotation, polygon-based annotations were created for each pipe instance using the Labelme tool. These annotations were then converted into the COCO format to ensure direct compatibility with the Mask R-CNN model [19]. Figure 2 shows an example of an annotated image. The performance of the model was evaluated under near-real-time monitoring conditions using an 18-second video containing multiple pipe instances

3.2 Data augmentation

Vrious data augmentation operations were applied to each original image to enhance the robustness of the model in complex real-world scenarios. As shown in Figure 3, these include blur, brightness, color, contrast, horizontal flip, and sharpness adjustments. Such strategies effectively increase the diversity of the dataset, enabling the model to adapt better to different lighting conditions, camera angles, and image quality variations [20]. A total of, 2,040 augmented images were generated, and together with the original 340 images, yielded a dataset of 2,380 images. The dataset was then split into training, validation, and test sets in a ratio of 6:2:2 to ensure reliable training and evaluation.

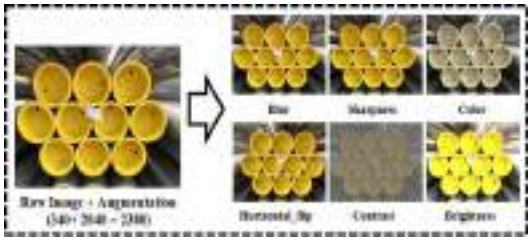

Figure 3. Examples of the data augmentation operations

3.3 Model Architecture and Counting Head Design

The model architecture and experimental workflow are shown in Figure 5. To achieve rapid and accurate global object counting, this study integrates a counting head into the standard Mask R-CNN framework. This integration enables the model to produce high-quality instance-level segmentation while estimating the total number of targets in the entire image from a global perspective. The base structure uses a ResNet-50 architecture combined with a feature pyramid network (FPN) as the backbone. And a region proposal network (RPN) generates initial proposals. Each proposal undergoes region of interest(ROI) align and box head feature extraction, resulting in a 1024dimensional feature representations. By leveraging these representations, the box regression and classification branches provide precise object detection and localization, whereas the mask branch delivers instance-level semantic segmentation [8]. However, the conventional Mask R-CNN architecture does not directly count the total number of objects across an entire image.

As shown in Figures 4 and 5, the proposed counting head is introduced at the output of the box head to address this limitation. Instead of simply averaging the ROI features, a global token is extracted from a lower-level FPN feature map (P2 layer) using global average pooling. The global token is concatenated with all the ROI features (ROI Tokens) to form a sequence comprising one global token and multiple ROI tokens. The sequence is then fed into a Transformer encoder, where multi-head self-attention and feed-forward layers achieve deep fusion of global and instance-level features. In the Transformer output's, the first token corresponds to the global token, and can be regarded as a fused global feature representation.

A linear classifier (count_classifier) subsequently maps the fused global features to scores over a set of predefined discrete intervals representing plausible target counts (e.g. dividing the range of 0–50 into several bins). Instead of predicting a continuous number directly, the model selects the bin with the highest score to infer the total object count. This classification-based strategy stabilizes the training process and enhances interpretability. Moreover, the counting head imposes a minimal additional computational overhead, offering an efficient and innovative solution that integrates both local and global features for object detection and counting tasks.

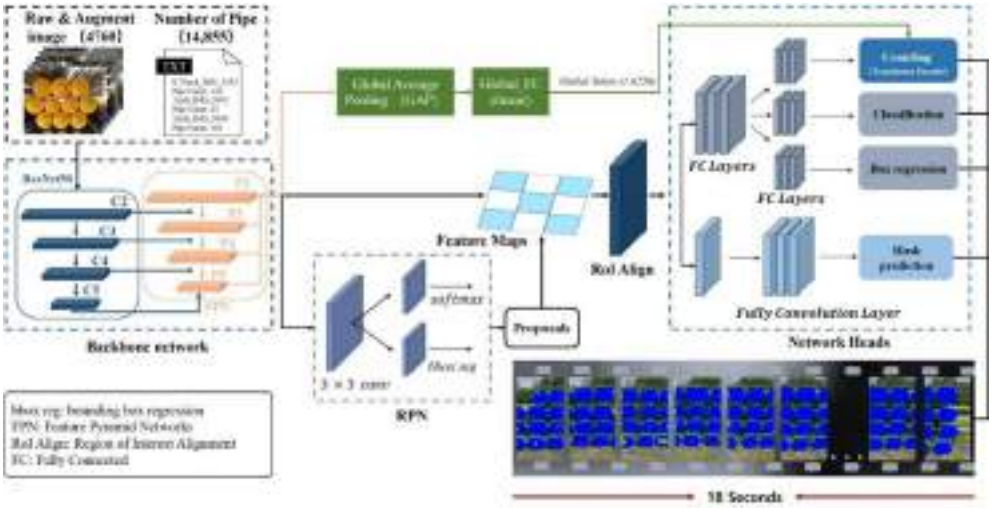

Figure 5. Model architecture and experimental workflow

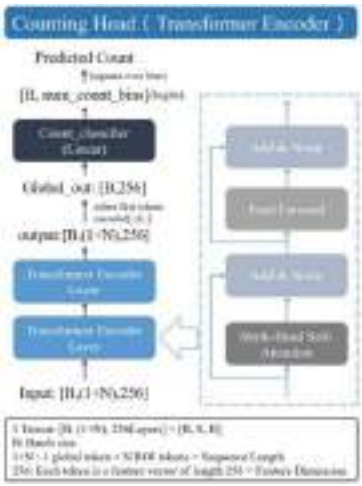

Figure 4. Internal structure of the counting head

3.4 Experimental Settings

This study employed a multi-stage multi-task optimization strategy when integrating the counting head, ensuring steady improvements in the detection and segmentation performance. Initially, the backbone weights were obtained from a ResNet-50+FPN model pre-trained on the COCO dataset. To maintain stable convergence and avoid abrupt parameter shifts, the backbone parameters were frozen during the early training stage (the first two epochs), and only the ROI heads and counting head parameters were updated. At this point, the loss weight for the counting branch was set relatively low (0.1) to prevent the counting task from dominating the training process too soon.

Once the detection, segmentation, and counting tasks achieved a preliminary balance, as indicated by completion of the freezing phase, the backbone parameters were unfrozen, allowing the entire network to be fine-tuned. This step enabled the model to adapt better to the characteristics of the target data and enhance its overall performance. Thus, to overcome the two major challenges in multitask training, namely, the interference of the counting branch with the overall network and the imbalance of loss weights, we ensured in the early stage, through a lower counting loss weight and dynamically adjusted learning rates, that the counting head does not cause excessive gradient impact when jointly training with the detection and segmentation tasks. In the later stage, when the backbone was unfrozen and fine-tuned jointly, the counting loss weight was moderately increased and a staged learning rate schedule was adopted, enabling the counting head to acquire richer semantic information without undermining the previously learned detection and segmentation capabilities. During training, the AdamW optimizer and a StepLR scheduler were employed to gradually reduce the learning rate in phases, ensuring a smooth transition from rapid initial convergence to more refined adjustments. Owing to this multi-stage approach, the model preserved the detection and segmentation improvements after incorporating the counting head. In addition, it achieved a significant increase in the global counting precision, demonstrating effective multi-task optimization. Details of the experimental environment and parameter settings are listed in Table 1.

Table 1. Details of the experimental environment and parameter settings

Parameter	Description
Operating System	Windows 11 Pro
Hardware	GPU: RTX 3060 (12GB), CPU: AMD Ryzen 5 5600 RAM: 32GB
Development Environment	PyTorch 2.5.1, Python 3.9, CUDA 12.4
Optimizer	AdamW (lr=1e-5, weight_decay=1e-4)
LR Scheduler	StepLR: halving lr every 5 epochs; total 100 epochs
Initial Weights	MaskRCNN_ResNet50_FPN_ Weight. COCO_V1
Training Strategy	Batch=2; First 2 epochs: freeze backbone (train ROI & counting head)

3.5 Evaluation Metrics

To objectively evaluate the performance of the instance segmentation model proposed in this paper, we define the evaluation metrics at two scales: bounding box and mask. Specifically, the metrics average precision (AP) and mean intersection over union (mIoU) were used to assess the model's overall detection ability and its fine localization performance. We calculated $\boldsymbol{AP_{50}}$ and $\boldsymbol{AP_{75}}$ at IoU thresholds of 0.5 and 0.75, respectively. The AP metric is defined as

$$\boldsymbol{AP} = \int_{0}^{1} \boldsymbol{p}(\boldsymbol{r})\boldsymbol{dr} \quad (1)$$

where $\boldsymbol{p}(\boldsymbol{r})$ is the interpolated precision value under the precision–recall curve. The AP computed at the bounding box scale is used to measure the overall localization ability of the model, whereas the AP at the mask scale further reflects the fine segmentation performance of the model at pixel level [5,6]. The AP metric has been widely applied in the field of instance segmentation because it effectively evaluates the overall detection and fine localization capabilities of the model, and intuitively and comprehensively reflects the recognition performance of the model under varying

degrees of strictness [6,8]. In addition, we computed mIoU at both the bounding box and mask scales using the general formula defined as follows:

$$\boldsymbol{mIoU} = \frac{1}{N}\sum_{i=1}^{N}\frac{\boldsymbol{R}_{pred}^{i} \cap \boldsymbol{R}_{gt}^{i}}{\boldsymbol{R}_{pred}^{i} \cup \boldsymbol{R}_{gt}^{i}} \quad (2)$$

where $\boldsymbol{R}_{pred}^{i}$ and $\boldsymbol{R}_{gt}^{i}$ are the predicted and ground-truth regions for the ith target, respectively. This formula is applicable to both the bounding box and mask scales. At the bounding box scale, the mIoU emphasizes the overall localization ability of the model, whereas at the mask scale, it more precisely reflects the model's ability to delineate target boundaries at pixel level [5,8]. Therefore, computing the mIoU at both scales can comprehensively demonstrate the performance advantages of the model at different granularity levels. To evaluate the object counting performance, we compared the number of instances predicted by the model with the counting module to those predicted by the native detection output without parameter adjustments to assess the contribution of the counting module to counting accuracy and its impact on overall model performance. We designed a multitask joint loss function that integrates detection (classification and bounding box regression), mask segmentation, and object counting.

$$\boldsymbol{L_{Total}} = \boldsymbol{L_{cls.}} + \boldsymbol{L_{bbox\,reg}} + \boldsymbol{L_{mask}} + \boldsymbol{\lambda L_{count}} \quad (3)$$

where λ is used to control the influence of the counting loss term, thereby achieving collaborative optimization among the different task losses. Compared with other potential metrics, such as the Dice coefficient or pixel accuracy, the AP and mIoU metrics offer more comprehensive, intuitive, and stable advantages, enabling an effective and detailed evaluation of the precision and generalization performance of the instance segmentation model.

4 Results

4.1 Results of Training and Validation

During model training, both the training and validation losses were monitored, as shown in Figure 6. Although the initial plan was to train for 100 epochs, the model adapted quickly. Initially, the training loss was 1.11, and the validation loss was 0.71. By the 5th epoch, the training loss decreased to 0.23, and the validation loss was 0.22, indicating effective feature learning. After the 15th epoch, both training and validation losses stabilized at 0.14. However, given that the transformer model is strongly dependent on global information and positional features, it generally requires a longer training period to fully integrate the features and achieve stable convergence. Therefore, in this experiment, the training process was extended to 100 epochs to ensure that the model achieved stable, low-loss convergence and exhibited strong generalization capabilities under the chosen optimization strategy.

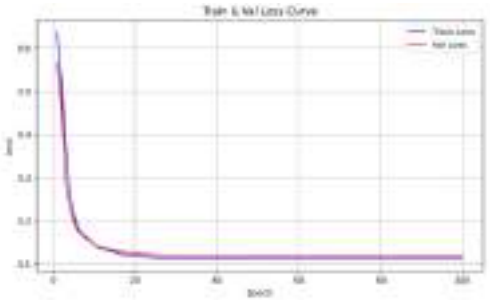

Figure 6. Training and validation losses

4.2 Model Evaluationusing Test Images

Comparative experiments were conducted to evaluate the performance of the standard Mask R-CNN (ResNet-50) and the proposed model under identical datasets and configuration settings. As shown in Table 2, the test results indicate that our model slightly outperformed the standard Mask R-CNN when evaluated at both the bounding box and mask scales. Although the improvements are modest, these results demonstrate that our model exhibits greater stability in terms of capturing object details and segmentation accuracy.

Table 2. Comparison of model performance

Model	Mask R-CNN		Our Model	
Label	BBox	Mask	BBox	Mask
AP 50	97.71%	97.26%	98.07%	97.45%
AP 75	97.50%	96.98%	97.89%	97.20%
mIOU	85.56%	76.47%	87.32%	76.54%
Counting Accuracy	65.55%		85.50%	

For the counting task, Mask R-CNN employs a shared confidence scoring mechanism for detection boxes and segmentation masks; thus, the counting accuracy is computed as a unified metric rather than separately for different scales. Furthermore, no confidence threshold was set in this study to ensure that all predicted instances were counted. The experimental results showed that the counting accuracy of the standard model was 65.55%. By contrast, Our model incorporates an independent counting module, which integrates a transformer encoder to consolidate global information and instance features, and employs a discrete bin classification strategy to directly output the instance count. Owing to this improvement, the counting accuracy of the new model increased to 85.50%, indicating that the introduced counting head provides more stable global statistical information for the model, thereby overcoming the potential instability of relying solely on detection outputs.

However, as shown in Figures 7(c) and 7(d), the segmentation and counting accuracies of our model remained limited in scenarios with extremely dense and small-diameter pipes. Such conditions involve blurred boundaries, severe overlap, and low feature distinctiveness, thereby increasing the difficulty of detection and counting. By contrast, as shown in Figures 7(a) and 7(b), our model achieved nearly 100% counting accuracy in scenarios with fewer pipes. These findings indicate that although the proposed approach is effective in less congested environments, further improvements are required to address highly crowded and complex conditions.

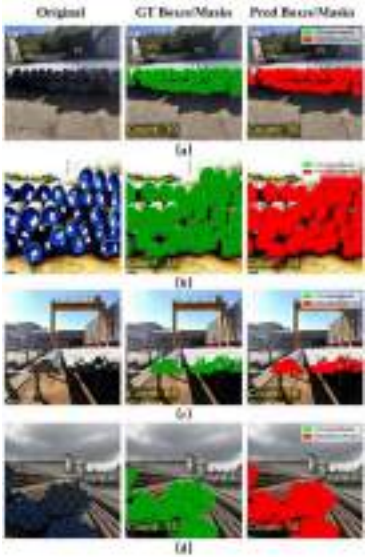

Figure 7. Our model's pipe segmentation and counting examples under different densities

4.3 Video Testing

To further assess the practicality and adaptability of the improved model, inference was conducted on an unlabeled, real-world video (608×1080, 18s, 30 FPS) containing 460 pipes characterized by a high density and small object size. Operating in the evaluation mode with float32 precision, the model processed each frame without additional training. An IoU-based matching strategy was employed to avoid multiple counts of the same pipe, either by updating existing Identifications (IDs) or assigning new IDs as required.

By applying frame-by-frame inference, the model detected 469 pipes, achieving approximately 98.1% counting accuracy compared with the actual total of 460. This result demonstrates that even without annotated training data, the counting head approach can significantly enhance the counting precision in real-world scenarios. Although the average per-frame inference time was about 0.4176 seconds (approximately 2.39 FPS) and thus did not meet strict real-time requirements, the method maintained a relatively high degree of accuracy under dense conditions.

The visualization results (Figure 8(a) show the initial frame and Figure 8(d) shows the final frame) indicate stable detection and counting performance, even in complex, tightly arranged scenes. These findings provide a valuable reference for future research and practical applications of unannotated video monitoring.

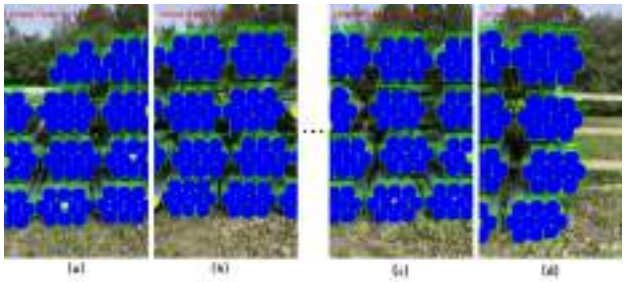

Figure 8. Sample of sequential frames

5 Conclusions

This study focused on pipe counting issues in petrochemical plants. It proposes a counting method that integrates instance segmentation with a Transformer, and through a multi-task joint training strategy, achieves outstanding performance in complex, densely populated, and highly variable construction site environments. The experimental results showed that the model achieving an AP50 of 98.07% (BBox) / 97.45% (mask), an AP75 of 97.89% (BBox) / 97.20% (mask), and an mIoU of 87.32% (BBox) / 76.54% (mask), and inceased the counting accuracy from 65.50% (without the counting head) to 85.50%. When applied to real-world, unlabeled video data, the model demonstrates strong generalization capability and achieves a counting accuracy of about 98.1%, confirming its practical value in real scenarios. Nevertheless, certain limitations remain in practical applications. Although the proposed model demonstrated robust generalization ability and counting accuracy in practical application scenarios, there is still room for improvement in the detection performance of densely packed, small-diameter targets and inference speed. Future research, in addition to further expanding the dataset scale and diversity, should consider optimizing the internal structure of transformers by incorporating multiscale attention mechanisms or local-global feature fusion strategies to enhance the recognition of dense and small-sized targets. The current backbone network can be replaced with a more efficient and lightweight CNN or transformer architectures (e.g., EfficientNet, Swin-Tiny, and MobileViT) and integrated with model compression and pruning techniques to further reduce computational costs and inference time while preserving accuracy, thus better addressing the practical deployment requirements

in industrial settings. This study provides a technological foundation for pipe counting and information management in petrochemical facilities, establishing a solid basis for further improvements in speed, data expansion, and framework optimization, thereby contributing to the intelligent and automated advancement of this field.

Abstract -

Reliable quantification of localized construction and demolition waste (CDW) stockpiles is crucial for promoting sustainable waste management and recycling practices. While prior Structure-from-Motion (SfM) research predominantly focuses on methodological parameters, comparatively limited research has addressed the role of environmental and capturing factors in small-scale reconstructions. This study investigates the accuracy of SfM-based 3D reconstructions for volumetric estimation of localized CDW stockpiles, benchmarking against a consumer-grade handheld LiDAR device. A comprehensive workflow was developed to achieve volume estimation from video sequences, encompassing data acquisition, pre-processing, processing, and post-processing steps. Unlike previous studies that typically prioritize high-resolution images and overlook camera positioning and lighting conditions, this study experimentally assesses these critical parameters. Results indicated minimal influence of lighting conditions, with optimal camera positioning identified as 1.5 times the stockpile height, a frame extraction rate of 1 FPS, and 720p resolution providing the most accurate reconstructions. Analysis of 30 stockpile samples demonstrated a strong correlation (R^2 = 0.929) between SfM and LiDAR volumes, demonstrating that SfM achieves volume accuracy comparable to LiDAR data while offering a faster (3.8 times) and cost-effective solution for the given experimental setup.

Construction and Demolition Waste; Structure from Motion (SfM); Waste Management; Point Cloud; Optimization.

1 Introduction

The global generation of over 10 billion tons of construction and demolition waste (CDW) annually presents a critical environmental and economic challenge, particularly when not effectively managed [1]. Accurate quantification of the localized CDW stockpile, which is often deposited illegally along the street, isolated land areas, and water bodies (an example shown in Figure 1), is essential for enabling efficient and improved waste management and reverse supply chain (RSC) [2]. Inefficiencies in waste collection operations, such as unknown quantity, location, and composition on the upstream side of the RSC, bring logistical complexities and a decline in the quality and quantity of recycled materials [3]. The unknown volumes of localized CDW stockpiles present a critical bottleneck among these challenges. Recent research has increasingly emphasized optimizing the RSC through technological interventions and digitization [4]. However, the existing research has primarily focused on minimizing waste generation, and the literature on technical interventions for other critical processes like waste collection and transportation is relatively scarce.

Figure 1. Examples of localized CDW.
(Source: Authors)

Accurately capturing a three-dimensional (3D) scene is vital to reliably quantifying the volume of a stockpile [5]. Point clouds have emerged as a widely adopted data format for representing 3D environments, providing real-world details, including spatial coordinates and color attributes. Recent advancements have leveraged diverse data acquisition devices, such as Terrestrial Laser Scanners, Unmanned Aerial Vehicles, Simultaneous Localization and Mapping, and RGB-D sensors [6]. However, these acquisition devices are often accompanied by operational challenges, extended processing, and high costs, limiting their applicability for small-scale applications like localized CDW stockpiles

and underscoring the urgent need for portable and scalable solutions.

Recent advancements in consumer-grade handheld LiDAR-equipped devices, such as the iPhone, have established their reliability and versatility as practical solutions for small-scale applications [7]. In addition to handheld LiDAR, Structure from Motion (SfM) is another significant technology that can be employed for small-scale applications [5]. SfM is a pivotal computer vision technique widely employed to reconstruct (3D) structures from two-dimensional (2D) image sequences and is frequently used in scientific research and engineering [8]. A wide range of SfM tools is available. In particular, the interface of Meshroom can be easily customized as it covers very minute details from a research point of view [9]. Generally, SfM is effective for 3D reconstruction. However, it is shaped by various influencing factors, like methodological, environmental, and capture parameters [10]. Among these, methodological parameters include factors related to the process of a tool, which stands out as the most refined, given the extensive research and advancements achieved over recent decades [8].

While significant progress has been made in improving SfM methodology, less attention has been given to two other key aspects: environmental and capture-related parameters. Environmental factors, like lighting and shadows, affect the scene's conditions. In contrast, capture-related factors, including the number of images, their quality, and camera setup, directly impact the accuracy of the SfM-generated point cloud [11]. A notable study focused on point clouds in tunnel environments, specifically examining the influence of lighting conditions and the number of images [10]. While it highlighted essential aspects, the study primarily addressed tunnel-specific scenarios and lacked consideration of broader applications, such as small-scale reconstructions. The existing body of literature recommends including more images and a higher percentage of overlap, which is necessary for effective 3D reconstruction [8]. However, these recommendations often lack specificity and fail to consider critical variables such as scene complexity and camera model used. In addition, image quality and resolution are rarely addressed in detail, particularly for small-scale, such as those involving localized CDW [11]. While high-quality images are generally assumed to be integral to the reconstruction process, the specific influence of these factors remains insufficiently explored. This highlights the pressing need for more precise, context-specific guidelines to inform 3D reconstruction practices across various applications.

To address the research gap, this study aims to address the following research question: *"How do environmental and capture parameters impact the quality and accuracy of SfM-based 3D point clouds for estimating localized CDW stockpile volumes from video sequences?"* By exploring this question, the study aims to extend an understanding of the influence of parameters on 3D reconstruction while offering practical understandings for optimizing volume estimation workflow. Accordingly, the study's primary objective is to investigate environmental and capture parameters affecting SfM-based point cloud accuracy for volume estimation of localized CDW stockpile compared with handheld LiDAR-based point cloud.

The structure of the paper is as follows. Section 2 outlines the proposed methodology. Section 3 presents the experimental design focusing on parameter influences. Section 4 presents the experimental results, discussion, and conclusions in Section 5.

2 Methodology

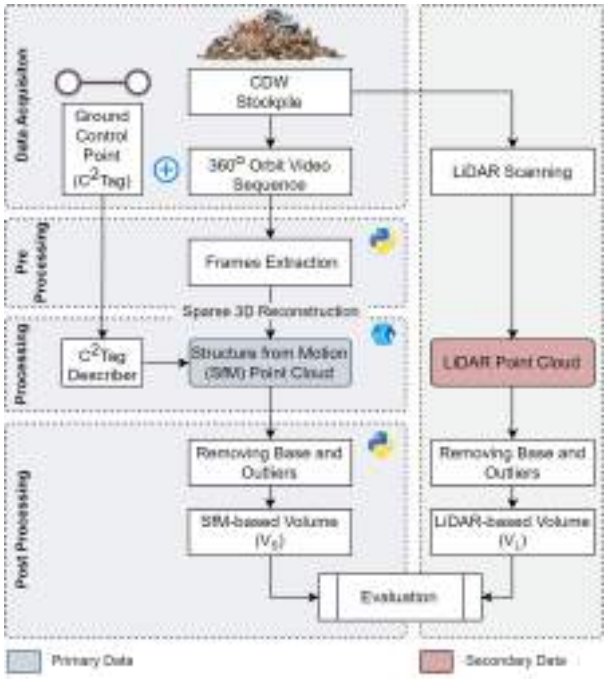

Figure 2. The overall workflow for CDW volume estimation using smartphone video sequence.

Figure 2 illustrates the proposed workflow for comparing the volume of CDW stockpiles from the SfM-based point cloud to the LiDAR-based point cloud. The process begins with a video sequence of the stockpile, captured using a smartphone camera as input. This video is transformed into a precise volume estimate through a systematic step sequence. Initially, individual frames are extracted from the video to facilitate sparse 3D reconstruction. Subsequently, post-processing techniques are employed to eliminate base and outliers, as well as

the final volume estimation of the stockpile. A detailed breakdown of each step is provided in the sections that follow.

2.1 Data Acquisition

Data acquisition in this study involves the formation of CDW stockpiles within a laboratory setup. The laboratory was illuminated using a three-point lighting system, providing sufficient brightness to ensure optimal experimental conditions. The primary smartphone camera for capturing visual data was an iPhone 15 Pro with a 48 MP rear camera. Video sequences were recorded in 4K (2160p) resolution at 60 frames per second. They typically lasted around 30 seconds, covering a complete orbit around the stockpile while maintaining walking speed, as shown in Figure 3a. The stockpile was positioned at the center of the setup, and a 360-degree orbital video sequence was captured to ensure comprehensive coverage, keeping the stockpile consistently framed at the center throughout. To maintain consistency, lighting conditions were standardized at 1000 lux for all experiments except those explicitly testing shadow and lighting parameters.

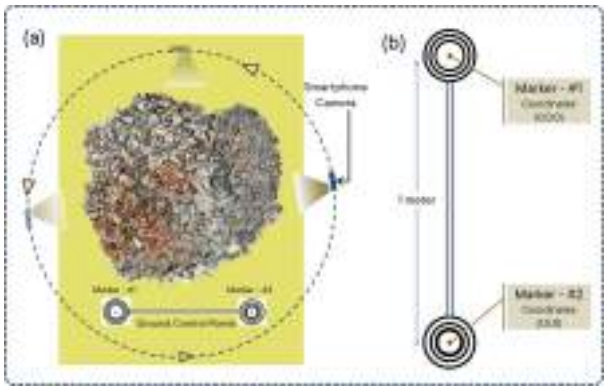

Figure 3. (a) Laboratory setup for data acquisition (b) C^{2}Tag calibration stick developed for this study.

In addition to primary data collection through video sequences captured with the iPhone camera, secondary data were obtained by scanning the stockpiles using the integrated LiDAR sensor of the iPhone 15 Pro. According to the literature, the iPhone's LiDAR sensor has been proven to rapidly produce precise and detailed 3D models, with its applications increasingly documented across various scientific research fields [7]. This secondary dataset was used as a validation reference, ensuring the robustness and accuracy of the primary data derived from video sequences. Monocular SfM fundamentally faces challenges with scale uncertainty, as it reconstructs scenes up to an arbitrary scale factor due to the absence of direct depth information from a single camera view [8]. This limitation necessitates external references, such as Ground Control Points (GCPs), to ensure geometric accuracy and enhance the georeferencing of 3D models. To address the challenge of scale accuracy during 3D reconstruction in this study, C^{2}Tag markers were employed as GCP, facilitating precise calibration and reconstruction [12]. A calibration stick was customized and utilized for accurate scale reference during scanning. The stick, measuring 1 meter in length, featured C^{2}Tag markers affixed to each end, as illustrated in Figure 3b. All the video sequences were obtained by placing the calibration stick.

2.2 Pre-Processing

The pre-processing step employed Python's OpenCV library to extract images from video sequences [13]. A custom Python script was developed using the CaptureVideo function of OpenCV to perform this operation. The script was designed to be alterable, allowing for modifying parameters such as frame extraction rate and resolution to tailor the output based on specific experiment requirements.

2.3 Processing

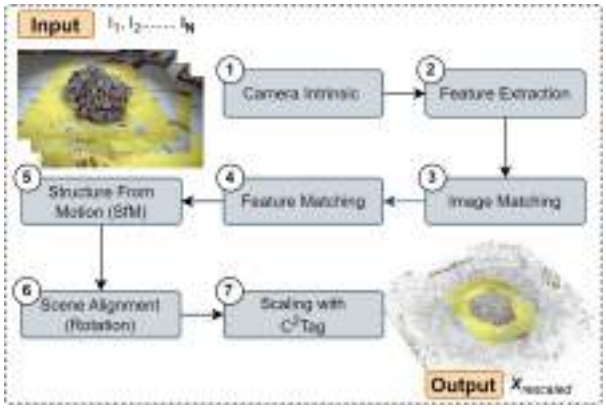

Figure 4. 3D reconstruction pipeline in Meshroom, including scaling with scene alignment and C^{2}Tag Node.

For 3D reconstruction from the extracted images, this study utilized AliceVision Meshroom 2023.3.0, an open-source 3D reconstruction pipeline known for its robust processing [9]. The reconstruction was performed in an HP Workstation Z2, with an Intel i9 processor, 64 GB RAM, and an Nvidia A4000 GPU. The detailed pipeline adopted for transforming images into a point cloud for this study is depicted in Figure 4. Each node in the pipeline is numerically labeled from 1 to 7. The pipeline initiates with N input images. Initially, in Node 1, the camera intrinsic matrix (K) is generated, which

is used to interpret image geometry accurately. In Node 2, features are extracted from each image using multiple feature detection describers like DSP-SIFT, AKAZE, and C^{2}Tag. Node 3 focuses on pairwise image matching to establish relationships between images. Node 4, feature matching uses Euclidean distance to align features across the matched images accurately. A detailed explanation of Node 5-7 is mentioned below.

Node 5, which implements Structure from Motion [9], first estimates the camera's orientation and position (R_t) in 3D space, commonly called the extrinsic matrix, by leveraging epipolar geometry. Matched features from Node 4 are fused into tracks, where each track corresponds to a point in space visible from multiple camera perspectives through triangulation and bundle adjustment. This process allows for the projection and reconstruction of the 3D scene. The relationship between 3D points (X) and their corresponding 2D pixel (x) is mathematically expressed in Equation (1). Z represents the depth of the point in the camera coordinate, which is determined using triangulation.

$$X = Z \cdot (K \cdot R_t)^{-1} \cdot x \tag{1}$$

Upon examining several point clouds generated through the pipeline mentioned above, using images captured by the iPhone 15 Pro camera, it was observed that its orientation was misaligned (see Figure 5a). A manual transformation is applied to resolve the misalignment by introducing Node 6, named Scene Alignment. Specifically, the point cloud is rotated 90 degrees clockwise around the x-axis by multiplying the entire point cloud X with the rotation matrix R_x:

$$R_x = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & -1 & 0 \end{bmatrix}$$

Thus, the aligned point cloud X_{aligned} is (see Equation (2)).

$$X_{\text{aligned}} = R_x \cdot X \tag{2}$$

As discussed earlier, SfM suffers from inherent scale ambiguity. To address this, a C^{2}Tag calibration stick was placed during the data acquisition process, and subsequently, Node 7, named Scaling with C^{2}Tag, was introduced in the pipeline to scale the aligned point cloud (see Figure 5b). To achieve this, a scaling factor S is computed as (Equation 3):

$$S = \frac{d_{\text{real}}}{\left| X_{\text{aligned}(1)} - X_{\text{aligned}(2)} \right|} \tag{3}$$

Where, $X_{\text{aligned}(1)}$ and $X_{\text{aligned}(2)}$ are points in the point cloud corresponding to the same markers 1 and 2 in the real world, respectively. d_{real} is the calibration stick length. The scaling factor S is then applied to the aligned point cloud X_{aligned}, resulting in the rescaled point cloud (see Equation (4)).

$$X_{\text{rescaled}} = S \cdot X_{\text{aligned}} \tag{4}$$

This entire Meshroom pipeline ensures the 3D reconstructed scene is correctly oriented and accurately scaled, facilitating further analysis and visualization.

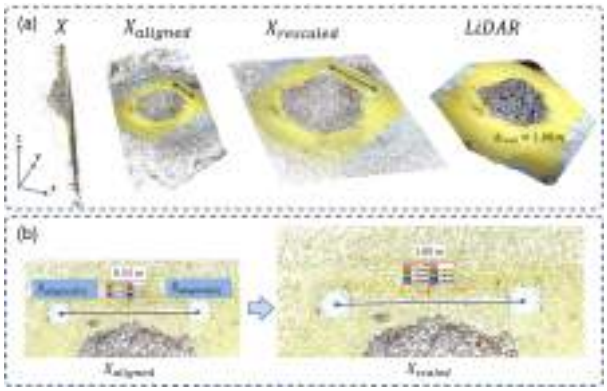

Figure 5. (a) Transformation of the point cloud from Node 5 to Node 7, (b) visual illustration of scaling with C^{2}Tag.

2.4 Post-Processing

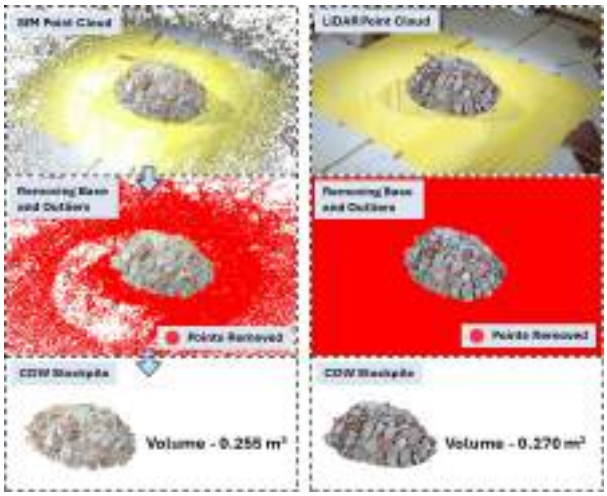

Figure 6. Visual representation of the post-processing step to estimate the SfM and LiDAR point cloud volume.

To ensure precise volume calculation of the CDW stockpile, a yellow sheet was placed beneath to establish a reference base plane (see Figure 3a). Following the

point cloud generation, the subsequent step involved refining the point cloud by eliminating the base plane and extraneous outliers (see Figure 6). Specifically, all points corresponding to the yellow sheet were identified and assigned as the base plane, ensuring that the calculated volume exclusively represents the stockpile material above this plane. The volume estimation was then conducted using the Delaunay Triangulation.

3 Experimental Design

A series of systematic experiments were conducted to evaluate the impact of environmental and capture parameters on 3D reconstruction and volume estimation. These experiments were carefully designed to identify optimal conditions for achieving efficient and reliable outcomes. Among capture parameters, camera height and distance were selected due to their direct impact on the field of view [14]. Shadows and lighting were examined, as they significantly affect feature detection [8]. Frame rate extraction and resolution were also investigated to balance temporal resolution and computational efficiency, ensuring capturing sufficient details without introducing unnecessary computational overhead [10]. The investigations were conducted in the following order: (1) camera height and distance, (2) shadows and lighting, (3) frame rate extraction, and (4) frame resolution. To ensure comprehensive analysis, the experiments were conducted on three separate CDW stockpiles in a controlled environment, with results reported based on the average values across these trials.

3.1 Camera Height and Distance

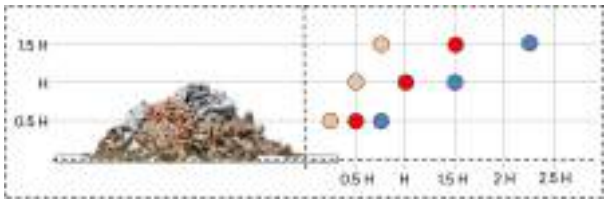

Figure 7. Visual representation of camera height and distance experiment matrix.

To assess the influence of camera height and distance of capture on the 3D reconstruction of a stockpile, an experiment was conducted with the height of the stockpile (H) as a reference parameter. Three camera heights were selected relative to the stockpile: 0.5H, H, and 1.5H to account for varying localized CDW stockpile sizes and ensure diverse camera positions. For instance, 0.5H represents scenarios where the stockpile height is twice the camera height. Similarly, the distance from the stockpile's edge was determined using three distance-to-height (D/H) ratios: 0.5, 1, and 1.5, ensuring that the camera distance scaled proportionally to the stockpile height. This setup resulted in 9 unique camera positions, as shown in Figure 7.

3.2 Shadow and Lighting

This experiment evaluated the effect of shadow and lighting with a design intended to replicate field environmental lighting scenarios where shadows are often unavoidable. This experiment aimed to determine whether variation in lighting conditions during repeated scans of the same stockpile affects reconstruction accuracy and volume accuracy. Figure 8 illustrates the three lighting conditions tested to evaluate their impact on 3D reconstruction:

Case 1: 10 lux lighting (complete darkness).

Case 2: 1000 lux with a single-point light source, which created a shadow on the opposite side of the stockpile.

Case 3: 1000 lux with a three-point light setup, ensuring even illumination and minimizing shadows.

Figure 8. (Case 1) Experimental setup for 0 lux lighting, (Case 2) 1000 lux with a single-point light source, and (Case 3) 1000 lux with a three-point light source.

3.3 Frame Extraction Rate

In this experiment, the number of frames extracted (e.g., FE03 for three frames extracted per second) was varied to identify the optimal requirement for reconstruction and volume estimation, independent of the video length. For this experiment, the custom Python script developed for the pre-processing step was used to perform the frame extraction from video sequences. While increasing the number of extracted frames typically enhances reconstruction precision, it also prolongs the processing time, potentially hindering the requirement to perform quick volume estimation of localized CDW. To balance these factors, nine different frame extraction rates were tested, including FE30, FE10, FE06, FE04, FE03, FE2, FE01, and FE0.5, to determine the optimal frame extraction value.

3.4 Frame Resolution

The literature indicates that frame resolution is typically expected to be used at the raw quality captured. This experiment investigated the effect of reduction in frame resolution on reconstruction to determine the optimal value. The resolution of frames extracted from the video sequence was progressively reduced from the original raw image quality to 2160p, 1080p, 720p, 480p, and 360p using the custom Python script described in the pre-processing step.

3.5 Evaluation Criteria

This study employs two primary evaluation criteria to identify the optimal values. The first criterion focuses on the accuracy of the volume estimation when compared to secondary data, calculated using Equation (5):

$$\text{Volume Accuracy (\%)} = \left(1 - \frac{|V_S - V_L|}{V_L}\right) \times 100 \quad (5)$$

where V_S and V_L are the SfM-based and LiDAR-based volume estimates obtained after the post-processing step. The second criterion assesses the points generated per unit time, representing the total number of points generated during the entire 3D reconstruction process divided by the reconstruction time. A higher value indicates an optimized reconstruction with a shorter processing time, reflecting the optimal value, provided that the volume accuracy remains high for the same condition.

4 Results and Discussion

4.1 Results of Camera Height and Distance

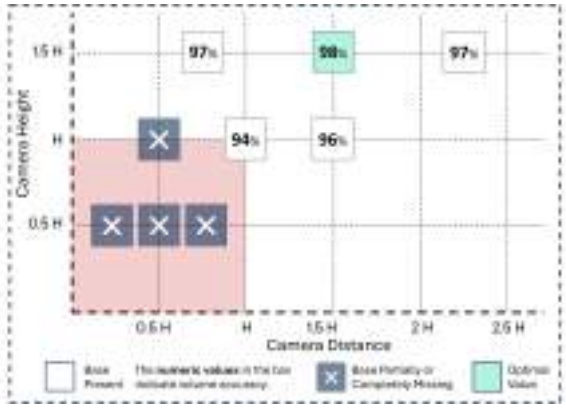

Figure 9. Result matrix of camera height and distance experiment.

The findings from this experiment reveal that the camera positions below the height and distance threshold of H resulted in incomplete reconstruction, with the reference base partially or entirely missing, hampering the post-processing step. (see Figure 9). In contrast, camera positions above the height and distance threshold of H enabled complete reconstruction, allowing for the effective removal of the base and outliers, which ultimately led to successful volume estimation. Among the camera positions, a height and distance of 1.5H proved optimal, achieving the highest volume accuracy of 98%. The points generated per unit of time remained consistent at approximately 330 for camera positions above the H threshold. However, the points generated per unit of time were inconsistent for positions below the threshold, where the reconstruction was incomplete. This suggests that for localized CDW volume estimation, a threshold of camera height and distance above H can be effectively utilized.

4.2 Results of Shadow and Lighting

This experiment was conducted using the optimal camera height and distance, fixed at 1.5H. As shown in Figure 10a, the volume accuracy remained consistently close to 97% across all tested conditions. However, a noteworthy observation is that the point generation rate per unit time in Case 1 was significantly lower than in the other two cases, with the total number of generated points being approximately half that of Case 3. This variation is attributed to reduced feature matching in Case 1, highlighting the key role of lighting in reconstruction. Despite these variations, no significant changes in volume accuracy were observed, indicating that lighting has minimal impact on localized CDW volume estimation.

4.3 Results of Frame Extraction Rate

Figure 10b illustrates that accuracy remained consistent despite a decreased frame extraction rate from FE30 to FE01. However, a marked drop in volume accuracy was observed for FE0.5. Simultaneously, the number of points generated per unit of time steadily increased until reaching FE01, beyond which it sharply decreased. These results suggest that FE01 represents the optimal parameter for maximizing both reconstruction efficiency and volume accuracy, as it is associated with the lowest reconstruction time of 93 seconds and a 98% volume accuracy.

4.4 Results of Frame Resolution

This experiment was carried out using the optimal frame extraction rate of FE01 while varying the frame resolution. The results shown in Figure 10c indicate that reducing the frame resolution below 720p caused a significant decline in volume accuracy. However, this reduction in resolution also decreased reconstruction time from 93 seconds to 56 seconds. Therefore, 720p was identified as the optimal

resolution, balancing volume accuracy and reconstruction efficiency. In contrast, the iPhone LiDAR exhibited much slower performance, requiring an average of 350 seconds per scan.

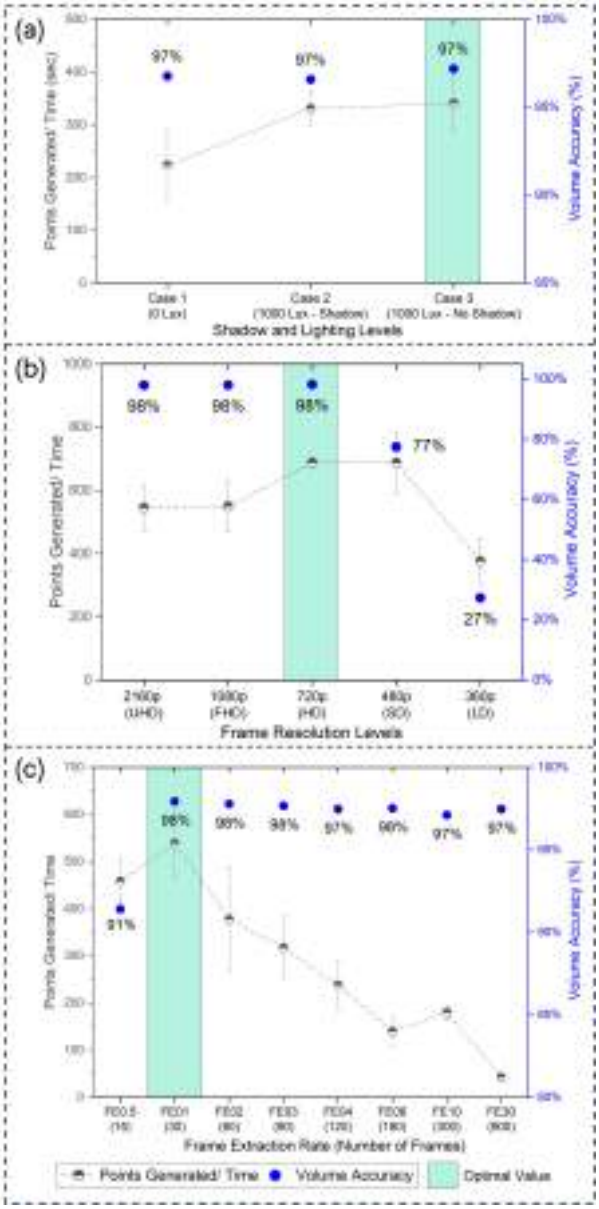

Figure 10. (a) Plot of shadow and lighting experiment, (b) frame extraction rate experiment, and (c) frame resolution experiment.

4.5 Accuracy Assessment

The optimal results derived from the experiments were subsequently employed to evaluate the SfM-based CDW volume estimation workflow. Using the optimized conditions, video sequences of 30 distinct CDW stockpiles were captured to evaluate the performance of the workflow. Figure 11 illustrates a scatter plot comparing volume estimates derived from the SfM-based method (V_S) to those obtained using LiDAR (V_L), yielding a high correlation with an R^2 value of 0.929. This high degree of correlation highlights the proposed SfM-based workflow's suitability for localized CDW volume estimation. Furthermore, the SfM-based workflow shows exceptional efficiency, achieving an average end-to-end time of approximately 97 seconds from data acquisition to post-processing. This time represents a performance that is 3.8 times faster than the 373 seconds required by the LiDAR-based volume estimation workflow, highlighting its operational efficiency. However, the SfM-based end-to-end time includes the processing time, which depends on the system specification used for reconstruction and is subject to change. It also highlights the practicality of the SfM-based workflow for on-site applications.

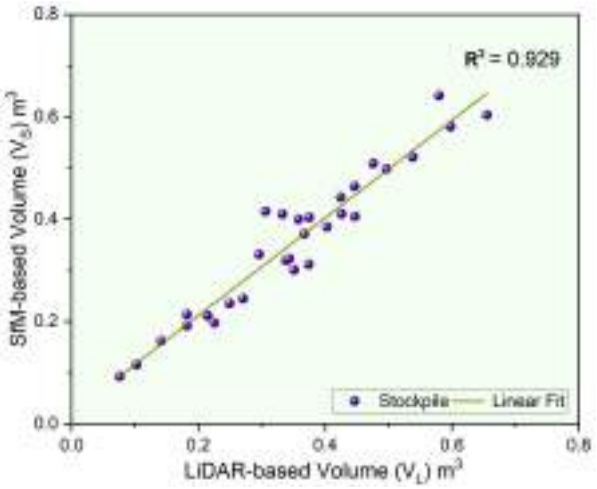

Figure 11. Scatter plot of SfM-based CDW stockpile volume comparison with the LiDAR volume.

4.6 Limitations and future research directions

The present study highlights the potential of SfM for quantifying localized CDW under controlled environments, specifically evaluating the influence of environmental and capture parameters. However, practical application in real-world field environments is limited by several factors, such as site layout, terrain complexity, material composition, spatial variability, and climate conditions. Future research should systematically address these factors to enhance the proposed workflow effectiveness and applicability in the real world. Another limitation of this study is its reliance on the iPhone as the representative smartphone camera, excluding alternative smartphone models. Preliminary investigation indicated that the SfM point clouds remains largely consistent across

different devices under identical capturing conditions, with the only significant change observed in terms of scene alignment. Consequently, Node 6 of reconstruction pipeline require adjustment when using another smartphone camera.

5 Conclusion

Quantifying localized CDW stockpiles is critical in enhancing waste collection and recycling practices. With the rapid advancements in SfM-based 3D reconstruction technologies, it is essential to understand how environmental and capture parameters influence small-scale reconstructions, particularly in the context of localized CDW quantification. This study systematically investigates and identifies, through rigorous experimentation, the optimal environmental and capture conditions required for efficient reconstruction and accurate quantification of CDW stockpiles. Key experimental findings suggest that environmental parameters, such as shadows and lighting, have an insignificant impact on accuracy but moderately affect feature detection during reconstruction, which aligns with the previous studies. However, no significant changes in volume accuracy were observed. In contrast, capture-related parameters, including camera position, frame extraction rate, and frame resolution, emerge as primary determinants of SfM-based 3D reconstruction performance. Notably, optimal point cloud generation and volume accuracy were achieved when the camera height and distance were 1.5 times the stockpile height. A frame extraction rate of FE01 and a resolution of 720p were identified as optimal settings for efficient reconstruction and accurate volume estimation, suggesting that high-fidelity images can be avoided to reduce reconstruction time. Using the optimal values derived from experiments, this study analyzed 30 CDW stockpile samples, demonstrating a high correlation (R^2 = 0.929) between the volume estimates derived from SfM and those obtained from LiDAR. These results showcase the optimization of key parameters, enabling efficient 3D reconstruction and accurate volume estimation of localized CDW stockpiles, making it particularly suitable for small-scale applications.

Abstract –

This study proposes a multi-resolution fast 3D reconstruction framework that integrates transformer-based damage detection with rapid 3D modeling to enhance bridge surface defect identification and spatial localization. The framework consists of three phases: (I) 3D reconstruction using Structure from Motion (SfM) to generate a structural model with sparse point cloud, (II) damage segmentation via a customized Swin UNETR model for precise defect detection, and (III) multi-resolution dense reconstruction that prioritizes high-resolution modeling of detected defects while reducing the resolution of non-critical areas to improve efficiency. Experimental validation on the High Level Bridge in Edmonton, Canada, demonstrated the framework's capability to accurately map surface defects onto a 3D model, providing an intuitive and detailed localization for structural assessment. This approach offers significant potential for efficient and accurate bridge inspection, supporting data-driven maintenance strategies.

Keywords –

Transformer; Point Cloud; 3D Reconstruction; Structure from Motion; Structural Damage Detection

1 Introduction

Bridges are critical components of civil infrastructure but are subjected to various adverse loads throughout their service life, accelerating structural deterioration [1]. The accumulation of these loads induces repeated stress and strain, leading to the formation of surface cracks that gradually compromise structural integrity over time [2]. Thus, regular inspections and timely repair based on damage assessment are essential to ensure bridge safety [3]. Recent advances in computer vision have greatly improved defect detection methods, enabling efficient analysis of large-scale image datasets for rapid damage assessment [4-5]. However, the widespread and varied nature of bridge damage presents challenges for existing techniques in simultaneously detecting and localizing surface defects [6]. Moreover, mapping surface damage onto a 3D model has proven beneficial for effective bridge maintenance, offering critical insights that support accurate decision-making by bridge owners [7]. Therefore, achieving precise detection and localization of bridge surface damage within a 3D model is of significant importance [8].

Currently, vision-based damage detection methods can be mainly divided into image classification, object detection, and semantic segmentation [9]. With advancements in deep learning, semantic segmentation has become a leading approach [10]. Various convolutional neural networks (CNNs) have been applied to damage segmentation, including U-Net [11], ResNet [12], DenseNet [13], Mask R-CNN [14], DeepLabV3+ [15], and hybrid models [16]. However, due to the limited receptive fields of CNN-based models, capturing global features in complex real-world scenarios remains challenging [17]. One promising solution is the use of transformer. Since Dosovitskiy et al. [18] introduced the encoder-based Vision Transformer (ViT), transformer has gained attraction in computer vision. Its embedding and self-attention mechanisms have shown superior accuracy compared to complex CNN models for image segmentation tasks [19]. Swin UNETR [20], which integrates the Swin Transformer [21] with an enhanced ViT, has demonstrated outstanding accuracy and efficiency across benchmark datasets [22]. Moreover, combining Unmanned Aerial Vehicle (UAV) with advanced algorithms offers significant potential for rapid inspection of high-risk areas, such as bridge piers and abutments [23].

To obtain the 3D spatial information of bridge damage, point cloud data is commonly used to generate a 3D bridge model. With the development in localization technology, stereo vision-based local positioning methods have been applied, addressing the reliance of

UAVs on the Global Positioning System (GPS) [24]. And Structure from Motion (SfM) is widely regarded as one of the common techniques for 3D reconstruction from a series of sparse images. This method enables the creation of a complete 3D model, integrating local detection results and reflecting the spatial position of objects [25]. Although semantic segmentation can classify damage at the pixel level, it faces challenges in consistently identifying and matching the same damage across sequential image frames, thus hindering the integration of damage segmentation with spatial localization [6]. Additionally, generating 3D bridge models with SfM presents several challenges. First, precise image capture and detailed trajectory planning are often required to avoid motion blur during data collection to ensure successful reconstruction. This time-consuming process significantly reduces efficiency [26]. Second, processing large volumes of images with SfM greatly extends computation time, further limiting reconstruction efficiency [27].

In response, this study integrates the high accuracy of image-based damage detection with the spatial localization capabilities of 3D reconstruction. A new method is proposed that combines transformer-based damage detection with rapid 3D reconstruction, enabling seamless and efficient mapping of surface damage on bridges onto the 3D model. This approach offers decision-makers an intuitive and comprehensive localization of structural assessment.

2 Methodology

The proposed multi-resolution 3D reconstruction framework comprises three phases: (I) 3D reconstruction, (II) transformer-based damage segmentation, and (III) multi-resolution dense reconstruction. Phase I generates a 3D structural model with data captured by UAV using SfM. Phase II employs a transformer model to detect and segment surface defects from feature images. Phase III performs multi-resolution dense reconstruction, producing a dense point cloud where defects are rendered in high resolution while the overall structural resolution is reduced, enabling fast and precise damage localization. The overall scheme is shown in Figure 1.

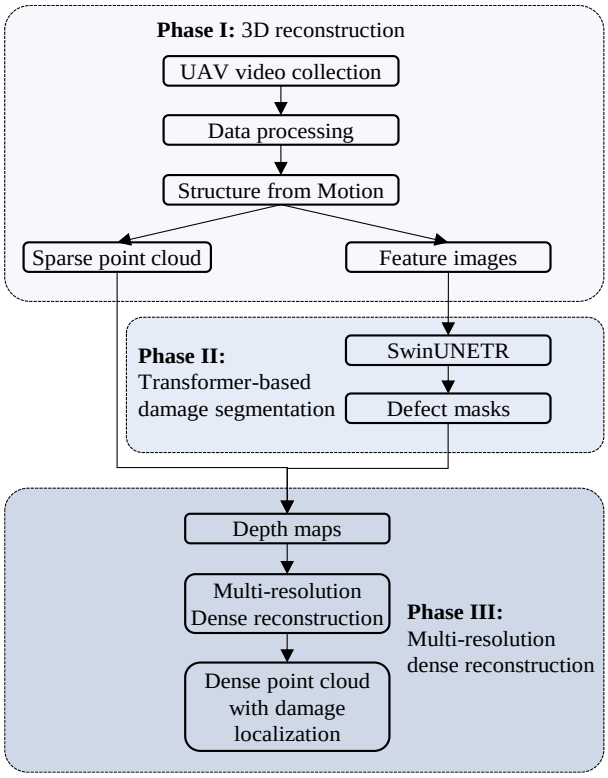

Figure 1. Proposed Framework

2.1 3D reconstruction

In this phase, the incremental SfM [28] is used to process RGB images collected from UAV inspections, with each image associated with a local coordinate system (LCS) defined by the camera's field of view and orientation. The goal is to convert these LCS-based observations into a global coordinate system (GCS) to enable accurate 3D reconstruction. This process requires the extraction of intrinsic and extrinsic camera parameters and involves feature matching and incremental reconstruction.

To accurately represent the reconstructed model in a global coordinate system, it is essential to convert the image data from the LCS to the GCS [29]. The intrinsic camera matrix $\mathbf{K}$ (see Equation (1)) and the extrinsic rotation and translation matrix $\mathbf{R}|\mathbf{t}$ (see Equation (2)) are necessary for transforming coordinates from the LCS to the GCS. The intrinsic matrix $\mathbf{K}$ captures the camera's internal parameters, including the focal length (f_x, f_y), camera lens distortion s and the principal point coordinates (c_x, c_y).

$$\mathbf{K} = \begin{bmatrix} f_x & s & c_x \\ 0 & f_y & c_y \\ 0 & 0 & 1 \end{bmatrix} \quad (1)$$

While the extrinsic matrix $\mathbf{R}\,|\,\mathbf{t}$ defines the camera's rotation and translation in the global frame, including the camera position transformation matrix $r_{i,j}$, and the translation vector $\mathbf{t} = \left[t_x, t_y, t_z\right]^T$.

$$\mathbf{R}\,|\,\mathbf{t} = \begin{bmatrix} r_{11} & r_{12} & r_{13} & t_x \\ r_{21} & r_{22} & r_{23} & t_y \\ r_{31} & r_{32} & r_{33} & t_z \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{2}$$

Finally, the relationship in Equation (3) can be used to transform a 3D point in the LCS (x_L, y_L, z_L) into the GCS (X_G, Y_G, Z_G) through the extrinsic parameters:

$$\begin{bmatrix} x_L \\ y_L \\ z_L \\ 1 \end{bmatrix} = \left[\mathbf{R}\,|\,\mathbf{t}\right] \begin{bmatrix} X_G \\ Y_G \\ Z_G \\ 1 \end{bmatrix} \tag{3}$$

where the rotation matrix **R** is further decomposed into rotations around the X, Y, and Z axes as shown below.

$$\mathbf{R} = \begin{bmatrix} \cos\theta_z & -\sin\theta_z & 0 \\ \sin\theta_z & \cos\theta_z & 0 \\ 0 & 0 & 1 \end{bmatrix} \times \begin{bmatrix} \cos\theta_y & 0 & \sin\theta_y \\ 0 & 1 & 0 \\ -\sin\theta_y & 0 & \cos\theta_y \end{bmatrix} \times \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\theta_x & -\sin\theta_x \\ 0 & -\sin\theta_x & \cos\theta_x \end{bmatrix} \tag{4}$$

2.2 Transformer-based damage segmentation

In this phase, the Swin UNETR, designed for 3D tumor segmentation, is customized for 2D structural damage segmentation. The model processes 2D structural images with two channels by dividing them into non-overlapping patches using a patch partition layer. These patches are transformed into windows suitable for self-attention operations. The encoded features from the Swin transformer are passed through skip connections at various resolutions to a CNN-based decoder. The final output is a segmentation map with two channels, identifying damaged areas in the structure. The architecture of the customized Swin UNETR is shown in Figure 2.

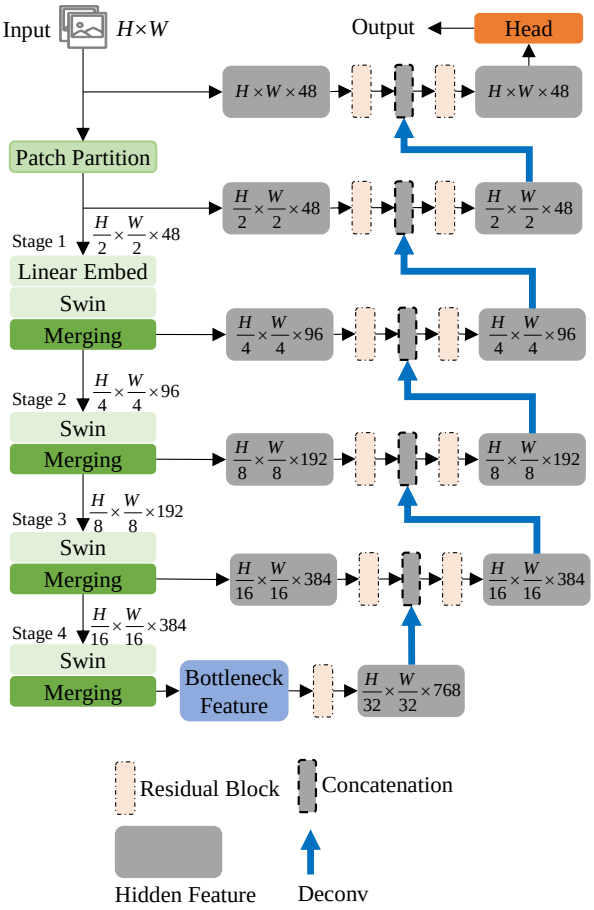

Figure 2. Architecture of the customized Swin UNETR

For the encoding part, the model input $\chi \in \mathbb{R}^{H\times W\times S}$ represents a token with a patch resolution of (H', W') and a dimension of $H'\times W'\times S$. Initially, the model uses a patch partitioning layer to segment the input image into fixed-size, non-overlapping patches with dimensions $\frac{H}{H'}\times\frac{W}{W'}$. These patches are then embedded into a feature space of dimension *C*. Self-attention is applied to these patches within non-overlapping windows to efficiently model relationships between tokens. Specifically, windows of size $M\times M$ partition the token into $\frac{H'}{M}\times\frac{W'}{M}$ regions at a given layer l in the transformer encoder. In the following layer, window positions are shifted by $\left(\frac{M}{2},\frac{M}{2}\right)$ pixels to capture cross-region interactions. The encoder computes layer outputs using the following equations:

$$\begin{aligned} \tilde{z}^{l} &= W\text{-}MSA\left(LN\left(z^{l-1}\right)\right) + z^{l-1} \\ z^{l} &= MLP\left(LN\left(\tilde{z}^{l}\right)\right) + \tilde{z}^{l} \\ \tilde{z}^{l+1} &= SW\text{-}MSA\left(LN\left(z^{l}\right)\right) + z^{l} \\ z^{l+1} &= MLP\left(LN\left(\tilde{z}^{l+1}\right)\right) + \tilde{z}^{l+1} \end{aligned} \tag{5}$$

where W-MSA and SW-MSA represent standard and shifted window-based multi-head self-attention modules. LN and MLP denote layer normalization and multi-layer perceptrons. $\tilde{z}^{l}$ and $\tilde{z}^{l+1}$ indicate the output of W-MSA and SW-MSA, respectively.

For the 2D task, the encoder begins with a patch size of 2×2 and a feature dimension of 2×2×4=16. The embedding dimension C is set to 48. The encoder consists of four stages, each with two transformer blocks, totalling eight layers. A linear embedding layer reduces the spatial resolution by half at each stage, resulting in feature maps of size $\frac{H}{2}\times\frac{W}{2}$, $\frac{H}{4}\times\frac{W}{4}$, $\frac{H}{8}\times\frac{W}{8}$, $\frac{H}{16}\times\frac{W}{16}$.

The decoder adopts a U-shaped architecture where feature representations from the encoder are integrated through skip connections at corresponding resolutions. In each stage i, $i \in \{0,1,2,3,4\}$, the feature maps are reshaped to $\frac{H}{2^i}\times\frac{W}{2^i}$ and processed through residual blocks composed of two 3×3 convolutional layers, followed by instance normalization. To progressively restore spatial resolution, deconvolutional layers double the size of feature maps, and these upsampled features are concatenated with the outputs from the encoder. This process continues until the original resolution is recovered. Finally, a 1×1 convolutional layer and a sigmoid activation function are used to generate the segmentation mask, highlighting regions of structural damage.

The Focal Loss [30] was employed as the loss function, which can effectively address the class imbalance commonly present in damage detection tasks, where damaged regions occupy a much smaller area compared to the background. As displayed in Equation (6), it modifies the standard cross-entropy loss by adding a modulating factor that down-weights easy examples.

$$FL\left(p_t\right) = -\alpha_t\left(1-p_t\right)^{\gamma}\log\left(p_t\right) \tag{6}$$

where p_t is the predicted probability for the true class, and

$$p_t = \begin{cases} p, if\ \ y=1 \\ 1-p, if\ \ y=0 \end{cases} \tag{7}$$

where p is the predicted probability and y is the ground truth label. α_t is a balancing factor for class imbalance, γ is the focusing parameter that adjusts the rate at which easy examples are down-weighted.

For performance evaluation, several metrics are used to assess the segmentation quality, including Intersection over Union (IoU), Dice Coefficient, and Pixel-wise Accuracy:

$$IoU = \frac{TP}{TP+FP+FN} \tag{8}$$

$$Dice = \frac{2TP}{2TP+FP+FN} \tag{9}$$

$$Accuracy = \frac{TP}{TP+FN} \tag{10}$$

where *TP*, *FP* and *FN* stand for True Positive, False Positive, False Negative, respectively.

By leveraging the Swin transformer's ability to model multi-scale contextual information and long-range dependencies, the network can effectively capture complex patterns of structural defects.

2.3 Multi-resolution Dense Reconstruction

SfM provides essential camera parameters (intrinsic and extrinsic), sparse 3D points, and their 2D image correspondences. However, this sparse representation lacks the detail needed for comprehensive modeling. To overcome this, Multi-View Stereo (MVS) leverages the camera's internal and external parameters to perform stereo-matching and identify points in space that have photometric consistency [31], thus transforming sparse point clouds into dense models. In this phase, Open Multi-View Stereo (OpenMVS) [32], an open-source library, is adapted for dense 3D reconstruction.

OpenMVS primarily employs a depth map fusion-based MVS approach, which consists of several stages. Initially, for each input image, the most relevant neighboring images are selected to form stereo pairs. Depth maps are then estimated for each image by identifying photometrically consistent points across these pairs. Once individual depth maps are computed, they are fused into a unified and dense point cloud that captures fine surface details.

To optimize the dense 3D reconstruction process and prioritize defect areas over the whole structure, a significant modification is to ignore specified regions in the input corresponding images during the dense reconstruction stage. In this workflow, the structural components of the object are reconstructed at a reduced resolution, significantly accelerating the dense point cloud generation for the overall structure. Meanwhile, defect regions identified by Swin UNETR are preserved and processed at full resolution. By this way, the fine details of critical defect areas are captured with high fidelity, while the less critical structural areas are downsampled to minimize computational load. As a result, the overall dense reconstruction process becomes

faster and more efficient compared to standard methods that process the entire structure uniformly.

3 Experiments and Results

Figure 3. Data Collection

To evaluate the proposed multi-resolution 3D reconstruction framework, experiments were conducted on the High Level Bridge in Edmonton, Canada (see Figure 3). Opened in 1913, the bridge accommodates both Light Rail Transit (LRT) and vehicle traffic with concrete piers, making it a suitable structure for testing defect detection and 3D reconstruction methods.

A DJI Mini 3 Pro drone was employed to collect visual data of the first concrete pier following the approach bridge. The UAV was operated to fly around the pier, capturing continuous 4K video footage to ensure comprehensive coverage of the structure's surface. After the data collection, frames were extracted from the recorded video at a rate of one image per second.

The extracted images were processed using SfM to obtain a sparse 3D point cloud and corresponding camera poses. The SfM pipeline effectively reconstructed the pier's general geometry by identifying and matching feature points across images, followed by incremental camera pose estimation and 3D point triangulation. The resulting sparse point cloud and the associated camera positions are visualized in Figure 4.

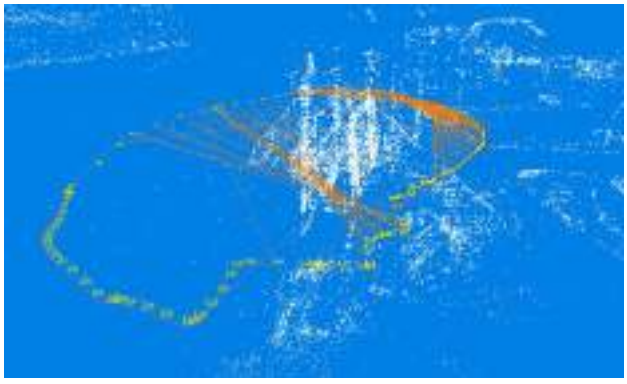

Figure 4. Sparse point cloud with camera pose

To achieve optimal performance in segmenting surface defects on the concrete pier, the Swin UNETR model was trained using domain-specific data. The public dataset Crack5769 [33] was selected for training. This dataset consists of 5,769 pixel-wise labeled concrete crack images, each with a resolution of 256×256 pixels, making it well-suited for the concrete pier context. The dataset was divided into training, validation, and testing sets in a ratio of 8:1:1 to ensure balanced evaluation and prevent overfitting. The model was trained on an Ubuntu 22.04 system equipped with an NVIDIA RTX A6000 GPU. The training was configured with batch size of 16, feature size of 48, learning rate of 0.0001, Adam optimizer and a total of 300 epochs.

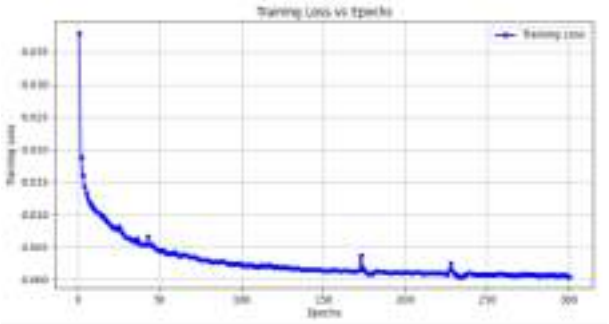

Figure 5. Training loss

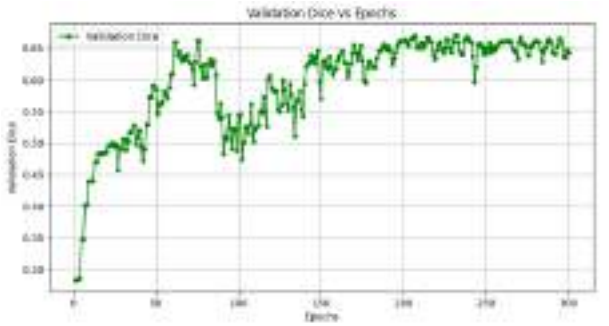

Figure 6. Validation Dice Coefficient

Throughout the training process, the model's performance was monitored by tracking both the training loss and validation Dice coefficient across epochs. Figure 5 illustrates the training loss over 300 epochs, showing a gradual and consistent decrease, which indicates effective model convergence and learning stability. Figure 6 presents the validation Dice coefficient across epochs, demonstrating steady improvement and stabilization in segmentation performance as the training progressed. These plots confirm that the model was learning meaningful features for crack detection without overfitting. Finally, the trained model achieved an average IoU of 0.54, an average Dice coefficient of 0.67, and an average pixel-wise accuracy of 0.69 on the testing set. These results suggest that the Swin UNETR model

effectively learned to detect and segment cracks on concrete surfaces.

After achieving the optimal transformer model, the undistorted images from SfM were then passed through the customized Swin UNETR for damage segmentation. The segmentation results were subsequently integrated into the multi-resolution dense reconstruction process.

Using sparse point cloud generated by SfM and the segmentation masks from Swin UNETR, the OpenMVS pipeline was employed to perform multi-resolution dense reconstruction. The process began with depth map estimation, where depth information was calculated for each image to guide point cloud densification, as illustrated in Figure 7.

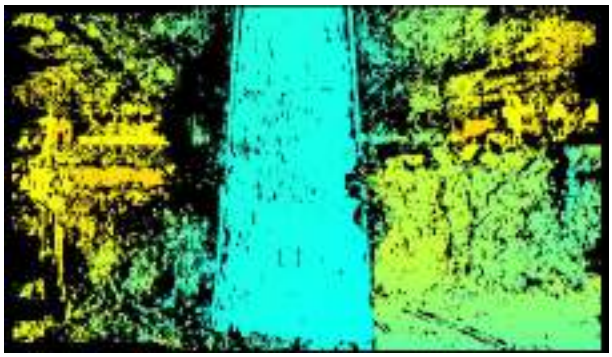

Figure 7. Depth map

The final output consisted of a dense 3D point cloud with varying levels of detail. Structural areas such as flat pier surfaces were reconstructed with 2 times reduced point density, whereas cracks maintained high-density point clouds, as shown in Figure 8.

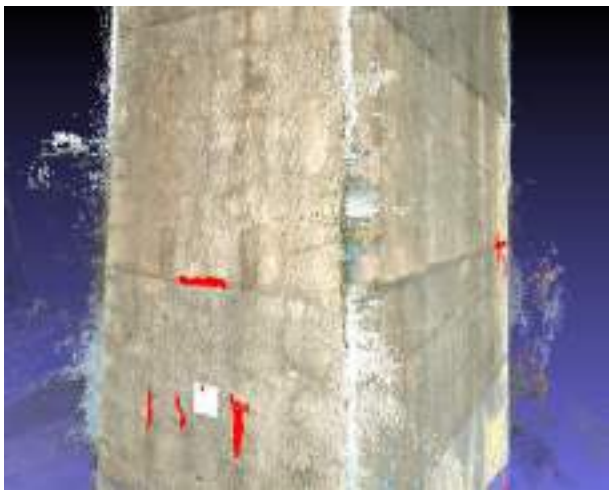

Figure 8. Dense point cloud

To evaluate the efficiency of the proposed method, a runtime comparison was conducted between the uniform-resolution reconstruction and the proposed multi-resolution approach. The results, summarized in Table 1, demonstrate a significant reduction in processing time while maintaining high detail in defect areas. Specifically, the multi-resolution approach achieved substantial reductions in processing time across all reconstruction stages, particularly in depth-maps estimation and point cloud densification. The multi-resolution approach reduced the total reconstruction time by around 64% and decreased memory consumption, while maintaining defect quality. This balance between efficiency and accuracy makes the proposed framework well-suited for large-scale structural health monitoring applications where both accuracy and speed are critical.

Table 1. Runtime Comparison

Action	Normal	Multi-Resolution	Improvement
Estimate Depth-maps	25 m 10 s 221 ms	8 m 3 s 478 ms	↓ 17.1 m
Geometric Consistency	6 m 22 s 885 ms	2 m 28s 319 ms	↓ 3.9 m
Dense fused Depth-maps	1 m 11 s 192 ms	51 s 758 ms	↓ 0.3 m
Densify Point Cloud	39 m 23 s 54 ms	14 m 19 s 721 ms	↓ 25.1 m

Overall, the experimental results validate the effectiveness of the proposed framework in achieving efficient and precise structural damage reconstruction.

4 Conclusion

This study introduces a multi-resolution fast 3D reconstruction framework that integrates UAV-based data collection, transformer-based damage segmentation, and multi-resolution dense reconstruction for efficient and precise structural damage detection. The use of SfM effectively captures the global geometry of the structure, while the customized Swin UNETR model accurately segments surface defects. By prioritizing high-resolution reconstruction in damaged areas and reducing detail in non-critical regions, the proposed framework significantly improves computational efficiency without compromising defect detection quality. Experimental results on the High Level Bridge demonstrated a 64% reduction in processing time and effective defect localization, validating the framework's applicability for structural health monitoring.

However, the current approach has limitations. The model's performance is constrained by the quality and diversity of the training dataset, potentially impacting defect detection under varying lighting and environmental conditions. Additionally, the focus on crack detection limits its generalizability to other defect types, such as spalling, mold or corrosion, etc.

Real-world implementation also presents challenges such as environmental factors affecting UAV inspections, the trade-off between computational efficiency and accuracy, and the need for robust generalization across different defect types and structural conditions. Addressing these limitations, future developments will explore adaptive flight planning, cloud-based computing for real-time processing, and multi-task learning strategies to extend defect detection capabilities. Expanding the framework to identify various defect types, integrating real-time processing and optimizing the system for large-scale infrastructure inspections will further enhance the framework's scalability and practical deployment for long-term structural health monitoring.

Abstract

Concrete bridges are critical infrastructure assets that require regular inspection to ensure public safety and efficient functionality. Traditional methods for crack detection are often manual, time-consuming, and prone to subjectivity, which can compromise inspection accuracy and efficiency. Deep learning techniques have been increasingly utilized in bridge crack detection. However, very few efforts have developed instance segmentation models that can be used to detect and quantify cracks in bridges. Different than other computer vision methods, instance segmentation provides pixel-level classification while also differentiating between individual cracks, facilitating crack measurement and proper maintenance decision-making. This study presents a framework for real-time crack detection and segmentation in bridges. The study assesses the performance of advanced deep learning segmentation models including both single-stage detector (YOLOv9 and YOLOv11) and two-stage architectures (Mask-RCNN) coupled with backbone feature extractors (ResNet). A comprehensive dataset of annotated bridge crack images was utilized to train and test the developed models. YOLOv11 emerged as the most efficient model, achieving the highest precision for bounding box detection (96.0%) and segmentation (91.2%) while maintaining the fastest inference time (19 ms per image) and the shortest training duration (127.49 minutes). Mask R-CNN, while excelling in bounding box accuracy (95.59%), demonstrated slower training and inference times, highlighting its limitations in real-time applications. The performance was further evaluated through precision-recall curves, showing strong precision across a wide range of recall values. This research emphasizes the potential of deep learning to transform bridge condition assessment by offering scalable and accurate crack detection tools.

Keywords –

Bridge condition assessment; Crack detection; Instance segmentation; YOLO; Mask R-CNN.

1 Introduction

Bridges are vital infrastructure systems for economic development and public welfare. Nonetheless, their ubiquitous nature, accelerated deteriorating, and increased public demand in the light of tight maintenance budgets pose a momentous challenge [1]. It is essential to develop innovative and reliable tools to support optimization of maintenance and repair decisions for bridges. Holistic asset management framework is needed to bridge the gap between the demand for renewal measures and the inadequate allocated resources [2].

Infrastructure asset management is a systematic approach for monitoring and maintaining physical infrastructure assets, including roads, bridges, during their entire lifecycle [3]. This approach entails evaluating, enhancing, and ultimately substituting these assets to ensure their safety, functionality, and cost-efficiency over time. The objective of infrastructure asset management is to optimize the value and lifespan of assets utilizing data-informed decisions that balance performance and cost [4]. It encompasses multiple phases that often begin with routine inspections of infrastructure assets followed by forecasting their deterioration behavior over time under various environmental and usage conditions. Subsequently, optimal maintenance plans, repairs schedules, and rehabilitation programs are determined to maximize the assets service life [3].

This research intends to investigate the first step of bridge asset management, condition assessment. In this step, bridges are inspected to detect any existing defects and determine their severity. Condition assessment models provide the foundation for capital renewal programs and restoration efforts, particularly following extensive hazards [5]. Traditional visual inspection methods though simple can be misleading due to the inherent subjectivity arising from being greatly dependent on the expertise and skills of inspectors [6]. In

addition, these methods are laborious, tedious, and hazardous in some situations [7]. As a result, newer techniques for bridge assessment, such as Ground Penetrating Radar (GPR), thermography, and image processing, have been explored. Nonetheless, their widespread adoption has been limited due to high equipment costs and the need for expert interpretation.

Recently, deep learning methods have emerged as a cost-effective alternative for assessing bridge conditions. However, most of the developed models focused on detecting cracks with little emphasis on estimating their areas/severities. This research aims to evaluate various deep learning models for instance segmentation of bridge cracks by comparing their accuracy and real-time detection capabilities . This is a hot research area due to the difficulty in attaining both high precision and recall crack detection. In infrastructure condition assessment, it is crucial to identify cracks with high precision to prevent false alarms, while simultaneously achieving high recall scores to ensure that most cracks are detected. To achieve this, innovative crack identification models based on instance segmentation will be developed. Instance segmentation is the best suited computer vision task for bridge crack detection as it identifies and segments each crack separately, enabling detailed analysis (e.g., length, width, and direction) of each crack. These details are essential for severity assessment and individual crack propagation. By isolating individual cracks, instance segmentation generates precise data for scheduling maintenance, hence ensuring structural safety.

2 Literature Review

Due to the evident drawbacks of visual inspections, both researchers and professionals opt to explore alternative methods for bridge condition assessment. For example, Alsharqawi et al. [8] developed a condition assessment model of bridge decks utilizing Ground Penetrating Radar (GPR). Employing GPR to identify subsurface anomalies enhanced detection accuracy. However, GPR is an expensive apparatus that requires skilled inspectors for data acquisition and analysis. In a different approach, Omar et al. [9] utilized infrared thermography to assess defects of concrete bridges. Although the model achieved accurate results, it was sensitive to weather conditions and surface moisture, which could significantly compromise the quality and interpretability of thermal data.

Other researchers exploited image processing methods such as edge detection and thresholding to detect defects on bridges [10,11]. However, these methods are highly sensitive to environmental conditions and image quality. They may fail in real-world scenarios characterized by varying illumination conditions [12]. In addition, the requirement to manually design feature extractors makes generalizing the obtained results rather challenging [13].

Recently, deep learning techniques have been increasingly utilized in bridge crack detection achieving remarkable performance driven by rapid advancements in computer vision [14]. Unlike image processing methods, deep learning detection techniques may directly learn from image data, facilitating self-adaptation and automated cracks feature extraction with minimal or no human intervention [14,15]. Deep convolutional neural networks (DCNNs) were successfully utilized for various crack detection tasks. These tasks are typically divided into three categories: crack classification, which detects cracks at the image level; crack object detection, which identifies cracks at the object level; and crack segmentation, which pinpoints cracks at the pixel level [16]. Most of the developed models involved either crack classification or carack object detection. Various DCNN architectures have been used for these purposes such as AlexNet [14] VGG-net [17] or ResNet [18]. For example, Zhang et al. [19] developed a detection model to locate bridge surface defects like cracks and spalling. Teng et al. [20] compared the performance of several CNNs to detect cracks on concrete bridge decks. However, these efforts lack the potential accurate estimates of the length and width of cracks, thereby rendering them less suitable as crack measurement algorithms [21].

DCNN-based crack segmentation methods can offer high-resolution detailed pixel-level crack classification [14]. Thess methods assign a class label (crack or background) to each pixel in an image. Several DCN architectures were used for crack segmentation such as RCNN-ResNet50, Faster RCNN-ResNet101, RetinaNet-ResNet50, and RetinaNet-ResNet101 [22]. Nonetheless, most of the developed segmentation models are semantic-based ones. These models attempt to capture the overall structure and semantics of the image without differentiating between individual cracks. Instance segmentation, another computer vision task, goes beyond semantic segmentation by not only assigning class labels to pixels, but also differentiating between individual instances of the same class. Very few efforts provided instance segmentation models to detect bridge cracks [23]. In addition, no attempts were reported to evaluate the performance of different DCNN architectures in instance segmentation.

The scarcity of instance segmentation models that were developed to detect bridge cracks can be attributed to several challenges such weak crack features, noisy images, and imbalanced data [24]. This study tries to address this gap by developing a novel instance segmentation model to identify and quantify cracks in bridges. In addition, this paper provides a comparative study between the performance of single-stage and two-stage detectors in cracks instance segmentation. This is

achieved by comparing the accuracy and speed of instance segmentation models developed utilizing cutting edge DCNN algorithms including (You-only-look-once) YOLOv9, YOLOv11, and Mask R-CNN. To the best of the authors' knowledge, this is the first investigation of the capabilities of these algorithms in instance segmentation tasks.

3 Methodology

Figure 1 illustrates the methodology employed in this research. After conducting literature review, crack image data were gathered from publicly available online sources. In addition, a drone was also used to collect some crack images and footages from bridges in Kuwait. Data was then preprocessed before being used to create the instance segmentation models utilizing YOLOv9, YOLOv11, and MaskR-CNN algorithms. These algorithms represent the state-of-the-art single-stage and two-stage detectors. Multiple metrics were then exploited to assess and compare the perspective performance of those algorithms in terms of detection speed and accuracy.

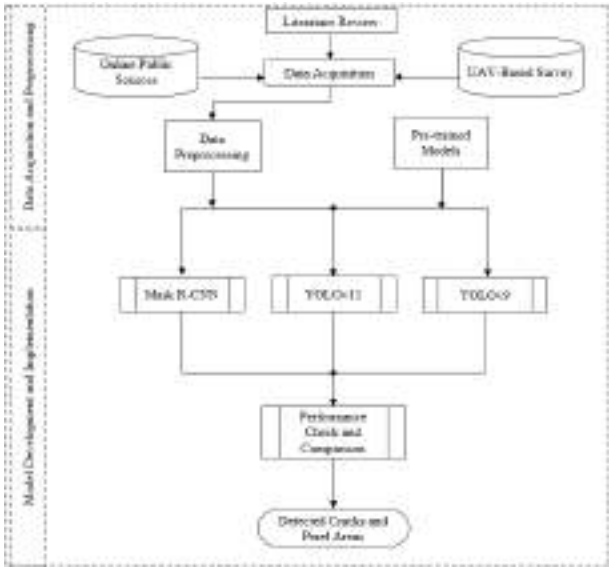

Figure 1. Research methodology

3.1 Overview of deep learning segmentation models

Deep learning models for object detection can be broadly classified into two main categories: one-stage and two-stage detectors [25]. Two-stage detectors, such as Mask R-CNN, initially produce regions of interest (ROIs) through a region proposal network [26]. The regions are then categorized and refined in the second stage to ensure accurate object localization and classification. This method is known for its accuracy resulting from the meticulous enhancement of identified objects. Unlike traditional CNNs, one-stage detectors such as YOLO process an entire image in a single pass through the network, compromising some accuracy in exchange for substantial speed enhancements [25]. One-stage models provide detections without independent region proposals and refinement stages, enabling faster operation and making them ideal for real-time applications [25].

Mask R-CNN is a deep learning model for object detection and segmentation, characterized by its precision and efficiency. It can accurately detect and each object within an image, making it exceptionally effective for complex image processing tasks. Mask R-CNN was developed by researchers at Facebook AI Research in 2017 to enhance the Faster R-CNN object detection model [26]. This was achieved by incorporating a parallel branch for predicting object masks alongside the existing bounding box detection branch [26]. Mask R-CNN's design comprises three primary components: a backbone network, a region proposal network (RPN), and two concurrent branches for bounding box identification and mask prediction. The backbone is typically a convolutional neural network that collects information from the input images to be utilized by both branches. In this analysis, we used ResNet-50 FPN as the backbone for Mask R-CNN due to its well-established balance between accuracy and computational efficiency. The ResNet-50 architecture, coupled with the feature pyramid network (FPN), enhances multi-scale feature extraction, making it highly suitable for detecting and segmenting cracks of varying sizes. The RPN produces a collection of region proposals that could encompass objects, utilizing the feature maps created by the backbone network. The bounding box branch predicts the class label and bounding box coordinates for each region proposal, whereas the mask branch generates a binary mask for each object instance within the bounding box [26]. The utilization of Mask R-CNN necessitates considerable computational resources for both training and inference [27], posing a constraint in real-time crack segmentation applications where such resources are scarce.

YOLOv9 and YOLOv11 are the latest versions of the YOLO algorithms that can be used to perform instance segmentation tasks [28-30]. The architecture of YOLO is composed of three parts: backbone, neck, and head. The backbone is the deep learning architecture that acts as a feature extractor. The neck combines the features acquired from the various layers of the backbone. The head predicts the classes and bounding box regions. In YOLOv9 the concept of programmable gradient information (PGI) was proposed. PGI provides complete input information to calculate the objective function so that reliable gradient information is obtained to update

network weights. This is achieved by introducing a new auxiliary head to the architecture that links the input data to the target output to pass the additional information. In addition, YOLOv9 incorporates reversible functions within its architecture to prevent information loss during data transmission through deep networks. A generalized efficient layer aggregation network (GELAN) was also adopted in YOLOv9 to enhance feature extraction by facilitating efficient layer aggregation, allowing the model to capture information across different layers while reducing the computational complexity [28-29].

In YOLOv11, the backbone is made of numerous convolution layers that extract distinct features at various resolution levels. These layers are connected through multiple C3K2 blocks to the neck components. C3K2 blocks replace the C2f block in the earlier versions (like YOLOv8) and employ two smaller convolutions instead of one large convolution, reducing processing time. The neck consists of spatial pyramid pooling fast (SPPF) that generates a fixed feature representation of objects regardless of their sizes without compromising spatial information. There is also a newly introduced cross-stage partial with spatial attention (C2PSA) block which facilitates learning global relationships between pixels at different positions while focusing more effectively on important regions. The neck component is connected to the head layer via three C3K2 blocks with each exclusively used to predict certain object sizes (small, medium, and large). Introducing the novel C3K2 and C2PSA blocks enhances the performance for more complex tasks with much fewer parameters [24]. While YOLOv9 offers two variants, YOLOv11 offers five variants with varying depth, width, and max channel parameters to accommodate different needs of computational speed and accuracy [30]. In this analysis, we used YOLOv9c and YOLOv11l models due to their comparable sizes in terms of the number of parameters.

3.2 Data Acquisition and Pre-processing

A comprehensive dataset of bridge crack images was carefully collected reflecting diverse real-world conditions. Images with no cracks or redundant images were removed. We initially gathered 2,650 raw images from various web sources, of which 2,408 were kept after the initial preprocessing and quality checks. Additionally, we collected 660 high-resolution images via UAV survey, giving a combined set of 3,068 images. Cracks were then annotated utilizing Roboflow, an online platform for image data management [31]. Once annotated, the dataset was divided into three subsets: training, validation, and testing with percentages of 70%, 20%, and 10%, respectively. The training dataset was used to train and calibrate the model. The validation set was used for performance enhancement while avoiding overfitting. The testing dataset was used for the final evaluation to provide an unbiased measure of the model's accuracy.

The training dataset was enriched by some augmentation techniques to simulate variations encountered in real-world scenarios, hence, improving the robustness and generalizability of the model. In this step, images were rotated randomly within a range of -15° to +15° to account for variations in object orientation. The hue values of the images were altered randomly within a range of -9° to +9°, introducing color variations to mimic different lighting conditions and reduce sensitivity to color changes. Brightness levels of the images were adjusted randomly between -15% and +15% to account for diverse illumination conditions. Finally, random noise, up to 0.1% of the total pixels, was introduced to the images to simulate distortions that may occur in real-world data acquisition. Data augmentation techniques expanded the training dataset to 6,443 images.

3.3 Model Training and Validation

All models were trained on an Nvidia Tesla T4 (16 GB memory) GPU. The stochastic gradient descent (SGDM) optimizer was used in all training experiments with a momentum set to 0.9. An initial learning rate of 0.01 was selected with a cosine learning rate decay. Cosine learning rate decay facilitates faster initial training, improved convergence, and better generalization by avoiding abrupt changes that can destabilize training. The batch size was set to 16 for all models. All models were trained for at least 50 epochs, or until their training loss converged. For fair comparison, the number of iterations for Mask R-CNN was calculated by multiplying the number of epochs with the ratio of the number of training samples to the batch size (e.g., number of iterations = epochs × (training samples/batch size)). A patience parameter was added to stop the training if the training loss plateaued with no improvements for at least 10 epochs. To avoid overfitting, batch normalization was used in YOLO models while L2 regularization was applied for Mask R-CNN.

In addition, transfer learning was used to speed up the learning process. This was achieved by exploiting pre-trained model weights as starting points for training the cracks instance segmentation models. Configurations and associated pre-trained weights for Mask R-CNN and YOLO models were retrieved from the Detectron 2 and perspective GitHub repositories, respectively [29-30,32].

3.4 Performance Evaluation

The aim of this step is to evaluate the efficacy of the developed models in bridge cracks detections and segmentation. The accuracy was assessed utilizing the popular object detection evaluation metric, mean average precision (mAP). Average precision (AP) is defined as

the average detection precision under various recalls, computed independently for each class. *AP* is calculated as the numerical integration of the precision-curve:

$$AP = \int_0^1 p(r)dr \quad (1)$$

Where p is the precision and r is the recall. The mean of the average precision among all considered classes, mAP, provides a holistic assessment of the detector's performance. To obtain the precision recall curve, classification predictions and the intersection-over-union (*IOU*) between the predicted bounding boxes (B_p) and ground truth ones (B_g) shall be calculated for each image:

$$IOU = area(Bp \cap Bg) / area(Bp \cup Bg) \quad (2)$$

True positive, false positive and false negative predictions are defined based on the *IOU* and some predefined threshold value. In this context, true positive represent the correct prediction where (IOU > threshold + correct classification). Similarly, false positives represent that the incorrect predictions with (IOU < threshold). On the other hand, false negative denotes that undetected, objects. Thus, precision (p) is defined as the proportion of correctly predicted positive instances out of all predicted positives while recall (r) is the proportion of correctly predicted positive instances out of all actual positives. These metrics are given by the equations below:

$$p = TP/(TP + FP) \quad (3)$$
$$r = TP/(TP + FN) \quad (4)$$

Where TP is true positive predictions, FP is false positive predictions, and FN is false negative predictions. In this study, *AP* is calculated at *IOU* threshold of 0.50, yielding mAP0.50.

4 Results and discussion

Figure 2 depicts the loss curves for the training and validation phases using the YOLOv11 model. The training loss curve exhibits a consistent and gradual decline, demonstrating effective learning of the model. Similarly, the validation loss curve shows a steady decrease, indicating the model's ability to generalize on unseen data. The convergence of the training loss to a low value (less than 0.4) reflects the model's successful acquisition of complex features required for the bridge crack detection task. While similar trends were observed for YOLOv9 and Mask R-CNN detectors, these curves are not included here due to space constraints.

In segmentation tasks, the bounding box regression measures how accurately the model is predicting the bounding box coordinates. On the other hand, segmentation prediction measures how well the model is predicting the pixel-level mask or outline of the detected crack.

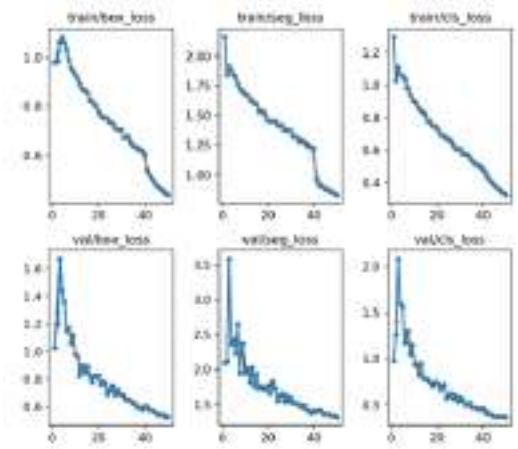

Figure 2. Training vs. validation loss for YOLOv11

Figure 3 summarizes the achieved mean average precision (mAP0.50) of both box and mask predictions for each detector. It can be observed that all three models achieved high performance in bounding box detection, with mAP0.50 exceeding 94%. Mask R-CNN achieved the highest score (95.59%), closely followed by YOLOv9 (95.0%) and YOLOv11 (94.9%). However, YOLOv9 and YOLOv11 achieved higher segmentation accuracies with mAP0.50 of 87.8% and 87.1%, respectively, reflecting strong performance in pixel-level accuracy. Mask R-CNN lags at 75.5% possibly due to limitations in handling finer details compared to the anchor-free architecture of YOLO models. In addition, YOLO models were able to significantly reduce the training time compared to the Mask R-CNN detector. For example, YOLOv11 reduced training time by approximately 82.6% from 12.22 hours for Mask R-CNN model to only 2.12 hours.

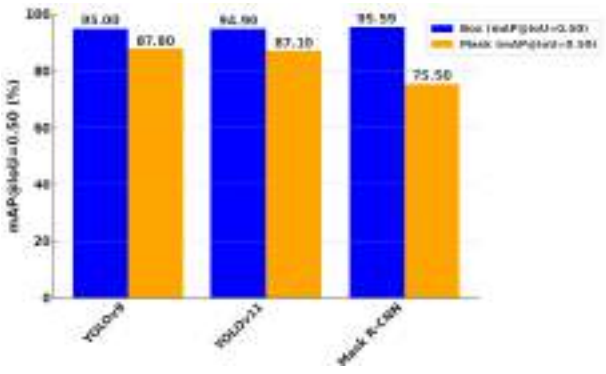

Figure 3. mAP of the investigated models

Due to their superior detection speed compared to Mask R-CNN, Table 1 depicts a detailed performance assessment of YOLOv9 and YOLOv11 models. Based on Table 1, YOLOv11 presents a better trade-off between precision, inference speed, and training time compared to

YOLOv9. YOLOv11 achieves a higher precision in bounding box detection (96.0%) and almost similar segmentation precision (91.2%), while maintaining faster inference speed of 19 ms/image and significantly shorter training time of 127.49 minutes. Regarding the recall metric, YOLOv9 achieved slightly higher bounding box recall (95.5%) compared to YOLOv11 (93.8%). Similar results were obtained for segmentation recall metrics as can be shown in Table 1 suggesting that YOLOv9 is better at identifying more crack objects in an image. Despite this marginal reduction in recall for both bounding box detection and segmentation, YOLOv11 overall performance and efficiency make it highly suitable for real-time applications. The smaller model size of YOLOv11 (27.6M parameters) further contributes to its speed and practical applicability. YOLOv9 on the other hand has competitive recall and mAP0.50 metrics, suggesting it may detect more objects when longer inference times are acceptable where exhaustive crack identification is required.

Table 1 Detailed performance assessment

Metric	YOLOv9	YOLOv11
Bounding Box		
Precision (p)	93.3%	96.0%
Recall (r)	95.0%	93.8%
mAP@IoU=0.50	95.0%	94.9%
Segmentation		
Precision (p)	91.5%	91.2%
Recall (r)	91.0%	89.0%
mAP@IoU=0.50	87.8%	87.1%
Training Time	270.91mnts	127.49mnts
Inference Time	34.1ms/image	19ms/image
Number of Parameters (M)	27.9	27.6

Table **2** presents performance comparison of the developed models with previous studies in the literature. Our YOLOv9 and YOLOv11 models outperform several other models in terms of accuracy while still maintaining competitive inference speeds. YOLOv11 offers the optimal trade-off between accuracy, speed, and computational efficiency.

Table 2 Performance comparison with prior studies

Model	mAP0.50 (%)	Inference time (ms/image)	Params (M)
YOLOv9	87.8%	34	27.9
YOLOv11	87.1%	19	27.6
YOLOv7 [22]	74.8%	22	36.9
RetinaNet [22]	72.8%	65	56.0
YOLOMF [33]	77.3%	12	11.5

The Precision-Recall curve in Figure 4 demonstrates YOLOv11 performance in crack instance segmentation task. With a mean average precision (mAP) of 0.871 at IoU=0.50, the model achieves a high level of precision across a wide range of recall values. The near-plateau at high precision values indicates the model's ability to maintain accurate predictions even as recall increases, indicating robust detection capabilities. The steep drop at the tail of the curve suggests a natural trade-off between precision and recall as the threshold for detection decreases. Overall, the curve highlights effectiveness in achieving a strong balance between precision and recall for crack detection and segmentation tasks.

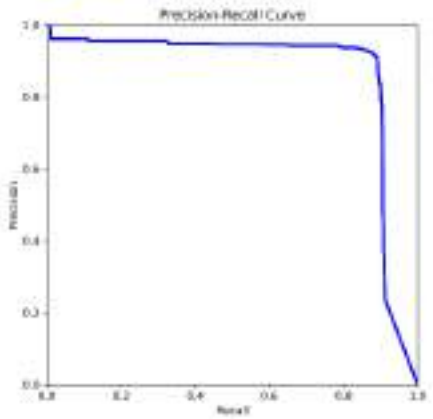

Figure 4. Precision-Recall curve for crack detection using YOLOv11

Figure 5 displays segmentation results for crack instance segmentation utilizing the YOLOv11 model. The blue overlays highlight the detected crack regions, with confidence scores labeled for each prediction. The figure demonstrates the model's capability to capture fine details and complex geometries of cracks, even in challenging cases with varying shapes and sizes. The high-confidence predictions (e.g., Crack 1.0) indicate robust performance. To calculate the pixel area of each identified crack, each segmented mask generated by the model was converted to a grayscale region. The boundaries of the segmented regions were identified, and the pixel area was calculated using OpenCV's contour methods [34]. This provides the total number of pixels enclosed within each mask, representing the crack's segmented area in the image. The calculated pixel areas can then be converted into real-world units if the spatial resolution of the image is known.

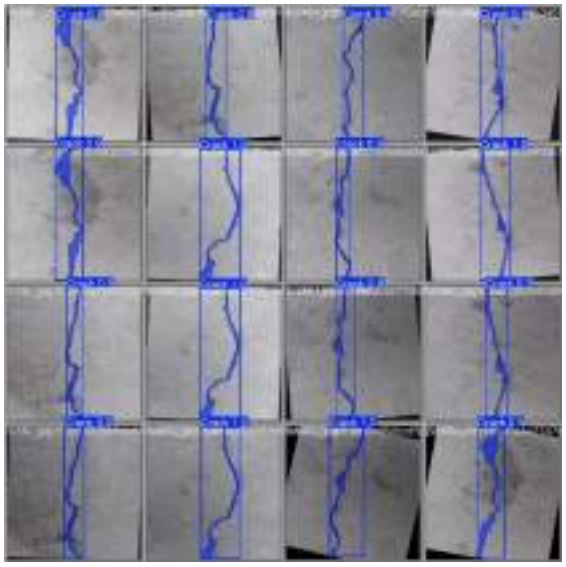

Figure 5. Sample of crack detection and segmentation using YOLOv11

5 Conclusion

Despite the extensive advancements of deep learning in crack detection, the development of instance segmentation models capable of assessing crack severity remains significantly underexplored. This study provides a comprehensive evaluation of single-stage and two-stage detectors for automated crack detection and segmentation in bridges. The findings highlight that YOLOv9 and YOLOv11 excel in speed and efficiency, while Mask R-CNN with ResNet-50 FPN demonstrates competitive accuracy. Notably, YOLO models achieved almost same accuracy with significant time savings, reducing training time by approximately 82% and inference time by 76%. This makes YOLO models highly practical for real-time crack detection applications. Leveraging novel architectures, data augmentation techniques, and transfer learning, YOLOv11 balances precision (91.5%) and recall (91.0%), presenting an effective candidate for large-scale infrastructure inspections. The results emphasize the importance of selecting segmentation models based on specific application requirements, such as prioritizing speed for real-time detection or accuracy for detailed analysis.

The developed segmentation models can be readily integrated with existing bridge management systems. UAVs can be used to capture high-resolution images, which are processed to extract and quantify crack features. The results can be shown on mobile applications for real-time assessments complementing traditional visual inspections. This integration combines automated analysis and expert judgment to enhance bridge evaluations and enable more informed maintenance and repair decisions.

While the model performed well in controlled conditions, environmental factors may impact its accuracy during real-world inspections. Variations in lighting, differences in crack textures, and weathering can challenge segmentation. Although our dataset was enhanced using augmentation techniques to simulate real-world scenarios, these measures may not capture all field complexities. Future work should thoroughly explore these effects and further enhance the model by focusing on quantifying the actual areas of cracks.

Abstract

Accurate representation of building semantics—encompassing both generic object types and specific subtypes—is essential for effective AI model training in the architecture, engineering, construction, and operation (AECO) industry. Conventional encoding methods (e.g., one-hot) often fail to convey the nuanced relationships among closely related subtypes, limiting AI's semantic comprehension. To address this limitation, this study proposes a novel training approach that employs large language model (LLM) embeddings (e.g., OpenAI GPT and Meta LLaMA) as encodings to preserve finer distinctions in building semantics. We evaluated the proposed method by training GraphSAGE models to classify 42 building object subtypes across five high-rise residential building information models (BIMs). Various embedding dimensions were tested, including original high-dimensional LLM embeddings (1,536, 3,072, or 4,096) and 1,024-dimensional compacted embeddings generated via the Matryoshka representation model. Experimental results demonstrated that LLM encodings outperformed the conventional one-hot baseline, with the "llama-3 (compacted)" embedding achieving a weighted average F1-score of 0.8766, compared to 0.8475 for one-hot encoding. The results underscore the promise of leveraging LLM-based encodings to enhance AI's ability to interpret complex, domain-specific building semantics. As the capabilities of LLMs and dimensionality reduction techniques continue to evolve, this approach holds considerable potential for broad application in semantic elaboration tasks throughout the AECO industry.

Keywords –

Building semantics; Large language model (LLM) embedding; Building information model (BIM); Graph neural network (GNN); Artificial intelligence (AI)

1 Introduction

The effective application of artificial intelligence (AI) technologies within the architecture, engineering, construction, and operation (AECO) industry hinges on the accurate representation of construction project information in machine-comprehendible formats. Extensive research has focused on utilizing diverse high-level data formats [1]—such as site photos for real-time site and worker condition monitoring [2,3], point clouds for tracking as-built construction progress [4–7], building information model (BIM) graphs for representing building topologies [8–10] and textual descriptions of project intents [11–13]—to represent information relevant to deliver the contextual information of the building projects. Representing and interpreting these digitally represented project information associated with planning, designing, constructing, and operating building projects (i.e., concepts that are significant for managing the projects), referred to as "building semantics" in this paper, are not only essential for AI systems to support reliable and informed decisions in construction projects, but also for their training.

To enable AI models to comprehend the high-level data format through supervised learning, this high-level information is labeled (partially or fully) and entered into AI models utilizing encoding methods. While these encodings play a critical role in differentiating the classes during training, prior studies often overlook the selection of encoding method, defaulting to conventional methods such as one-hot or label encodings. Although the advent of large language models (LLMs) and their generated embeddings has demonstrated the ability to capture domain-specific contextual nuances within the AECO fields [14,15], their utilization has primarily been confined to retrieving semantically similar information. The potential of leveraging these semantically rich LLM embeddings to provide task-relevant contextual nuances during AI model training remains largely unexplored.

This study proposes a novel AI model training

method that employs LLM embeddings as encodings (i.e., "LLM encoding") to preserve finer distinctions between building semantics. To evaluate performance differences compared to conventional encoding methods, we conducted an experiment focusing on a building object subtype classification task using GraphSAGE models [16]. For 42 building object subtypes and 5 BIM models utilized in the practice by a major contractor in the Republic of Korea, GraphSAGE models were trained for the node classification task. The experiment was designed to contrast one-hot encoding with LLM encodings generated by various models, including OpenAI's 'text-embedding-3-small' and 'text-embedding-3-large' [17], as well as Meta's 'llama3' [18]. Additionally, we investigated diverse embedding dimensions, compacted using the Matryoshka representation model, to assess whether compacted LLM embedding still preserves semantic nuances during the training.

The remainder of this paper is organized as follows: Section 2 introduces the background and motivation for this study, including a review of previous research on semantic enrichment. Section 3 explains how LLM embeddings can be used as encodings to train AI models. Section 4 describes the experimental design used to validate the proposed method. Section 5 presents the experimental results and Section 6 discusses academic and practical implications, current limitations, and future studies. Finally, Section 7 concludes the paper.

2 Background

With the continually increasing efforts to employ AI in the AECO industry, there has been growing interest in training AI to understand the terms and concepts used in our field. In other words, there is a recognized need to teach computers the terminology and concepts we use to plan, design, construct, and operate construction projects. This study collectively refers to the information used in managing building projects as "building semantics."

The understanding of these building semantics by AI is largely achieved via supervised learning. In supervised learning, the objects of study—namely, the object, the concept (or class) in the target domain, and the encoding method used to distinguish and convey them—correspond to the components of the triangle of reference (i.e., the semantic triangle) [19], which are *referent*, *thought* (*reference*), and *symbol*. For example, in AI training aimed at classifying BIM object types, the wall objects in a BIM model (the *referent* in Figure 1) belong to the "Wall" category (*reference*). This might be represented to a computer as [1, 0, 0, 0, 0, 0], i.e., the first of six object types (*symbol*).

Previous research has shown that building semantics—that is, the diverse concepts or classes that exist in real or digital project representations—encompasses a wide range of meanings. For instance, to verify whether a construction worker on site is wearing the proper personal protective equipment (PPE), such as straps, hardhats, harnesses, and hooks, AI is used to recognize different types of PPE and check correct usage [2,3]. For studies focused on construction progress monitoring [4–7], AI that recognizes objects on an as-built construction site and tracks progress compared to the as-planned schedules. Other studies aim to predict object types or their subtypes in BIM models [8–10]. In short, there has been extensive research on enabling AI to interpret a broad range of building semantics.

Furthermore, the building objects used as examples of these concepts and classes, as well as the subjects of analysis, have been represented in ways that are suitable for AI comprehension. For instance, when monitoring the correct use of PPE, images of workers on site can be used; for as-built progress monitoring, point clouds can be adopted; and for object relationships in a BIM model, graph data can be employed. These representations help convey real or digitally depicted states to AI in forms appropriate for training.

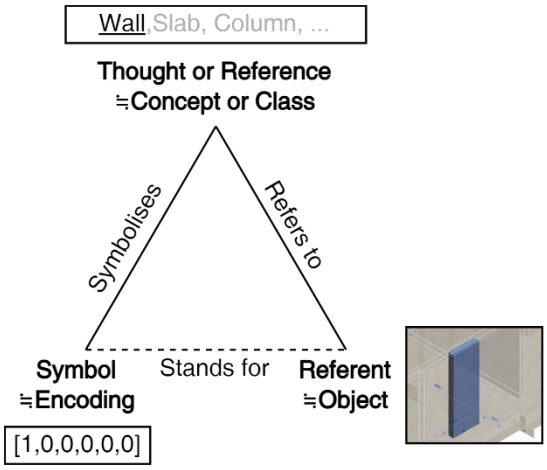

Figure 1. The triangle of reference (i.e., semantic triangle) in AI training for building semantics.

All these efforts show how to convey objects (the *referent*) to AI models, enabling them to interpret concepts (the *reference*) to understand building semantics. However, the types and effects of symbol—that is, the encodings used to help AI distinguish among concepts and classes—are comparatively underexplored. Although state-of-the-art large pretrained models can directly interpret concepts that are provided as images or text (i.e., can directly interpret referents), such models demand excessively high computational costs and datasets, making it difficult to train or fine-tune them for

new purposes. Hence, it is more common to develop smaller models via supervised learning. In this context, conventional encoding methods that do not capture the relative similarities among classes and concepts (e.g., labels or one-hot encoding) have long been used without much question. For instance, one-hot encoding treats all categories as equidistant from one another, as illustrated in Figure 2A, where generic building object types ("Wall," "Column," "Foundation," "Beam," "Stair," and "Slab"), while ignores inherent similarities and differences between the categories.

This study proposes using semantically rich LLM embeddings (i.e., LLM encoding) as the encoding method for supervised training, thereby preserving building semantics. Unlike one-hot encoding, LLM embedding uses semantic knowledge learned from large training corpora to generate highly contextualized vector representations that can capture the relative similarities and differences among building semantics. Figures 2A and 2B illustrate how LLM embeddings represent semantic distances between generic object types (i.e., "Wall" and "Slab") and their subtypes using t-SNE visualization for OpenAI's 'text-embedding-3-large' (3,720 dimensions) and Meta's 'llama-3' (4,096 dimensions). In both Figures 2A and 2B, the embeddings form clearly distinct clusters of subtypes—one each for the generic types "Wall" and "Slab" (with a horizontal distinction in Figure 2B and a diagonal distinction in Figure 2C). In addition, both LLM embeddings recognize that parapet-related wall subtypes are more closely grouped together, compared to other wall subtypes (highlighted with gray backgrounds in Figures 2A and 2B). Comparing the x-axis and y-axis scales for OpenAI's GPT-based embedding in Figure 2B and Meta′s LLaMA-based embedding in Figure 2C, it is evident that the two embeddings use different scales to distinguish each subtype (for example, $x \in [1,2]$, $y \in [-1.2,0]$ for 'text-embedding-3-large' in Figure 2B, and $x \in [1.2,2.6]$, $y \in [8,10]$ for 'text-embedding-3-large' in Figure 2C). Additionally, judging from the proportions of the ellipses around the parapet subtype clusters, we can see that the two LLM embeddings perceive the building semantics in subtly different ways.

Although it is reasonable to suspect that LLM embeddings might better symbolize the relative building semantics compared to one-hot encoding, this hypothesis remains underexplored. Building upon the premise that incorporating such building semantics into an AI model's encoding could enable more effective supervised learning, this study was conducted to propose a method that makes this approach feasible in practice.

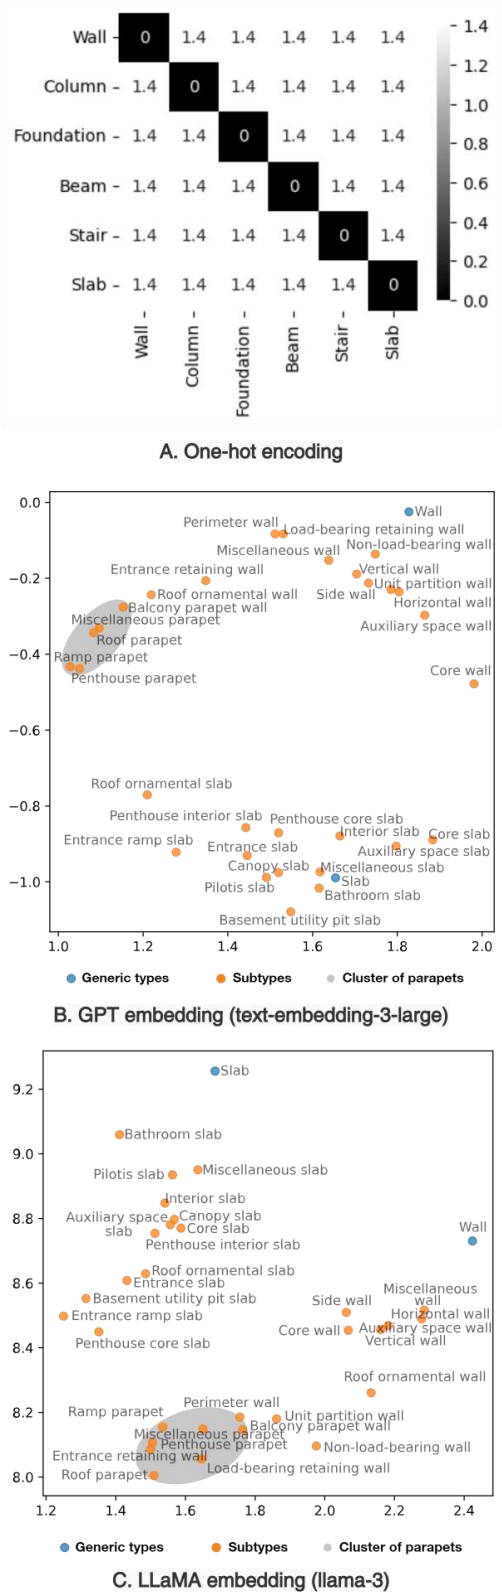

Figure 2. Building semantics represented using diverse encoding types.

3 LLM Encoding and Matryoshka Representation Model

3.1 LLM Encoding

Typically, encodings are used to enable computers to distinguish between given classes. In neural network training, the model evaluates whether the output—derived from label encoding or one-hot encoding—matches the target class via a sigmoid function. If the output aligns with the target, the loss decreases, and training proceeds to minimize that loss. However, to utilize LLM embeddings as encodings (i.e., LLM encoding) in neural network training, the loss calculation method needs modification. LLM embeddings reside in high-dimensional spaces, capturing various semantic nuances. Applying a sigmoid function, which retains only the highest-value cell, can dilute these semantic features and hinder proper learning.

Instead of using a sigmoid at the final layer, LLM encoding sets the final layer's dimension to match that of the target LLM embedding. The loss is then computed based on the quantitative difference between the neural network's output embedding e_p and the target label's LLM embedding e_t. One way to achieve this is by using cosine embedding loss, defined as equation (1):

$$L(\mathrm{e}_p, \mathrm{e}_t) = 1 - \frac{\mathrm{e}_p \cdot \mathrm{e}_t}{\|\mathrm{e}_p\| \|\mathrm{e}_t\|} \quad (1)$$

where $\cdot$ denotes the dot product and $\|\cdot\|$ denotes the Euclidean norm. This approach preserves semantic relationships in the embedding space, unlike one-hot encodings or sigmoid-based methods that force a single "correct" cell to dominate.

This training method is applicable to general tasks where each class carries semantic meaning. Once trained, the model can return the class closest to the predicted output by comparing the predicted embedding e_p against each candidate embedding e_t and selecting the one with the smallest loss.

3.2 Matryoshka Representation Model

LLMs generate embeddings in high-dimensional spaces, such as OpenAI's text-embedding-3-small (1,536 dimensions), text-embedding-3-large (3,072 dimensions), or Meta's LLaMA-3 (4,096 dimensions), to encode rich semantic information. However, leveraging these embeddings for real-world applications often requires dimensionality reduction to address computational inefficiencies. The Matryoshka representation model addresses this challenge by projecting high-dimensional embeddings into lower-dimensional spaces while preserving semantic features [20]. For implementation, the 'tomaarsen/mpnet-base-nli-matryoshka' model available on Hugging Face, was utilized.

4 Experiments

The experiment aims to evaluate whether utilizing LLM encoding improves the performance of AI models in enriching building semantics. Specifically, we assessed the AI model's performance on a subtype classification task of semantic elaboration, as depicted in Figure 3.

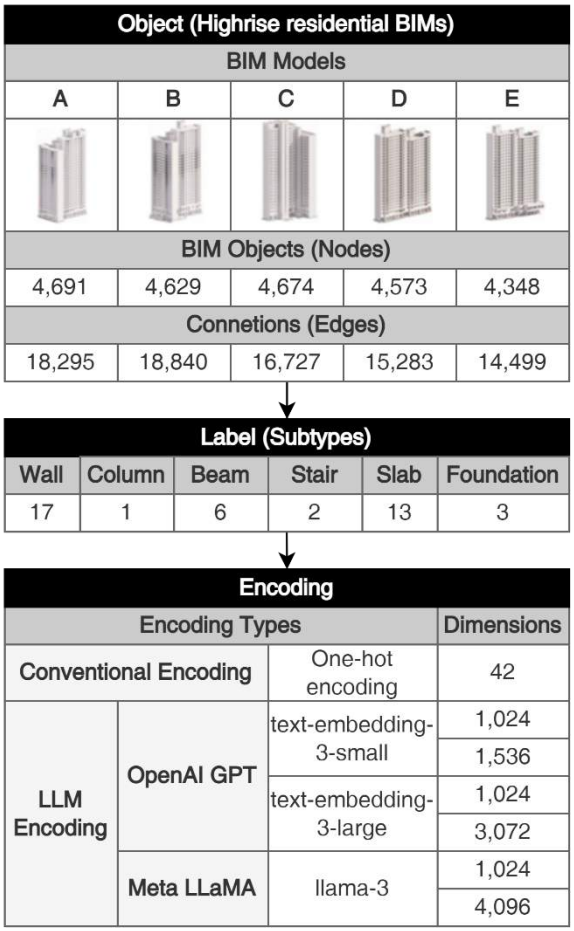

Figure 3. Experimental design.

For the experiment, five BIM models of high-rise residential projects, denoted A, B, C, D, and E, each containing over four thousand generic BIM objects, were utilized. Across these projects, we identified 42 subtypes managed by one of the major contractors in Republic of Korea (Table 1), ranging from "core wall" and "bathroom slab" to "transfer column" and "penthouse core slab from our prior study [10]. These projects were cross-validated by using each as a test dataset while the others served as training datasets. On these datasets, we trained GraphSAGE [21] models with three layers, each having a layer dimension of 1,024. Within this setup, we

tested various encodings with varying dimension sizes using the Matryoshka Representation Model. The encodings included: (1) one-hot encoding, a conventional method; (2) 'text-embedding-3-small' with a 1,024-dimension compacted representation; (3) 'text-embedding-3-small' with its original 1,536 dimensions; (4) 'text-embedding-3-large' with a 1,024-dimension compacted representation; (5) 'text-embedding-3-large' with its original 3,072 dimensions; (6) 'llama-3' with a 1,024-dimension compacted representation; and (7) 'llama-3' with its original 4,096 dimensions.

Table 1. Subtypes utilized in the experiment.

Code	Subtype	Code	Subtype
0	Core wall	21	Wall girder
1	Horizontal wall	22	Interior lintel
2	Vertical wall	23	Non-loadbearing lintel
3	Perimeter wall	24	Entrance stairs
4	Side wall	25	Interior stairs
5	Entrance retaining wall	26	Core slab
6	Loadbearing retaining wall	27	Entrance slab
7	Miscellaneous wall	28	Entrance ramp slab
8	Unit partition wall	29	Piloti slab
9	Non-loadbearing wall	30	Basement utility pit slab
10	Auxiliary space wall	31	Interior slab
11	Roof ornamental wall	32	Bathroom slab
12	Roof parapet	33	Miscellaneous slab
13	Penthouse parapet	34	Auxiliary space slab
14	Ramp parapet	35	Penthouse interior slab
15	Balcony parapet wall	36	Penthouse core slab
16	Miscellaneous parapet	37	Roof ornamental slab
17	Transfer column	38	Canopy slab
18	Core beam	39	Entrance strip foundation
19	Transfer beam	40	Mat foundation
20	Miscellaneous beam	41	Haunch

To compare the impact of different encoding strategies on the model's ability to classify building object subtypes, the average F1-score was primarily utilized. In addition, statistical tests were conducted to determine the significance of the performance differences between encoding methods. The normality of F1-score differences was tested using the Shapiro-Wilk test with a significance level of $\alpha = 0.05$. When the normality assumption was satisfied ($p > 0.05$), the paired t-test was employed to evaluate the statistical significance of the mean differences between paired observations. In cases where the normality assumption was violated ($p \leq 0.05$), the Wilcoxon signed-rank test was utilized as a non-parametric alternative, with statistical significance set at $\alpha = 0.05$.

5 Results

Table 2 presents the average F1-scores for classifying each subtype using both one-hot and LLM-based encodings. The encodings examined include text-embedding-3-small, text-embedding-3-large, and LLaMA-3, each tested in both compacted (1,024-dimensional) and original formats (1,536, 3,072, or 4,096 dimensions). Overall, subtypes with larger training and test sets demonstrated higher predictive performance.

Table 2. Weighted average F1-scores for different encoding types.

Encoding type	Dimensions	Weighted average F1-score
One-hot encoding	42	0.8475
text-embedding-3-small	1,024	0.8705
	1,536 (original)	0.8498
text-embedding-3-large	1,024	0.8655
	3,072 (original)	0.8529
llama-3	1,024	0.8766
	4,096 (original)	0.8714

With the original LLM embeddings, the weighted average F1-score increased sequentially from one-hot encoding (0.8475) to text-embedding-3-small (0.8498), text-embedding-3-large (0.8529), and finally LLaMA-3 (0.8714). However, when using the compacted 1,024-dimensional embeddings, the ranking of text-embedding-3-large and text-embedding-3-small reversed compared to their original counterparts, resulting in a slight overall increase in weighted average F1-scores to 0.8705, 0.8655, and 0.8766, respectively. These findings suggest that GraphSAGE, which outputs a 1,024-dimensional representation, may not adequately capture the semantic richness of higher-dimensional LLM embeddings (e.g., 1,536, 3,072, or 4,096 dimensions).

5.1 One-hot and LLM Encodings

In this subsection, we analyzed the significance of performance differences between one-hot and LLM encodings, including both original and compacted formats. The Shapiro-Wilk normality test (n=42) indicated that the normality assumption was violated in the F1-score differences for five out of six comparisons (p-values < 0.05), necessitating the use of the non-parametric Wilcoxon signed-rank test (Table 3). Among LLM embeddings, 'llama-3 (compacted)' exhibited a distinctly low p-value (0.000007), indicating a more skewed fold-by-fold performance distribution that may arise from uneven semantic feature retention after the largest dimensional compression (4,096 to 1,024).

Table 3. p-values of the Shapiro-Wilk test for identifying the normality of the difference in performance between one-hot and LLM encodings.

Shapiro-Wilk test	One-hot encoding
text-embedding-3-small (compacted)	0.065730
text-embedding-3-small (original)	0.006618
text-embedding-3-large(compacted)	0.013222
text-embedding-3-large (original)	0.011914
llama-3 (compacted)	0.000007
llama-3 (original)	0.049937

The results of the paired t-test and Wilcoxon signed-rank test (n=42) are presented in Table 4. Although the performance of the model slightly improved when LLM encodings were utilized, statistical analysis revealed that no significant differences were found, except for 'text-embedding-3-large (compacted)' (p=0.006596). This suggests that compressing text-embedding-3-large to 1,024 dimensions appears to preserve key semantic cues while removing noise, thus yielding more consistent performance gains and a statistically significant improvement over one-hot encoding.

Table 4. p-values of paired t-test and Wilcoxon signed-rank test for identifying the significance of the difference in performance between one-hot and LLM encodings.

Paired t-test and Wilcoxon signed-rank test	One-hot encoding
text-embedding-3-small (compacted)	0.285281 (z=1.06852)
text-embedding-3-small (original)	0.873084 (t = -0.16074)
text-embedding-3-large(compacted)	0.006569 (z=2.71792)
text-embedding-3-large (original)	0.163854 (z=1.39222)
llama-3 (compacted)	0.714148 (z= 0.36629)
llama-3 (original)	0.219283 (z= 1.22843)

5.2 Between LLM Encodings

In this subsection, we analyzed the statistical significance between different LLM encodings. Similar to the one-hot comparisons, the Shapiro-Wilk test (n=42) identified violations of normality assumptions in all cases, leading us to employ the Wilcoxon signed-rank test (n=42) for all comparisons. For original LLM embeddings, no significant differences were observed despite slight performance increases (Table 5).

Table 5. p-values of Wilcoxon signed-rank test for identifying the significance of the difference in performance between original LLM encodings.

Wilcoxon signed-rank test	text-embedding-3-large (original)	llama-3 (original)
text-embedding-3-small (original)	0.068390 (z = 1.82243)	0.529727 (z = 0.62842)
text-embedding-3-large (original)	-	0.751786 (z = 0.31628)

Conversely, for compacted LLM encodings, significant differences were observed (Table 6). This demonstrates that compacted LLM embeddings effectively leverage the semantic richness provided by large datasets and advanced architectures. For example, 'llama-3 (compacted)' benefits from its extensive training corpus of over 1.4 trillion tokens and 65 billion model parameters, compared to the smaller 'text-embedding-3-large (compacted)'.

Table 6. p-values of Wilcoxon signed-rank test for identifying the significance of the difference in performance between compacted LLM encodings.

Wilcoxon signed-rank test	text-embedding-3-large (compacted)	llama-3 (compacted)
text-embedding-3-small (compacted)	0.010346 (z = 2.56403)	0.011765 (z = 2.51910)
text-embedding-3-large (compacted)	-	0.000583 (z = 3.43962)

These results suggest that as LLM technology continues to evolve, the utility of LLM encodings for AI-based training will further improve. A notable observation is the consistent outperformance of compacted LLM encodings compared to their original counterparts, highlighting the effectiveness of

dimensionality reduction techniques like the Matryoshka representation model in preserving essential semantic information. Additionally, the findings imply that increasing the size of AI models may be necessary to fully harness the potential of semantically rich LLM encodings. Future research should explore the optimal balance between model size and computational efficiency to maximize performance in semantic elaboration tasks.

6 Discussion

6.1 Academic and Practical Implications

This study underscores the importance of integrating semantically rich encodings into AI models to enhance the understanding of building semantics. From an academic perspective, the approach broadens current research by demonstrating that LLM embeddings—when compacted appropriately—can outperform conventional one-hot methods, thereby offering a more nuanced way to represent complex object subtypes. Practitioners, on the other hand, gain a practical encoding method that leverages widely available pretrained LLMs for improved decision support. By preserving finer distinctions among building semantics, AI models can more accurately comprehend real-world project information, ultimately helping industry professionals make more context-aware informed decisions supported by AI models.

6.2 Limitations

Despite its promising outcomes, this study has several limitations that call for cautious interpretation. First, the experiments limitedly covered a subtype classification task involving 42 subtypes across five high-rise residential BIM models. These may not comprehensively reflect the full range of building types or the myriad semantic tasks encountered in real-world practice. Additional work is needed to validate the proposed method on more diverse building typologies (e.g., hospitals, commercial complexes, infrastructure) and under different project conditions (e.g., varying project phases, levels of detail). Second, while the focus here was on subtype classification using a graph neural network, building semantics encompasses a broad range of tasks—such as construction scheduling, cost estimation, and design intent capture—that might benefit differently from LLM encodings. Lastly, the reliance on existing LLMs means that domain-specific terms not extensively represented in their training corpora may still suffer from suboptimal embeddings, highlighting the need for either fine-tuning or training domain-specific LLMs on specialized AECO datasets.

6.3 Future Directions

Building on the insights gained in this study, several avenues for future work emerge. First, exploring alternative loss functions—beyond cosine similarity—may further refine model training for specific semantic tasks. Second, investigating different dimensionality-reduction techniques could help preserve even more nuanced contextual information while mitigating the computational overhead of high-dimensional embeddings. Third, training or fine-tuning LLMs on construction-centric corpora, such as project specifications or technical standards, may yield embeddings that better capture domain-specific language and nuances. Finally, a more holistic approach that combines text-based encodings with additional data modalities—such as 2D/3D images, point clouds, or sensor data—could offer a deeper, multimodal understanding of building semantics. By expanding the scope of tasks and data types, future research can further validate the robustness and applicability of LLM encodings in increasingly complex AECO environments.

7 Conclusion

This paper tackled the challenge of preserving and enriching building semantics in AI models by introducing a training method that employs LLM embeddings as encodings. Through extensive experiments on BIM object subtype classification, we demonstrated that compacted LLM encodings, such as "llama-3 (compacted)," outperform conventional one-hot encoding, achieving higher weighted average F1-scores (0.8766 over 0.8575) and showing stronger potential to represent subtle semantic distinctions. Although statistical significance was not uniformly observed for all embeddings, the results highlight the growing promise of leveraging advanced language models to capture the domain-specific context vital to the AECO industry.

By integrating LLM-based encodings into class labeling for supervised AI model training, this study contributes a viable solution for domain practitioners and researchers seeking to improve model accuracy and semantic fidelity. As LLM technology continues to advance—and as construction datasets become richer—opportunities to refine these methods will likely multiply. Ultimately, the framework presented here offers a stepping stone toward more intelligent, context-aware AI systems capable of handling the increasing complexity and specialization inherent in modern building projects.

Abstract – Automated Fault Detection and Diagnostics (AFDD) is a data-driven approach that enables the timely detection of faults, their types, and severity in Heating, Ventilation, and Air Conditioning (HVAC) systems. Machine learning models can be used to develop and implement AFDD models for HVAC at the system, sub-system, and equipment levels. However, there is a discrepancy between experimental facilities and actual buildings in practice.

This study implements sensitivity analysis to determine how variations in the features used in the case study under investigation affect the performance of the AFDD models. The analysis includes techniques such as correlation analysis and machine learning models (Support Vector Machine (SVM) and Artificial Neural Network (ANN)) to assess the sensitivity of the models to changes in input features. The results depict how sensitive the AFDD models are to different features and the extent to which variations in these features can impact the models' performance. These findings can facilitate the selection of robust features for machine learning-based Fault Detection and Diagnostics (FDD) models of HVAC in buildings by building operators, including facility managers, asset managers, and owners.

1 Introduction

Automated Fault Detection and Diagnostics (AFDD) is crucial for maintaining the efficiency and reliability of HVAC systems [1], [2]. AFDD models are constructed using data that reflects the behavior and performance of facilities and HVAC systems, enabling the prediction of fault occurrences and types. In this regard, machine learning models offer a promising approach to FDD, but there is a significant gap between the controlled environments of experimental facilities and the real-world conditions of actual buildings. This study aims to bridge this gap by performing a sensitivity analysis to understand how variations in features affect the performance of AFDD models [3] .

Presently testing facilities used for AFDD development are often using controlled environments to reduce uncertainty. They are heavily instrumented, which means that test facilities contain many sensors installed in different building spaces and HVAC equipment to detect subtle changes in the system and building space environment. However, in practice, the existing stock of commissioned buildings does not possess the same sensor variety and is limited in numbers compared to experimental labs. The current differences in real case scenarios and research facilities do not make the machine learning-based AFDD models feasible for utilization in actual buildings [4].

This study implements sensitivity analysis to determine how variations in the features used in the case study under investigation affect the performance of the AFDD models. The analysis includes techniques such as correlation analysis and data mining techniques to assess the sensitivity of the models to changes in input features. The study investigates how sensitive the AFDD models are to different features and the extent to which variations in these features can impact the model's performance. In addition, the results of feature importance can be used to facilitate the selection of robust features for machine learning-based FDD models of HVAC in buildings.

2 Methodology

This study utilizes data from a Building Information Model (BIM), which contains building spatial data, and Building Management System (BMS), which includes time-series data representing HVAC, to create a comprehensive dataset for fault detection and diagnostics of an HVAC system. The BIM model includes static features such as room area, window area, door area, opening area, distance to HVAC from VAV (Variable

Air Volume), room adjacency to shafts, and whether rooms are exterior or interior. These features collectively form 80 static features representing the facility's contextual information. The BMS dataset includes 68 dynamic features such as VAV temperature, room temperature, humidity, status, supply and return temperature, metered data, set points, and flow rates.

A key aspect of our methodology is feature engineering, where we generate new features from existing data to enhance the accuracy and effectiveness of machine learning models. For instance, we created a calculated feature called "space air conditioning," which combines contextual information from BIM and air conditioning conditions from BMS for each room. This feature is crucial for identifying faults related to occupancy patterns and other contextual factors.

Feature engineering in AFDD involves generating new features from existing data to improve the accuracy and effectiveness of machine learning models. This is particularly important when dealing with limited sensor data, a common problem in real-world building environments. For example, one can combine time-series data from BMS (e.g., supply air temperature) with spatial data from BIM (e.g., room occupancy) to create a new feature that represents the air conditioning state of a space. This type of feature can help to identify faults that are related to occupancy patterns or other contextual factors.

To make the features workable, two grouping systems were formed: one based on system-related features or zone/space features, and the second based on the feature source.

Table 1: Grouping based on System related features or Zone/Space related features

Grouping based on level	No of groups	Feature groups formed based on simillarity names
Zone/Space level	4	VAV temp, Room temp, humidity, set point
System level	3	Circuit 1 and 2, supply and return, Flow rate
Mix	1	Status
Building	1	Meter

Table 2: Grouping based on feature source and type (Static/Live)

Grouping based on source and type	No of Features	Full form
BMS	68	BMS dataset
BIM	80	BMS + Live BIM dataset
Dy+St	160	BMS + Live BIM dataset + Static BIM dataset
St BIM	148	BMS + Static BIM dataset

Two approaches were used the first being feature impact analysis and second sensitivity analysis. Feature impact analysis evaluates the importance of groups of features, while sensitivity analysis assesses the impact of individual features on model performance. Sensitivity analysis helps to identify the most important features for fault detection and diagnosis, as well as to understand how the model's performance is affected by missing or incomplete data. One way to perform sensitivity analysis is to train multiple models with different combinations of features and compare their accuracy. For example, one might train a model with all available features, then train another model with a subset of features, and compare their performance.

Feature impact analysis is useful when the set of features is large, as in the case of the facility, which will enable the modelers to identify which features are suitable for the machine learning algorithm to identify the faults of the HVAC systems.

3 Model Development

This study utilizes data from the LBNL (Lawrence Berkeley National Laboratory) Automated Fault Detection for Buildings Data [5], [6], [7], [8], [9], [10], [11]. A Building Information Model (BIM) is developed based on the specifications, and further, the Building Management System (BMS) is used to create a comprehensive dataset for fault detection and diagnostics of an HVAC system [12], [13], [14], [15]. The BIM model of the facility is created using the documentation of the test facility. The dataset generated for fault detection and diagnostics of the HVAC system includes a rooftop unit (RTU) connected to variable air volume (VAV) systems.

The BIM and BMS data were combined to form a comprehensive dataset [4]. The BIM features were grouped into categories such as distance to HVAC from VAV, room area, window area, door area, opening area, room adjacency to shafts, and whether rooms are exterior or interior. The BMS features were grouped into categories such as VAV temperature, room temperature, humidity, status, supply and return temperature, metered data, set points, and flow rates.

In this research, various machine learning algorithms are modeled to identify the most impactful features for fault detection and diagnostics. For feature importance analysis, classifiers like XGBoost, Random Forest, and Decision Tree were used. The machine learning algorithms specifically employed for fault detection and diagnostics (FDD) were Support Vector Machine (SVM) and Artificial Neural Network (ANN). They were selected based on the findings of earlier research, which

highlighted their adoption for system-level and subsystem-level faults [16]. The performance of each algorithm was evaluated based on its ability to identify impactful features and detect faults. The faults considered in this study included condenser fouling, HVAC setback errors (delayed onset, early termination), excessive infiltration, lighting setback errors (delayed onset, early termination), no overnight HVAC setback, and thermostat measurement bias.

For feature importance evaluation, several models were developed. In the case of the Random Forest classifier, feature importance was computed as the mean and standard deviation of the impurity decrease within each tree, also known as Gini importance. For the Decision Tree classifier, feature importance was determined by the normalized total reduction of the criterion brought by that feature. XGBoost classification was based on gain, which measures the improvement in accuracy brought by a feature to the branches it is on.

Table 3: Machine Learning algorithms used as classifier for feature importance analysis

XGBoost Classification	Random Forest Classification	Decision tree classification
Condenser Outlet Pressure (Circ 1)	Condenser Outlet Pressure (Circ 1)	Condenser Outlet Pressure (Circ 1)
VAV Reheat Status	Room 205 Air Humidity	Discharge Temperature (Circ 2)
Discharge Temperature (Circ 2)	Room 206 Air Humidity	Room 204 Air Humidity
Room 203 Air Humidity	Room 204 Air Humidity	Room 205 Air Humidity
Room 203 Air Temperature	Room 106 Air Humidity	Room 206 Air Humidity
Discharge Pressure (Circ 1)	Suction Temperature (Circ 2)	Room 202 Air Humidity
X Air Humidity	Room 203 Air Humidity	Room 102 Air temperature
X Air Humidity	Room 102 Air Temperature	Room 106 Air Humidity
Suction Temperature (Circ 2)	Room 103 Air Humidity	Lighting system
X Air Humidity	Discharge temperature (Circ 2)	Room 205 Air Temperature

The calculated air conditioning feature shows a negative correlation and is the only feature that is found to have an impact when brought in from BIM, as shown below.

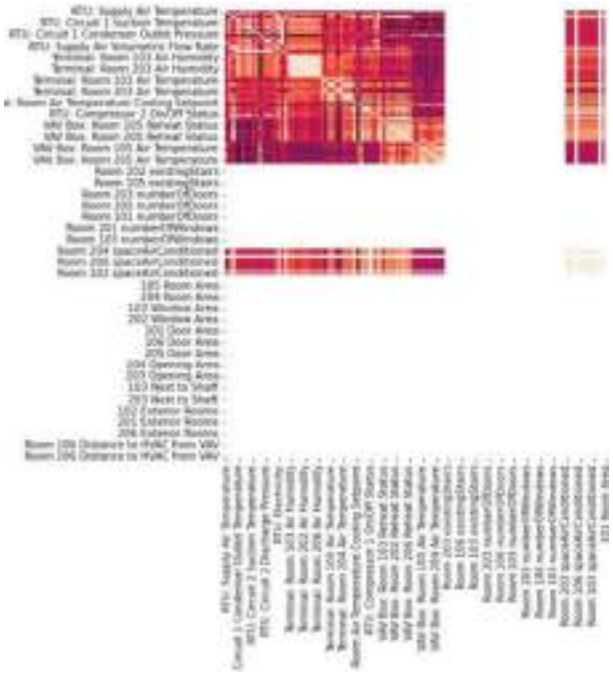

Figure 1: Excerpt of correlation analysis and of important features for AFDD in the curated dataset including BIM features

4 Results and Discussion

The result of this research indicated that the Random Forest classifier was most suitable for the dataset, particularly when it came to calculated features. For sensory data features, the classification algorithms showed similar feature types, with humidity being the most impactful feature.

The comparison of SVM and ANN indicates that the ANN is more sensitive to selected features, showing higher levels of sensitivity. The maximum impact that a feature can have on fault detection is 67% for both the suction temperature feature and the air-cooling temperature. Additionally, the diagnostics models show that the air temperature cooling setpoint can have a 62% impact, followed by the discharge temperature with a 37% impact.

The top 5 groups of features identified are then checked to see what percentage of accuracy impact these features have on the dataset for each of the algorithms for both fault detection and diagnostics.

Table 4: Impact of top 5 features on Fault detection and diagnosis using SVM Machine Learning Algorithms

Top 5 features	SVM Accuracy for Fault Detection	SVM Accuracy for Fault Diagnostics
Air Humidity	80%	71%

Discharge temperature (Circuit 2)	67%	38%
Suction Temperature (Circuit 2)	67%	38%
Room Temperature	79%	71%
Cooling setpoint	67%	33%

Table 5: Impact of top 5 features on Fault detection and diagnosis using ANN Machine Learning Algorithms

Top 5 features	ANN Accuracy for Fault Detection	ANN Accuracy for Fault Diagnostics
Air Humidity	87	55
Discharge temperature (Circuit 2)	71	37
Suction Temperature (Circuit 2)	67	39
Room Temperature	85	41
Cooling setpoint	65	33

The analysis illustrate that the random forest classifier is most suitable for the dataset when it comes to calculated features. For sensory data features, classification algorithms show similar feature types, with humidity being the most impactful feature. The top features identified include air humidity, discharge temperature, suction temperature, room temperature, and cooling setpoint.

The calculated feature, "space air conditioning," is the only feature in the BIM dataset that shows a negative correlation and is present in the important feature list when analysis is performed using a random forest classifier, which has a weak correlation of an average of 25%.

The results highlight the importance of certain features in the performance of AFDD models. For instance, air humidity and room temperature consistently show high impact across different models. The findings suggest that incorporating dynamic BIM features can enhance the sensitivity of AFDD models, especially when certain BMS features are unavailable. This has practical implications for facility managers and asset owners in selecting robust features for fault detection and diagnostics.

This study demonstrates the significance of feature impact analysis in developing effective AFDD models for HVAC systems. By identifying the most impactful features, facility managers can improve the accuracy and reliability of fault detection and diagnostics. Future work should explore the integration of additional contextual features and the application of these findings to a broader range of building types.

Abstract -

Efficient road maintenance is vital for long-lasting and safe transportation networks, but traditional methods that rely on manual inspection are labour-intensive and error-prone. The integration of Natural Language Processing (NLP) and Large Language Models (LLMs) presents a transformative solution for automating text-based tasks in road maintenance. This study investigates the application of LLM-based text classification models to process unstructured textual data from road maintenance logs, with a focus on resource-constrained scenarios characterised by limited labelled datasets. Two primary approaches were evaluated: traditional fine-tuning and few-shot learning. Using a public dataset from New York City roadwork inspections containing 83 distinct classes, we performed extensive model comparisons. Pre-trained transformer models *Llama* and *BERT* were fine-tuned to achieve baseline performance. Additionally, a few-shot learning method, SetFit, was employed to address data scarcity through efficient task adaptation using minimal labelled examples. Results showed SetFit outperformed fine-tuning in low-resource scenarios, achieving high accuracy and F1 scores with as few as 1-10 examples per class, reducing annotation efforts. This highlights the potential of few-shot learning for real-world deployment. Future work will address scalability, multimodal data fusion, and integration into predictive maintenance.

1 Introduction

Effective road maintenance is essential for the safety, reliability and longevity of transportation networks. However, increasing traffic volumes and ageing infrastructures present challenges, such as identifying deteriorating assets, ensuring timely intervention, and optimising resource allocation. Inspection logs provide valuable information on road maintenance. However, manually analysing an enormous volume of inspection reports is labour-intensive, time-consuming, and error-prone [1, 2]. These issues are further amplified in a resource-constrained setting where funding and manpower are limited [3].

The advent of artificial intelligence (AI) and natural language processing (NLP) offers the potential for automating road maintenance tasks like analysing inspection data, prioritising repairs, and generating insights [4]. Transformer-based models like BERT and GPT have become state-of-the-art for text processing [5], yet their application in road maintenance remains underexplored, especially in low-resource settings with limited labelled data.

This paper aims to bridge this gap by systematically evaluating the use of transformer-based text classifiers in road maintenance applications, particularly in resource-constrained settings. Specifically, the study focuses on:

1. **Comparative Analysis**: Evaluating the performance of traditional fine-tuning approaches across various pre-trained transformer model architectures and sizes, highlighting their effectiveness in processing road maintenance-related textual data.
2. **Few-Shot Learning**: Assessing the capability of dedicated few-shot models to deliver robust performance with minimal labelled data, catering to the constraints of limited resources often encountered.

The paper is structured as follows: Section 1 introduces the topic, followed by background in Section 2. Section 3 outlines the methodology, while Section 4 discusses the findings, limitations, and future research directions. Finally, Section 5 presents the conclusions.

2 Background

2.1 Challenges in Leveraging Text Data for Road Maintenance

Malihi et al. [6] emphasise the untapped potential of textual records such as inspection and maintenance reports in road maintenance, noting that their unstructured and inconsistent nature limits their utilisation. Unlike numerical or sensor data, text is inherently diverse in format, structure, and terminology. Inspection reports, for example, may describe similar issues in varied ways depending on

*Co-First Authors (Equally Contributed to this work).

the inspector's language and style. This lack of standardisation makes it difficult to extract consistent and actionable insights. Another challenge is the volume of data generated across extensive road networks. Maintenance operations often produce large quantities of text data over time, including daily logs, contractor reports, and communications. Manually sifting through this information to identify critical issues is time-consuming and prone to human error. The ambiguity and context-dependence of language further complicate the processing of text data. Terms like "minor crack" or "urgent repair" may vary in meaning depending on the context, location, or maintenance standard, leading to inconsistent interpretation. Similarly, implicit details, such as the severity of a reported defect, may not be readily apparent without supplementary information [5].

Additionally, there is a lack of annotated datasets specific to road maintenance applications. Developing effective machine learning models often requires large, labelled datasets to train algorithms. In road maintenance, creating such datasets is challenging due to the domain-specific nature of the text and the expertise required to accurately label data. This echoes [7], which raised concerns about the lack of annotated and high-quality data in the Architecture, Engineering, and Construction (AEC) domain.

These challenges underscore the need for innovative methods to efficiently classify, interpret, and utilise textual data in road maintenance.

2.2 NLP as an Opportunity in Road Maintenance

NLP, a field that enabling machines to comprehend natural language, is transformative for extracting insights from unstructured maintenance data like logs and inspection reports. Machine learning models can identify patterns in defect descriptions and prioritise tasks based on urgency. Advanced transformer-based NLP architectures like LLMs excel in handling language's contextual nuances. Khalil et al. [4] highlight the significant advancements of LLMs, such as GPT-3, in reasoning tasks, further enhanced by techniques like "Chain of Thought" prompting. In construction, [8] designed an automated system for construction specification review using NLP techniques such as named entity recognition (NER) with Bi-LSTM and document embedding through Doc2Vec to streamline processes and improve construction risk management. Recognising the difficulty in many AEC applications in collecting sufficient training data, [9] proposed a few-shot NER model for information extraction from bridge inspection texts.

2.3 LLM-Based Text Classification Approaches

LLMs have extensive capabilities in classifying texts due to their ability to accurately encode sentences [10]. They use the transformer architecture [11], a neural network leveraging the attention mechanism [12] to model dependency, to process long inputs at once without loss of information as is the case with recursion in approaches such as Recurrent Neural Network. LLMs utilise pre-trained models that possess task-agnostic knowledge through training on vast amounts of general text, akin to reading a million books. To adapt LLMs for downstream tasks such as text classification, architecture-specific fine-tuning using a task-specific dataset is performed. The following sections elaborate on different architectures and their associated fine-tuning techniques.

2.3.1 Traditionally Fine-tuned Models

The most common LLM-based text classifier, shown in Figure 1, appends a small task-specific classification head to produce class probabilities or logits. It typically consists of an uninitialised fully connected layer with neurons equal to the number of classes. Pre-trained models vary in size: smaller models (100M parameters), often termed Pre-trained Language Models (e.g., *BERT*), and larger models (7B+ parameters), such as *Llama*. For instance, BERT was pre-trained on 800M words from BooksCorpus and 2,500M words from English Wikipedia [13]. In this work, both 100M and 7B models are referred to as LLMs. Fine-tuning adapts the classifier to a specific task by updating pre-trained model parameters and initialising the classification head in a single step, using a cross-entropy loss function on model output logits.

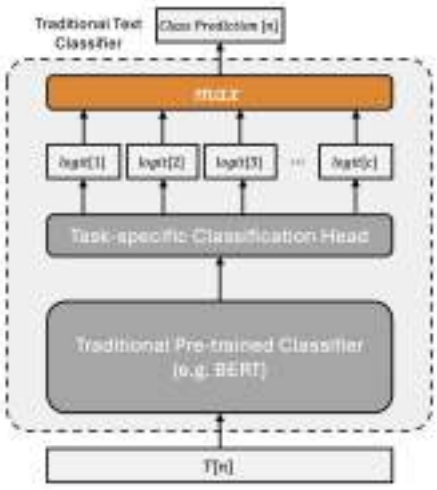

Figure 1. Architecture of a traditional transformer-based text classifier.

2.3.2 Few-shot Learning - SetFit

Few-shot learning refers to adapting models to a task using only a small number of examples (or shots). This is particularly useful for resource-constrained applications where large-scale annotated data is unavailable. A popular transformer-based few-shot learning technique is Sentence

Transformer Fine-Tuning (SetFit) [14].The classifier embeds text using Sentence-BERT (SBERT), a BERT variant pre-trained on pairwise similarity tasks, and adds a lightweight classification head to generate class scores. This setup produces semantically rich embeddings suited for classification.

SetFit is fine-tuned in a two-step process. First, the SBERT encoder is fine-tuned to produce accurate embeddings through contrastive learning by providing a pair of texts and training the model to determine whether they belong to the same class. This is followed by training the entire model (SBERT plus the classification head) to perform the classification task through cross-entropy. The contrastive learning adopted in the embedding training step is what allows SetFit to be data efficient in that it can train the model to explicitly separate the embeddings of texts from different classes.

The literature highlights the potential of NLP and LLMs in extracting insights from road maintenance texts, yet challenges remain due to unstructured data, inconsistency, and limited annotated datasets. While LLMs and few-shot learning methods like SetFit show promise, their application to domain-specific classification and automated maintenance prioritization is underexplored. This study addresses these gaps by evaluating LLM-based classification approaches for structured information extraction.

3 Research Methodology

3.1 Dataset

A public dataset on roadwork inspection comments was used to validate the proposed approach. It is the "Street Construction Inspections and Corrective Action Requests" from the New York City (NYC) Open Data [15], which is a collection of inspection comments on roadwork performed by non-governmental third parties that record instances of road code violations. Examples of inspection comments and their associated violated road code are listed in Table 1. From the dataset, the free text inspection comments come from the "DetailsofViolation" column and the associated violated road codes from "NOVCodeDescription".

The dataset underwent a series of cleaning processes and random subsampling to create few-shot datasets that can simulate data constraints. Figure 2 shows the steps taken to generate the datasets used in this work.

The raw dataset was first cleaned, starting by inspecting for irregularities. It was found that there were road codes that contained duplicate meanings that essentially refer to the same sets of violations. Table 2 outlines such examples that were manually merged. Following this, codes with fewer than 100 examples were excluded to ensure sufficient testing examples for representative conclusions to be drawn. This resulting dataset has a total of 400,000

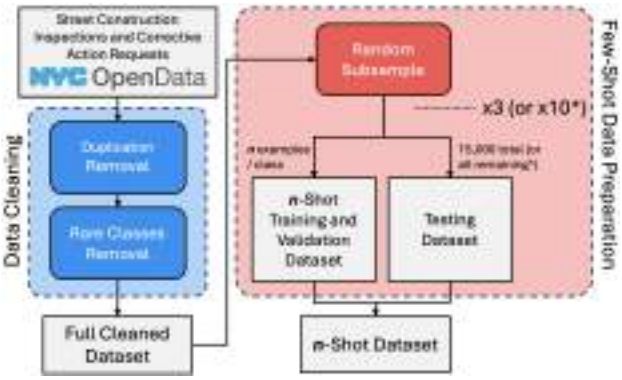

Figure 2. Illustration of the data preparation process for an *n*-shot dataset. (*further experiments with smaller models were performed using more datasets per shot and more testing examples per dataset.)

texts that belong to 83 classes.

The full, cleaned dataset was then randomly subsampled to form few-shot datasets. *Training datasets* were generated by subsampling 1, 2, 3, 4, 5, and 10 examples per class (shots), each shot was subsampled from all available data three times to create three statistically independent draws which helps mitigate the instability that can occur with small training datasets [14]. Each *Training datasets* is coupled with a corresponding *Validation dataset* and *Testing dataset*. *Validation datasets* were subsampled for roughly 1/3 of the shot to maintain the ratio of training to validation data common in standard machine learning datasets (minimum of 1 example per class), while the remaining unsampled data were used as a potential testing pool. For *Testing datasets*, 15,000 examples were subsampled (similar order of magnitude to relevant works [8]) to reduce computational costs, particularly for models with 7 billion parameters.

Note that to assess the impact of these subsampling operations, a further set of experiments were conducted with only smaller 100 million parameters models: First, few-shot scenarios used the full remaining unsampled testing pool (as opposed to 15,000) and ten individual datasets per shot (as opposed to three). Second, an all-data training scenario was introduced using the full dataset with an 8/1/1 split for the training, validation, and testing sets.

3.2 Simulated Task

The task simulated in this case study involves training a transformer-based text classifier using limited data to classify roadwork inspection comments into the violated road code. Each inspection comment records the details of an instance of a code violation, which in this dataset, can belong to one of 83 road codes. The simulated task highlights two key challenges: limited training examples and a large number of classes, reflecting a complex technical text classification scenario.

Table 1. Examples of pairs of free text comments describing instances of code violation (textual inputs) and static code descriptions (class descriptions)

Free Text Inspection Comments	Associated Road Code Violated
A/T/P/O I observed that the respondent has failed to remove the ramping material from the roadway after the completion of the final restoration or prior to the expiration of the permit as per subsection (vii). Respondent was notified to fix this condition via CAR [#20184520373] issued on 12/31/18.	Failure to remove plating and decking after final restoration and prior to DOT permit expiration.
Respondent failed to display required signs at work site with permit number,work type, start date ,completion date.No one on site at time of inspection. If not admitting the charge, you MUST APPEAR IN PERSON.	Identifying signs improperly displayed or missing
A/T/P/O I observed respondent identified by "BIC 3179" markings on Commercial Refuse Container, having a container in the roadway without any visible reflective markings capable of producing illumination or warning glow when struck by vehicle headlamps. No one onsite.	Commercial refuse container without proper reflective markings on all four sides

Table 2. Examples of road codes with duplicating definitions.

Code 1	Code 2	Reason for duplication
Commercial refuse container/debris obstructing sidewalks, gutters, crosswalks or driveway	Commercial refuse container/debris obstructing sidewalks, gutters, crosswalks, bike lanes or driveway	Semantically identical: Code 1 is strictly contained within code 2
Failure to post âSteel Plates Aheadâ or âRaise Plowâ sign; failure to countersink plates flush with roadway	Failure to post “Steel Plates Ahead” or “Raise Plow” sign; failure to countersink plates flush with roadway	Character encoding error: The “â” is a result of a character encoding error originating from the publisher

Limited data refers to training models with a small number of violation examples per road code (number of shots n). Various ns were experimented with to simulate different levels of data constraints. 10 was selected as the maximum, considering that it would amount to 830 total examples with 83 classes, which can already be difficult to replicate in many resource-limited real-world engineering applications. This will provide insight into how well different models perform under different data availabilities.

A unique characteristic of the employed dataset is the large number of classes. Using natural language to infer one of 83 road codes that are being violated can be challenging due to the complexity of the classification task. However, this is a common characteristic in many road maintenance and AEC applications that are tightly regulated and stringent. For example, the dataset used records instances of road code violations which correspond to regulations on roadwork, having an impact on both safety for road users and disruptions caused.

3.3 Models

The two types of transformer-based models outlined in Section 2.3 were experimented with. Traditionally, fine-tuned models represent standard transformer-based text classifiers, which typically require a larger amount of training data to be performant, while SetFit is an example of a technique that specialises in tasks where there is a limited number of training data, like road maintenance.

Traditionally Fine-tuned For traditionally fine-tuned models that were explored in Section 2.3.1, different pre-trained models were experimented with, which have different numbers of parameters. They mostly belong to two groups: those with roughly 100 million parameters and 7 billion parameters. Table 3 lists the pre-trained models used as traditionally fine-tuned text classifiers along with hyperparameters that affect model weights updates and convergence. The 100 million parameters model was the three best-performing models of this size in a comparison study [16], and they can be run on a wider range of hardware (tested with an M1 MacBook Pro with 32GB of unified memory). The 7 billion models are also widely quoted in literature [17][18] and exhibit high performance at the expense of requiring much more computational power, including GPU and VRAM.

Table 3. Pre-trained models used and their associated training hyperparameters (search range in [ ])

Model	Hyperparameters		
	No. params	Learning rate	Batch size
bert-base-uncased	110M	4e-5$_{[1e-6,1e-4]}$	16$_{[4,32]}$
roberta-base	125M	2e-5$_{[1e-6,1e-4]}$	16$_{[4,32]}$
xlnet-base-cased	110M	2e-5$_{[1e-6,1e-4]}$	16$_{[4,32]}$
Llama-2-7b-hf	6.74B	2e-4$_{[1e-3,1e-5]}$	3
Meta-Llama-3-8B	8.03B	2e-4$_{[1e-3,1e-5]}$	3
Mistral-7B-v0.1	7.24B	2e-4$_{[1e-3,1e-5]}$	3

Few-shot Additionally, SetFit, a transformer-based few-shot technique discussed in Section 2.3.2, was also experimented with to evaluate performance improvements in a low-resource workflow brought by dedicated few-shot techniques. The experimental design was modeled after the methodology described in the study by [14], with the 300 million parameter *paraphrase-multilingual-mpnet-base-v2* used as the pre-trained SBERT model and hyperparameters affecting model weights updates and convergence for the two training phases [14] listed in Table 4. SetFit has not been focused on in works relating to classifying AEC texts such as road inspection comments, and

its performance can be validated against more traditional techniques in various data-constrained settings.

Table 4. SetFit training hyperparameters for the two fine-tuning stages [14]. The first value corresponds to the SBERT encoder, and the second to the classification head. During the *Embedding* phase, no classification head is involved (N/A).

Hyperparameters	Fine-tuning	
	Embedding	Classifier
Learning rate	2e-5, N/A	1e-5, 1e-2
Batch size	16, N/A	16, 2
No. epochs	1, N/A	1, 16

3.4 Implementation Details

The models in this study were trained using the Transformers and SetFit libraries on an RTX 4080 (16GB VRAM). Hyperparameters were selected on validation set performance. Training lasted up to 20 epochs with the best model being chosen automatically on validation results.

3.5 Metrics

Accuracy and $f1$ score are the reported metrics in this study and are defined by the following equations:

$$accuracy = \frac{tp + tn}{tp + tn + fp + fn} \quad (1)$$

$$f1 = 2 \times \frac{precision \times recall}{precision + recall} \quad (2)$$

Accuracy values reported are micro-averaged, meaning that it assigns equal importance to each testing example. It is the overall number of correct classifications over all classifications. $f1$ values reported are macro-averaged, where equal importance is assigned to each class, meaning that performances in underrepresented classes in testing examples are taken into account in the overall metric values, which is useful in class imbalanced applications.

4 Results and Discussion

This section outlines the key results. Table 5 lists averaged *accuracy* and $f1$ values of all evaluated models for each few-shot scenario tested, including 100M and 7B traditionally fine-tuned models and SetFit.

4.1 SetFit Outperforms all Traditionally Fine-tuned Models

Classification performance is critical in road maintenance as errors can compromise safety and reliability. For instance, misclassifying "Identifying signs improperly displayed or missing" can lead to possible accidents due to the lack of warning for works. As a classifier specifically designed for resource-constrained settings, SetFit outperformed all traditionally fine-tuned and structured transformer-based classifiers in every few-shot scenario. In a 10-shot setting, SetFit achieved an $f1$ score of 0.539 and an accuracy of almost 70%, while the best traditionally fine-tuned model attained an $f1$ of 0.524 and an accuracy of 66%, respectively. This trend becomes more apparent as the number of shots is reduced. At a 1-shot setting, SetFit outperformed the best performing traditionally-fine-tuned model by more than 3 times in terms of $f1$ score, achieving 0.232 vs 0.074 with just 1 violation example per road code. Figure 3 plots the results of SetFit against three 7B models. Despite utilising 20 times more parameters, the 7B traditionally fine-tuned models were not able to outperform SetFit. This signifies that computationally efficient models can outperform state-of-the-art text classifiers in a resource-constraint domain-specific setting if they are effectively used, such as the case of SetFit. The contrastive learning stage of SetFit allows the text encoder to effectively distinguish between classes, making efficient use of model parameters. This demonstrates that the use of SetFit in a resource constrained setting in road maintenance is more suitable than traditionally fine-tuned techniques.

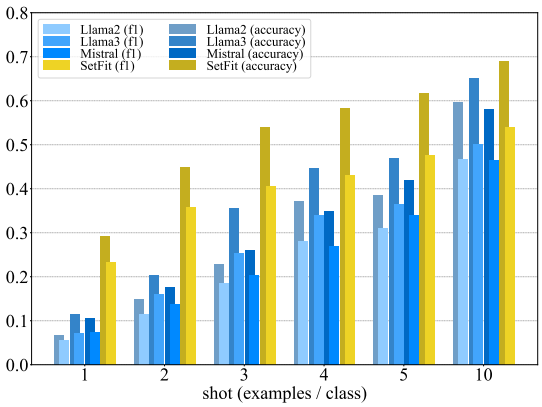

Figure 3. *Accuracy* and $f1$ scores for 7 billion parameter traditional models and SetFit.

4.2 Model Sizes Have Little Impact on Few-Shot Performance

Looking at the results for traditionally fine-tuned models with 100M and 7B parameters, the model's performances do not correlate with size. For instance, by looking at metric values in Table 5, the 100M *bert-base-uncased* model outperformed all 7B models in a 10-shot setting.

This observation indicates that increasing the number of parameters in traditionally fine-tuned models will likely not bridge the gap in performance with SetFit. This can be due to the use of SBERT in SetFit, where the pre-training objective focusing on semantic similarity can potentially better capture the semantics of the inspection comments than the objectives of other models, such as text generation.

Table 5. $F1$ and $accuracy$ results for all tested models. Testing results per shot were calculated with three independent subsampled datasets on a total of 15,000 testing examples.

Shots	Traditionally Fine-Tuned						Few-Shot
	100M			7B			
	BERT	RoBERTa	XLNet	Llama2	Llama3	Mistral	SetFit
	f1 scores						
1	0.031	0.053	0.049	0.056	0.072	0.074	0.232
2	0.107	0.143	0.097	0.114	0.160	0.137	0.357
3	0.195	0.183	0.143	0.186	0.254	0.203	0.405

4.3 Subsampling Testing Data Did Not Impact Observations

Due to the need to generate few-shot samples and to account for computational constraints, the above experiments were performed with subsampling steps. To verify the observations above and to assess the impact these subsampling operations have, further experimentation was performed by using both a higher number of independent datasets per shot (10 up from 3) and by eliminating subsampling for testing data to utilise all available testing examples (up from 15,000). Results for these experiments are listed in Table 6, which includes all 100M traditionally fine-tuned models and SetFit.

Figure 4 visualises the $accuracy$ and $f1$ values for this additional set of experiments. The same observation as the prior sections remains valid in that SetFit outperforms all other traditionally fine-tuned models. Despite having a general shift in metric values from having a different set of samples, the relative performance has remained consistent.

Figure 4. $Accuracy$ and $f1$ scores in different few-shot settings for 100 million parameter traditional models and SetFit.

4.4 Absolute Performance Low in Extremely Constrained Settings

It is important to note that the absolute performance of all models tested remains moderate in few-shot settings. This is especially apparent given model performances when all data are available (~300,000), where all 100M traditionally fine-tuned models achieved $accuracy$ scores of above 95% and $f1$ of around 0.9. When given only 10 examples per class, the best performing model ($bert-base-uncased$) only retained around 60% of its all-data $f1$ score.

In AEC applications like road maintenance, the tolerance for error is low as tasks often require strict adherence to codes and regulations. For instance, the road inspec-

Table 7. Road codes attaining the highest and lowest classwise $f1$ scores for a 10-shot SetFit.

Road Code C	Classwise $f1$
Highest	
Failure to use plating and/or decking that is skid-resistant in its entirety on roadway	0.962
Failure to begin emergency work within 2 hours after authorisation	0.946
Construction material/equipment without proper reflective markings	0.942
Lowest	
Failure to restore in kind any parking or regulatory signs or supports	0.085
Failure to maintain a 5-foot pedestrian walkway on sidewalk	0.076
Failure to obtain permit for temporary roadway pavement markings changes	0.058

tion text classification task in this work involves road codes from roadwork licenses which have important implications for safety and disruption mitigation. By only attaining moderate values in few-shot settings, merely using traditionally fine-tuned models, even state-of-the-art LLMs, is not sufficient. Specialised few-shot techniques appear to be a better choice in resource-constrained settings even in a technical many-class application like road maintenance.

4.5 Classwise Performance Imbalance

There is a wide variation in the performance on each of the 83 classes. Figure 5 shows the histogram of the $f1$ scores for individual classes for a SetFit model trained with 10 examples per road code. There is a relatively high standard deviation across classes of 0.262, considering values are bounded between 0 and 1. Most classes exhibit moderately high $f1$ scores of around 0.75 or more, though a few classes with very low scores of below 0.25.

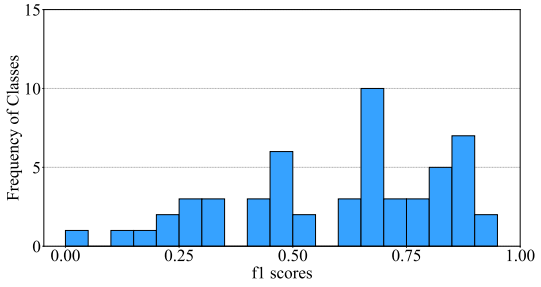

Figure 5. Histogram of $f1$ scores of individual classes for a 10-shot SetFit model.

Table 7 lists the three road codes with the highest and lowest $f1$ scores. The top codes all have high scores of around 0.95, whereas the bottom three have less than 0.1. One potential reason for the latter is that some codes have very specific definitions, such as requiring a "5-foot pedestrian walkway". In addition, there can be potential code duplications, such as the codes *Failure to obtain permit for temporary roadway pavement markings changes* and *Failure to obtain DOT permit for any changes to, or installation of, temporary roadway pavement markings and temporary construction, parking or regulatory signs and supports*, both of which cover very similar violation instances. These can lead to inconsistently annotated data that can both confuse the model during training and lead to a drop in prediction metric values.

To inspect the model's outputs, Table 8 provides examples of the predicted road code P for the inspection comment T with ground truth label L. The first example shows a correct classification where the model inferred that the code *Failure to properly place and ramp plating and decking* relates to examples with ramp elements. However, the second example shows an example of when it fails to infer this relationship for another code, possibly due to the presence of unrelated information from the inspection comments, such as instructions for charge admission.

5 Conclusions

Results indicate that dedicated few-shot techniques can outperform traditionally fine-tuned LLMs when classifying technical road maintenance texts in a resource-constrained setting, in addition to requiring less training data and computational resources than big LLMs with 7B parameters. For example, in 1-shot, the few-shot model SetFit outperformed the traditionally fine-tuned *Llama3* by three times in $f1$. In particular, SBERT used in SetFit appears to be a better pre-trained model choice than many larger models not pre-trained on similarity-based tasks.

However, an unresolved issue of few-shot techniques is that absolute performance is still moderate. With one example per class, the $accuracy$ is only 29%, though that increases to 69% with ten. In road maintenance and many tightly regulated AEC applications where reliability is crucial, this can impact their practicality. For instance, in this study on classifying inspection comments into roadwork licensing codes, there are important safety and disruption implications and necessitate high reliability. This prompts the need to explore alternative, specialised techniques that can tackle the domain-specific nature of the task in a more accurate and data-efficient manner.

Automated Extraction of Structural Elements and Section Views from Bridge Drawings Using Deep Learning

Hakan Bayer[1] **and Markus König**[1]

[1]Chair of Computing in Engineering, Ruhr University Bochum, Bochum, Germany

hakan.bayer@ruhr-uni-bochum.de, koenig@inf.bi.rub.de

Abstract -

Technical drawings are essential for managing and maintaining existing bridges, especially in creating accurate digital models and integrating them into Building Information Modeling (BIM) workflows. However, digitizing older bridges, which often lack BIM models is challenging due to the time-consuming and error-prone process of manual data extraction from 2D drawings. Therefore, this study focuses on detecting key structural components, such as anchors, tendons, and section views, which are critical for structural analysis, maintenance, and retrofitting. Using state-of-the-art object detection models, YOLOv8 and YOLOv11, the proposed pipeline achieves a mean average precision (mAP) of 97.4% for anchors, 95.7% for tendons, and 63.9% for section views. Optical Character Recognition (OCR) tool Pytesseract further enhances the process by accurately extracting IDs for anchors and tendons with 90% precision. Combining object detection with precise text extraction simplifies the creation of high-quality digital bridge models and improves BIM integration. Specifically, the extracted data provides semantic information on key structural components. This information can facilitate the process of creating a digital model and integrating it into BIM workflows.

1 Introduction

Bridges are a crucial component of transportation infrastructure that enables the transportation of people and goods. Maintaining their functionality and ensuring safe operations requires routine inspections and effective maintenance management. Digital tools like Building Information Modelling (BIM) can enhance maintenance planning efficiency. BIM is a collaborative digital methodology that involves creating and sharing interdisciplinary digital models of structures [1]. These models contain semantic and geometric information, sharing the state of the project in real time.

Among all phases of a project's life cycle, the operations and maintenance (O&M) phase presents significant opportunities for BIM application [2]. A key challenge however lies in the limited availability of accurate digital building models for existing structures [3]. In many cases, this is because the old constructions were designed and constructed without the implementation of BIM. Consequently, it is necessary to develop these models in retrospect.

The digitization of existing high-rise buildings and infrastructure is particularly difficult, requiring the expertise of architects and engineers to reconstruct geometric and semantic information from various sources such as point clouds, images, and construction drawings [4]. While point clouds and images are valuable resources, they often rely on costly equipment and fail to reveal internal structural details. In contrast, construction drawings offer a more accessible and practical alternative, especially for older bridges where they are often the only available source of information. As a result, construction drawings are frequently the preferred choice for creating digital building models.

Extracting key information from bridge construction drawings, including section views, structural elements, and their identifiers, is a crucial initial step in developing accurate digital models. These drawings often feature critical internal components like anchors, tendons, and section views, which are essential for understanding bridges' structural integrity and functionality. Anchors for instance are vital elements in prestressed concrete bridges used to secure tendons and transfer tensile forces to the surrounding concrete. Tendons act as reinforcement ensuring the bridge can handle heavy loads and maintain stability. On the other hand, section views offer detailed representations of inner components enabling engineers to understand their precise placement and spatial relationships within the bridge structure.

This research focuses on automating the extraction of these critical components, including section views, anchors, tendons, and their identifiers from CAD based bridge technical drawings to support the development of accurate digital models. Using state-of-the-art deep learning frameworks, such as YOLOv8 [5] and YOLOv11 [6] in combination with OCR tools like PyTesseract [7], the proposed method achieves precise detection of these components and extracts relevant semantic information. This output data facilitates the creation of digital bridge models, enabling better integration into BIM workflows hence supporting more efficient bridge maintenance and management.

2 Related Work

In deep learning and computer vision, significant attention has been given to reconstructing high-rise building models from technical drawings, with a primary focus on detecting and reconstructing external elements such as walls, rooms, and openings [8]. For instance, [8] utilized ResNet to identify walls in floor plans, while [9] leveraged conditional GANs (cGANs) to generate heat maps and vectorized representations of building layouts. These approaches have proven effective for creating digital building models from architectural drawings.

However, the digitization of technical drawings, particularly for infrastructures such as bridges has received limited attention in research [10]. Although some studies are exploring semi-automated analysis of such drawings, the field remains underdeveloped. [11] proposed a semi-automated process employing the Douglas-Peucker algorithm to detect corner points of illustrated components. These corner points are then used to reconstruct the external geometry of the components, which ultimately generates the structural outline of the bridge. [12] introduced a different semi-automated framework that converts drawings into vector-based formats. This process aligns the extracted views and uses the gathered data to reconstruct the geometry of the bridge. The resulting digital model is then exported in the IFC (Industry Foundation Classes) format for further use.

More recently, deep learning-based approaches have been explored in this domain. [13] presented a pipeline using YOLOv5 and the CRAFT text detector to identify individual components and labels on technical drawings. The detected objects were clustered based on their labels to account for multiple views, with experts manually reviewing the clustered data to create bridge models. Similarly, [14] employed Faster R-CNN to detect section symbols and applied OCR to extract view titles, linking symbols to their corresponding views and establishing interconnections across drawing sets. [15] utilized YOLOv5 for gradient symbol detection and integrated EasyOCR for text extraction, automating the process of extracting bridge gradients from construction drawings. Additionally, the study by [16] introduced a computer vision-based process for generating bridge superstructure models from pixel-based construction drawings. Their approach leverages Keypoint R-CNN for symbol pose estimation, enabling the spatial organization of drawing views and facilitating the development of accurate digital bridge models.

Despite these advancements, no study to date has addressed the automated extraction of inner structural components of bridges, such as anchors, tendons, and section views, from pixel-based technical drawings. This study fills this gap by employing YOLOv8 [5] and YOLOv11 [6] to detect these critical components and PyTesseract [7] to extract their associated IDs. These advancements enable the digitization of bridge inner structures and facilitate the creation of digital models for integration into BIM workflows.

3 Methodology

This study presents a semi-automated pipeline for detecting anchors, tendons, and section views in CAD based 2D bridge technical drawings, as well as extracting associated IDs for anchors and tendons. The methodology integrates classical computer vision techniques, deep learning-based object detection, and OCR for text recognition. The workflow, as illustrated in Figure 1, consists of three main stages: (1) Object Detection, (2) Shape Detection, and (3) Text Extraction.

As shown in Figure 1, the pipeline begins with a pixel-based bridge drawing input, which contains cross-sectional representations of internal structural components such as anchors, tendons, and section views. The first stage involves object detection, where elements such as anchors, tendons, and section views are detected using an object detection model. In the second stage, shape detection was performed using OpenCV to locate ID boxes by detecting rectangular regions related to anchor and tendon elements. Finally, the text extraction stage employs OCR to extract the ID numbers from the identified rectangle regions. The pipeline outputs the detected section views, anchors, tendons, and associated IDs, enabling efficient process and analysis of bridge drawings.

3.1 Dataset Creation and Annotation

Due to the limited availability of real bridge technical drawings, a combination of real and synthetic data was used to create the dataset. The original dataset comprised 62 internal structural drawings of bridges from Germany. These drawings were divided into sections, resulting in 71 images. Of these, 42 images were designated for training and validation, while 29 were set aside for testing the pipeline. The 42 training-validation images were particularly large, with an average width of 11,290 pixels and an average height of 7,744 pixels.

Since the 42 training-validation images were insufficient for effective model training, synthetic data was generated by overlaying cropped symbols (anchors, tendons, and section views) onto real construction drawing backgrounds that did not initially contain these symbols using copy-paste method. This approach ensured a diverse and robust dataset for training and validation.

The train validation dataset consists of three primary components: anchor element dataset, tendon element dataset, and section view dataset. The anchor element dataset includes two classes: longitudinal anchor sections

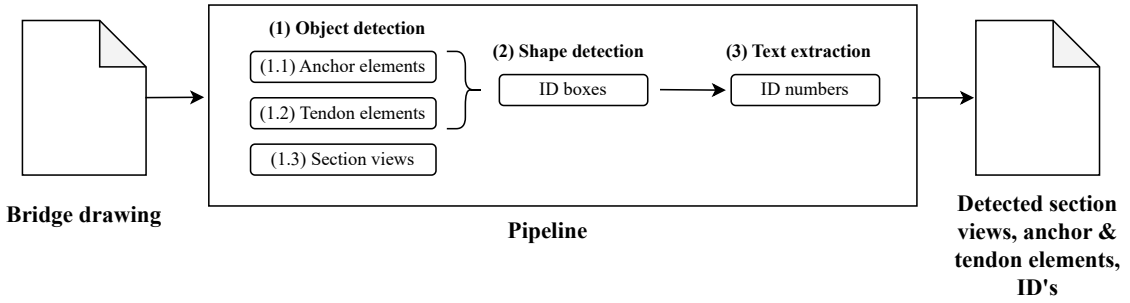

Figure 1. Workflow diagram illustrating the detection of anchors, tendons, and section views in bridge drawings, along with the extraction of associated IDs.

and front anchor sections. Similarly, the tendon dataset contains only one class which is front tendon sections. The section views dataset contains four types of classes: longitudinal section view, front sectional view of the final anchor point, cross-section view, and longitudinal section view of the final anchor point. Some example annotated objects of the dataset classes are shown in Fig. 2. These annotations capture the variability and complexity of the internal structural drawings.

3.1.1 Anchor Dataset

From the real training-validation dataset, 204 longitudinal anchor symbols and 74 front anchor symbols were selected and cropped out. The longitudinal anchor symbols had an average width of 292 pixels and an average height of 163 pixels, while the front anchor symbols had an average width of 93 pixels and an average height of 95 pixels. These symbols were randomly rotated (0°, 90°, -90°) and overlaid onto real construction drawing backgrounds to create synthetic images. This process generated 500 synthetic labeled images, which were automatically annotated in YOLO bounding box format. This dataset was then combined with the 42 annotated real bridge drawings, which created final anchor dataset of 542 images. The dataset was then split into 80% training and 20% validation sets.

3.1.2 Tendon Dataset

The tendon dataset was created using 53 tendon front sectional views extracted from the real training-validation dataset. These tendon elements had an average width of 41 and height of 41 pixels. These cropped symbols were randomly positioned on real construction drawing backgrounds, and their locations and dimensions were automatically labeled in YOLO bounding box format. Similar to the anchor dataset, this process generated 500 synthetic labeled images, resulting in a final tendon dataset of 542 images, which was also split into 80% training and 20% validation sets.

3.1.3 Section View Dataset

The section view dataset includes four types of classes: longitudinal section view, front section view of the final anchor point, cross-section view , and longitudinal section view of the final anchor point. The longitudinal section view depicts the internal arrangement of the entire bridge along its length, while the front section view of the final anchor point focuses on the final anchor point and its components from a frontal perspective. Cross-section view shows vertical cuts along the bridge's width, highlighting structural details, and longitudinal section view of the final anchor point provides a longitudinal perspective of the anchor components. The section views are pixel wise relatively large compared to tendon and anchor elements. Due to their complexity, size, and variability, huge number of synthetic data was generated compared to the other datasets. CAD files of the training and validation set were used to generate additional data by modifying attributes such as size, perspective, and surrounding text. Also a copy-paste method similar to that used for the anchor and tendon datasets was employed. In total, 1,842 images were generated including 42 annotated real bridge drawings. All images were automatically labeled using the YOLO bounding box format. Then the final dataset was divided into 80% training and 20% validation sets.

3.2 Object Detection

The detection pipeline utilizes multiple YOLO architectures, YOLOv8 [5] and YOLOv11 [6], trained on separately annotated datasets for anchor elements, tendon elements, and section views. Each dataset was trained on models of varying scales, such as medium and large configurations. The inference image size was chosen to match the respective training image size to maximize accuracy.

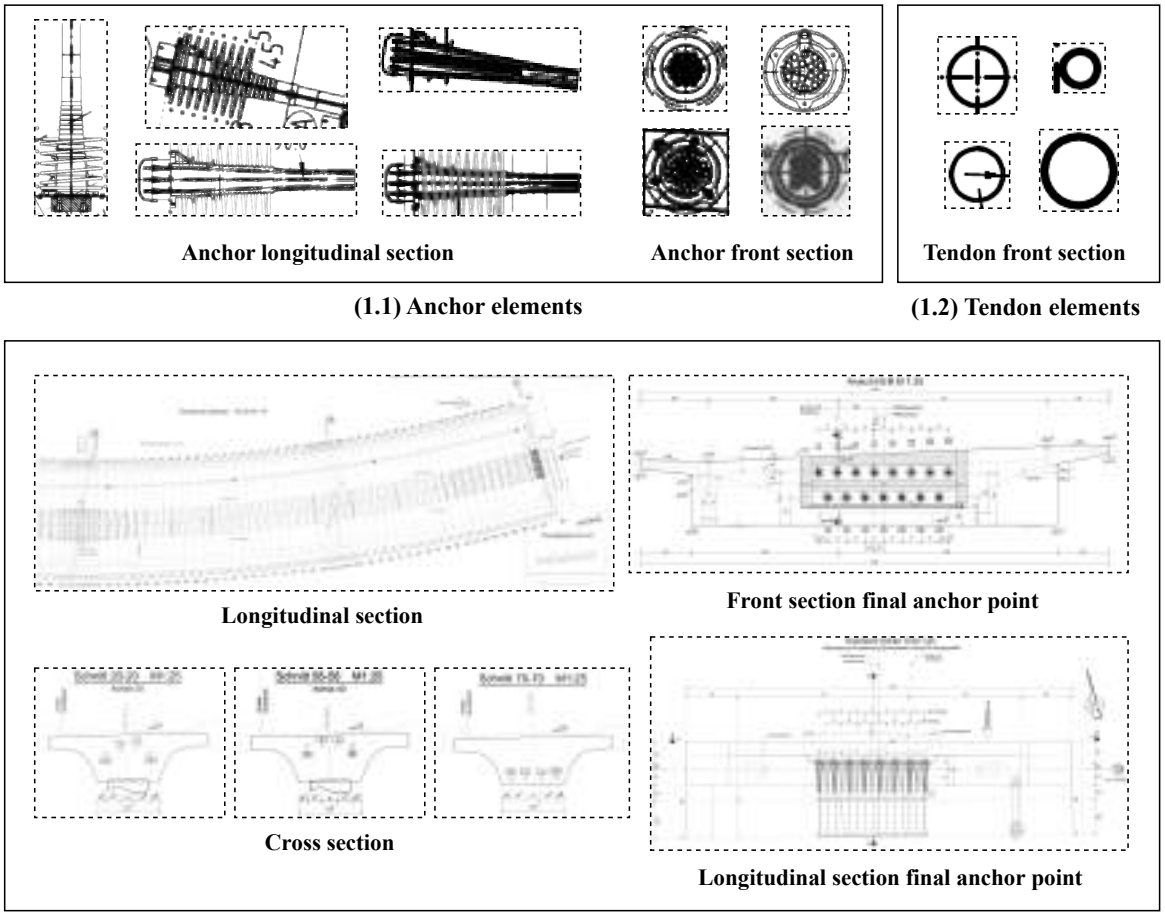

Figure 2. Examples of annotations from the dataset, highlighting anchor elements (1.1) and tendon elements (1.2), along with 4 different section views (1.3). These include longitudinal section views, cross-sections, front section views of the final anchor point, and longitudinal section views of the final anchor point. These annotations are crucial for training object detection models and generating synthetic data.

After training, the best models were integrated into the detection pipeline to accurately detect objects.

3.3 Shape Detection

The shape detection stage focuses on identifying rectangular regions in the drawings that likely contain IDs associated with anchors and tendons. This is achieved using classical computer vision techniques implemented with OpenCV. The process starts by converting the input images to grayscale, followed by applying Gaussian blur to reduce noise and enhance edge details. Adaptive thresholding is then applied to create a binary image, which simplifies edge detection.

Contours are extracted from the binary image to detect potential rectangular shapes. These shapes are filtered based on specific criteria, such as their area and aspect ratio, to isolate valid ID boxes. During this stage, we assume that IDs are enclosed within rectangular shapes based on the standard drawing conventions of a specific drawing format. It is important to note that some firms may use different drawing conventions, such as enclosing IDs within circular or elliptical shapes. Our pipeline, however, is made to function with rectangular ID boxes following the conventional norms utilized in these particular drawings for accuracy and consistency.

3.4 Text Extraction

The text extraction stage employs PyTesseract to extract textual identifiers from the ID boxes identified during the shape detection process. To enhance the precision of text recognition, the images are preprocessed prior to applying OCR. This preprocessing involves converting images to grayscale and using adaptive thresholding to improve contrast and text clarity within the ID boxes. To prevent errors caused by extracting text from unrelated elements in the drawings, the OCR process is restricted to a predefined character set that includes numbers, letters, hyphens, slashes, and periods. This restriction ensures that only valid identifier formats are captured, minimizing the inclusion of irrelevant or incorrect text. Once the text is extracted, it is mapped to the corresponding tendon or anchor elements based on the spatial relationship between the detected text and ID boxes. As section views do not include associated identifiers, text extraction is performed exclusively for tendon and anchor elements.

4 Training and Results

4.1 Training Process

The training process utilized eight NVIDIA A100 GPUs. The datasets for anchors, tendons, and section views were trained independently due to their unique characteristics, varying object sizes, and complexities. To evaluate detection performance, input image sizes were adjusted based on the relative scale and complexity of the objects in each dataset.

Both YOLOv8 [5] and YOLOv11 [6] models were trained for 100 epochs on each dataset, using two different image resolutions to compare the impact of varying sizes on model performance. Additionally, two model configurations, medium and large, were employed. Higher resolutions were used for the tendon and anchor datasets, as these objects are relatively small compared to the overall size of the drawings. In contrast, moderate resolutions were applied to the section view dataset, which contains larger objects. Specifically, the tendon dataset was trained with image sizes of 3200 and 3600 pixels, the anchor dataset with 2560 and 3200 pixels, and the section view dataset with 640 and 1280 pixels.

This setup allowed the models to effectively capture the distinct features of each dataset, enabling robust detection performance and ensuring adaptability to the diverse complexities of technical bridge drawings.

4.2 Object Detection Results

The performance of the YOLOv8 and YOLOv11 models was evaluated across three datasets: section view, anchor, and tendon, using a testing set of 29 unseen images. Evaluation metrics included Precision (P), Recall (R), and mean Average Precision at 50% IoU threshold (mAP50). Table 1 summarizes the results for each dataset and model configuration.

For the anchor dataset, the YOLOv11 large model achieved an impressive overall mAP50 of 0.974, with a Precision of 0.917 and a Recall of 0.970. Among the specific classes, the Anchor front section class achieved the highest mAP50 of 0.994, demonstrating near-perfect detection accuracy. The Anchor longitudinal section class also showed strong performance, with a mAP50 of 0.954.

In the tendon dataset, the YOLOv11 large model delivered a mAP50 of 0.957, with a Precision of 0.914 and a Recall of 0.952. The use of high-resolution images during training and testing allowed the model to effectively capture and detect the fine-grained details of small and elongated objects like tendons.

For the section view dataset, the YOLOv11 large model achieved an overall mAP50 of 0.639, with a Precision of 0.712 and a Recall of 0.623. However, performance varied significantly across individual classes. The Cross-section class achieved the highest mAP50 of 0.858, demonstrating robust detection capabilities. In contrast, the Longitudinal section and Longitudinal section final anchor point classes showed lower mAP50 values of 0.436 and 0.565, respectively. The Front section final anchor point class achieved a moderate mAP50 of 0.697. The lower performance in section view detection can be explained due to the high variability in section drawings and limited real dataset samples. Unlike anchors and tendons, section views differ significantly across drawings making object detection more challenging.

Overall, the YOLOv11 large model consistently outperformed YOLOv8 across all datasets, demonstrating superior accuracy and robustness in handling diverse object detection tasks. The results also highlight the importance of using appropriately high-resolution images during training and testing particularly for datasets with smaller objects as it significantly enhances detection performance.

4.3 Overall Pipeline Results

The proposed pipeline demonstrates strong performance in detecting section views, anchor and tendon symbols, and extracting IDs even when faced with challenges such as rotation, scale differences, and partial visibility. Testing on 29 real images showed that the pipeline reliably identified anchors, tendons, and section views, achieving high object detection accuracy. However, text extraction faced some issues, particularly when shapes were rotated, making it harder to identify IDs. As outlined in the *Shape Detection* section, the pipeline's shape detection relies on drawings adhering to standard conventions such as rectangular ID boxes commonly used by a specific firm. Based

Table 1. Object Detection Results of YOLOv8 and YOLOv11 Models on Test Dataset (29 Images) for Section View, Anchor, and Tendon Datasets with Different Image Sizes. Metrics include Precision (P), Recall (R), and mAP50. The table provides the average performance across all object classes within each dataset, offering an overall assessment of detection accuracy. Bold fonts indicate the best results for each metric.

on this assumption the text detection accuracy was calculated by determining the percentage of correctly recognized parameters relative to the total number of parameters present. The pipeline achieved 90% accuracy in text extraction, demonstrating its ability to extract IDs in most cases. However, performance was hindered by rotated text boxes and slight variations in font styles and sizes. Future refinements could include pre-processing techniques like rotation correction and fine-tuning the model for the dataset to enhance recognition accuracy.

An example of the pipeline's performance is illustrated in Fig. 3, where it successfully detects objects and extracts text from real test drawings. These results highlight the pipeline's ability to support the automatization process of digitization of technical drawings and extract critical information, making it a valuable tool for further applications in bridge modeling.

5 Discussion and Conclusion

This study presents a semi-automated pipeline for extracting structural components and their identifiers from bridge technical drawings, addressing the challenges of digitizing older structures. By integrating deep learning-based object detection models, YOLOv8 and YOLOv11, with the optical character recognition tool PyTesseract, the pipeline achieves high accuracy in identifying and extracting critical elements and their associated information.

The YOLOv11 large models demonstrated the best performance, achieving mAP50 scores of 0.974 for anchor elements and 0.957 for tendon elements. Detection of section views showed moderate success, with an mAP50 of 0.639. Text extraction using PyTesseract achieved 90% accuracy. However, the pipeline was tested on a limited number of drawings following specific rectangular ID standards, which restricts its generalizability. This limitation highlights the need to generalize the approach for broader applicability. Additionally, the assumption of rectangular ID boxes restricts generalizability to other formats such as circular or elliptical IDs. Furthermore, OCR struggles with rotated or noisy text which could be improved with advanced preprocessing techniques.

Despite these achievements, challenges remain particularly in text recognition and adapting the pipeline to diverse drawing standards. Future research could focus on fine-tuning the OCR model for bridge drawings, expanding shape detection to accommodate circular or elliptical ID boxes, and increasing the range of synthetic training datasets. Exploring alternative detection models may also enhance performance, especially for complex components like section views.

Overall, this study presents a solution for automating the digitization of bridge technical drawings. The extracted section views and elements, along with their IDs, can serve as structured inputs for BIM software enabling efficient reconstruction. The proposed method streamlines the creation of accurate digital models and facilitates their integration into BIM workflows.

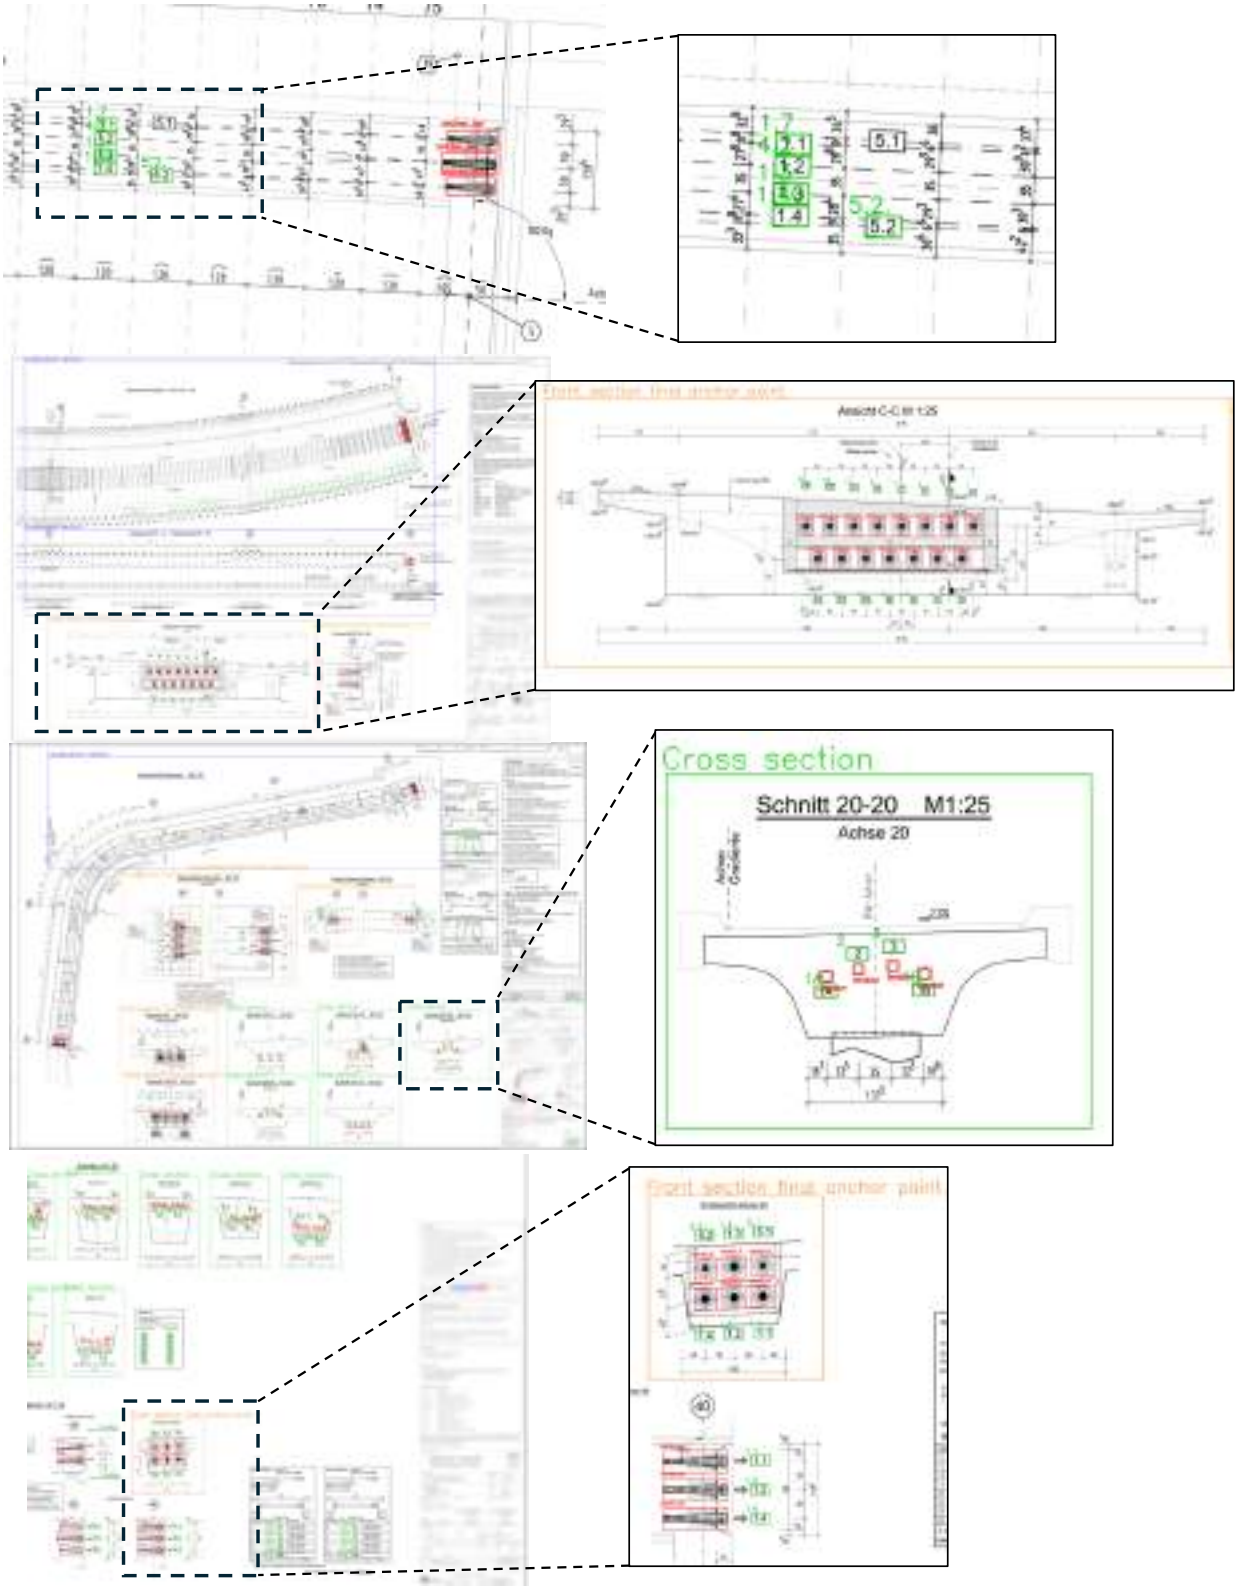

Figure 3. Demonstration of the pipeline's performance on a real test dataset using the best-performing models with the highest mAP50 values. The figure showcases the accurate detection of section views (e.g., cross sections, front section final anchor points), identification of symbols, and precise extraction of their associated IDs. Enlarged views highlight specific areas of successful object detection and ID extraction, underscoring the pipeline's effectiveness in processing complex engineering drawings.

Abstract -

Building Information Modeling (BIM) has significantly advanced design efficiency and collaboration in the architecture, engineering, and construction (AEC) industry. However, current BIM workflows remain hindered by complex interfaces, repetitive tasks, and limited automation options, which result in a steep learning curve and labor-intensive design processes. To address the challenges, this research presents a proof-of-concept framework that explores the integration of Artificial Intelligence (AI) and Large Language Models (LLMs) with BIM environments to streamline design modifications through natural language interaction. Using a specialized FreeCAD integration layer, the framework demonstrates the feasibility of translating high-level user instructions into basic BIM operations. Initial testing shows this approach can successfully create simple parametric building elements while reducing token consumption and user effort compared to a baseline approach using generic tools. This feasibility study suggests potential for developing more intuitive BIM interfaces, though further research is needed to achieve robust domain knowledge integration and handle complex architectural relationships. The findings indicate promising directions for future development of LLM-driven BIM automation tools that could enhance accessibility for AEC professionals.

BIM Design Automation; Natural Language Processing; Computer-Aided Design; Human-Computer Interaction

1 Introduction

Building Information Modeling (BIM) has revolutionized the architecture, engineering, and construction (AEC) industry by providing comprehensive digital representations of the physical and functional characteristics of buildings [1]. Although BIM platforms have significantly improved design efficiency and collaboration, practitioners still face challenges such as complex interfaces, repetitive tasks, and redundant manual operations, which increases the need for automated workflows [2]. However, current BIM workflows lack user interaction and accessibility to automation. Traditional approaches to BIM interaction lack intuitive interfaces for design modifications and automation capabilities, leading to reduced efficiency and increased risk of errors during the design process [3].

Recent advances in Artificial Intelligence (AI) and Large Language Models(LLMs) have shown promising capabilities to understand natural language commands and execute complex computer operations [4]. The remarkable progress in AI has enabled architects to harness computational power and data-driven algorithms to generate and assess design options [5]. AI technologies in the design process have enabled architects to explore innovative and eco-friendly design solutions. Similarly, construction industry professionals have witnessed the evolution of digital data acquisition technologies, which have enhanced monitoring processes by delivering efficient and effective results [3]. Moreover, AI's ability to evaluate enormous volumes of data, including building performance, environmental conditions, and user preferences, enables architects to create structures that are not only visually appealing but also ecologically friendly, energy-efficient, and suited to specific user needs [2].

Current approaches to BIM automation mainly rely on visual programming tools such as Dynamo for Revit or scripting languages such as Python with IFCOpenShell [6]. Although these methods have proven to be effective, they require users to have programming knowledge or understand visual programming concepts, which creates a significant barrier for many AEC professionals [2]. Furthermore, existing automation solutions often lack the flexibility to adapt to varying user needs and project requirements, particularly when handling complex visual and spatial tasks [7]. The integration of AI in the design workflow can create a collaborative and symbiotic relationship between human designers and AI technology, where AI operates as a creative partner, increasing the architect's expertise and vision by offering design options and innovative ideas [5].

Natural language-based BIM modeling offers key advantages over traditional methods: reduced cognitive load when navigating complex interfaces, faster prototyping

by translating concepts directly to visual models, improved accessibility for AEC professionals with varied technical expertise, contextual design assistance through embedded standards, and enhanced collaboration through conversation-like interactions.

This research aims to enable natural language-driven BIM operations for architects and AEC professionals without requiring programming knowledge. We developed a proof-of-concept framework integrating AI and LLMs with BIM software operations. The prototype implements parameter-based modeling within FreeCAD [8], leveraging anthropic-defined computer use API and BIM-specific prompts.

Initial testing shows promising results. Compared to baseline systems, our prototype improved efficiency with reduced token usage and better parameter handling while avoiding GUI-based trial-and-error approaches. These results suggest LLM-driven BIM automation could provide more accessible tools for AEC professionals. This research validates that LLM-driven BIM automation can overcome traditional usability barriers, offering a foundation for future BIM-oriented AI developments as the AEC industry continues to digitalize.

2 Literature Review

The AEC industry is undergoing a major transformation, shifting from traditional and labor-intensive methods to automation driven by information technology, with BIM as a key factor in this change [9]. BIM is a technology-based method that applies and maintains a complete digital representation of building information throughout a project life cycle [10]. The process begins with conceptual design, progresses through functionality and construction details, and culminates in fabrication drawings, with analysis tools for energy efficiency, construction, and acoustics supporting design decisions [11].

BIM offers numerous practical benefits including visualization, code compliance checks, cost estimation, scheduling, clash detection, and forensic analysis [12]. However, adoption faces challenges related to high costs, training time, unclear data ownership, lack of standardization, and software compatibility issues [13]. Bridging the gap between advanced BIM technologies and their practical application remains important [10].

Industry 4.0 advancements have influenced the construction sector, leading to "Construction 4.0" with its emphasis on digital data, automation, connectivity, and digital access [14]. Automation in construction improves efficiency with repetitive tasks, reduces expenses, enhances quality, and improves coordination [15]. In BIM specifically, automation tools like Dynamo enable custom scripts for repetitive tasks [16], while IFC ensures data exchange between platforms [17]. Such automation supports real-time clash detection before construction [18].

AI has emerged as a promising solution for automation in the AEC sector, making notable improvements in operations, safety, and productivity [19]. AI transforms architecture through generative platforms that create visuals from text prompts, making design processes more efficient. Generative algorithms allow architects to explore multiple design options considering site conditions and structural requirements [20], while also improving space planning [21] and sustainability through data-driven decision making [22].

Recently, researchers have explored human-AI collaboration in design, with Lee et al. [23] integrating LLMs with BIM for speech applications and Dai et al. [24] introducing semantic AI into architectural design. However, practical integration of AI tools into BIM-enabled projects remains limited. Interoperability and data transfer challenges between AI systems and BIM platforms pose significant barriers. More proof-of-concept testing is needed to bridge the gap between innovative AI solutions and their practical application in BIM workflows [25].

3 Methodology

This research integrates LLMs with BIM environments using direct computer control and custom tool integrations. By leveraging the anthropic-defined computer use API and FreeCAD as the BIM platform, this approach enables natural language-driven BIM operations without requiring programming knowledge.

Research Approach and Environment Setup The study employs a controlled case evaluation focusing on key representative BIM operations. The experimental environment runs in a Linux-based virtual machine with Docker containerization, ensuring reproducibility and isolation. FreeCAD serves as the primary BIM software, chosen for its robust Python API and scriptability. The system uses the Anthropic API(Claude) [26] to handle human-LLM-BIM interaction loops.

Tool Integration and Execution Flow The methodology uses a modular tool collection: ComputerTool for UI control, BashTool for system commands, EditTool for file operations, and FreeCADTool for BIM-specific operations. The LLM orchestrates these tools through a "sampling loop" process, translating natural language into structured commands. The system validates outputs through iterative interactions, ensuring creation of geometrically correct walls with precise dimensions, proper spatial relationships between elements, accurate parameter assignments, and verification of element connectivity.

Parameterization and Prompt Optimization The methodology incorporates iterative prompt optimization with domain knowledge and context-specific guidelines.

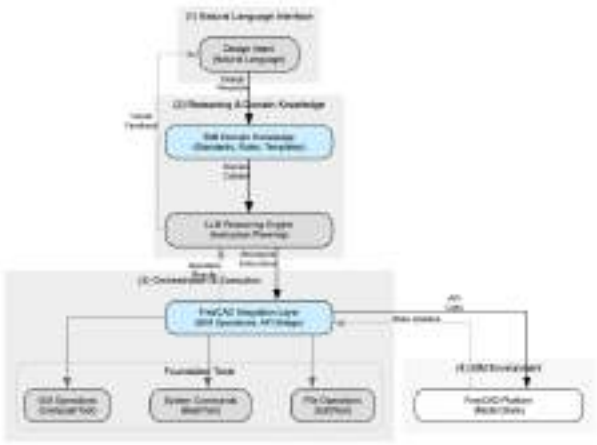

Figure 1. Framework architecture showing the hierarchical organization of components. The system flows from top to bottom: starting with the Architect's natural language instructions, through the BIM Knowledge and Prompt Layer, to the LLM (Claude), then to the FreeCAD Tool orchestrator, supported by base tools (ComputerTool, BashTool, EditTool), and finally to the FreeCAD Environment where modifications are realized.

This layered approach combines system prompts with specialized instructions for BIM tasks, enabling accurate interpretation of spatial information and parameter validation.

Evaluation Metrics and Validation The study compares baseline and enhanced frameworks using metrics including task completion success, resource efficiency (tokens, API calls, processing time), parameter accuracy, and visual verification. A rectangular room creation task serves as the benchmark for framework feasibility assessment.

4 Framework Design

The proposed framework implements a top-down hierarchy that transforms the intentions of natural language design of the architect into tangible BIM modifications within FreeCAD. As illustrated in Figure 2, the prompt structure and BIM knowledge form a conceptual foundation that guides the LLM (Claude) in understanding and interpreting the user request. These prompts encapsulate domain rules, measurement handling, and quality control, ensuring that the LLM reasons about BIM tasks in a way that is contextually rich and technically correct.

Building on this conceptual layer, the architectural diagram shown in Figure 1 represents the system as a vertical sequence of layers. At the top, the architect issues design instructions in plain language. These instructions flow downward through layers of reasoning, domain-specific BIM knowledge, and an orchestration tool (FreeCADTool). Ultimately, this cascade of logic and commands reaches the FreeCAD environment, where the requested modifications (e.g., creating a wall, inserting a window) materialize.

This hierarchical design simplifies complexity: each layer focuses on its core responsibilities. The LLM interprets intent and plans operations, the FreeCADTool orchestrates BIM-related commands, and the base tools perform low-level tasks such as GUI manipulation or file edits. By carefully layering the system in this manner, the framework allows nontechnical users to harness sophisticated BIM operations without directly dealing with scripting or intricate APIs.

4.1 Base Architecture from Claude and Tool Collection Framework

The initial foundation of this system comes from a Claude-based computer use platform equipped with a collection of core tools.

- **ComputerTool:** Handles GUI interactions within the virtual environment (e.g., mouse clicks, keystrokes).
- **BashTool:** Executes shell-level commands to manage environment states or run auxiliary programs.
- **EditTool:** Provides the ability to modify files dynamically, such as generating or adjusting Python scripts on-the-fly.

These tools, originally developed for generic computer interactions, form the base layer of the system (see lower half of Figure 1). On their own, they lack the contextual understanding needed for BIM-specific tasks. To address this, a BIM-oriented layer is introduced above them.

In this enhanced structure, the LLM uses the BIM knowledge and context templates (as summarized in the prompt mind map) to reason about the user's request. Then, it relies on FreeCADTool to translate these high-level, BIM-specific instructions into precise commands. When necessary, FreeCADTool invokes the base tools to perform GUI actions, execute scripts, or handle system configurations. This vertical chain, Architect $\rightarrow$ LLM $\rightarrow$ FreeCADTool $\rightarrow$ Base Tools $\rightarrow$ FreeCAD Environment, ensures a clean and logical flow from human intent to model modification. To illustrate this vertical chain with a concrete example, consider the user request: 'Create a wall that is 5 meters long, 3 meters high, and 200mm thick.' This natural language instruction flows through the system as follows:

- The Architect's design intent ('Create a wall...') enters the system at the Natural Language Interface layer.
- In the Reasoning & Domain Knowledge layer:
  - The BIM Knowledge component interprets measurements (5m length, 3m height, 200mm

Figure 2. Mind map visualization of the structured prompt categories and BIM knowledge guiding the LLM. The map illustrates the interconnections between system capabilities, BIM knowledge, quality control, and context templates, providing a rich semantic landscape for interpreting user requests.

thickness) and recognizes 'wall' as a standard BIM element with specific properties.

  - The LLM Reasoning Engine generates a structured plan: 'Create a baseline, extrude to height, apply thickness parameter, and verify orientation.'

- In the Orchestration & Execution layer:
  - The FreeCAD Integration Layer translates the plan into specific API calls:
    ```
    line = Draft.makeLine(FreeCAD.Vector(0,0,0),
    FreeCAD.Vector(5000,0,0))
    wall = Arch.makeWall(line, height=3000,
    width=200)
    ```
  - The system leverages foundation tools like ComputerTool for console input, BashTool for screenshots, and EditTool for file operations.
- In the BIM Environment layer, FreeCAD executes the commands, creating the wall object with proper parameters, updating the model state, and returning visual feedback.

This bidirectional flow allows for iterative refinement, where the LLM can verify outcomes against the original intent, make corrections if needed, and provide explanatory feedback to the user.

4.2 Incorporation of BIM Layer and Prompt Refinements

The key innovation that enables this natural language-driven BIM interaction is the incorporation of a BIM layer through FreeCADTool. This component understands FreeCAD's Python API and the semantics of BIM elements, such as walls, windows, and their associated parameters (dimensions, alignments, placement).

To support this BIM reasoning, the prompt system is refined to include:

- **Domain Knowledge Blocks:** Codified standards and best practices that inform the LLM about typical construction dimensions, unit conversions, and spatial reasoning.
- **Context-Specific Templates:** Ready-made patterns for tasks like wall or window creation, making it straightforward for the LLM to map user instructions to actionable steps.
- **Quality and Error Handling Guidelines:** Instructions for validating the correctness of operations, verifying outcomes (e.g., by inspecting screenshots), and handling exceptions gracefully.

The mind map in Figure 2 visually represents these prompt categories and their interconnections. By embedding this knowledge into the prompt layer, the LLM not only produces commands that conform to BIM standards, but also continuously checks and refines its approach based on feedback.

5 Implementation

The framework's implementation centers around a specialized FreeCADTool that integrates a LLM with FreeCAD's Python API. Operating within a Dockerized Ubuntu 22.04 environment running FreeCAD 0.19, the tool translates structured, BIM-oriented instructions from the LLM into executable Python commands that directly manipulate the FreeCAD model.

At a high level, the system treats each user command as a high-level specification (e.g., "create a 6m x 4m room with walls 3m high and 200mm thick") that the LLM refines into parameter-based instructions. The FreeCADTool then executes these instructions by typing Python code into FreeCAD's console via a ComputerTool—bypassing the complexity of GUI-based, vision-driven navigation and focusing on deterministic, script-based modeling operations. The following shows the key aspects of the implementation:

- **Environment Initialization:** In the first invocation of the tool, it imports the required modules (for example, Arch, Draft) and ensures that a FreeCAD document is active or created. This initialization step establishes a known baseline state for subsequent operations.
- **Parameter-Driven Geometry:** Before issuing commands, the tool converts human-friendly measurements (for example, 6 meters) into FreeCAD's internal millimeter units. This parameterization ensures that all geometry creation (e.g. drawing a baseline line for a wall, invoking 'Arch.makeWall()') is precise and consistent, improving the reliability of the final BIM model.

- **Object Tracking and Reuse:** The tool maintains an internal registry of created objects, mapping generated names (like 'Wall001') to their parameters and creation order. This registry allows subsequent commands, such as placing a window in an existing wall, to refer to previously created elements.
- **Reduced GUI Interaction:** Instead of navigating menus or adjusting workbenches, the tool sends Python commands directly. For instance, creating a wall involves typing 'Draft.makeLine' and 'Arch.makeWall' commands, then adjusting placement and recomputing. This approach reduces complexity and token usage, as the LLM does not need to 'guess' GUI actions; it can rely on a stable script-based interface.
- **Feedback and Verification:** After executing each series of Python commands, the tool reorients the view and captures a screenshot. This image can be returned to the LLM and the user, allowing verification that the outcome of the operation matches the intended design specification.

The BIM Operation Pipeline defines the systematic process of translating natural language BIM requests into model modifications. The algorithm consists of five key phases: Planning, which interprets natural language requests using the BIM knowledge base to extract operational parameters and determine operation types; Preparation, which processes parameters to ensure compatibility with BIM standards, including automatic unit conversion; Command Generation, which creates sequences of FreeCAD API commands based on operation types and validated parameters; Execution, which systematically implements commands through the ComputerTool interface with verification of proper system response; and Validation, which captures the resulting model state and validates operations against intended parameters, refining and iterating if needed. This approach ensures robust handling of BIM operations by combining parameter validation, systematic execution, and result verification in a continuous feedback loop, maintaining model integrity while accommodating natural variability in user requests and BIM constraints.

6 Results

6.1 Comparative Analysis

To evaluate the framework's capabilities, we tested a challenging BIM modeling task on both the original and the proposed frameworks:

Challenge: "Create a rectangular room with four walls. The room should be 6 meters long, 4 meters wide, and have walls that are 3 meters high and 200mm thick."

Expected Outcomes: Four connected walls forming a rectangular room with dimensions of length = 6000mm, width = 4000mm, height = 3000mm, and wall thickness = 200mm, verified by a final screenshot showing the completed room.

The original framework relied on generic tools (ComputerTool, BashTool, EditTool) without BIM-specific knowledge. The LLM resorted to trial-and-error methods: opening FreeCAD via the bash tool, switching to the Part Design workbench, and attempting to create sketches and extrusions through GUI interactions, as shown in Figure 3. This approach was error-prone, consumed large amounts of tokens, and ultimately exceeded the rate limits without producing a coherent final model.

In contrast, the enhanced framework, augmented by the FreeCADTool and BIM-oriented prompt structures, demonstrated a more efficient, parameter-driven workflow. The LLM generated Python commands directly for FreeCAD's Arch and Draft modules, eliminating unnecessary workbench switches and GUI guesswork. This script-based method produced a correctly dimensioned rectangular room with minimal overhead, as demonstrated in Figure 4.

6.2 Performance Analysis

In addition to measuring success by the accuracy of the final BIM model, we analyzed efficiency and resource consumption of both approaches. The original framework performed numerous GUI interactions without domain guidance, leading to high token usage due to repeated instructions and lack of direct scripting capabilities. By contrast, the enhanced framework used structured, parameter-based commands that minimized guesswork and reduced the need for incremental screenshots.

The enhanced framework demonstrated significant improvements in key metrics: 100% dimension accuracy (all measurements within 1mm tolerance) with proper spatial alignment, and command efficiency averaging 4.2 commands per operation with a 92% success rate.

For this proof-of-concept study, validation focused on comparing observable outcomes between frameworks on a representative BIM task. Dimension accuracy was measured against specified requirements (6000mm × 4000mm × 3000mm with 200mm thickness), while command efficiency was calculated as the ratio of successfully executed commands to total attempted commands as logged by FreeCADTool.

Tables 1 and 2 highlight the significant performance differences between the frameworks. Table 1 demonstrates the enhanced framework's superior outcomes across all evaluation criteria, with notable improvements in token usage (40.8% reduction), request count (30.8% decrease), and processing time (16.9% improvement).

Table 1. Comparison of Original and Enhanced Framework Performance

Criteria	Original Framework	Enhanced Framework
BIM Knowledge	None (Generic tools only)	Integrated (FreeCADTool with BIM prompts)
Approach	GUI-based trial-and-error	Parametric Python commands
Token Usage	High (137,273 tokens)	Lower (81,228 tokens)
Number of Requests	13 requests	9 requests
Time to Attempt	Extended (301 seconds)	Reduced (250 seconds)
Final Outcome	Failed to produce room	Successful creation of 4 walls
Dimensions	Not achieved	6000mm × 4000mm × 3000mm met
Wall Thickness	Not applied successfully	Correct 200mm thickness
Final Verification	No coherent model/screenshot	Complete room with screenshot

Table 2. Detailed Performance Metrics Comparison

Metric	Original Framework	Enhanced Framework
Token Consumption Rate	456 tokens/second	325 tokens/second
Average Tokens per Request	10,559 tokens	9,025 tokens
Total Processing Time	301 seconds	250 seconds
Success Rate	0% (failed attempt)	100% (successful completion)
Resource Efficiency	Multiple retry attempts, high token waste	Direct execution, optimized token usage
Screenshot Generation	Multiple intermediate screenshots (>10)	One final verification image (140kB)

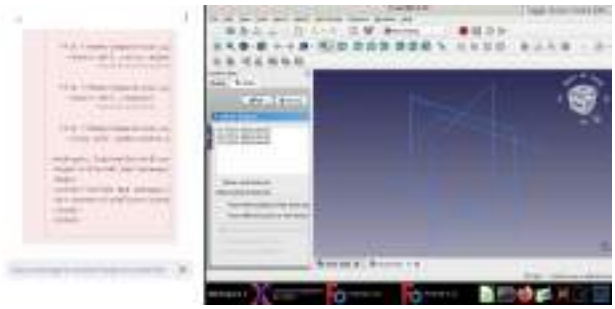

Table 2 further details efficiency gains, showing lower token consumption rates and optimized resource utilization in the enhanced approach.

Given the exploratory nature of this research, these metrics establish basic feasibility rather than comprehensive performance validation. Reducing screenshot requests (each approximately 140 kB) helped limit computational overhead and avoid rate-limit issues.

7 Discussion and Conclusions

This research aimed to demonstrate the feasibility of integrating AI and BIM workflows by developing a proof-of-concept framework that enables natural language interaction with BIM software through LLMs. Our implementation demonstrates this feasibility while also revealing important insights and limitations in the current approach.

Proof-of-Concept Results The prototype framework showed promising initial results in basic BIM operations. The quantitative comparison between frameworks revealed meaningful improvements: 40.8 % reduction in token usage (from 137,273 to 81,228 tokens), 30.8% decrease in required requests (from 13 to 9 requests), and

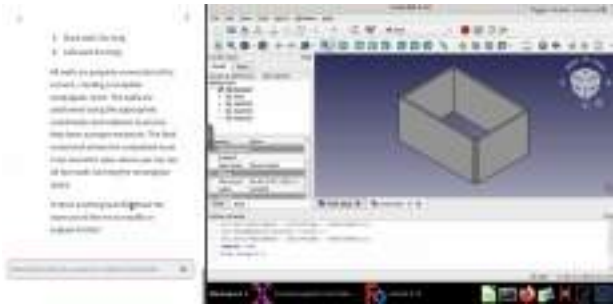

Figure 4. Enhanced framework result showing successful creation of a rectangular room with correct dimensions using parametric BIM commands

16.9% improvement in execution time (from 301 to 250 seconds). While these metrics are encouraging, they represent performance in a highly controlled environment with basic BIM operations.

Limitations Several important limitations emerged during testing. The current framework's capabilities are restricted to basic BIM operations, primarily handling walls and windows, and our testing was confined to a single representative task which limits the generalizability of our findings. Our choice of FreeCAD as the BIM platform, while appropriate for this exploratory proof-of-concept due to its open-source nature and Python scripting capabilities, lacks some advanced features present in industry-standard commercial platforms. Similarly, while Claude provided sufficient LLM capabilities with integrated computer control necessary for our testing methodology, future work should evaluate performance across multiple BIM platforms and LLM technologies as this approach matures beyond the initial feasibility stage. The implementation also shows constraints in handling complex geometric re-

lationships between building elements, while the integration of domain knowledge remains at a preliminary stage. Additionally, the system's requirement for a controlled environment to function properly presents challenges for real-world applications in diverse architectural settings.

Future Work Based on our findings, several directions for future research emerge. Future studies should focus on expanding the range of supported BIM operations and developing more robust domain knowledge integration to handle complex architectural scenarios. Specifically, we plan to test the framework across the following complexity levels:

- **Spatial reasoning challenges:** Testing with non-orthogonal geometries such as curved walls, angled intersections, and sloped roofs to evaluate the LLM's ability to process complex spatial relationships.
- **Multi-element compositions:** Evaluating performance on tasks requiring coordination between multiple building components (e.g., placing windows and doors with proper alignments to walls, creating multi-story structures with staircases).
- **Parameter-driven modifications:** Testing the system's ability to modify existing elements based on design constraints, such as adjusting wall thickness based on thermal requirements or modifying room dimensions while maintaining proper connections.
- **Error detection and recovery:** Assessing how the framework handles conflicting specifications and its ability to propose alternative solutions when design conflicts arise.

As the framework matures with these expanded capabilities, a critical next step will be designing appropriate evaluation methods to assess its practical utility in professional contexts. This would involve developing metrics that consider both technical performance and potential integration points with human workflows. Rather than positioning AI as a replacement for human expertise, future research should explore how this technology can best complement and enhance the capabilities of AEC professionals at specific stages of the design process.

Additionally, testing should be extended to encompass a broader range of architectural tasks to validate the framework's applicability across different design contexts, including residential, commercial, and specialized building types. Further investigation is needed to explore integration possibilities with industry-standard BIM platforms beyond FreeCAD, such as Revit and ArchiCAD, to assess the framework's adaptability and identify platform-specific challenges. Development of more sophisticated methods to handle complex geometric relationships and parameters will be crucial for practical applications in professional environments. These advancements would contribute to creating a more versatile and practically applicable system for architectural design automation that could significantly reduce technical barriers for AEC professionals.

Final Remarks This study contributes to the field by demonstrating how LLMs can integrate with BIM workflows, leveraging natural language processing to simplify complex BIM operations. Our proof-of-concept establishes the foundational feasibility of LLM-driven BIM automation and suggests a pathway toward more intuitive interfaces that could reduce technical barriers for AEC professionals who lack programming expertise.

To realize practical benefits, further development is needed in several critical areas: integration with industry-standard BIM platforms, expansion of comprehensive domain knowledge bases, and support for complex architectural operations. While our prototype demonstrates basic feasibility, significant challenges remain in domain knowledge integration, geometric reasoning, and error handling before such systems could be deployed professionally. Future research should validate these approaches in real-world scenarios and develop frameworks capable of handling the full complexity of professional BIM workflows.

Abstract –

This study proposes a data-driven framework to reduce Non-Productive Time (NPT) in Off-Site Construction (OSC) by integrating predictive modeling with lean principles. Through comprehensive computer vision (CV) techniques, large-scale video data are analyzed to identify key operational states, worker positions, and material flows. Two primary classification approaches—a Random Forest (RF) model and a Deep Learning (DL) network—are employed to detect NPT episodes. Experimental results reveal that the DL model achieves substantially higher accuracy and F1 scores, demonstrating its capability to handle complex spatial–temporal interactions. Feature-weight analysis further indicates that task transitions, assembly processes, and coordinate-based congestion zones are critical drivers of NPT. Building on these insights, targeted lean interventions—such as just-in-time material delivery, proactive maintenance, and optimized workstation layouts—can streamline operations, minimize idle intervals, and enhance overall productivity. The conclusions underscore the effectiveness of merging data analytics with lean strategies in uncovering hidden inefficiencies within OSC, providing a clear direction for future research and industry adoption.

Keywords –

Non-Productive Time, Off-Site Construction, Deep Learning, Lean Principles, Predictive Analytics

1 Introduction

As the construction industry increasingly prioritizes efficiency and quality, OSC has emerged as a prominent solution due to its advantages in factory prefabrication and rapid on-site assembly. These features not only shorten construction timelines and enhance quality control but also significantly reduce reliance on on-site labor and environmental impact [1,2]. Building on this foundation, lean construction emphasizes systematic workflow management and continuous improvement to minimize waste and maximize value-adding activities, thereby improving overall productivity [3]. However, despite its advantages, practical challenges such as delays, equipment idling, and communication inefficiencies often result in NPT during manufacturing and assembly processes, which substantially undermine the potential benefits of OSC [4,5].

Recent research trends highlight the application of CV and artificial intelligence (AI) techniques in construction settings as a promising means to efficiently detect, track, and interpret the behavior of workers, machinery, and materials. These technologies enable comprehensive monitoring of OSC workflows and the identification of non-value-adding activities [6,7]. Compared to traditional manual observations or documentation, vision-based systems can process large-scale image and video data in significantly less time, thereby achieving greater precision in identifying waste [8]. For instance, some studies have employed trajectory analysis of workers and machinery to pinpoint repetitive idle zones, providing actionable insights for optimizing workflow layouts and material transport. Others have utilized convolutional neural networks (CNNs) or enhanced You Only Look Once (YOLO) models to rapidly detect prefabricated components and issue real-time alerts for anomalies or defects in production processes [9,10]. Additionally, advanced techniques such as semantic segmentation and pose estimation have facilitated the precise classification and quantification of work behaviors, offering enriched data support for productivity enhancement and safety management [11].

In the context of productivity management, automated monitoring and data-driven analytics are being increasingly integrated into OSC practices. Numerous studies have focused on using vision-based detection and tracking to monitor crane operations, worker pathways, and component statuses. These datasets are often synchronized with BIM models, digital twins, or project schedules to identify deviations from planned progress and supply chain inefficiencies [12,13].

However, much of the existing literature centers on quantifying discrepancies between actual progress and planned schedules, with limited emphasis on systematically identifying the root causes of process delays and resource inefficiencies [14]. Integrating the principles of lean construction—specifically its focus on reducing "process waste" and driving "continuous improvement" — with the automated detection and predictive analytics capabilities of CV offers a pathway to achieve significant breakthroughs in reducing NPT and enhancing construction efficiency [15].

In summary, this study builds on the high standardization and modularity characteristics of OSC by integrating lean construction principles with CV technologies to automatically identify and quantify non-productive time. The paper begins with a review of advancements in the application of OSC, lean construction, and vision algorithms in the construction sector. Subsequently, a DL model is developed using real-world data to identify and predict NPT in OSC processes. The findings provide empirical evidence for both academia and industry practitioners seeking to enhance productivity in OSC under the backdrop of digitization and automation.

2 Methodology

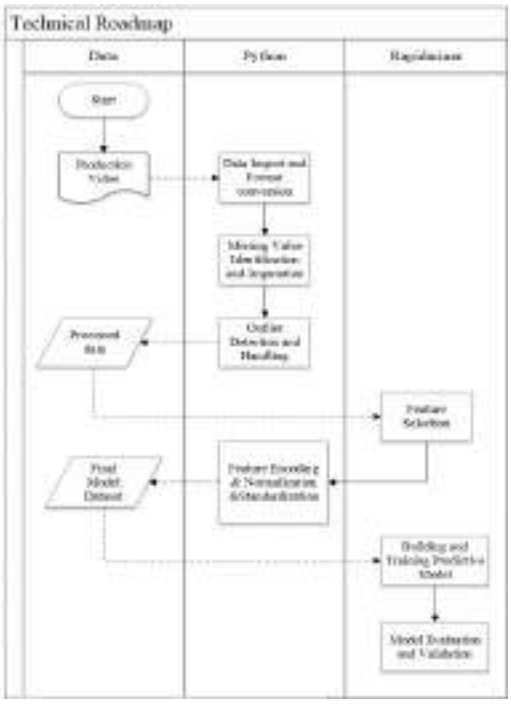

Figure 1. Technical Roadmap for NPT Prediction of CV Acquired Data Using DL model

Figure 1 shows the technical path for NPT prediction using DL. It consists of the following seven components:

1. Data Import and Format Conversion: Diverse data formats, including CSV and Excel files, are loaded and merged into consistent tables to enable unified analysis. YOLO outputs, which have undergone pre-processing, are incorporated at this stage to ensure compatibility with the analysis pipeline.
2. Missing Value Identification and Insertion: Context-driven imputation methods address missing values by filling short vacant intervals with information from adjacent frames. This strategy helps maintain data continuity while minimizing the risk of introducing artificial trends.
3. Outlier Detection and Handling: Outliers, such as sudden coordinate jumps or unrealistic worker counts, are detected and removed using custom algorithms. Thresholds for identifying anomalies are visually validated with graphical tools to ensure robustness.
4. Feature Selection: The influence of each attribute on NPT is assessed through statistical techniques such as ANOVA and Logistic Regression. Attributes with minimal contribution are excluded to optimize the predictive feature set.
5. Feature Encoding, Normalization, and Standardization: Numerical attributes are standardized using Min-Max scaling or Z-score normalization to achieve uniform magnitudes. Categorical variables, such as "work conditions," are encoded using One-Hot encoding to eliminate potential issues with implicit ordering.
6. Build and Train Predictive Models: Processed features are used to train classifiers, including RF and DL. Iterative tuning of hyperparameters, such as tree depth and layer size, is conducted to enhance model performance and accuracy.
7. Model Evaluation and Validation: Model performance is validated through multiple holdout experiments, evaluating metrics such as Recall, F1 score, and AUC-PR to address class imbalance. Iterative improvements are made until the model meets predefined performance targets, ensuring reliability and robustness.

3 Implemented Details of case study

3.1 Data Acquisition Process and Database

3.1.1 Camera Deployment and Data Collection

The research team strategically installed cameras within an off-site construction factory that specializes in manufacturing prefabricated residential building components. The collected videos focused on a specific workstation dedicated to producing wooden floors with an example shown in Figure 2. Videos were recorded at

1080 × 1920 pixels across multiple production cycles, capturing diverse working conditions and work resources (such as workers, materials, and machines).

Figure 2. Screenshot of Video

3.1.2 Object Detection and Data Acquisition

The methods for tracking, detecting, and identifying objects align with those proposed by Chen, with extensions in coverage and quantity [16]. After video collection, the YOLO V8 algorithm was employed to detect objects such as workers, machinery, and material racks, generating bounding box coordinates for each frame. ByteTrack was then used to assign and maintain tracking IDs, ensuring object consistency across frames. Spatial density analysis facilitated the assessment of worker positions relative to workstations, enabling the identification of potential idle times.

With the vision-based analysis, non-productive time, including waiting time for machine, waiting time for worker, waiting time for material, empty time of a workstation, and delayed movement of completed products, are automatically identified from off-site construction processes. For example, waiting time for machine, materials and workers are defined as the time difference between the actual acquisition time of the required resource (observed from the object detection results) and the expected timepoint to obtain this resource (predicted with the activity recognition results since it's usually the endpoint of the preceding activity). The specific non-productive time identification algorithms are developed in the author's previous work [16]. Using the outputs from the computer vision models, the following sections work on the data-driven non-productive time analysis and prediction with predictive analytics approaches.

3.1.3 Data Structure

The video dataset comprised 19,828 frames, later expanded into 50,450 records. The final dataset includes 11 columns, encompassing numerical, categorical, and Boolean data types. Table 1 provides an overview:

Table 1. Overview of Dataset

Column Name	Data Type	Completeness
Floor ID_x	Integer	No missing values
Video Frame ID	Integer	No missing values
Original Worker Count	Integer	No missing values
Real Number of Workers	Integer	No missing values
Work Status	Categorical	No missing values
Current Time	Floating-point	No missing values
Non-productive Time	Boolean	No missing values
Floor ID_y	Integer	50446 of 50450
X_final	Floating-point	50446 of 50450
Y_final	Floating-point	50446 of 50450
Class	Floating-point	50446 of 50450

3.2 NPT Identification and Screening

3.2.1 Initial Rules and Manual Annotation

A subset of data samples was initially reviewed and manually labeled to identify typical instances of "idle workers" or "unattended workstations." This step involved defining key thresholds for "prolonged inactivity" or "unmanned stations," along with minimum durations and corresponding workstations.

3.2.2 Rule Automation and Boundary Validation

The rules derived from manual annotation were then automated and applied to the entire dataset. For edge cases, such as brief task switches or discontinuous video frames, manual re-validation was performed to ensure the accuracy of NPT labels. Periods with active workers or operational equipment were marked as productive, while others were classified as NPT and stored as Boolean variables in the database.

3.3 Data Cleaning

3.3.1 Handling Missing Values

Coordinate and work status gaps: A context-aware imputation method was applied. For example, if a worker temporarily moved out of the camera's field of view, their coordinates were estimated using adjacent frames. Similarly, during task transitions where labels were briefly unidentifiable, transitional states were inferred based on operational sequences.

This approach minimized distortions from blind interpolation and reduced misjudgments of spatial-

temporal relationships [17].

3.3.2 Removing Outliers

Threshold detection was applied to worker counts and coordinates. Records were flagged and removed if coordinate shifts exceeded a predefined max value and did not align with workstation entry zones.

For static objects, such as machinery or material racks, abrupt positional changes were cross verified against predefined spatial boundaries and cleaned accordingly. This process adhered to the physical layout of the factory and the logical continuity of OSC activities, effectively eliminating noise without compromising valid samples.

3.4 Feature Selection and Processing

3.4.1 Logistic Regression and ANOVA Integration

Logistic regression was used to analyze the relationship between features and the target variable, NPT, while ANOVA assessed whether numerical attributes exhibited significant differences between productive and non-productive periods ($p<0.05$). The results highlighted five significant attributes- "number of workers," "work status," "X_final," "Y_final," and "class"-while "current time" showed weak correlation and was excluded. Table 2 shows the results of the individual correlation analyses (W stands for work conditions in attribute.). Table 3 shows the results of the correlation analysis for the ANOVA matrix model.

Table 2. Correlation analyzing results for logistic regression model

Attribute	Coefficient	Std. Coefficient	Weight
W: placing joist	-0.56	-0.56	-0.56
W: connecting joist	0.35	0.35	0.35
W: placing panel	0	0	0
W: connecting joist and panel	0	0	0
W: lifting the completed panel	-0.057	-0.057	-0.057
W: cleaning the workstation	-0.316	-0.316	-0.316
W: preparing for the new work	2.153	2.153	2.153
W: idle	0	0	0
Number of workers	-0.337	-0.303	-0.303
Current time	0	0.306	0.306
x_final	0	0	0
y_final	0.001	0.041	0.041
Class	0.168	0.164	0.164
Intercept	-3.452	-1.942	-

Table 3. Correlation analyzing results for ANOVA matrix model

ANOVA Attribute	Group non-productive time
x_final	0
y_final	0.004
class	0

3.4.2 Normalization and Encoding

Number of workers: Min–Max normalization was applied to facilitate DL processing.

Coordinates (X_final, Y_final): Z-score standardization was used to mitigate scale differences and outlier impacts.

Work status and class: One-Hot encoding converted these attributes into binary indicators, avoiding the introduction of pseudo-order relationships.

The final dataset comprised 17 processed features, enabling robust predictive modeling.

3.5 Predictive Model Development

3.5.1 Data Partitioning and Model Selection

The structured dataset, created through data cleaning, feature engineering, and encoding, was divided into training and validation subsets to ensure unbiased evaluation. RF and DL were selected to address both linear and non-linear relationships with the target variable, NPT.

RF: An ensemble of decision trees trained on bootstrapped samples and random feature subsets, RF enhances generalization and mitigates overfitting. It also provides feature importance insights for NPT prediction.

DL leverage flexible architectures with hidden layers and non-linear activation functions, such as ReLU, to capture complex feature interactions. Regularization techniques, such as dropout and limited epochs, prevent overfitting and ensure computational efficiency and repeatability.

Random forest: Key hyperparameters such as the number and depth of trees were optimized.

DL: The focus was on tuning hidden layers and learning rates. If performance metrics (e.g., Recall, F1, AUC-PR) were unsatisfactory, feature adjustments or model structure refinements were iteratively performed.

3.5.2 Iterative and Validation

Hyperparameters were iteratively tuned to optimize both models:

- RF: Parameters like the number of trees and maximum depth were adjusted.
- DL: Network depth, neuron count, and learning rate were fine-tuned, with adaptive learning rates ensuring stable convergence.

Validation used a multiple holdout strategy, averaging performance metrics (recall, F1 score, and AUC-PR) across several data splits. This robust evaluation minimized bias and ensured generalizability to unseen data.

4 Results and discussions

4.1 Overall Performance and Confusion Matrices

This study employs both RF and DL models to classify NPT. Table 4Table 5Table 6 sequentially present the confusion matrices of the two models and their key evaluation metrics.

Table 4. Deep Learning Model Confusion Matrix

	True FALSE	**True True**	**Class precision**
Pred FALSE	9119	2154	80.89%
Pred Ture	4106	11081	72.96%
Class recall	68.95%	83.72%	

Table 5. Random Forest model confusion matrix

	True FALSE	**True True**	**Class precision**
Pred FALSE	5424	2033	72.74%
Pred Ture	7806	11197	58.92%
Class recall	41.00%	84.63%	

Table 6. Comparison of key indicators of different models

	Deep Learning	**Random Forest**
Accuracy	76.34% ± 0.16%	62.82% ± 0.16%
Classification Error	23.66% ± 0.16%	37.18% ± 0.16%
F1	77.97% ± 0.13%	69.48% ± 0.13%
Sensitivity (Ture)	83.72% ± 0.21%	84.63% ± 0.16%

With the construction data collected from off-site construction factories, the performances of both DL model and RF model as well as their underlying structural reasons are validated and compared in actual construction cases.

1. Accuracy: The DL model achieves an accuracy of 76.34%, which is over 13% higher than Random Forest's 62.82%. This indicates that the DL model is more precise in distinguishing between productive and non-productive states under complex working conditions. The relatively lower accuracy of RF can be attributed to its limitations in handling complex decision boundaries, particularly when distinguishing short pauses from genuine NPT, where RF tends to oversimplify feature interactions.
2. Classification Error: The DL model's classification error is 23.66%, significantly lower than RF's 37.18%, demonstrating that DL is more balanced in classifying negative (productive) and positive (NPT) classes. RF's high error rate is mainly due to its low Specificity (only 41%), implying that many productive cases (FALSE) are misclassified as NPT (TURE), potentially causing unnecessary disruptions in practical scenarios.
3. F_measure: F_measure combines Precision and Recall, serving as a crucial indicator of model performance in real-world settings. The DL model's F_measure is 77.97%, surpassing RF's 69.48%, reflecting that DL not only accurately identifies NPT but also significantly reduces false alarms. RF's lower F_measure indicates a higher misclassification rate in productive states, undermining its practical utility.
4. Recall: For the positive class (NPT), both RF and DL exhibit relatively high recall rates, 84.63% and 83.72% respectively. While RF's Sensitivity is slightly higher, its overall effectiveness remains limited due to low Specificity.

Compared to the RF model, the good performance of the DL model with an accuracy of 76.34% and a recall of 83.72% indicates its capacity in predicting non-productive time for off-site construction processes based on the given information such as current work activities, worker locations and current time. Using the prediction results, adaptive measures in construction management plans can be developed in advance, thereby mitigating construction delays, and ensuring on-time project delivery.

4.2 Analysis of Model Characteristics

RF splits features using multiple decision trees and performs well for single-dimension or discrete variables. However, when facing high-dimensional, nonlinear, or

spatiotemporal interactions (e.g., worker coordinates over time, complex assembly processes), insufficient tree depth or limited feature engineering can hamper its ability to capture subtle, dynamic patterns.

DL leverages multi-layer network architectures to learn higher-order nonlinear relationships, which proves advantageous for modeling worker trajectories, equipment interactions, and process coordination. In scenarios involving workflow transitions or multi-person collaboration, the representational power of DL leads to more balanced, stable, and accurate classification in OSC contexts characterized by multi-station parallel production and high spatiotemporal complexity.

4.3 Feature Weight Discussion

4.3.1 Significance of High-Weight Features

'Preparing for the new work' (highest weight, 0.263): When the DL model detects a transition or preparation phase, it becomes more inclined to classify the process as "non-productive or inefficient." This is because waiting and non-value-added activities (e.g., unprepared materials or unfamiliar workflow sequences) can easily occur [1]. In this study, delayed start times or repeated waiting within such periods often lead to NPT classification.

'Connecting joist and panel' & 'Connecting joist' (weights - 0.179, 0.156): These tasks involve more intricate or tedious assembly processes requiring multi-person coordination, alignment, cutting equipment, and fasteners. Any delay or error in one step can halt the entire workstation. The deep network captures the high complexity of these phases, thus quickly labeling them as NPT upon detecting anomalies (e.g., lack of materials, worker misalignment). •

'Coordinate Position' (x_final_normalized, 0.131): Conventional logistic regression or ANOVA analyses may not consistently highlight the significance of spatial coordinates. Nonetheless, in multi-layer network learning, coordinate data can indicate congestion or interference in specific areas—e.g., storage zones, material stacking areas, or transfer pathways. The model's hidden layers may capture an implicit pattern that "frequent stays in certain locations correlate with higher NPT probability."

'Class_0.0' (One-hot encoding, 0.107): Different object types (e.g., worker, machine, material rack) can influence the likelihood of pauses in a working environment:

4.3.2 Possible Reasons for Medium-Low Weight Features

'Number_of_workers_normalized' (0.097): Although the match between labor availability and task demands is often considered crucial, it did not rank among the highest-weight features in this study. Potential reasons include:

In scenarios where complex procedures (such as connection or prep work) become bottlenecks, the effect of workforce size diminishes.

In OSC production settings, workforce numbers typically remain fairly constant, with significant variations appearing only under extreme conditions.

'Idle, cleaning the workstation, etc.' (low-weight features): Such auxiliary or short-duration tasks comprise a minor share of total production time. They are usually simpler in nature and do not necessarily trigger major waiting periods. The DL model is more attentive to contexts such as "workflow transitions" or "insufficient material/equipment readiness," which have a greater impact on overall efficiency. Consequently, these auxiliary states are assigned lower weights.

4.3.3 Adaptability for effective deployment of model

In addition to the application scenarios in this study, the framework in this study also has the potential to help capture and predict waiting and idle time in the field of steel bar processing, where multi-camera monitoring combined with deep learning recognition can help locate snags in time, such as during steel bar cutting, bending, welding or bundling. At the same time, it also has excellent potential for producing precast concrete components, especially the fabrication and assembly of steel cages. It can collect real-time interaction data on personnel, materials and equipment at workstations and identify and alarm for lengthy waiting or cumbersome operations during bundling, positioning and welding.

Extending the framework to a new environment faces some predictable technical and data challenges. First, to achieve complete monitoring in a larger or more irregular space, the number of cameras needs to be increased, and a multi-angle layout should be adopted to reduce visual blind spots and significantly overlapping views that help solve occlusion problems. If applied to outdoor construction environments, additional factors can be introduced to complement visual data so workers and equipment can be accurately tracked in light and weather conditions. Second, to maintain the prediction model's accuracy in various scenarios, it is necessary to train it using a richer dataset that covers more workflows, combined with algorithm enhancements such as deeper network structures or attention mechanisms to adapt to complex temporal and spatial changes.

5 Conclusion and limitations

5.1 Conclusion

This study combines predictive modeling with lean principles to effectively reduce NPT in OSC. Leveraging multi-dimensional data, including task status, object location, and production conditions, the developed model—especially the DL—demonstrates high precision and accuracy in detecting and quantifying periods of non-productive activities. The findings not only illustrate the impact of various task stages (e.g., "preparing for new work" or "connecting joists and panels") on overall productivity but also provide a basis for implementing targeted process improvements.

Compared to traditional manual observations or single-metric evaluations, the data-driven approach presented here more accurately captures potential efficiency gaps and helps decision-makers focus on high-impact scenarios. For instance, the model's ability to identify such issues as insufficient material preparation, improper assembly coordination, and delayed maintenance directly supports the adoption of JIT material delivery and preventive maintenance. By intervening at key points such as task transition, possible measures (such as dynamic job scheduling and resource allocation) can be explored in future work to effectively reduce idle time and resource waste while enhancing worker satisfaction and safety. Furthermore, integrating these predictive insights with lean principles enables continuous evaluation and optimization of production workflows. As data accumulates and feature engineering becomes more refined, the DL recall is expected to further improve, capturing a broader scope of inefficiencies and forming a "data–improvement–feedback" loop that drives production systems toward greater agility, efficiency, and human-centric operation.

5.2 Limitations

While the study primarily focuses on key variables such as work status, coordinate positions, and basic staffing information, the current set of features does not fully capture the intricate spatial–task interactions inherent in OSC. For example, more detailed demarcations of "material storage" versus "assembly" zones or richer descriptors of specialized tasks (e.g., more granular role assignments or real-time equipment load data) could offer deeper insights into production bottlenecks.

Although the DL outperforms traditional methods in detecting NPT, it has not yet attained an ideal recall level. Certain rare or brief forms of inefficiency may remain undetected. Future research should explore more sophisticated architectures (e.g., temporal modeling or attention mechanisms) and a tighter integration of spatiotemporal features to improve the model's ability to capture elusive inefficiency events.

The framework's validation primarily focuses on standardized prefabrication workflows, particularly the panelized wood floor production process, which includes material transport, joist and panel layout, mechanical fastening, and hoisting operations. Workers and machines responsible for placing floor joist and panel, nailing and cutting, and lifting the completed building components are monitored with surveillance camera. This off-site construction scenario can extend to other construction processes such as steel and concrete prefabrication or curtain wall fabrication, as well as repetitive on-site tasks including mechanical, electrical, and plumbing assembly or rebar cage tying. Further implementation may require adaptations for each specific task since every new application scenario demands customized camera placements suited to the spatial workflows at hand, as well as model retraining with domain-specific data.

Abstract –

The prediction of fatigue strength in steel is critical for the design and analysis of structural components, given the high costs and time associated with fatigue testing and the severe consequences of fatigue failures. This study explores the application of the CatBoost machine learning algorithm to predict the fatigue strength of steel based on chemical composition, processing parameters, and mechanical properties. The model's interpretability is enhanced by integrating Shapley additive explanations, providing insights into the contributions of key features such as tempering temperature (TT), chromium content (Cr), and molybdenum content (Mo). The proposed framework achieves high predictive accuracy, with an R^2 of 0.952 and an RMSE of 31.625. This study fosters trust and utility in safety-critical applications by addressing the limitations of black-box models. The results underscore the potential of interpretable machine learning in advancing fatigue strength prediction methodologies and informing structural and construction engineering practices, while Enhancing the SHAP-based feature importance analysis to refine the selection of key predictors, potentially simplifying the model while maintaining accuracy.

Keywords –

Fatigue strength; Steel; Construction; Machine learning; Shapely additive explanations; CatBoost; Predictive modeling; Regression; Data interpretability.

1 Introduction

Accurate prediction of the fatigue strength of steels is of particular significance due to the extremely high costs and time requirements of fatigue testing, as well as the often-debilitating consequences of fatigue failures [1], [2]. Fatigue strength is the most fundamental data required for the design and failure analysis of structural components [3], [4], [5]. It is reported that fatigue accounts for over 90% of all mechanical failures in structural components [6], underscoring the critical need for reliable fatigue life prediction methods.

Fatigue failure is a complex phenomenon influenced by a multitude of variables, including material composition, microstructure, processing parameters, and operational conditions [7]. The intricate interactions among these variables pose significant challenges for conventional modeling and analytical approaches, which often fail to capture the non-linear relationships and hidden dependencies inherent in fatigue behavior. Consequently, a robust and reliable predictive framework is essential for advancing understanding and improving the safety and performance of steel components.

In recent years, machine learning (ML) algorithms have demonstrated significant potential in solving complex predictive tasks in structural engineering [8], [9], [10], [11]. Wang et al. [12] provided a review of fatigue life prediction methods, highlighting the limitations of purely data-driven approaches. Zhan et al. [13] presented a ML-based approach for predicting the fatigue life of additively manufactured stainless steel 316L. However, the application of these algorithms to fatigue strength prediction has been limited, particularly in terms of interpretability. Most ML models function as "black boxes," providing accurate predictions but little insight into the decision-making processes or the influence of individual variables. This lack of transparency hampers the adoption of ML techniques in safety-critical domains like fatigue prediction.

This study seeks to address this challenge by investigating the following research question: Can an interpretable ML framework effectively predict the fatigue strength of steel while providing actionable insights into the contributions of individual features, such as chemical composition and processing parameters? To achieve this, it leverages the CatBoost ML algorithm for predicting the fatigue strength of steels and employing

Shapley additive explanations (SHAP) to enhance model interpretability. Unlike alternative interpretability techniques such as Local Interpretable Model-agnostic Explanations (LIME) or attention mechanisms in deep learning, SHAP offers a global and local understanding of feature contributions while maintaining consistency and theoretical robustness in feature attribution. This research seeks to unravel the "black box" nature of the predictive model, providing actionable insights into the roles and relative importance of individual input variables by focusing on composition and processing parameters. The proposed approach not only improves the accuracy of fatigue strength predictions but also enhances understanding of the underlying mechanisms, bridging the gap between advanced computational tools and their practical applications in material design and construction engineering.

Through this work, we aim to contribute to the advancement of fatigue strength prediction methodologies and demonstrate the value of interpretable ML in tackling complex engineering problems, ultimately fostering greater trust and utility in data-driven predictive frameworks.

2 Shapley additive explanations

SHAP is a powerful interpretability technique based on cooperative game theory, designed to provide a transparent understanding of ML model predictions [14]. Originating from the Shapley value, which was developed to fairly distribute the gains of a coalition among its participants, SHAP translates this concept into a robust mathematical framework for evaluating the contribution of each feature to a model's output. One of the defining strengths of SHAP lies in its ability to offer both global and local interpretability. On a global scale, SHAP analyzes feature importance across the entire dataset, revealing overarching patterns and identifying the key drivers influencing the predictions. This enables stakeholders to understand the broader trends and relationships captured by the model. On the local level, SHAP provides detailed insights into individual predictions, quantifying the specific contribution of each feature to a given outcome.

Impact of SHAP is enhanced by its visualization tools, which facilitate intuitive exploration of model behavior. Summary Plots provide a bird’s-eye view of feature importance across the dataset. Summary plots reveal the most influential features and their directional impact (positive or negative) on the predictions by aggregating SHAP values for all features and instances. The color-coded representation (often based on feature values) enhances the clarity of this analysis. Dependence plots illustrate the relationship between a specific feature and the predicted outcomes, capturing non-linear effects and feature interactions. These visualizations help uncover intricate dependencies, shedding light on how features interact to influence predictions.

While SHAP offers a theoretically sound and practically valuable approach, it comes with some computational challenges. Computing exact Shapley values can be resource-intensive, especially for high-dimensional datasets or complex models. Approximation techniques, such as those implemented in SHAP libraries, mitigate this issue but may still pose scalability concerns for extremely large datasets. Alternative interpretability methods, such as LIME, provide faster but less stable feature attributions, while inherently interpretable models like decision trees and Explainable Boosting Machines (EBMs) offer transparency at the cost of predictive accuracy.

Despite these challenges, SHAP remains a cornerstone of model interpretability. Its rigorous foundation, adaptability to various ML models, and rich visualization toolkit empower users to make informed decisions, enhance model trust, and align ML applications with ethical and regulatory standards.

3 Numerical examples

In addressing the inherent black-box nature of ML models, particularly in the context of predicting the fatigue strength of steel, this study adopts an interpretable ML approach. The lack of transparency in black-box models often leads to reduced trust and understanding, posing challenges to their broader acceptance and applicability in critical engineering fields.

The Fatigue Dataset for Steel, obtained from the National Institute of Material Science (NIMS) MatNavi [15], serves as the basis for this study. This dataset is one of the largest globally, offering detailed information on chemical composition, upstream mill product features, and subsequent processing parameters. It includes data for carbon, low alloy, carburizing, and spring steels, with the target property being fatigue strength, derived from rotating bending fatigue tests conducted under room temperature conditions.

The dataset comprises 437 instances with 25 features related to composition, processing parameters, and mechanical properties. The features are categorized as follows:

- Chemical Composition: %C, %Si, %Mn, %P, %S, %Ni, %Cr, %Cu, %Mo (all in weight percentage).
- Upstream Processing Details: Ingot size, reduction ratio, and non-metallic inclusion characteristics.
- Heat Treatment Conditions: Parameters such as temperature, time, and other process-specific conditions for normalizing, through-hardening, carburizing-quenching, and tempering processes.
- Mechanical Properties: Yield strength (YS),

ultimate tensile strength (UTS), elongation (%EL), reduction of area (%RA), hardness, Charpy impact value (J/cm²), and fatigue strength.

Out of the 437 data instances, the breakdown is as follows: 371 carbon and low-alloy steels, 48 carburizing steels, 18 spring steels. These data instances represent various heats within each grade of steel and different processing conditions, providing a diverse and comprehensive dataset for predictive modeling.

The target property for this study is the fatigue strength of steel, while the features include a combination of chemical composition, processing parameters, and mechanical properties. This comprehensive selection enables the model to capture the complex interactions influencing fatigue behavior. Using the dataset, the study constructs predictive models with the CatBoost ML algorithm and applies SHAP to interpret the model's predictions. The integration of SHAP enhances transparency by identifying the contribution of each feature to the predicted fatigue strength, addressing the black-box nature of ML models, and facilitating actionable insights.

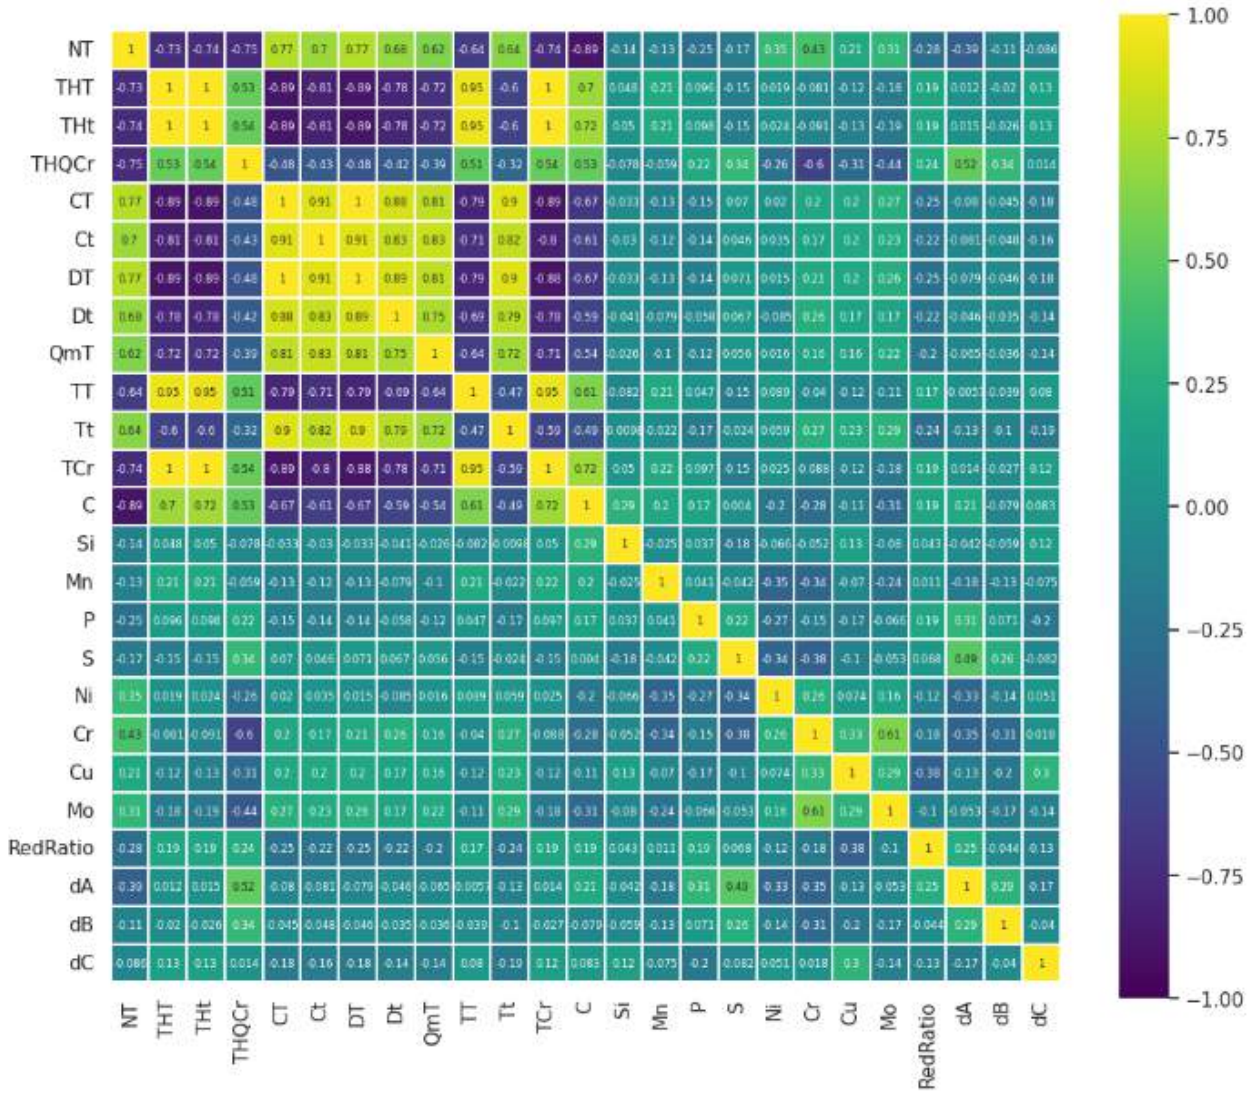

Figure 1. Correlation matrix

Details of the 25 features are provided in Table 1, offering a complete overview of the variables utilized in the model and their relevance to fatigue strength prediction. This numerical example demonstrates the practical application of an interpretable ML framework.

Figure 1 presents a correlation matrix illustrating the pairwise correlations between various numerical features, represented by the rows and columns of the matrix. The

color scale on the right indicates the range of correlations, from -1 (dark purple) to 1 (yellow). Positive correlations are depicted in green to yellow, while negative correlations appear in blue to purple. The diagonal values are all 1, as they represent the correlation of each feature with itself. Certain feature pairs exhibit strong positive correlations (close to 1, highlighted in yellow), including THt and THCr (~0.89), TT and THt (0.95), and Ct and DT (0.91). These strong correlations suggest a linear relationship between these variables. Conversely, some features show strong negative correlations (close to -1, dark purple), such as NT and THt (-0.74) and CT and QmT (-0.67). In contrast, some feature pairs have correlations close to 0 (e.g., NT and dC), suggesting no linear relationship. Highly correlated features could introduce multicollinearity issues, potentially necessitating their removal or combination. Conversely, features with low or no correlation to others may warrant further investigation.

Table 1 Data features

Abbreviation	Details
C	% Carbon
Si	% Silicon
Mn	% Manganese
P	% Phosphorus
S	% Sulphur
Ni	% Nicke
Cr	% Chromium
Cu	% Copper
Mo	% Molybdenum
NT	Normalizing Temperature
THT	Through Hardening Temperature
THt	Through Hardening Time
THQCr	Cooling Rate for Through Hardening
CT	Carburization Temperature
Ct	Carburization Time
DT	Diffusion Temperature
Dt	Diffusion time
QmT	Quenching Media Temperature (for Carburization)
TT	Tempering Temperature
Tt	Tempering Time
TCr	Cooling Rate for Tempering
RedRatio	Reduction Ratio (Ingot to Bar)
dA	Area Proportion of Inclusions Deformed by Plastic Work
dB	Area Proportion of Inclusions Occurring in Discontinuous Array
dC	Area Proportion of Isolated Inclusions
Fatigue	Rotating Bending Fatigue Strength (107 Cycles)

3.1 Regression model

A comparative study is conducted on several ML algorithms, including Decision Tree (DT), LightGBM, and CatBoost, to determine the most accurate one. Table 2 presents the R^2 and RMSE values for each algorithm. Hyperparameter tuning is performed using a grid search approach combined with 10-fold cross-validation to prevent overfitting. The hyperparameter values that yield the best performance are then selected for the ML models.

Table 2 Model performance

ML model	R^2	RMSE
DT	0.896	39.257
LightGBM	0.893	54.209
CatBoost	0.952	31.652

As a result of the comparative study, the CatBoost method achieved the highest accuracy with the optimal hyperparameter values as follows: Depth = 5, Iterations = 1000, and Learning Rate = 0.05. These optimal values were selected from the following ranges: Depth {5, 6, 7}; Iterations {500, 1000, 1500}; and Learning Rate {0.01, 0.03, 0.05}. Figure 2 presents the regression plot of the CatBoost model, which confirms its high accuracy. The data points generally align along a diagonal line, indicating that the predicted values closely match the actual values. Minor deviations from the diagonal suggest potential data quality issues, overfitting, or specific conditions affecting predictions. A strong correlation between the actual and predicted data is observed. The 10-fold cross-validation results in average R^2 and RMSE values of 0.952 and 31.652, respectively. Since the fatigue strength values in the dataset range widely from 225 MPa to 1190 MPa, an RMSE of 31.625 is relatively small, indicating good predictive performance. In the subsequent subsection, the CatBoost model is further analyzed using an interpretable method.

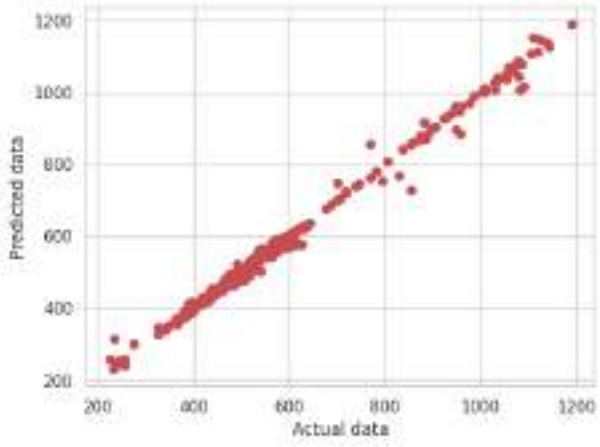

Figure 2. Regression plot

3.2 Interpretable method

Figure 3 represents the feature importance in CatBoost model, where each feature's contribution (relative importance) is measured and ranked. TT is the most significant feature, dominating the importance ranking. It dominates the analysis compared to other features. Tt, QmT, and Cr are the next most important features. There is a gradual decline in importance as we move down the list, with features like THt and RedRatio contributing minimal importance. The most important features have the largest impact on the performance of the model. Lower-ranked features contribute relatively little and might be considered for potential feature reduction or pruning in future analyses.

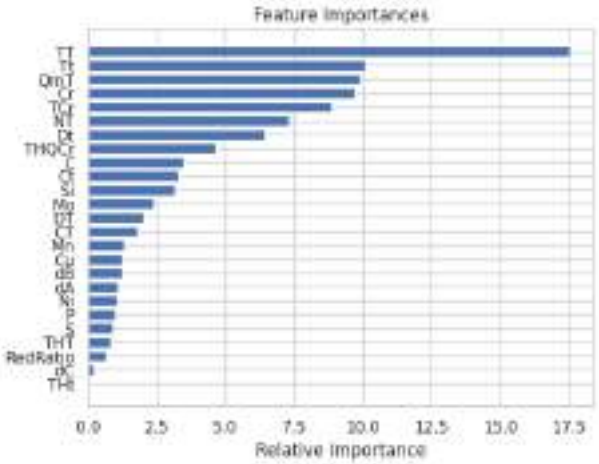

Figure 3. CatBoost importance factor

Figure 4 shows a SHAP summary plot. The features TT, Cr, and Mo have the largest SHAP values, meaning they have the most significant impact on the model's predictions. Their impact spans a wide range of positive and negative values. Features like Cr and Mo show a color gradient, meaning that low feature values (blue) and high feature values (red) influence predictions differently. For instance, high values of Cr (red) push predictions to the right (positive SHAP), while low values (blue) may push them to the left. Features lower down the list, like RedRatio, dA, dB, and P, have a much smaller spread of SHAP values. The varying spread of SHAP values (horizontal spread) reflects how much variance each feature causes in the predictions.

Figure 5 shows a SHAP summary plot that shows the importance of various features. TT has the highest importance in the model, contributing the most to the predictions. Cr follows closely, also playing a major role. Mo, QmT, Dt, and C show moderate impact compared to the top two. Features such as RedRatio, dA, dB, and P have very low SHAP values. The plot shows a clear skew towards the top features (TT, Cr), meaning the model's predictions rely heavily on just a few variables. Identifying the top contributing features (TT and Cr) helps focus on those key variables for further analysis or model optimization. Features with minimal contributions could potentially be excluded to simplify the model.

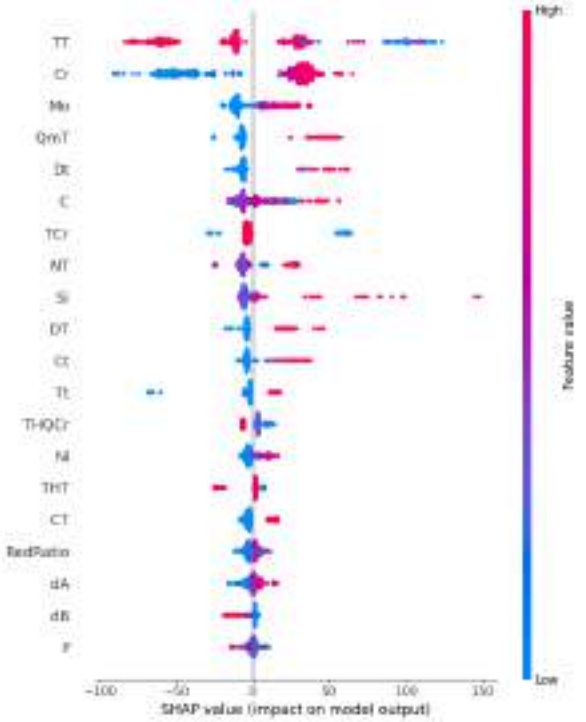

Figure 4. SHAP plots: Shapely value

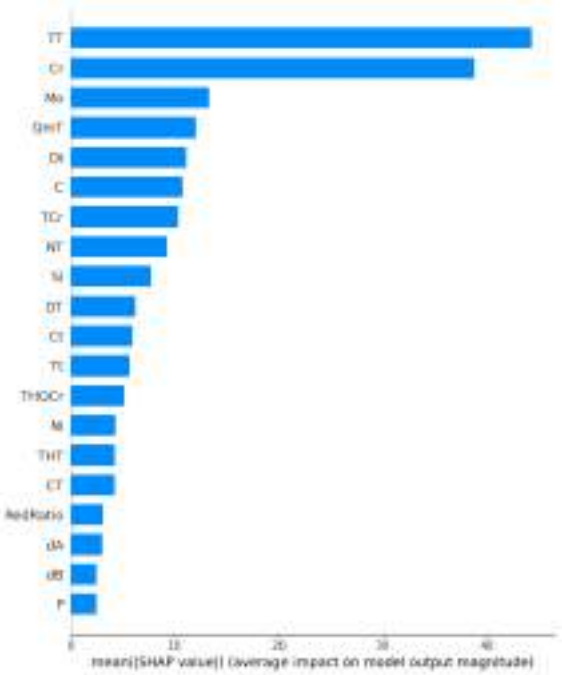

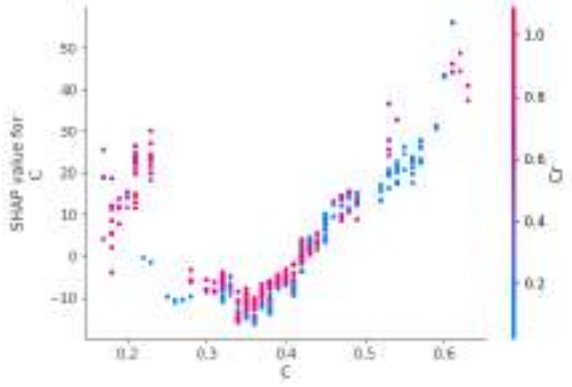

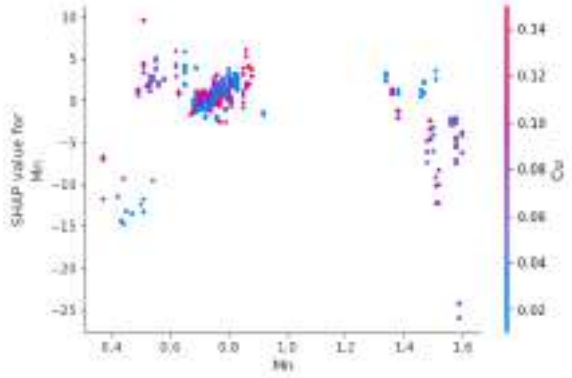

Figure 5. SHAP plots: Global importance factor.

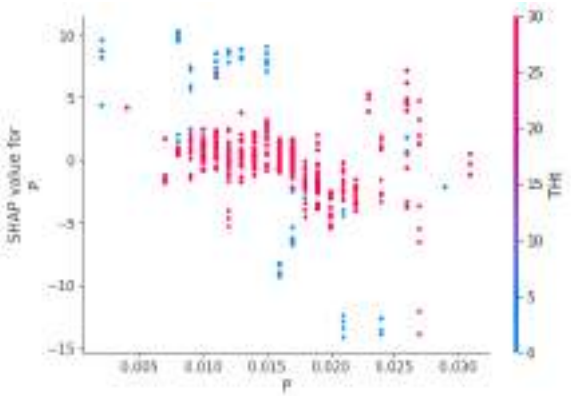

Figure 6 illustrates SHAP value plots that explain the contributions of various features to the model's predictions. Figure 6a shows that SHAP values increase non-linearly with rising "C" values, exhibiting a U-shaped pattern. Figure 6b highlights that the "Mn" feature forms two clusters with distinct SHAP patterns. Figure 6c demonstrates that SHAP values for "P" remain slightly positive for lower "P" values but become more dispersed as "P" increases. Figure 6d reveals a clear positive relationship between "S" and its SHAP values. Figure 6e indicates that SHAP values rise with "Ni" but are clustered into groups. Figure 6f shows that SHAP values increase with "Cr" in a strong positive linear trend. Figure 6g illustrates that SHAP values for "Cu" are mostly scattered around zero, with a slight positive correlation. Figure 6h demonstrates a positive relationship between SHAP values and "Mo" as "Mo" increases. Figure 6i shows that SHAP values fluctuate widely for lower "RedRatio" values but stabilize as "RedRatio" increases. Figure 6j indicates a slight upward trend in SHAP values as "dA" increases. Higher "Cr" appears to significantly influence the SHAP range. Overall, features such as "C," "Cr," "Mo," and "Ni" exhibit clear trends with SHAP values, while others, like "Cu" and "P," show more scattered distributions. These SHAP patterns suggest that specific features strongly contribute to predictions under particular conditions or value ranges.

4 Conclusions

This study demonstrates the significant potential of ML techniques, particularly the CatBoost algorithm, in accurately predicting the fatigue strength of steel while addressing the interpretability challenges commonly associated with black-box models. This research not only enhances predictive accuracy but also provides meaningful insights into the underlying relationships driving fatigue strength by incorporating a diverse dataset encompassing chemical composition, processing parameters, and mechanical properties. The use of SHAP further enables the decomposition of model predictions, offering a dual perspective on global trends and instance-specific behavior.

The analysis revealed that features such as tempering temperature (TT), chromium content (Cr), and molybdenum content (Mo) are the most influential in determining fatigue strength, with tempering temperature exhibiting the highest importance across predictions. The SHAP visualizations illustrated the nonlinear relationships and interactions among variables, highlighting how different combinations of features contribute to the overall predictions. For instance, the study identified synergistic effects between certain alloying elements and processing conditions, underscoring the complexity of fatigue behavior in steel and the importance of considering multivariate interactions in predictive modeling.

This research emphasizes the importance of interpretability in ML applications. The integration of SHAP enhances transparency, enabling engineers to gain actionable insights into the factors influencing fatigue strength. This interpretability fosters trust in the model's outputs, making it more suitable for safety-critical domains, such as structural engineering, where decision-making must be reliable and well-informed. From a practical perspective, this framework can support engineers in optimizing steel selection and processing decisions, reducing fatigue-related failures, and enhancing the sustainability and reliability of steel structures in construction engineering.

Furthermore, the study identified features with minimal contributions to model predictions, such as the reduction ratio and certain inclusion properties, which could be candidates for exclusion in future modeling efforts. This simplification has the potential to reduce computational demands and streamline predictive frameworks without sacrificing accuracy. Future research should explore feature selection methods to reduce redundancy and improve model efficiency, alongside alternative ML algorithms for comparison.

Future research can expand upon this framework by exploring the applicability of interpretable ML techniques to other material properties and engineering

challenges, such as fracture toughness or corrosion resistance. Additionally, incorporating larger and more diverse datasets, including environmental and operational factors, could further enhance the robustness and generalizability of the predictive models. The integration of additional techniques, such as explainable deep learning or hybrid models combining physics-based and data-driven approaches, may also provide deeper insights into complex structural behaviors.

Abstract -

The rapid data growth in smart building environments requires advanced tools to integrate, interpret, and utilize this information effectively. Smart buildings generate vast and heterogeneous data streams, including sensor readings, occupancy metrics, and environmental conditions, which are critical for optimizing energy efficiency, enhancing occupant comfort, and enabling predictive maintenance. However, the lack of a structured approach to automatically connect and contextualize these data sources limits the insights that can be derived. To address these challenges, this paper presents a framework for assessing data in a knowledge graph by automatically retrieving entities and establishing relationships from diverse data sources, incorporating metadata standards and time-series data relevant to smart buildings. A standard ontology from the domain is used to drive the experiment, enabling the automatic construction of a semantic graph-based model for a real-world smart building environment. The framework's objective is to ensure information is comprehensible as a preliminary step to intelligent decision-making in data-driven smart buildings, enabling applications like fault detection, performance measurement, and energy auditing. The proposed approach explores the potential of large language models (LLMs) to automate data integration, reducing reliance on experts. This paper addresses existing literature gaps on metadata mapping and lays the groundwork for future advancements in digital twin technologies for smart building applications.

Keywords -

Ontology; Knowledge graph; Digital twins; data-driven approach; Large language models;

1 Introduction

Achieving global Net Zero Emissions (NZE) by 2050 is a critical goal for mitigating climate change, demanding transformative actions across various sectors. Among these, the Architecture, Engineering, Construction, and Operation (AECO) sector plays a pivotal role, necessitating an accelerated transition to align with the NZE scenario [1]. To this end, many countries have implemented stringent building energy codes and minimum performance standards aimed at reducing energy consumption and greenhouse gas emissions. Technological advancements and industry efforts have led to the rise of data-driven smart buildings (DDSBs), which integrate digitalization technologies to optimize energy use dynamically, enhance indoor environmental quality, and improve occupant experiences [2]. DDSBs generate vast amounts of data through Internet of Things (IoT) technologies, collecting real-time and historical information via advanced sensors. Effectively leveraging this data requires robust frameworks for systematic organization and analysis [2]. Complementing DDSBs, digital twins (DTs) further enhance operational efficiency by enabling predictive maintenance, informed decision-making, and cost minimization [3]. Researchers define a DT as "a virtual representation of a physical system (and its associated environment and processes) that is updated through the exchange of information between physical and virtual systems" [4]. Initially developed for aerospace applications, DTs now extend to diverse domains such as industrial manufacturing, healthcare, smart cities, education, and agriculture [5]. DTs are real-time digital replicas of physical entities or processes that enable a two-way flow of information. The virtual model can be updated in real-time, allowing simulations and informed decision-making to guide physical system adjustments [6]. When integrated with DDSBs, DTs leverage real-time and historical data to enhance data-driven processes, optimizing energy efficiency, indoor environmental quality, and overall system performance [2]. A critical aspect of DT implementation is the integration of a robust data schema, a structured framework essential for defining how data is organized, stored, and managed throughout the building's lifecycle [7]. Integrating appropriate data schemas requires specialized domain knowledge experts and a deep understanding of building systems. The lack of accessible, standardized solutions often hinders the practical deployment of DTs in the built environment, leading to underutilized data, ineffective decision-making, and inefficient practices with significant cost implications. This research introduces a framework that automates the mapping of data generated

by smart buildings into a standardized model, serving as the foundational step in constructing a comprehensive DT. This paper seeks to address these limitations by answering the following questions:

1. How can we address the lack of generic tools for building digital twins in data-driven smart buildings?
2. What is the most effective method for automatically structuring heterogeneous data from a data-driven smart building into a coherent data schema?
3. Does our method perform well regardless of the data model used?

The paper is structured as follows: Section 2 reviews related work, providing context and highlighting existing approaches. Section 3 presents the proposed framework, which leverages Large Language Models (LLMs) for automated knowledge graph (KG) construction, significantly reducing the need for human intervention. The utilization of a prebuilt standard semantic graph ontology serves to enhance the organization of metadata, facilitating better efficiency and accuracy. Section 4 evaluates the framework through its implementation at the Dijon Metropolitan Campus, demonstrating its practical applicability in handling real-world datasets. Finally, Section 5 concludes the paper by summarizing the key findings and discussing potential avenues for future research and development.

2 Related work

Ontologies are essential for achieving data integration and interoperability in DDSBs and DTs. By providing a formalized vocabulary and structured taxonomy, they enable the systematic organization of domain-specific knowledge through well-defined classes, properties, and relationships [8]. Lygerakis et al. [9] identified over 40 ontologies relevant to energy optimization across the lifecycle of connected buildings. However, the authors highlighted that most remain theoretical, with limited real-world applications in operational settings. This literature review identifies several key ontologies as potentially relevant [10, 7], including the Building Ontology Topology (BOT) [11], SSN/SOSA [12], Brick [13], SAREF4BLDGG [14], the RealEstateCore ontology [15], and Google's Building Digital Ontology (DTO) [16]. While these ontologies provide a foundational schema for building data management, their implementation often necessitates significant domain expertise, posing challenges to scalability and automation. Knowledge graphs offer an alternative approach to managing heterogeneous and dynamic data in DDSBs and DTs. As graph-based data models, KGs structure knowledge in a machine-readable format, with nodes representing entities and labeled edges capturing relationships [17]. This flexibility enables KGs to augment digital twins by integrating real-time and historical data while supporting advanced analytics [18]. Unlike ontologies, KGs facilitate linking structured and unstructured data, offering actionable insights and enhancing decision-making capabilities. Despite these advantages, constructing KGs for DDSBs remains a non-trivial task, requiring the resolution of data ambiguities, alignment with specific application requirements, and managing diverse data sources [19]. Existing methodologies have primarily relied on semi-automated approaches. For instance, Chamari et al. [20] proposed a methodology to generate metadata schemas by correlating Building Automation System (BAS) identifiers with ontology classes through text search. This process, while partially automated, relies on human intervention for refining mappings. Similarly, Waterworth et al. [21] addressed inconsistencies in BAS metadata abbreviations using rules and language models to extract and classify semantic information. Koh et al. [22] developed a workflow utilizing machine learning algorithms to convert unstructured BAS metadata into structured formats like Brick. However, these approaches fall short of delivering fully automated solutions and often depend on significant manual effort or predefined rules.

To address these limitations, we propose a novel methodology for automating the construction of KGs from DDSB data. This approach proposes to limit the dependency on domain expertise by systematically mapping heterogeneous data into a standardized model, representing a foundational step toward the comprehensive implementation of digital twins. By directly addressing challenges such as data ambiguity and integration complexity, this methodology advances the field of DDSB data management and supports scalable, interoperable solutions. The following section details the design and implementation of our proposed framework.

3 The proposed approach

This study proposes a methodology to automate the generation of a KG from DDSB data using a large language model (LLM). As advanced generative AI systems, LLMs excel in processing and generating natural language, making them particularly effective for automating tasks such as entity and relationship extraction, competency question formulation, and metadata organization [23]. By reducing the dependence on manual effort and domain expertise, LLMs enhance both the scalability and precision of KG construction. However, a human-in-the-loop approach remains crucial for critical evaluation stages to ensure accuracy and reliability [24].

At the core of the methodology is the Retrieval-Augmented Generation (RAG) technique, further refined

by the GraphRAG method[1]. RAG enhances the contextual relevance and accuracy of LLM outputs by combining semantic similarity retrieval from proprietary data sources with generative language capabilities [25]. This dual approach ensures that generated outputs align closely with domain-specific requirements, making RAG particularly valuable for knowledge-intensive domains such as DDSBs. GraphRAG extends RAG by introducing a KG-centric enhancement. The GraphRAG methodology organizes implicit knowledge from text into graph representation and creates communities based on the graph structure. The generated graph serves as context for RAG tasks, leveraging summaries from high-level communities to produce more diverse outputs. Comparative studies show that GraphRAG outperforms standard RAG methods in terms of accuracy, scalability, and cost-efficiency [26, 27].

Our approach is inspired by the GraphRAG process but uses a pre-built domain ontology as the context graph instead of generating one from raw data. In this manner, the domain ontology provides the context for the RAG operations, which empowers the retrieval process to extract entities from the domain-specific graph. This innovative approach addresses the challenges of data heterogeneity and complexity inherent to DDSBs, facilitating the creation of interoperable and standardized DTs. As illustrated in Figure 1, our proposed framework comprises three main phases: *data collection*, *KG construction*, and *KG visualization*. The following sections detail each phase of our process.

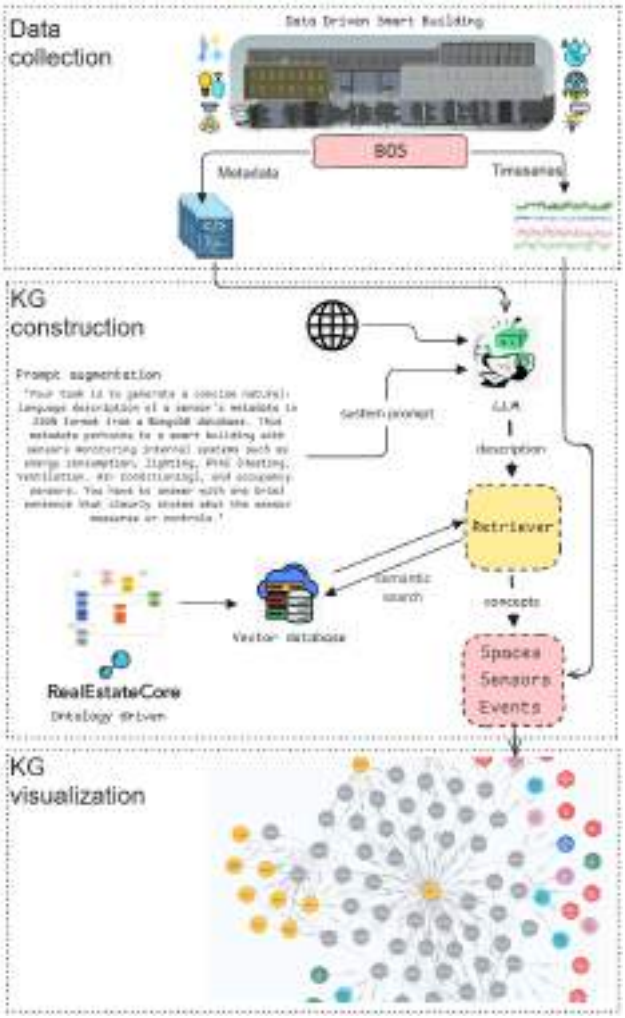

Figure 1. The architecture of the proposed approach.

3.1 Data collection

The data collection phase represents the foundational step in our framework, aimed at systematically gathering and organizing the diverse data sources intrinsic to DDSBs. Smart buildings produce a wide spectrum of heterogeneous data, including IoT identifiers, time-series data from building management systems, and Building Information Modeling (BIM) files, often distributed across siloed and disparate databases. IoT metadata typically captures device-specific attributes such as type, operational parameters, control commands, and spatial topology, defined either by vendor-specific schemas or standardized frameworks. In our approach, the Building Operating System (BOS) plays a central role as the primary data aggregator, integrating information from interconnected devices and systems within the DDSB. This centralized integration ensures a unified flow of data, enhances compatibility with third-party applications, and facilitates the systematic identification and extraction of critical entities and relationships required for KG construction. By addressing the challenges of data heterogeneity and accessibility, this initial phase prepares the collected data for seamless transition to the subsequent phase.

[1]https://github.com/microsoft/graphrag

3.2 KG construction

The second phase of our framework focuses on constructing a domain-specific KG by leveraging an enhanced LLM adapted to the GraphRAG methodology. This approach uses the LLM to generate concise natural-language descriptions from metadata provided by the DDSB and incorporates a predefined ontology to guide the semantic retrieval of appropriate concepts. The process begins with **(1) ontology integration**, where the GraphRAG system's context is set using a predefined ontology that semantically describes each asset of the DDSB, providing a structured framework for metadata interpretation. Next, **(2) metadata description generation** involves prompting the LLM to produce concise natural-language descriptions of the DDSB metadata, which includes dynamic data such

as sensor readings (e.g., temperature, humidity, energy usage) and static data like spatial and topological information (e.g., classrooms, parking areas, laboratories, and building levels). Following this, **(3) concept retrieval** is performed, where a semantic similarity search is used to identify and retrieve the most relevant concepts from the ontology, aligning them with the metadata descriptions. Finally, **(4) KG construction** links the retrieved concepts with time-series data, organizing the information into a cohesive structure. Relationships are established between nodes representing topology, sensors, and time-series values, all formatted according to the ontology schema. This comprehensive process ensures that the constructed KG is semantically accurate, contextually relevant, and capable of representing the complex relationships inherent in DDSB data.

3.3 KG visualization

The final phase of our framework focuses on the visualization and evaluation of the constructed KG to ensure its accuracy and usability. The KG is exported to a graph database management system, which provides robust tools for querying and visualizing the graph's structure. Visualization plays a critical role in the validation process, enabling a thorough review of the interconnections between nodes. Specifically, this step involves verifying the alignment of the building topology, ensuring that sensors are correctly assigned to their respective locations, and confirming that observation values are accurately linked to the corresponding sensors, along with their associated timestamps. These visual checks are essential to identify and rectify any inconsistencies or errors that may arise during the KG construction phase. Additionally, the visualization phase facilitates an intuitive understanding of the underlying relationships and patterns in the data, making the KG more accessible to domain experts and stakeholders. This step concludes the methodology by ensuring that the KG is not only accurate and reliable but also ready for downstream applications, such as querying, analysis, and integration into digital twin systems.

4 Experimental results

This section presents the experimental results to evaluate the performance of the proposed method and analyze its effectiveness.

4.1 Evaluation setup

This study is conducted at the Dijon Metropolitan Campus[2], a $10,000\ m^2$ smart building certified under the Ready2Service (R2S) standard for its advanced digital infrastructure. The campus employs 14 types of sensors to monitor various parameters, including occupancy, temperature, CO2 levels, humidity, illuminance, and energy consumption, across 350 distinct areas encompassing 32 spatial categories such as waiting rooms and classrooms. The system stores the collected data in a schema-less MongoDB database in JSON format. A one-month subset of this time-series data amounts to approximately 11 GB and comprises over 50 million entries.

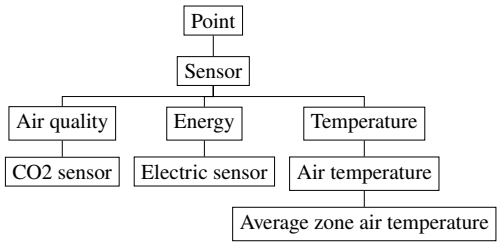

Figure 2. Part of REC ontology for sensor hierarchy.

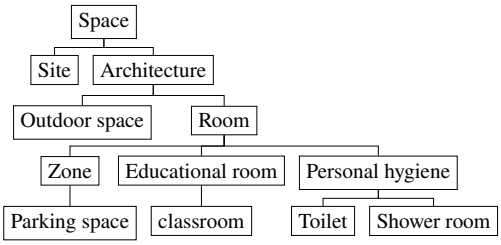

Figure 3. Part of REC ontology for space hierarchy.

To guide our methodology, we identify the RealEstateCore ontology (REC) as the most suitable framework due to its robust and comprehensive structure [15]. REC provides a detailed taxonomy that includes 240 sensor types (e.g., humidity, motion, temperature, lighting), as illustrated in Figure 2, and 92 spatial and architectural categories (e.g., back office, entrance, laboratory, warehouse), depicted in Figure 3. These categories are organized hierarchically to accommodate diverse use cases, enhancing the accuracy of KG construction and optimizing data retrieval processes. Moreover, REC employs the Label Property Graph (LPG) format, a data-centric model that facilitates real-time operations by enabling efficient storage and access of large datasets through graph databases [28]. Originally developed as an OWL ontology for RDF-based knowledge graphs, REC has been adapted into the Digital Twin Definition Language (DTDL)[3] to better align with user requirements and streamline deployment. DTDL, built on the JSON-LD format[4], ensures compatibility with the existing campus database, thereby eliminating the need

[2]https://www.estp.fr/en/dijon-campus

[3]https://learn.microsoft.com/en-us/azure/digital-twins/concepts-models

[4]https://json-ld.org/

for additional storage solutions while streamlining the integration process. This combination of hierarchical organization, real-time graph database performance, seamless integration, and compatibility with existing systems underscores REC's efficacy as the foundational framework for our approach.

4.2 Results and discussion

We present the results of applying the methodology to generate a KG at the Dijon Metropolitan Campus for a given day. The objective is to identify the pertinent classes within the REC ontology that align with the disparate points on the Dijon Metropolitan Campus and establish a relationship with the time series data. The resulting KG is exported to the Neo4J graph database[5] for storage and visualization. Figure 4 depicts a part of the resulting KG, in which the time-series data are linked to the standard semantics of the sensors and spaces of the Dijon Metropolitan Campus, encapsulated within the REC ontology model. Figure 5 illustrates an example of a node representing a cafeteria room that contains several attributes, including designation and display name, which have been retrieved from the metadata. This example demonstrates the hierarchy of the nodes, whereby the cafeteria room inherits from the food handling room, a room, and a space, corresponding to the REC ontology hierarchy and taxonomy. Figure 6 illustrates an example of a node representing a time series value connected to a node representing a temperature sensor. Node's properties include the temperature value and the timestamp. The objective is to demonstrate the enrichment of time-series data with standard semantics, facilitating its linkage to the sensors and equipment for efficient querying.

We evaluate the proposed methodology by presenting results from multiple perspectives, including processing execution time, repeatability, comparison of LLMs, concepts retrieval evaluation, and KG query evaluation.

4.2.1 Computational efficiency

The efficiency of the proposed methodology was assessed based on its execution time for generating the KG. The retriever identifies all relevant concepts within one minute, followed by KG construction in less than 20 seconds for a specific day's time-series data. Using a laptop equipped with an Intel Core i7 processor and 32 GB of RAM, the system generated 42, 728 JSON-LD documents (nodes) within this timeframe.

[5]https://neo4j.com/

4.2.2 Model consistency

The consistency of the retrieval methodology was assessed using three LLMs: Llama3.2[6], Mistral7B[7], and Gemma2[8]. Each model underwent 20 trials, with conservative parameter settings to minimize response variability. The results demonstrated that the retrieval process was reliable within individual models, with minimal fluctuations in performance due to the conservative configurations. However, notable discrepancies arose in how the models interpreted and retrieved concepts from the REC ontology. These differences highlight the distinct semantic inference strategies employed by each LLM, emphasizing the importance of carefully selecting the appropriate model for specific use cases and applications.

4.2.3 Model comparison and performance

The results shown in Table 1 illustrate pairwise comparisons that quantify the percentage of identical REC concepts retrieved by each LLM. Low values indicate that each LLM retrieved different concepts, while high values suggest greater homogeneity in the retrieved REC concepts across the models. The results generally show low to moderate values, indicating weak overlap in the retrieved concepts. This variation highlights differences in how each language model interprets and processes the semantics of the metadata and the REC ontology concepts, emphasizing the inherent differences in their inference mechanisms.

Table 1. Retrievability analysis across LLMs for 14 sensors (Se.) and 32 spaces (Sp.).

LLM	Llama		Mistral		Gemma	
	Se.	Sp.	Se.	Sp.	Se.	Sp.
Llama	-	-	28%	53%	21%	68%
Mistral	28%	53%	-	-	28%	50%
Gemma	21%	68%	28%	50%	-	-

4.2.4 Semantic retrieval accuracy

A manual qualitative assessment was conducted to evaluate the identification of 32 spaces and 14 sensor types from the REC ontology. Each retrieved concept was categorized as "correct," "ambiguous," or "incorrect." The ground truth for each sensor and space category was established through direct analysis of the data or reference to the BIM model. For instance, an incorrect retrieval was observed when the Gemma model classified a *meeting room* as a *workshop room*, while both the Mistral and Llama models correctly identified a *conference room*. In cases where ambiguity was present, all LLM models

[7]https://docs.mistral.ai/
[8]https://github.com/google-deepmind/gemma

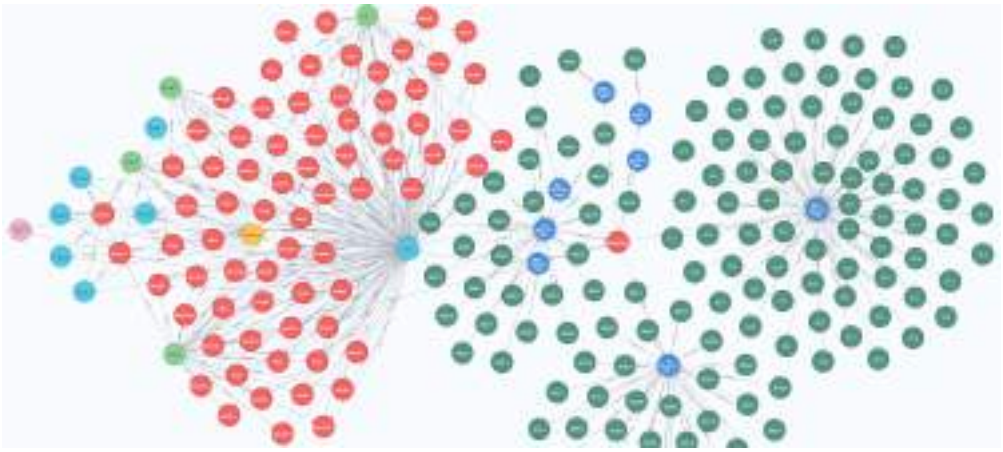

Figure 4. Part of the generated KG for the Dijon Metropolitan Campus: red nodes represent spaces, blue nodes represent sensors, and green nodes represent values.

Figure 5. Cafeteria room node with hierarchy.

Figure 6. Temperature observation node with values.

classified *toilets* as *personal hygiene rooms*, despite the explicit existence of the toilet concept in the REC ontology. An example of a correct retrieval is the occupancy sensor, which was accurately mapped to the corresponding concept within the REC ontology. The Dijon Metropolitan Campus employs energy sensors that monitor electricity consumption in kilowatt-hours (kWh) across various equipment, such as lighting, power outlets, and heating systems. The most appropriate concept for this data in the REC ontology is the *Electric Energy Sensor*. However, depending on the LLM, the retrieved concepts varied between Energy Usage Sensor and Energy Sensor. While both of these concepts are valid, they do not fully align with the ground truth, and as such, these responses were categorized as "ambiguous," leading to a loss of semantic precision regarding the type of electrical energy. Table 2 summarizes the performance of the models, revealing that the Llama model consistently outperformed the others, exhibiting high accuracy with minimal errors in both space and sensor retrieval tasks. The Gemma model demonstrated moderate performance, excelling in space retrieval but encountering more ambiguities in sensor retrieval. The Mistral model, in contrast, showed the weakest performance, particularly in space retrieval, with a significant number of incorrect responses.

However, ambiguous responses are not necessarily erroneous, though they do not invariably correspond with the ground truth. The models performed consistently across various scenarios, achieving an overall correct identification rate of 73% when ambiguous answers were considered accurate

Table 2. Retrievability evaluation of sensors (Se.) and spaces (Sp.) across LLMs: distribution of correct, ambiguous, and incorrect retrievals.

LLM	Correct		Ambiguous		Incorrect	
	Se.	Sp.	Se.	Sp.	Se.	Sp.
Llama	12	27	2	2	0	3
Mistral	5	17	3	2	6	13
Gemma	5	20	8	2	1	10

4.2.5 KG query evaluation

We leverage the semantics of metadata and time-series data structured within the REC ontology to assess the generated KG. The relevance of semantic relationships is explored through a series of Cypher queries[9], a declarative query language designed for use with the Neo4j graph database. The evaluation involved conducting automated queries on the KG and validating the results against a predefined ground truth. A total of 15 queries were formulated and categorized into three distinct types: **(1) room type query** counting, which examines the distribution of room types within the KG; **(2) sensor type query** counting, focusing on the frequency of occurrence of various sensor types; and **(3) sensor-to-room relationships**, aimed at evaluating the connections between sensors, their associated time-series data, and the specific spaces they monitor. For a complete list of queries, please refer to the file `queries_for_kg_evaluation.md` in the GitHub repository[10]. The results of these evaluations are summarized in Table 3, which presents the number of correct answers for each LLM. The ground truth was established by querying the original MongoDB database or through manual analysis of data from the BIM model. The Llama model demonstrated the most consistent performance, achieving near-perfect scores across all query types, thereby illustrating its robust ability to handle both sensor and spatial data. The Mistral model performed reasonably well in sensor-to-room mapping but exhibited weaker results in the room type and sensor type queries. The Gemma model, while excelling in sensor-related queries, faced challenges in accurately identifying room types. These findings highlight the effectiveness of using automated unit tests for evaluating and refining the performance of knowledge graph queries.

Table 3. Automatic query evaluation.

LLM	Room type	Sensor type	Sensor-to-room
Llama	4/5	5/5	4/5
Mistral	2/5	3/5	4/5
Gemma	1/5	5/5	5/5

5 Conclusion and future work

This paper presents an LLM-based framework that leverages an ontology to guide the automatic construction of a KG, facilitating the management of data in smart buildings. By integrating LLMs, the framework reduces reliance on human expertise while improving the accuracy of KG development. Experimental results demonstrate the effectiveness of the REC ontology in guiding KG creation from unstructured data. However, while the method accelerates the process, human verification is still required to ensure the correctness of identified concepts, introducing potential delays and biases. These preliminary findings suggest promising directions for future research, including integrating BIM assets into the KG [29] to enhance organization and interoperability. Expanding the REC ontology to address ambiguous or incorrect concepts could further refine the KG's semantic alignment. Additionally, exploring the use of alternative ontologies, such as Brick, would increase user autonomy and broaden the framework's applicability. Further testing with metadata from other smart buildings would also be beneficial. Once established, the KG can serve as a foundation for LLMs, enabling natural language queries that improve accessibility for diverse stakeholders. Moreover, applying advanced graph algorithms, such as graph neural networks, could offer valuable insights, supporting classification and clustering tasks that enhance decision-making in complex smart building scenarios.

Abstract –

Various vision sensor-based platforms generate critical information for real-time construction site monitoring, but their independent applications limit the effective use of this data. This study proposes a framework that integrates three representative vision platforms—Unmanned Aerial Vehicle (UAV), Terrestrial Laser Scanner (TLS), and Closed-Circuit Television (CCTV)—to create a unified digital map. The framework operates as follows: UAVs capture aerial images for overall 3D digital map reconstruction, TLS refines vertical surfaces and structural details through map alignment, and CCTV cameras enable robust real-time 3D object tracking using ray marching and multi-view fusion, resulting in a dynamic digital map. Experimental results demonstrated that the framework enhances resolution of a digital map and improves dynamic object tracking compared to using individual platforms in isolation.

Keywords –

Unified Map, Registration, 3D Reconstruction, Object Tracking, UAV, TLS, CCTV

1 Introduction

In modern construction sites, various vision platforms such as Unmanned Aerial Vehicles (UAVs), Terrestrial Laser Scanners (TLS), and Closed-Circuit Television (CCTV) are actively utilized to enhance site monitoring by generating critical site information. However, Each platform has its strengths and limitations. UAVs, for example, offer high mobility and cost-effective coverage of large areas, making them widely used for 3D digital map generation in construction sites [1]. However, their high-altitude operations and the perpendicular orientation of cameras to the ground, commonly used in UAV surveys, result in low spatial resolution and a lack of information about vertical surfaces in their digital maps [2]. Furthermore, UAVs cannot capture the entire environment at once, which prevents representing real-time movements of dynamic objects on the digital map.

TLS, on the other hand, uses LiDAR and cameras for long-duration scans from the ground, producing high-resolution 3D digital models, particularly for vertical surfaces. While expensive(e.g., the FARO FOCUS S350 costs over $14,500), its benefits make it widely used in construction for applications such as detecting concrete cracks [3] and comparing as-is models with design plans [4]. Recent advancements in Scan-to-BIM technology [5] enable automatic BIM model generation from precise survey data, further driving TLS adoption [6]. However, its ground-level perspective limits the capture of horizontal surfaces like rooftops, and the extensive time and labor required for data collection make it impractical for large-scale mapping or dynamic object analysis [7].

CCTV systems offer a cost-effective solution for long-term, real-time monitoring, capturing sequential data with low operational costs [8]. Rising safety concerns over construction sites accidents have driven their widespread adoption [9]. They are particularly useful for tracking dynamic objects like heavy equipment productivity [10]. However, their limited field of view and issues with occlusion make it challenging to continuously track and monitor dynamic objects, such as materials and workers, in complex and active construction sites [11]. CCTVs, additionally, struggle to generate 3D spatial information about a scene because they are typically installed in scattered locations with fixed monocular cameras.

To summarize, while various vision platforms have been widely used in construction sites, their inherent limitations restrict the usability of the generated information when used independently. To produce comprehensive site information, it is essential to integrate the independent data from each platform into a unified system. UAVs can rapidly capture overall site data without being constrained by site complexity, while TLS can complement this by generating high-resolution models of critical structures and vertical surfaces that require greater detail. Meanwhile, CCTV systems can track dynamic objects, such as workers and equipment.

By integrating data from these platforms, a more complete and accurate digital models of the construction site can be achieved. To this end, this paper proposes a framework for the integration of information from each vision platform into a unified 3D digital map of the site, leading to more comprehensive construction site monitoring in real-time.

2 Literature Review

2.1 Integration of UAV and TLS Data

Many previous studies on aligning UAV and TLS data utilize the Iterative Closest Point (ICP). ICP is an algorithm that iteratively aligns two datasets by finding the closest point for each point and calculating the rotation and translation between them. However, it is highly sensitive to the quality of the initial alignment [12]. The previous studies often perform initial alignment using GPS data [13] or manual alignment via software [14], followed by fine alignment using ICP.

UAV-generated 3D digital maps, created from aerial imagery, and TLS-generated 3D digital models, created from ground-based LiDAR, differ significantly from the distribution and density characteristics of their points. These differences in point distribution can negatively impact alignment accuracy [15]. Moreover, construction sites are typically large-scale environments, resulting in digital maps with a high number of points. This makes it challenging to apply computationally intensive algorithms due to their high computational costs.

In response, this study aims to resolve the differences in point distribution and density characteristics, perform reliable automatic initial alignment, and maximize the performance of ICP fine alignment.

2.2 Camera-based 3D Object Tracking

Camera-based 3D object tracking can be broadly categorized into multi-view geometry-based methods and monocular methods. Multi-view geometry involves installing multiple cameras with overlapping fields of view and estimating relative spatial relationships through feature points to infer 3D coordinates. This approach, however, requires cameras to be installed with similar viewpoints and overlapping coverage, which is challenging to achieve in typical construction sites.

On the other hand, monocular methods primarily rely on homography or depth estimation models. Homography represents the transformation between points on two planes. Assuming the ground is a plane, a homography relationship can be established between the ground plane in the 3D real-world coordinate system and the 2D image plane. The relationship can be calculated if at least four corresponding point pairs are identified. However, since homography is limited to flat planes like the ground, accurately incorporating dynamic information captured by CCTV into a 3D digital map becomes challenging in more complex scenarios involving uneven or non-planer surfaces.

MiDaS [16], a state-of-the-art single-image depth estimation model, offers an alternative approach. MiDaS is trained to generate depth maps from 2D images labeled with depth information. However, monocular depth estimation models can experience significant performance degradation when applied to scenes that differ substantially from those seen during training.

3 Methodology

This study is conducted in three stages: overall 3D map reconstruction, map refinement with registration, and object tracking in a 3D map, as shown in Figure 1.

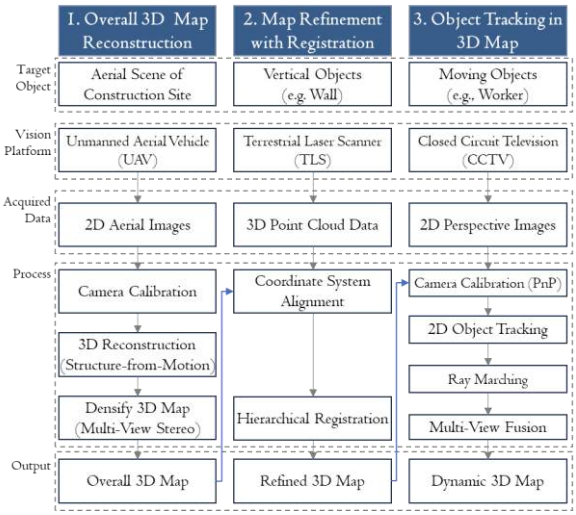

Figure 1. Framework of Vision Platforms Integration

The first stage involves generating an overall 3D map. A UAV is deployed to capture sequential 2D aerial images, and Structure-from-Motion (SfM) [17] is applied to reconstruct a sparse 3D map of the entire site. Subsequently, Patch-based Multi-View Stereo (PMVS) [18] creates a densified overall 3D map.

The second stage focuses on refining the generated 3D digital map. Aerial images alone have limitations in representing high-resolution details and generating 3D models of structures with vertical surfaces, such as walls. To address these limitations, high-resolution 3D point cloud data is collected using a TLS. The UAV-derived 3D digital map and the TLS-based 3D digital models are first coarsely aligned to a unified coordinate system. Subsequently, fine alignment is performed using hierarchical registration. The integration of UAV and TLS data enhances the level of detail and improves the representation of vertical surfaces in the initial map.

The third stage involves tracking objects and

incorporating this information into the 3D map. For CCTV footage, objects are tracked, and their positions in the 3D map are estimated using ray marching. Multi-view fusion is then applied to ensure robustness against tracking failures and maintain the consistency of object information across multiple CCTVs. By integrating these three stages, this study generates a unified 3D digital map that not only provides refined 3D representations but also incorporates dynamic object information.

3.1 Overall 3D Map Reconstruction

The process of generating an overall 3D digital map using UAV involves the following steps: camera calibration is first conducted to estimate the camera matrix, which defines the transformation between 2D image points and their corresponding 3D coordinates. The camera matrix is composed of intrinsic and extrinsic parameters. Intrinsic parameters, such as focal length and principal point, describe the internal characteristics of the camera. Extrinsic parameters define the camera's position and orientation relative to the world coordinate system. The intrinsic parameters are typically determined using a chessboard pattern, while the extrinsic parameters are estimated using Structure from Motion (SfM). SfM is a photogrammetry-based technique that iteratively computes camera poses and generates a sparse 3D map from sequential images, optimizing both pose estimation and mapping accuracy throughout the process. Subsequently, Patch-based Multi-View Stereo (PMVS) is employed to identify overlapping patches between consecutive images and reconstruct them in 3D, thereby densifying the sparse map.

3.2 Map Refinement with Registration

The TLS captures high-resolution 3D data of the surrounding area using LiDAR technology. The 3D data generated by UAV and TLS are represented in different coordinate systems, each with distinct scales and origins. To unify these coordinate systems, GPS data is used to restore the scale of each 3D map to real-world dimensions and align their coordinate system references. Since GPS inherently has an error margin of several meters, an additional hierarchical registration process is required to achieve accurate integration.

3.2.1 Coordinate System Alignment with GPS

Geo-registration converts the overall 3D digital map from the SfM coordinate system into the Earth-Centered Earth-Fixed (ECEF) coordinate system, a global 3D Cartesian coordinate system centered on the Earth. This transformation is essential for accurately positioning and orienting objects on a global scale. The process uses Random Sample Consensus (RANSAC) to determine the optimal similarity transformation between the two coordinate systems.

In contrast, TLS directly captures 3D points via LiDAR, generating maps based on GPS data. To unify digital maps, the TLS-generated 3D map is transformed into the ECEF coordinate system, ensuring coarse alignment with the UAV digital map.

3.2.2 Hierarchical Registration of 3D Digital Maps

Hierarchical registration is used to efficiently align large-scale UAV and TLS point clouds by breaking the process into two stages, as shown in figure 2. For initial alignment, a Fast Point Feature Histogram (FPFH) analyzes the relationships between neighboring points in the point cloud data to extract feature points that encapsulate local geometric information. These features are matched using a RANSAC algorithm to establish an initial transformation. While FPFH provides reliable initial alignment, it incurs high computational costs when applied to large point cloud datasets. To overcome this challenge, both 3D digital maps are down-sampled with voxelization, where the points within each cubic voxel are represented by their average position. This process reduces computational complexity while mitigating differences in point distribution.

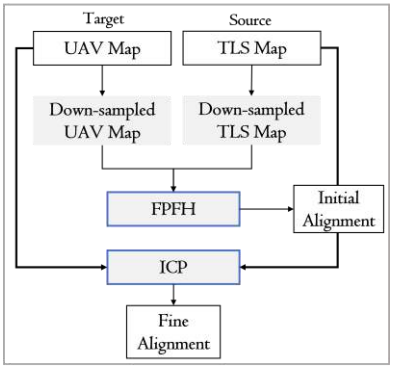

Figure 2. Hierarchical Registration Process

Following this, the ICP algorithm refines the alignment by identifying the closest corresponding points and updating the transformation matrix. Since finding the nearest points is a relatively simple operation and FPFH ensures a reliable initial alignment, ICP is performed on the entire point cloud. By combining FPFH for initial alignment and ICP for fine refinement, this hierarchical approach achieves efficient and accurate automatic alignment of UAV and TLS maps without succumbing to computational overhead or overfitting from differences in point distribution.

3.3 Object Tracking in a 3D Map

The proposed method for object tracking in a 3D map integrates information about dynamic objects into the map for enhanced situational awareness. The process

begins with camera calibration, during which the intrinsic and extrinsic parameters of each camera are estimated. This calibration establishes the relative position and orientation of the CCTV cameras within the registered refined digital map. Subsequently, YOLO-based 2D object detection is applied, identifying objects and determining their positions as 2D pixel coordinates x_{object}. These coordinates are then back-projected into the 3D space using ray marching to estimate the objects' 3D positions X_{object}. To improve the accuracy and consistency of tracking, multi-view fusion is employed, leveraging data from multiple perspectives.

3.3.1 Camera Calibration for CCTV Systems

For CCTV cameras, the extrinsic parameters are determined using the Perspective-n-Points (PnP) [19] algorithm. When four matching pairs between the 2D image and the 3D map are specified, the PnP algorithm calculates the camera's rotation and position. Further optimization is conducted using the Levenberg-Marquardt [20] to refine these estimates. Since the extrinsic parameters of a CCTV camera typically remain fixed after installation, calibration only needs to be performed once during the initial setup of the camera. This ensures that the camera's position and orientation are accurately aligned with the 3D digital map.

3.3.2 2D Object Tracking with Pose Tracker

2D object tracking is conducted using the BoT-SORT [21], a multi-object tracking method that performs object tracking without additional training. BoT-SORT can also extract key points of the detected objects. As illustrated in Figure 3, for a worker object, the 2D point of the object is defined as the center point (marked as a black cross) between the coordinates of the left foot and right foot (marked as red dots).

Figure 3. Definition of the worker's 2D point

3.3.3 Back Projection with Ray Marching

To represent the 2D point of an object into the 3D digital map, back projection is performed. Back projection is the process of reconstructing a 3D world point from a 2D image point.

$$\lambda P^{-1}\begin{bmatrix} u \\ v \\ 1 \end{bmatrix} = \begin{bmatrix} X \\ Y \\ Z \\ 1 \end{bmatrix} \quad (1)$$

In Equation 1, P is a 3×4 camera matrix, u and v are 2D image points, and X, Y, and Z are 3D world points. λ is a scale parameter that represents the depth from the 2D image point to the corresponding 3D world point. The camera matrix P is obtained through camera calibration, leaving the depth parameter λ as the only unknown variable. In essence, back projection is the process of determining this unknown depth.

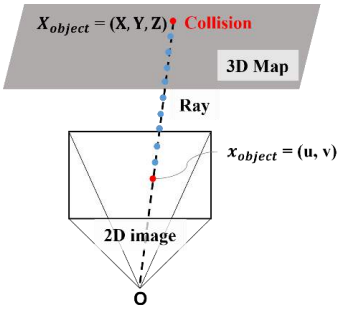

Figure 4. Ray Marching Method

Back projection can be achieved using ray marching. As shown in figure 4, ray marching is a technique that casts a ray from a 2D point x_{object} by sampling 3D points along the ray and searches for the point X_{object} where the ray collides with a surface in 3D space. Because this method directly interacts with the digital map, it requires a high-quality map that is noise-free, high-resolution , and free of voids. Fortunately, the registration of UAV and TLS data eliminates noise, enhancing both the resolution and completeness of the digital map. Ray marching involves sampling candidate 3D points along a ray extending from the camera's origin toward the corresponding 2D image point.

$$r(t) = O + tD \quad (2)$$

Equation 2 reformulates Equation 1 from the perspective of a ray, where O represents the camera origin and D is the direction vector of the ray. Both O and D are derived from the camera matrix P. The parameter t denotes a positive real number depth value, and by incrementing t, the 3D position $r(t)$ of a sample point along the ray is calculated. If the shortest distance between $r(t)$ and the points in the digital map falls below a predefined threshold, the corresponding point in the digital map is determined to be the object's position.

3.3.4 Multi-View Fusion

The 3D position obtained in the previous steps is

managed by assigning a unique track ID for each camera. A single camera, however, loses the ability to track the object if it moves out of the camera's field of view. When the object reappears, a new track ID is assigned, resulting in inconsistency between multiple cameras. Multi-view fusion overcomes this inconsistency in track IDs and enables a robust object tracking system by integrating data from multiple cameras into a unified 3D digital map.

The detailed algorithm for multi-view fusion is explained with an example in Figure 5. At T=3, when a new track ID appears in a camera, the system queries the database to check whether any object is being tracked near the 3D position of the newly detected object. If no such object exists, a new object ID is assigned, and the database begins tracking this object. Subsequently, at T=40, if the same object appears in another camera, track matching is performed to associate the track ID from the camera with the object ID in the database. Once matched, the object's position can be obtained from both CAM0 and CAM1. This ensures that even if a tracking failure occurs in one camera, such as CAM1 at T=40, the object can still be tracked using CAM0.

If, at T=50, all cameras fail to track the object, the system predicts the next position based on the average position change over the previous five timestamps stored in the database. This prediction enables continued tracking, even during temporary tracking failures. Finally, at T=109, if different track IDs are assigned to the same object in other cameras, track matching ensures that the same object ID is used. However, duplicated 3D positions estimated by distinct cameras can be different due to errors in object detection. To address this, the system calculates the tracking error for each 3D position and selects the point with the lower error, reducing redundancy and improving accuracy. The error in 2D object tracking propagates into the 3D position estimation error through back projection. Since the relationship between 2D and 3D points involves a nonlinear transformation, this propagation is described by the Jacobian matrix J.

$$cov(X_w) = J \times cov(x_{pixel}) \times J^T \quad (3)$$

In Equation 3, $cov(X_w)$ represents the covariance of the 3D point, indicating the 3D object tracking error, while $cov(x_{pixel})$ represents the covariance of the 2D point, characterizing the error in 2D object tracking. This systematic error propagation ensures that the system accounts for inaccuracies in both 2D and 3D tracking, leading to more precise object localization.

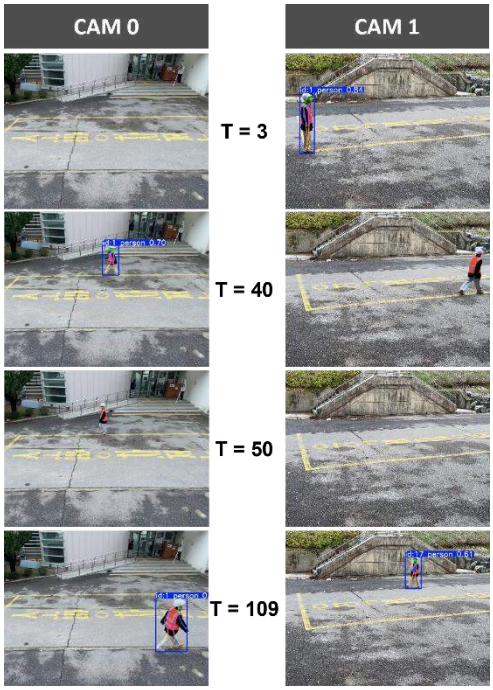

Figure 5. Example of Multi-view Fusion

4 Experiments

The experiments took place in a lane-marked area at Seoul National University. To simulate a multi-view CCTV system, two iPhone 12s were installed with overlapping fields of view, and their resolution was reduced to 360×640 to match typical CCTV settings. A DJI Mavic 3E UAV and a FARO Focus M Laser Scanner (TLS) were used for 3D map generation. The study consisted of two experiments.

- UAV and TLS Map Alignment

This experiment assessed the error in digital map alignment and the improvement in resolution for vertical surfaces. The evaluation metric for alignment was the Inlier Root Mean Square Error (Inlier RMSE) in meters. The metric was calculated by finding the nearest UAV-based neighbor for each transformed TLS point and calculating the RMSE. Points exceeding a set distance threshold were classified as outliers and excluded, ensuring a more precise alignment assessment. A voxelization size of 0.5m was used, with inlier thresholds of 0.5m, 1.0m, and 1.5m.

- Multi-View Fusion-based CCTV Object Tracking

This experiment evaluated the proposed ray marching-based object tracking method against baseline approaches using homography and the MiDaS depth estimation model. Since MiDaS generates only relative depth maps, four reference points were selected to obtain true depth values. A cubic spline interpolation was then

applied to convert the relative depth map into an absolute depth map for the analysis. Moreover, the effectiveness of multi-view fusion was validated. Object tracking performance was assessed using the mean and RMSE of the Absolute Trajectory Error (ATE). The mean ATE is a standard measure of position estimation accuracy, while RMSE is more sensitive to large errors, providing a comprehensive evaluation of tracking.

The ground truth trajectory for evaluation was defined as the yellow rectangle shown in Figure 6. The ATE was calculated as the distance between the estimated 3D points and the closest ground truth points.

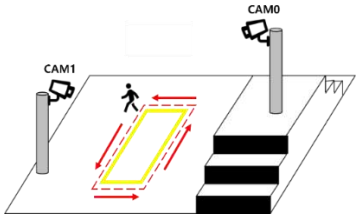

Figure 6. Testbed for Object Tracking

4.1 Evaluation of Detailed 3D Map

To validate the alignment accuracy, an ablation study, as shown in Table 1, compared the proposed hierarchical method against individual alignment algorithms. The best RMSE of 0.101m at a 0.5m inlier threshold was achieved using $FPFH_{down}$ with downsampling for initial alignment, followed by ICP. This highlights their complementary strengths: FPFH captures global geometric features for coarse alignment, while ICP refines precision during fine alignment.

The UAV-based digital map covers $150 \times 200m^2$ with 10.8 million points, while the TLS model spans $40 \times 76m^2$ with 74.2 million points. Table 1 analyzes runtime efficiency. Without downsampling, ICP successfully aligned in 4:36 minutes, whereas FPFH failed due to high computational costs. By applying 0.5m voxelization-based downsampling, FPFH completed in 3:12 minutes, approximately reducing UAV points to 207,000 (52 × reduction) and TLS points to 64,000 (1,188× reduction). Since FPFH iterates over all points, downsampling reduced computational costs by over 1,000×, confirming its necessity.

Table 1 Inlier RMSE with Varying Inlier Thresholds and Runtime of Registration

	0.5m	$1.0m$	$1.5m$	Time(m)
ICP	0.300	0.610	0.920	4:36
$FPFH_{down}$	0.124	0.187	0.253	3:12
Proposed	**0.101**	**0.172**	**0.238**	7:48

Figure 7 illustrates the benefits of the proposed method. In the first row, vertical surfaces missing in the UAV digital map were completed through alignment, showing the ability to enhance map completeness. In the second row, the resolution of 3D models for structures of interest was significantly improved, increasing their utility for applications requiring high-quality 3D digital models, such as construction error analysis. In representing the wall structure, the UAV-based digital map had an average density of $124\ pts/m^2$. In contrast, the aligned digital map achieved an average density of $11{,}066\ pts/m^2$, almost 100-fold density increase. This substantial improvement demonstrates the enhanced capability of the proposed method to generate refined 3D representations of structures.

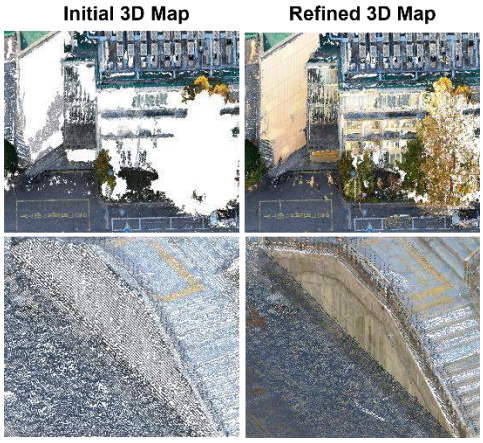

Figure 7. Qualitative Result of Registration

4.2 Evaluation of Object Tracking

Figure 8 illustrates the qualitative results of object tracking. The color gradient represents the progression of timestamps, with red indicating earlier timestamps and yellow indicating later ones. Ray marching exhibited a few errors near the bottom edge, while homography showed some errors along the top edge. Both the ray marching and homography methods, however, generally produced object trajectories that were closely aligned with the yellow rectangular ground truth path. In contrast, the depth estimation model demonstrated a trajectory that was relatively more deviated from the ground truth.

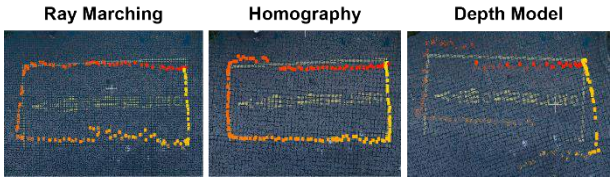

Figure 8. Qualitative Result of Object Tracking

As shown in Table 2, all methods achieved a mean ATE within 0.6m, indicating estimation errors in the tens-of-centimeters range. Among them, ray marching

demonstrated the highest accuracy. Homography showed larger errors, likely due to its assumption of a perfectly planar ground surface, which does not fully reflect real-world conditions. Ray marching, by directly interacting with the refined digital map, provides more precise estimation, leading to lower errors. Meanwhile, the depth model showed relatively higher estimation errors, highlighting the limitations of single-camera-based depth estimation models, particularly when no elaborate finetuning is performed for the specific site.

Table 2 ATE (meters) for 3D Object Tracking Results

	Ray Marching	Homography	Depth Model
Mean	**0.204**	0.367	0.595
RMSE	**0.285**	0.382	0.717

Figure 9 presents the results of multi-view fusion. Blue dots represent object positions from CAM0, red dots correspond to those from CAM1, and green dots indicate predicted positions due to tracking failure. Before applying multi-view fusion, overlapping areas contained redundant red and blue dots. After fusion, these redundancies were eliminated by selecting the point with the lower error. Additionally, green dots were appropriately placed to compensate tracking failures, ensuring continuity in the object's trajectory. In summary, multi-view fusion effectively mitigates camera tracking failures, enabling consistent and robust object tracking.

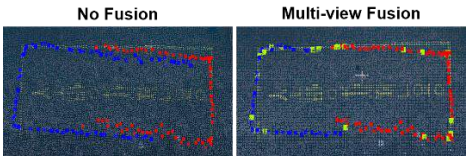

Figure 9. Validation Result of Multi-view Fusion

5 Limitations and Future Study

The experiment in this study was conducted in a controlled environment to accurately validate and compare the proposed methodology. However, real-world construction sites involve multiple objects and frequent occlusions, posing additional challenges in object tracking. As illustrated in Figure 10, when large objects obstruct the camera's view, ray marching may collide with obstacles before reaching the ground, resulting in inaccurate positioning. Furthermore, when multiple objects move in close proximity, mutual occlusion disrupts 2D tracking. While multi-view fusion helps mitigate tracking failures when objects are spaced apart, it becomes less effective in cases of close overlap, as shown in the right image of Figure 10, leading to track matching failures.

To address these challenges and enhance scalability, further enhancements are needed, such as integrating a depth estimation model for robust and seamless object tracking, along with further validation across diverse construction site scenarios.

Figure 10. Challenging Cases in Real-world Construction Sites

6 Conclusion

This study integrated commonly used vision platforms in construction sites—UAVs, TLS, and CCTV—to address their individual limitations. The proposed framework generated a unified 3D digital map, enabling seamless information sharing across platforms. A UAV provided an overall 3D digital map, while an alignment algorithm incorporating TLS enhanced resolution and vertical details. The refined map also served as a foundation for a robust CCTV-based 3D object tracking system, integrating dynamic object information into the 3D map.

Specifically, this study proposed a method to automatically align UAV and TLS maps using GPS, FPFH, and ICP in a step-by-step manner, effectively reducing computational costs for large-scale datasets and mitigating characteristic differences between heterogeneous data. In addition, the use of the ray marching technique and multi-view fusion enabled interaction with the refined 3D digital map, improving the robustness of CCTV-based 3D object tracking and ensuring consistency across cameras. The first experimental result demonstrated that the combination of FPFH and ICP significantly improved alignment accuracy compared to single alignment algorithms. The result of another experiment showed that the ray marching method achieved the highest accuracy in 3D object tracking.

In conclusion, this study highlights the significance of integrating vision platforms through a unified 3D digital map, improving the usability of site monitoring data. Nevertheless, challenges remain for the future research. A more robust object tracking system is needed to handle occlusions in complex construction environments, and further validation is required through real-world construction sites testing.

Abstract –

Construction sites are dynamic environments where fire hazards pose significant safety risks. Effective hazard recognition is the key step to prevent such hazards. While existing research has developed various training methods, limited studies focus on fire hazards in construction. Moreover, most approaches fail to adapt to evolving site conditions. To address these gaps, this study proposes a digital twin (DT)-based framework for dynamic fire hazard recognition training, with current validation progress presented. This framework integrates 360° imagery, 3D Gaussian Splatting, and Immersive Virtual Reality (IVR) to create an adaptive and interactive training environment. A user-centered training approach is designed to enhance personalized learning by incorporating individual trainee profiles and situation awareness (SA) assessments. Additionally, a cloud-based data system enables long-term tracking and scenario updates based on historical hazard data and trainee performance. This modular conceptual framework provides a foundation and guideline for future research on dynamic fire hazard recognition training. Further work will focus on framework validation through pilot studies in real construction settings to assess training effectiveness and usability.

Keywords –

Construction Fire; Hazard Recognition; Safety Training; Digital Twin; Situation Awareness

1 Introduction

Construction sites face continuous challenges in hazard prevention due to dynamic changing environments, diverse stakeholders, and complex interactions between people, equipment, and materials. Fire hazards, though less frequently than the "fatal four" hazards (i.e., falls, electrocutions, struck-by, and caught-in/between), often result in severe consequences, including risks to human life, significant property damage, and project delays. From 2016 to 2020, an annual average of 4,300 fires on construction sites were reported in the United States, causing five deaths, 62 injuries, and USD 376 million in property damage [1].

Fires can spread rapidly in construction sites with lots of combustibles, making early-stage hazard recognition critical [2]. With advancements in sensors and vision-based systems, such as computer vision and machine learning, automated detection systems are increasingly being developed to monitor, identify, and predict construction hazards [3]. While these systems provide valuable support, SA and human judgment remain indispensable [4]. SA involves three levels: perception (Level 1), perceiving the current state of the environment; comprehension (Level 2), understanding the meaning of the situation; and projection, anticipating potential future developments[5]. These abilities allow experts to make timely and accurate decisions and adapt to unexpected states [5]. Construction personnel (e.g., construction workers and managers) equipped with well-developed SA can adapt to unexpected situations, interpret subtle contextual signals, and make informed decisions that automated systems may not be able to address [6]. Unfortunately, individuals often struggle to identify hazards in dynamic and complex environments due to high cognitive demands and a lack of SA, stemming from the complexity of fully recognizing and predicting fire, a complicated process involving many factors, and the absence of structured training approaches [2]. Traditional training methods, such as classroom-based presentations, often adopt a one-size-fits-all approach, failing to engage workers and overlooking individual learning needs and weaknesses [7][8].

Immersive technologies, such as virtual reality (VR) and augmented reality (AR), have proven to be effective safety training tools, providing immersive and engaging learning experiences without exposing individuals to risks [9]. Despite their potential, existing studies on construction hazard training tend to focus on either broad categories of construction hazards or high-frequency hazards, such as slips and falls [10]. Research suggests

that workers often recall familiar hazards while overlooking less obvious but equally critical hazards, such as fire hazards [11]. Moreover, since each construction project is unique and evolves through different phases, the fire hazards workers encounter can vary significantly. For instance, the foundation phase involves fire hazards from flammable fuels for machinery, while the structure phase faces hazards from welding, cutting, and improper material storage. Additionally, tailoring training to the unique hazards of each construction site has proven to be more effective, as varying hazards impose different cognitive demands [12].

Collectively, there are gaps in (1) the lack of training systems specifically designed to improve SA in construction fire hazard recognition and (2) the absence of systems capable of dynamically adapting training focus to specific construction site conditions and evolving stages. To bridge these gaps and guide future research in this direction, this paper proposes a DT-based framework for fire hazard recognition training and presents the current progress in its validation.

2 Literature Review

2.1 Construction Hazard Recognition Training

The proposed training framework aims to improve construction personnel's SA ability to recognize and prevent fire hazards, a process influenced by various factors. Understanding these factors is vital for developing effective training programs. Environmental conditions, such as low visibility due to darkness or dust during construction, are one of the key factors [13], along with distractions prevalent in construction settings, which can hinder workers' focus [14]. Workers' physical or mental state (e.g., fatigue) also affects hazard recognition performance [6][15]. Furthermore, individual characteristics, such as age [16], personality traits [17], safety knowledge [18], and experience [19], affect how workers perceive, comprehend, and project potential risks. Additionally, cues provided during training, such as visual and question cues, affect trainees' performance [19]. Therefore, it is extremely important to consider the environmental variations trainees will encounter in the field, strategy, and trainees' individual features and needs when developing training programs.

Albert et al. [2] developed the first high-fidelity Building Information Modeling (BIM)-based augmented virtual environment. They categorized construction hazards into ten energy sources and incorporated cognitive retrieval mnemonics to improve long-term cue retention. Building on this work, Jeelani et al. [8] developed a personalized training strategy using eye-tracking data for individualized performance feedback and self-diagnosis correction. However, 3D BIM models face challenges in presenting real-world environments, as they offer an artificial, computer-generated representation of construction sites, potentially reducing training effectiveness [20]. Eiris et al. [21] observed that participants identified more hazards in BIM-based virtual environments than in 360 images of real construction sites due to clearer visuals. However, 360 images better reflected real-site conditions, raising concerns about the applicability of training methods that do not closely align with real-world environments. To address these limitations, researchers have adopted augmented 360 images, enhanced with cues (e.g., visual, audio) or instructions, as training environments, known as augmented virtuality, delivered by screen-based or VR head-mounted devices (HMDs) [22][23]. Given the page limitation, Table 1 summarizes key research in this field, detailing hazard type, training material and environment, cues, interaction, and assessment metrics. The literature review highlights a lack of focus on less frequent hazards, such as fire, as discussed in the Introduction section, as well as the insufficient integration of SA as training objectives to further improve hazard recognition abilities.

Table 1. Key studies on construction hazard recognition training

	Hazard Type	Training Material and Environment	Cues	Interaction	Assessment Metrics
[2]	Various types	BIM models augmented by experts and with construction images	Visual	Screen-based Devices	Hazard recognition index
[8]	Various types	Static real-world images annotated by experts	Visual	Screen-based Devices	Hazard-Recognition Level
[22]	Various types	Augmented stereo-panoramic videos and virtual models	Visual	Screen-based Devices	Hazard Recognition Score
[24]	Various types	BIM models enriched with avatars	Question	VR HMDs	The time used; the number of hazards identified
[23]	Fall hazard	Augmented 360-degree Panorama	Visual and audio	VR HMDs	Hazard Identification Index (HII)

[25]	Various types	construction site simulations with hazards	Visual and audio	VR HMDs	Eye-tracking metrics; hazard recognition accuracy
[26]	Fatal four	BIM model supplemented with regulations	Visual	VR HMDs	HII; Eye-tracking metrics

2.2 DT Frameworks for Construction Safety

In the architecture, engineering, and construction (AEC) industry, a digital twin is typically defined as a dynamic, real-time digital replica of physical assets, processes, and systems to enhance the management and optimization of construction and facility operations [27]. A DT system should include three key components: the physical artifact, the digital counterpart, and the bidirectional data exchange between them [28]. Unlike static models such as BIM, digital models, or digital shadows, which may only offer one-way updates, a true DT is characterized by its ability to synchronize with real-world changes in real time or near real time [27].

In the context of construction safety, DT applications are emerging but remain underdeveloped. In the area of hazard detection, DTs have been used to dynamically track workers' locations and detect risk events, such as falls, in real time [29]. For training, Vahdatikhaki et al. [30] developed a DT-based system for excavator training, allowing instructors to review trainee performance and provide targeted feedback dynamically. Harichandran et al. [32] further proposed a DT-based framework for dynamically updating VR safety training scenarios based on construction progress, enabling trainees to perceive and familiarize themselves with potential safety risks before entering the actual site.

A major advantage of DT-based training lies in its potential to improve SA [31]. In manufacturing, for instance, DT-enhanced training has been shown to improve operators' responsiveness and anticipation of risks by aligning VE with live system conditions [33]. DT can deliver higher-fidelity contextual information by dynamically reflecting environmental and operational changes, which is particularly valuable in fast-changing construction sites. Applying this concept in construction safety training, especially hazard recognition training, allows for site-specific interventions to support continuous hazard awareness and safer decision-making under realistic conditions. Despite its potential, research on integrating DT into construction safety training for enhancing SA remains limited and fragmented [31]. Furthermore, the application of DT in construction hazard recognition training has been largely unexplored.

3 System Architecture

To address the identified gaps, a conceptual framework was developed following a structured methodology for system architectures [34]. The primary objective of this framework is to provide context-specific training for construction personnel, aiming to improve their SA while strengthening their ability to effectively recognize and respond to fire hazards. Based on a comprehensive review of the literature, the system's key objectives and functions are outlined below, with detailed explanations in the following subsections.

- Objective 1: Enable trainees to perceive training environments realistically, ensuring their reactions and decisions reflect actual site conditions. Function 1: Capture real construction site environments with detailed representations of site objects and spatial arrangements.
- Objective 2: Provide context-specific training scenarios that adapt to evolving project phases. Function 2: Dynamically update virtual environments from real construction site data based on project checkpoints.
- Objective 3: Deliver personalized feedback and reinforcement training to foster targeted skill improvement. Function 3: Provide pre- and post-training assessments and a dynamic feedback mechanism to adapt training content (e.g., scenarios and strategies).
- Objective 4: Record identified construction site conditions for fire hazards and trainee performance metrics to support continuous improvement. Function 4: Provide an accessible database to store and manage historical data.

Accordingly, a system architecture has been proposed. As illustrated in Figure 1, it consists of four major components: (1) data acquisition and (2) data processing and integration, which together address objective 1, (3) user-centric training, which addresses objective 3, and (4) dynamic updating with cloud storage, which address objective 2 and 4. These components form a continuous loop, enabling the system to deliver effective and adaptive fire hazard recognition training. As this framework is based on existing DT frameworks, it can be integrated as a detailed subcomponent within broader DT-based construction safety frameworks. The following sections provide a detailed explanation of each function and current validation progress.

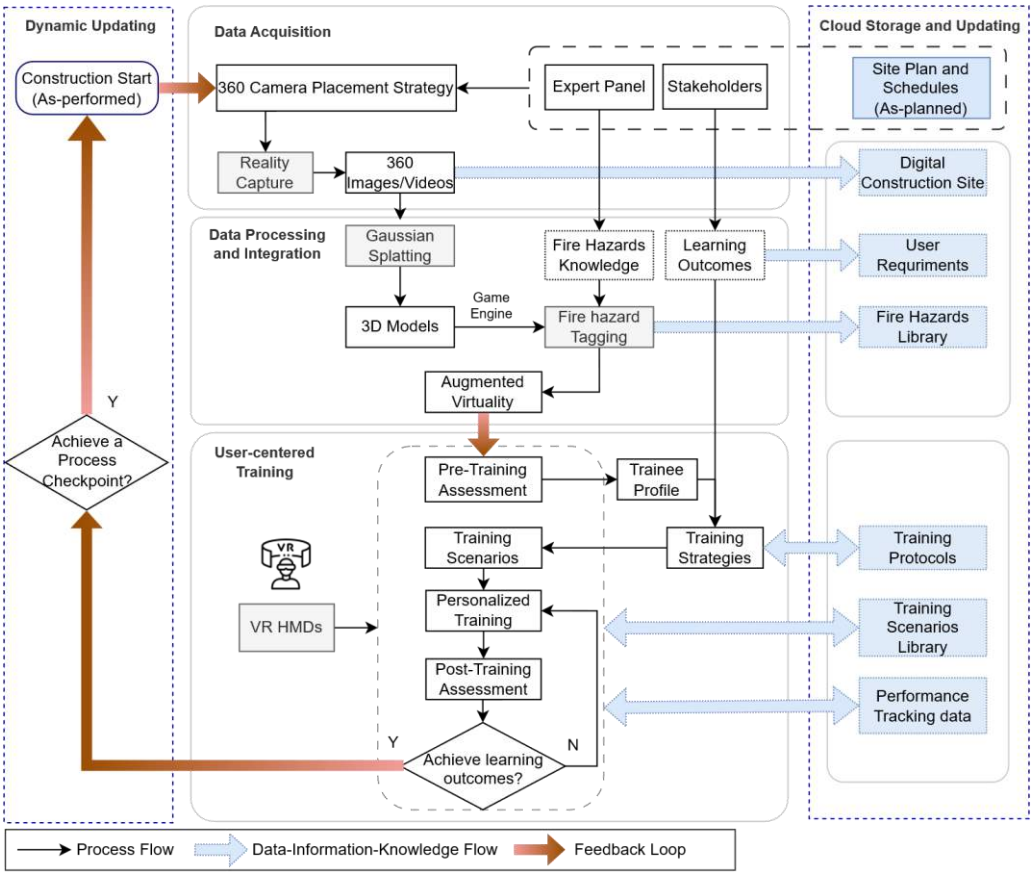

Figure 1. The system architecture of DT-based construction fire hazard recognition training system

3.1 Data Acquisition

Given the limited historical data (e.g., incident reports) and guidelines on construction fire hazards, obtaining input from stakeholders, such as safety managers and construction workers, and fire hazard experts, is the critical first step in building a reliable system (as shown in the dashed box in Figure 1). However, as more data becomes available, Artificial Intelligence-driven methods can be integrated to enhance autonomy over time. Regular with stakeholders, combined with analysis of site plans and schedules, help identify high fire risk zones, where fire hazards are likely to occur and relevant to training (e.g., areas requiring identification of hidden hazards such as electrical wiring). This guides the development of comprehensive camera placement plans, ensuring effective data collection aligned with real-world safety requirements and training needs. Additionally, fire hazards category and learning outcomes can be identified to further tailor training to specific objectives.

This paper proposes the use of 360° cameras to capture construction environments for training. Compared to synthetic, BIM model-based training scenarios, those captured from real construction site data, such as 360° imagery, are more effective in achieving training outcomes, as highlighted in the literature review section. However, recognizing the limitations of 360° images/videos in navigation and interactivity, this paper introduces 3D Gaussian Splatting (3DGS) [35] as a method to convert these images/videos into 3D models (detailed in Section 3.2). In a recent study, Rüter et al.[36] demonstrated the potential of 3DGS for construction site visualization, highlighting that it enables fast, high-quality 3D model generation while eliminating the need for time-consuming methods such as laser scanning. Given its efficiency, cost-effectiveness, and ease of deployment, the process of converting 360° images/videos into 3DGS was selected for this research.

To maximize environmental representation while avoiding obstructions and distortions caused by low ceilings or personnel, 360° cameras are proposed to be strategically placed across the construction site. Medium-height placements are prioritized to achieve optimal results. To ensure consistency in subsequent cube map conversions, the camera can be maintained in a vertical position. Frames can be extracted from recorded videos at regular intervals, producing a uniform and structured visual dataset. Using a dual-lens 360° camera, this method can generate equirectangular images, and rectangular projections of spherical data in a 2:1 aspect

ratio, ensuring full site coverage with minimal effort [37]. This approach reduces the need for precise camera framing while providing detailed, comprehensive captures of construction environments. Figure 2 shows an example of the generated data.

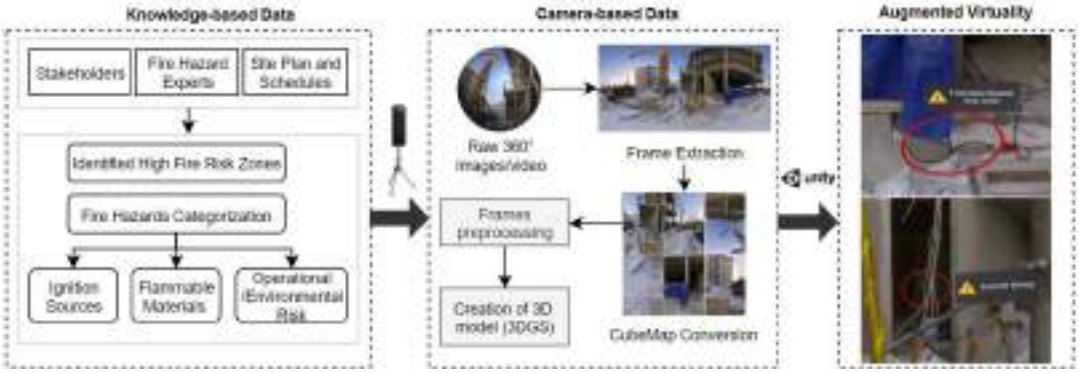

Figure 2. Illustration of data acquisition, processing and integration flow for the proposed system

3.2 Data Processing and Integration

In this phase, the collected raw 360 images or videos can be converted into 3D models, while input gathered from fire hazard experts is used to augment the generated 3D model in game engines (e.g., Unity 3D), to generate training scenarios. Figure 2 illustrates the data processing and integration process of knowledge-based and camera-based data, with an example provided to demonstrate current progress in the development effort. The acquired equirectangular images are processed for 3D model generation and training applications. First, to address the distortion inherent in spherical images captured with fisheye lenses, equirectangular images are converted into cube maps. This process projects the spherical data onto six cube faces, straightening perspective lines and removing distortions [35]. These cube maps, compatible with 3D modelling tools, enable further processing [35]. To optimize dataset quality and efficiency, only the left, right, and front views, which are central to the camera and environment, are retained [37]. Less relevant views, such as the top and bottom faces, are excluded to streamline the data and focus on critical environmental details. Furthermore, to ensure the usability of the curated cube map images, frames with poor lighting or obstructions are removed. Additional angles can be extracted using software (e.g., Insta360 Studio) that allows for frame extraction, stitching, and refinement of 360° images, ensuring dataset completeness and quality [37]. These processed images are then put into tools supporting gaussian splatting, such as Jawset Postshot and Polycam, to generate high-fidelity 3D point clouds.

To augment the generated 3D virtual environments for creating training scenarios, game engines are commonly used to enable interactivity and functionality [23]. In the development progress of this paper, Unity 3D, a widely used game engine known for its flexibility, was used for tagging fire hazards and enhancing interactivity. By using knowledge obtained from fire hazard experts and fire safety regulations, fire hazards in specific scenes can be identified and annotated. For instance, as shown on the right of Figure 2, exposed wiring and flammable materials near the cable that could potentially cause a fire are annotated with a red circle. The augmented scenarios form the foundation for further training scenario design. This structured and refined data acquisition, processing, and integration pipeline enables the system to deliver tailored, context-specific fire hazard recognition training.

3.3 User-centered Training System

The proposed system emphasizes a customizable and user-centered VR training framework, guided by four essential dimensions, learner specifics, context, representation, and pedagogy, adapted from established frameworks for immersive virtual training [38]. Learner specifics serve as the foundation, including trainees' roles and baseline SA. As shown in Figure 3(a), users can select their role, such as safety manager or construction worker, to tailor the training content based on their responsibilities. Baseline testing is typically conducted as a pre-training assessment, using a combination of questionnaires and virtual environments exploration [2]. During these explorations, trainees navigate scenarios with hazards but without any cues, allowing the system to evaluate their baseline hazard recognition abilities [2] [24]. Metrics such as the hazard recognition index and hazard identification index, summarized in Table 1, are commonly used to assess perception (Level 1 SA) by counting the number of hazards recognized. However, these metrics provide limited evaluations of comprehension (Level 2 SA) and projection (Level 3 SA). Given the visual nature of fire hazard recognition, data such as eye-tracking metrics could be incorporated to assess different levels of SA [4].

Context-specific scenarios developed in the data processing and integration phase form the foundation for

interactive design guided by pedagogical strategies. Representation of the training content is achieved through immersive VR simulations delivered via HMDs, recreating realistic and interactive construction site environments, ensuring that trainees exhibit behaviors and reactions approximately similar to those they would have in real-world scenarios [23]. For pedagogical strategies, the system incorporates scenario-based learning and interactive learning approaches widely adopted in existing research [22-26]. For example, as shown in Figure 3(d), hazards such as exposed wiring are annotated within the virtual environment. When the trainee points and clicks on the hotspot using a VR controller, the corresponding fire hazard label is displayed, as shown in Figure 3(e). This interaction helps develop fire hazard perception (Level 1 SA), which involves identifying fire hazard elements in the workplace. To further develop comprehension (Level 2), understanding that exposed wiring poses a fire hazard, and projection (Level 3), predicting the consequences of such a hazard and proposing interventions, detailed instructions are provided when the trainee clicks the "Instruction" button, as shown in Figure 3(f). However, more specific training strategies need to be developed to align with specific training objectives, and evaluating the effectiveness of different training strategies requires further well-designed experiments. Currently, there is limited research exploring how different training protocols affect trainees' performance [24]. Following each training session, a post-training assessment will be conducted using metrics in pre-training assessment, evaluating the trainee's performance on SA across all three levels. If it does not meet the learning outcomes, tailored reinforcement training will be conducted.

Figure 3. An Example of a VR Training Scenario in the Proposed System

3.4 Dynamic Training Scenarios Updating and Data Storage

The key role of DT in this system is to (1) dynamically update training scenarios, (2) track training performance over time, and (3) store historical data for continuous improvement. For scenario updating, the frequency depends on the specific project needs, as real-time data input is not required for training based on recognition site objects [32]. Instead, new training scenarios are updated when obvious changes occur in the construction layout or activities, such as the introduction of new materials or equipment. Milestones are typically a point when significant changes occur at the construction site. At each milestone, the system initiates the data acquisition phase to capture updated site environments. The triggering process can be initiated manually by construction managers who identify such changes or automatically through sensors integrated into the project that detect alterations in site conditions. Consequently, this data enters the data processing and integration procedure, identifying new fire hazards and ensuring training scenarios remain relevant and aligned with real-world requirements. The updating mechanism uses both the as-planned construction schedule and real-site conditions to determine when a milestone is reached. Regarding training performance, most existing construction training programs focus only on short-term learning without assessing how well trainees retain and apply knowledge over time [22]. By integrating DT, the proposed system stores trainees' performance data after every session. Over time, this data can be analyzed alongside construction phases and training frequencies to support skill development and reinforcement [23]. For historical data storage, the system uses a cloud storage platform (e.g., Amazon S3) to securely store identified fire hazards, established training scenarios, and training performance. Stored digital representations of construction sites can support not only fire but broader hazards, while also serving as training data for AI-based automated hazard detection to assist human detection. Notably, for smaller projects with limited data requirements, local or hybrid storage can be used as an alternative to cloud storage based on specific needs.

4 Conclusions and Future Work

This study presents a DT-based framework for construction fire hazard recognition training, designed to develop and improve trainees' SA. This framework contributes to the body of knowledge in construction fire safety by introducing a rapid workflow for creating augmented virtual construction environments, integrating SA into user-centered fire hazard recognition training, and integrating DT technology for dynamic training scenarios updating and long-term performance tracking. The proposed system has the potential to help trainees to better adapt to dynamic construction sites, develop and improve the SA of construction fire hazards, and ultimately reduce the risk of construction fires. Additionally, the modular structure of the framework allows for gradual adoption, reducing the need for a full-scale investment upfront. While the proposed system shows significant promise, several areas require further development. First, stakeholder engagement is needed to validate system requirements. Second, the framework's performance and scalability need to be validated through real-world implementation across various construction scenarios. Future work will focus on conducting pilot studies to evaluate training effectiveness, user experience, and SA improvements.

Abstract -

In construction quality monitoring, accurately detecting and segmenting cracks in concrete structures is paramount for safety and maintenance. Current convolutional neural networks (CNNs) have demonstrated strong performance in crack segmentation tasks, yet they often struggle with complex backgrounds and fail to fully capture fine-grained tubular structures. In contrast, Transformers excel at capturing global context, but lack precision in detailed feature extraction. We introduce DSCformer, a novel hybrid model that integrates an enhanced Dynamic Snake Convolution (DSConv) with a Transformer architecture for crack segmentation to address these challenges. Our key contributions include the enhanced DSConv through a pyramid kernel for adaptive offset computation and a simultaneous bidirectional learnable offset iteration, significantly improving the model's performance to capture intricate crack patterns. Additionally, we propose a Weighted Channel Attention Module (WCAM), which refines channel attention, allowing for more precise and adaptive feature attention. We evaluate DSCformer on the Crack3238 and FIND datasets, achieving IoUs of 59.22% and 87.24%, respectively. The experimental results suggest that our DSCformer outperforms state-of-the-art methods across different datasets.

Dynamic Snake Convolution; Crack segmentation;

1 Introduction

Monitoring the quality of concrete structures is crucial in industrial settings, as aging concrete buildings, such as pavements and bridges, often develop cracks that pose significant safety risks [1]. To ensure structural health, regular crack inspections are indispensable. While traditional inspection methods have been widely used, they often fall short in accuracy and efficiency. In contrast, deep learning models have emerged as a promising solution, demonstrating superior performance in crack segmentation tasks due to their accuracy and robustness.

While Convolutional Neural Networks (CNNs) excel at capturing local details due to their strong translational invariance and edge-detection capabilities, their limited receptive field can hinder performance in complex backgrounds [2, 3]. Conversely, Transformers leverage embeddings and self-attention mechanisms to model global dependencies effectively, which is advantageous for addressing complex backgrounds, but they often struggle to capture fine details [4]. Combining these two methods offers the potential to leverage both local detail extraction and global context modeling, addressing the respective limitations of each approach.

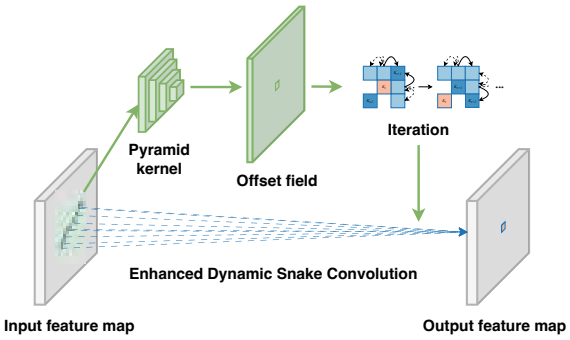

Figure 1. Overview of Enhanced Dynamic Snake Convolution.

The hybrid approach of combining CNNs and Transformers shows promise by leveraging both local detail extraction and global context modeling [5, 6, 7]. However, these methods often fail to account for the unique structure of crack segmentation, leading to suboptimal fusion. Additionally, combining CNNs and Transformers can introduce training fluctuations, making it challenging to fine-tune the model for both local and global features. In contrast, Dynamic Snake Convolution (DSConv) [8] is well-suited for crack segmentation due to its ability to focus on fine, curved local features, improving geometric perception. Despite its strengths, DSConv has limitations, such as fixed kernel sizes and limited adaptability in complex structures, suggesting room for improvement.

In this paper, we introduce DSCformer, a novel crack segmentation model that combines proposed enhanced DSConv with a Transformer-based architecture. Our approach introduces two key improvements to the original DSConv: a) a pyramid kernel for offset computation, consisting of convolutional kernels of varying sizes, and b) a method for learnable offset iteration that simultaneously operates in vertical and horizontal direction. Figure 1 shows the process for enhanced DSConv. These enhancements allow the model to capture fine crack structures more accurately. Additionally, we propose the Weighted Channel Attention Module (WCAM), which refines channel attention by utilizing separate Multi-Layer Perceptrons for average and max pooling. This leads to more adaptive and precise channel attention. The spatial attention module remains unaltered, contributing to spatial focus. By integrating these modifications into the DSConv encoder branch, which focuses on capturing fine local crack details, and combining it with a pre-trained SegFormer[9] encoder that specializes in capturing long-range dependencies, we fuse the extracted features and progressively upsample them to generate the final crack segmentation predictions. The principal contributions of this study are summarized as follows:

- We propose an enhanced DSConv with a pyramid kernel and bidirectional offset iteration, improving crack structure capture.
- We introduce WCAM, refining channel attention for greater adaptability and precision.
- We propose DSCformer, a hybrid model combining DSConv and SegFormer, outperforming state-of-the-art crack segmentation methods across two public datasets.

2 Related Works

2.1 Convolutional Networks for Crack Segmentation

Early works utilized CNN architectures like Fully Convolutional Networks (FCNs) [10] and U-Net [11] for segmentation. DeepCrack [2] follows an encoder-decoder structure. Among methods that alter convolution, Dilated Convolutions [12] expand the receptive field without sacrificing resolution, while Deformable Convolutions [13] improve feature adaptability by introducing learnable offsets to the kernels, enhancing object perception. Cracks, like blood vessels and roads, exhibit fine tubular structures, and enhancing their perception can significantly boost segmentation accuracy. Dynamic Snake Convolution (DSConv) [8] enhances geometric sensing for thin, curved structures by restricting deformable convolution sampling points, yielding improved performance. However, DSConv has limitations, such as a fixed offset kernel size and a one-directional learnable offset iteration, which may hinder adaptive topology perception.

2.2 Hybrid CNN-Transformer Models

Vision Transformers (ViT) [14] capture global image context through patch and position embeddings along with self-attention mechanisms. Swin Transformer [15] enhances computational efficiency with hierarchical shifted windows. Pyramid Vision Transformers (PVT) [16] combine multi-scale feature extraction with Transformer benefits, and SegFormer [9] introduces a hierarchical encoder without position embedding. However, pure Transformers struggle with fine detail capture.

Recent efforts combine CNNs and Transformers for crack segmentation. Crackformer [6] adds a convolution layer atop a Transformer encoder, while UTNet [5] and UCTransNet [17] integrate self-attention into U-Net structures. Crackmer [7] and DTrC-Net [18] employ parallel CNN-Transformer encoders. Despite these advances, more sophisticated hybrid models are needed for effective crack segmentation.

2.3 Attention Mechanisms for Feature Fusion

The Squeeze-and-Excitation (SE) network [19] recalibrates channel feature responses through average pooling, pioneering the concept of channel attention and enhancing the representational capacity of CNNs. Subsequently, the Convolutional Block Attention Module (CBAM) [20] extends the attention mechanism by sequentially applying a Channel Attention Module (CAM) and a Spatial Attention Module (SAM), utilizing both average and max pooling information to enable the network to more accurately focus on relevant features and their locations. In the context of crack segmentation, crackmer introduces a Complementary Fusion Module to more effectively aggregate multi-scale features, leveraging complementary information from different feature levels to improve segmentation accuracy. Nevertheless, the fusion of max and average poolings information is not sufficient.

3 DSCformer for Crack Segmentation

Figure 2 shows the DSCformer framework. Current hybrid crack segmentation methods combining CNN and Transformer mainly focus on feature fusion or sophisticated decoders. However, we believe the limitation lies in feature extraction, not fusion, as conventional convolutions struggle to capture crack features effectively. Dynamic Snake Convolution (DSConv) attempted to improve this but faced challenges with its offset calculation and iteration strategy. Inspired by this, we propose DSCformer, a dual-branch model combining enhanced DSConv and Transformer. The convolutional branch stacks DSC blocks with enhanced DSConv and Weighted Channel Attention

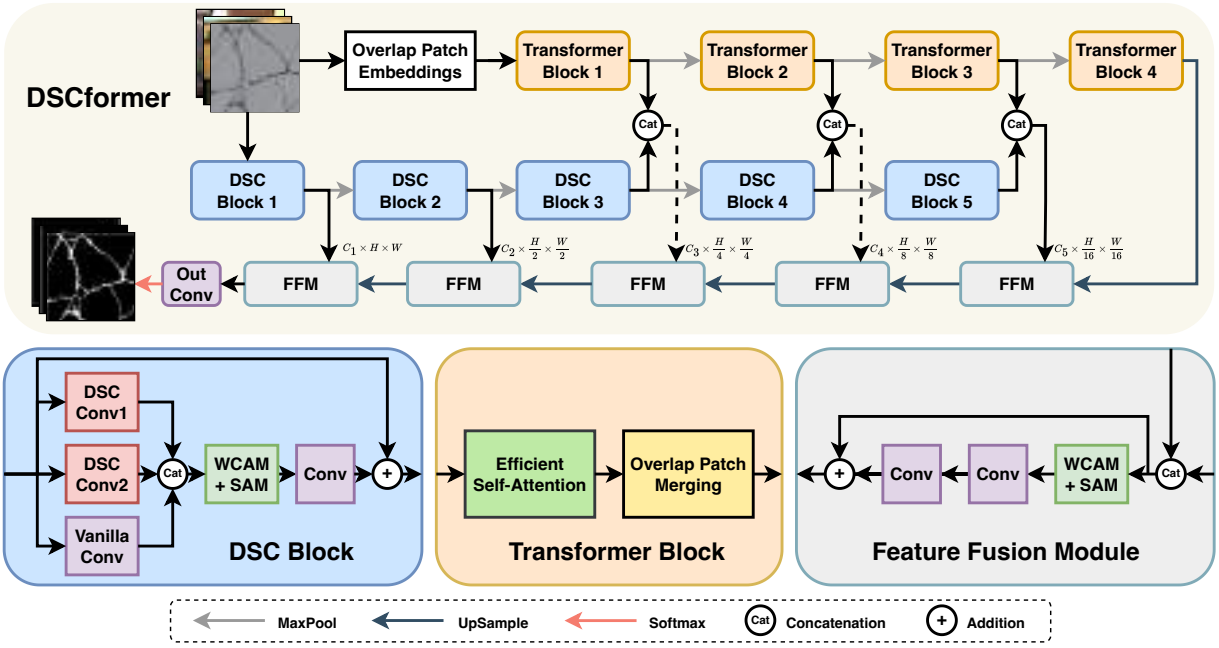

Figure 2. The overview architecture of the proposed DSCformer.

(WCAM), while the Transformer branch uses SegFormer. Crack segmentation masks are generated through progressive feature fusion and upsampling.

3.1 Enhanced DSConv encoder branch

The DSConv encoder branch is employed for local fine-grained structure feature extraction. We refine the computation strategy of DSConv, and propose a DSC block and WCAM. The DSC block incorporates WCAM to enhance feature fusion between vanilla convolution and enhanced DSConv. By stacking DSC blocks and adding max-pooling layers between DSC blocks, we perform progressive downsampling to obtain multi-scale feature maps at resolutions of 1/1, 1/2, 1/4, 1/8, and 1/16.

3.1.1 Enhanced Dynamic Snake Convolution

In this section, we introduce the computation process of Dynamic Snake Convolution (DSConv) and present our improvements. Given a standard $3 * 3$ convolution kernel with a dilation of 1 as K, the kernel samples information from nine points: the central point $K_i = (x_i, y_i)$ and its surrounding eight points, which is expressed as:

$$K = (x-1, y-1), (x-1, y), ..., (x+1, y+1) \quad (1)$$

To enable the convolution kernel to adapt to the tubular topological features around the current location, the goal is to allow the sampling points of the kernel to shift. Inspired by the concept of deformable convolutions, Qi et al. introduced deformation offsets Δ [8]. The offset convolution outputs offsets of 9 sampling points in the vertical and horizontal directions for a total of 18 channels. However, allowing the offsets to be completely learned freely can cause the receptive field to drift away from the target, which is unsuitable for capturing the characteristics of slender tubular structures. To address this, an iterative strategy is adopted to constrain the offsets, ensuring continuity in perception.

Unlike previous method that utilizes a $3 * 3$ convolution kernel to compute the sampling point offsets, we propose a pyramid-structured convolution kernel, which contains kernel sizes of $3 * 3$, $5 * 5$, $7 * 7$, $9 * 9$. Specifically, the $3 * 3$ kernel in our design outputs offsets for points near the center of the dynamic snake convolution, while the larger sizes of kernel outputs offsets for points further away, up to the $9 * 9$ kernel. This approach gradually perceives information from the outer layers, matching the receptive field for offset acquisition with the actual sampling points, thereby avoiding limited perception issues.

In the iterative offset strategy of DSConv, we consider a $9 * 9$ square, which is also its maximum receptive field. Each grid position in the kernel K is represented as $K_{t\pm c} = (x_{t\pm c}, y_{t\pm c})$, where $c = 0, 1, 2, 3, 4$. Unlike previous method, which fixes the offset as an integer in one direction while leaving the offset in the another direction unchanged, the enhanced DSConv do not fix the offset and iterate it in bi-direction simultaneously. So $t \pm c$ represents the iterative order of the convolution sampling points. Starting from the center point K_t,

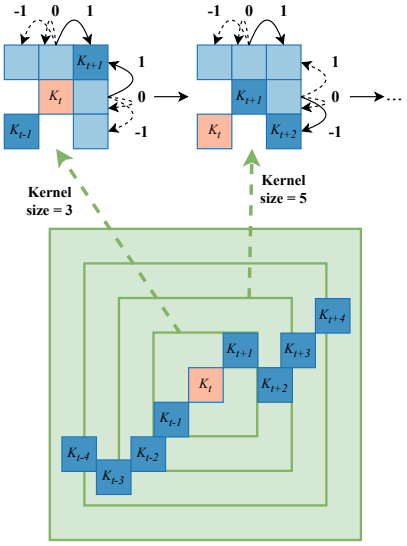

Figure 3. Offset iteration process. Iterating from the central point, each layer of the pyramid kernel represents its maximum receptive field.

$$K_{t+c} = (x_{t+c}, y_{t+c}) = (x_t + \sum_{t}^{t+c} \Delta x, y_t + \sum_{t}^{t+c} \Delta y) \quad (2)$$

$$K_{t-c} = (x_{t-c}, y_{t-c}) = (x_t - \sum_{t-c}^{t} \Delta x, y_t - \sum_{t-c}^{t} \Delta y) \quad (3)$$

After obtaining the coordinate of each sampling point after the offset iteration, the actual sampling point value is obtained by applying bilinear interpolation:

$$K = \sum_{K'} G(K', K) \cdot K' \quad (4)$$

Where K represents the position of the coordinates, K' represents the grid point near K, and G(·, ·) is the bilinear interpolation kernel. Note that G is two dimensional. It is separated into two one dimensional kernels as:

$$G(K, K') = g(K_x, K'_x) \cdot g(K_y, K'_y) \quad (5)$$

As shown in Figure 3, the enhanced DSConv improves the crack sensing ability of the snake chain away from the center point, and more flexibly captures the crack characteristics in the $9 * 9$ receiving field.

3.1.2 Weighted Channel Attention Module

In order to better focus on more relevant channel information, we propose WCAM, which is based on CAM, and makes better utilization of average pooling and maximum pooling information by introducing a few parameters. Reduces the deviation of attention due to accidental maximum values.

Mathematically, similarly, spatial information is first aggregated using max pooling and average pooling operations to obtain two distinct spatial identifiers: F^c_{avg}, F^c_{max}, each containing channel information. These two identifiers are then passed through independent MLPs, denoted as $M_{avg}(\cdot) = W^1_{avg}(W^0_{avg}(\cdot))$ and $M_{max}(\cdot) = W^1_{max}(W^0_{max}(\cdot))$ which, compared to a shared MLP, introduce only a small number of additional parameters with minimal impact on computational complexity. After applying the sigmoid activation function, the two output feature vectors are weighted, with the weights being learnable parameters. In summary, WCAM can be computed as follows:

$$M_c(F) = \sigma(w_{avg} M_{avg}(F^c_{avg}) + w_{max} M_{max}(F^c_{max})) \quad (6)$$

Here, σ denotes the sigmoid function, F contains F^c_{avg} and F^c_{max}, $W^0_{avg}, W^0_{max} \in \mathbb{R}^{C/r \times C}$, $W^1_{avg}, W^1_{max} \in \mathbb{R}^{C \times C/r}$, and $w_{avg}, w_{max} \in \mathbb{R}^C$. The ReLU activation function is followed by W^0_{avg}, W^0_{max}.

3.1.3 DSC block

In the DSConv branch, we propose the DSC block to extract features at different scales. Initially, the feature map is fed into three parallel convolutions: two enhanced DSConvs for extracting fine structural features especially and one standard convolution for capturing local features. The purpose of using two enhanced DSConvs is to better compare the original module (snake convolutions in both x- and y-directions), and the segmentation accuracy is virtually the same as when using only one enhanced DSConv. The outputs of the three convolutions are concatenated along the channel dimension and then processed through WCAM and SAM to adjust the feature map values, focusing on important channel information and spatial positions. This is followed by a standard convolution layer for feature fusion. Finally, a residual connection is introduced to mitigate the issue of gradient vanishing.

3.2 SegFormer encoder branch and decoder

To capture global information, often challenging for convolutional models, we integrate a Transformer branch using the SegFormer-b0 encoder, known for its efficient self-attention and Non-positional encodings, ideal for semantic segmentation. With only three million parameters, this encoder offers a lightweight yet robust solution. Fine-tuned on the ADE20k dataset [21], the pre-trained SegFormer-b0 enhances the DSConv branch by providing background context, improving crack segmentation. The encoder outputs multi-scale feature maps at 1/4, 1/8, 1/16, and 1/32 of the original resolution.

Table 1. Performance Comparison on Crack3238 and FIND Datasets with three test results.

Dataset	Methods	P. (M)	IoU (%) ↑	Pre. (%) ↑	Re. (%) ↑	F1 (%) ↑	HD (mm) ↓
Crack 3238	Unet	17.3	$53.43_{\pm 0.13}$	$65.74_{\pm 0.57}$	$67.67_{\pm 3.42}$	$66.30_{\pm 0.15}$	-
	DeepCrack	30.9	$54.22_{\pm 0.77}$	$65.86_{\pm 1.29}$	$72.06_{\pm 0.87}$	$67.25_{\pm 0.89}$	$56.28_{\pm 5.82}$
	DSCNet	2.1	$53.99_{\pm 0.16}$	$67.15_{\pm 1.69}$	$70.45_{\pm 1.98}$	$66.89_{\pm 0.19}$	$41.15_{\pm 0.90}$

	DSCformer(ours)	14.8	$\mathbf{87.31}_{\pm 0.12}$	$92.52_{\pm 0.35}$	$\mathbf{94.01}_{\pm 0.45}$	$\mathbf{93.04}_{\pm 0.09}$	$\mathbf{11.14}_{\pm 0.23}$

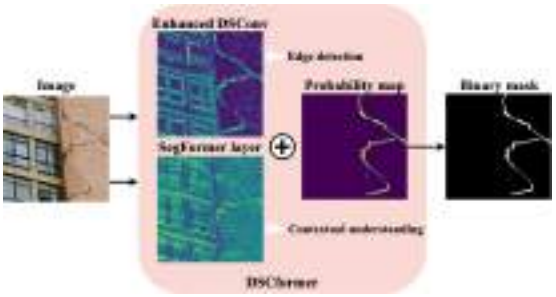

Figure 4. The difference between dual-branch encoder.

For the decoder, we fuse feature maps from the DSConv and SegFormer branches with upsampled lower-resolution features. These fused maps undergo WCAM and SAM processing to refine channel and spatial information. The refined features pass through two convolutional layers with residual connections to smooth the output and address vanishing gradients. As shown in Figure 4, enhanced DSConv excels at extracting edges and fine structures, while SegFormer is effective at global modeling. The final crack mask is obtained by fusing these features.

4 Experiments

4.1 Datasets

We use Crack3238 dataset [18], Fused Image dataset for convolutional neural Network-based crack Detection(FIND) dataset [22] to evaluate our method. Crack3238 dataset contains a total of 3,238 images, which consist of RGB images of cracks from various sources, featuring complex backgrounds, diverse crack patterns, and defective surfaces, significantly increasing the complexity of crack detection scenarios. The FIND dataset comprises 2,500 images, where fused image data is obtained by combining depth information with grayscale images. Both datasets encompass data from different sources and highly complex scenes, making them extremely challenging for crack segmentation tasks. We split the datasets, using 80% for training and 20% for testing.

4.2 Implementation Details

4.2.1 Training details.

Our model, implemented in PyTorch, was trained on a RTX 3090Ti GPU. To reduce overfitting, we applied data augmentation, including flips, rotations, and affine transformations. The SegFormer encoder uses pre-trained weights, while the DSConv encoder and decoder are randomly initialized. We used Adam (lr=0.0001, weight decay=10^{-4}) with cross-entropy and dice loss. Training ran for 100 epochs with a batch size of 8.

4.2.2 Performance metrics.

We evaluated segmentation performance using IoU, Recall, Precision, F1-score, and Hausdorff Distance. The formulations are as follows: IoU is given by $IoU = \frac{TP}{TP+FP+FN}$, Recall is given by $Recall = \frac{TP}{TP+FN}$, Precision is given by $Precision = \frac{TP}{TP+FP}$, and F1-score is given by $F1 = \frac{2\times Precision\times Recall}{Precision+Recall}$. Additionally, we employed the Hausdorff Distance, calculated as $d_H(A,B) = \max\left(\max_{a\in A}\min_{b\in B}|a-b|, \max_{b\in B}\min_{a\in A}|a-b|\right)$, to measure the maximum distance between the segmentation mask and the ground truth. All metrics for each image are calculated and averaged.

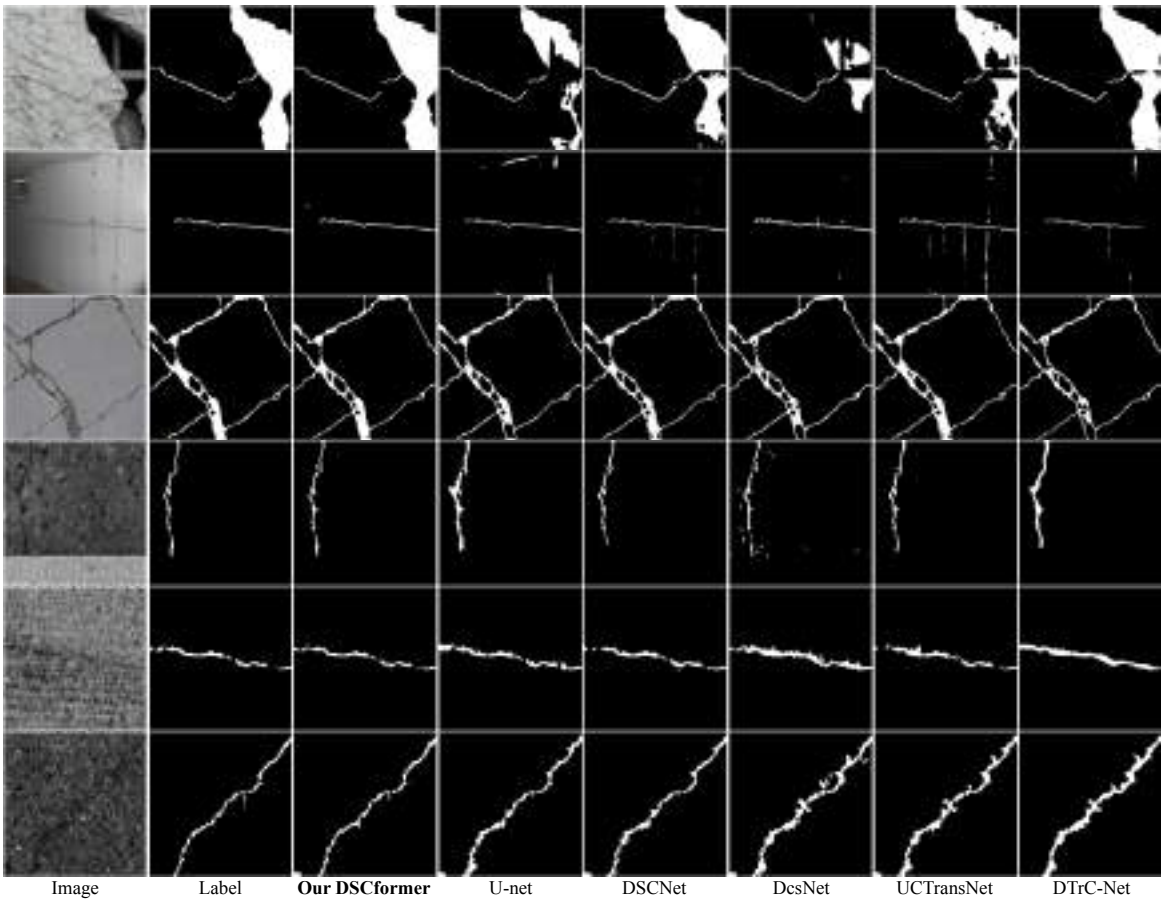

Figure 5. The qualitative comparison on the Crack3238 and FIND datasets.

4.3 Comparison with State-of-the-art Methods

We compare the proposed DSCformer with several state-of-the-art models, including U-Net, DeepCrack, DcsNet, UCTransNet, DTrCNet, and DSCNet. For fairness, we use their original code and settings, testing each model three times. Results are shown in Table 1, with metrics presented as mean ± standard deviation, highlighting the best results in bold. DSCformer outperforms all models, achieving an IoU of 58.74%, Precision of 72.38%, Recall of 73.99%, and F1-score of 71.74% on the Crack3238, and an IoU of 87.31% and F1-score of 93.04% on the FIND. It also balances Precision and Recall effectively, with Precision achieving second-best performance.

Additionally, a visual comparison in Figure 5 illustrates DSCformer's superior performance, particularly in handling noise and accurately capturing large defect areas. DSCformer also excels at delineating crack edges, avoiding the overestimation of crack width seen in other models, and ensuring more precise segmentation, especially at boundaries. This level of detail highlights DSCformer's strong generalization across varying defect types and sizes.

Table 2. Generalization performance on Crack3238 datasets.

Augmentation	DSCformer	DTrC-Net	DSCNet
None	**58.74%**	56.90%	53.99%
Geometric	**53.52%**	50.50%	49.94%
Appearance	**49.36%**	46.38%	48.04%
Combined	**42.40%**	37.50%	39.69%

We also conducted a generalization experiment to evaluate the performance of three models—DSCformer, DTrC-Net, and DSCNet—under various data augmentation conditions, including no augmentation, geometric augmentation, appearance augmentation, and combined augmentation. The results in Table 2 show that DSCformer consistently outperforms the other models across all augmentation types, though its performance declines with increased augmentation complexity, especially under combined augmentation (42.40%). In comparison, DTrC-Net and DSCNet exhibit more significant performance drops, particularly under appearance and combined augmentations. Al-

though affected by the complexity of data augmentation, DSCformer still shows strong generalization ability.

Additionally, in terms of computational efficiency, DSCformer achieves an inference speed of 30 FPS, which is comparable to the hybrid model UCTransNet, while other models range between 60-100 FPS. This shows that DSCformer balances accuracy and computational efficiency well without excessive resource consumption.

Overall, DSCformer's ability to manage noise, precisely segment large defects, and accurately delineate crack edges makes it a highly effective method for crack segmentation tasks, outperforming existing models both quantitatively and visually. Additionally, it demonstrates strong generalization ability, maintaining superior performance across different data augmentation conditions.

4.4 Ablation Studies

We conducted ablation experiments on the Crack3238 dataset to assess the impact of the proposed improvements on the performance of our model. As summarized in Table 3, the dual-branch architecture of DSCformer exhibits a significant advantage over the single-branch models, DSCNet and SegFormer. Specifically, DSCformer achieved an IoU improvement of 4.75% over DSCNet and 4.07% over SegFormer, highlighting the performance of integrating both branches for crack segmentation.

Table 3. Ablation experiments on Crack3238 datasets. 'CA' denotes the Channel Attention.

Methods	Conv	CA	IoU
DSCNet	DSConv	w/o	53.99%
SegFormer	w/o	w/o	54.67%
DSCformer	Vanilla Conv	WCAM	57.46%
	DSConv	WCAM	57.74%
	Enhanced DSConv	w/o	58.16%
	Enhanced DSConv	CAM	58.28%
	Enhanced DSConv	WCAM	58.74%

The enhanced DSConv also shows substantial benefits. By incorporating the enhanced DSConv into the model, we observed a notable 1.00% increase in IoU compared to the original DSConv, indicating that the improvements to the DSConv effectively contribute to more accurate crack boundary detection and segmentation. Additionally, the introduction of WCAM provided further gains in segmentation performance. When WCAM was applied within DSCformer, it outperformed the standard CAM, resulting in a 0.46% increase in IoU. This improvement reflects the value of our modifications to the attention mechanism. Overall, these results emphasize the significance of the hybrid model architecture and the specific enhancements to both the dynamic snake convolution and channel attention mechanisms. Each modification contributes to the overall effectiveness of DSCformer, leading to superior crack segmentation performance.

5 Conclusion

In this work, we introduced DSCformer, a hybrid model combining enhanced Dynamic Snake Convolution (DSConv) and Transformer architectures for crack segmentation. DSCformer addresses the limitations of CNNs and Transformers by capturing both fine local details and global context. The enhanced DSConv improves crack feature detection with a pyramid kernel and bidirectional offset iteration, while the Weighted Channel Attention Module (WCAM) refines channel attention for better feature fusion. Experiments show that DSCformer outperforms state-of-the-art methods on benchmark datasets, demonstrating its robustness and potential for broader applications in analyzing fine topological structures.

Abstract –

The monitoring of the road construction operation is critical to ensure high-quality roads. This is especially the case for the compaction of the asphalt surface layer since the operation is very time-sensitive and mostly irreversible. Historically, monitoring of the asphalt compaction is limited to temperature and compaction homogeneity. While useful, these pieces of information fail to generate direct insight into the resultant physical properties of the asphalt layer (e.g., density and roughness), which are the ultimate key performance indicators. Several sensor-based methods and approaches have been proposed but these methods are particularly suited for post-construction monitoring rather than real-time application. To address this gap, this research aims to conduct a preliminary feasibility study on the use of a computer vision-based method for the real-time monitoring of the asphalt properties during the compaction. Therefore, a framework is proposed to install cameras on the asphalt roller along with a Global Positioning System (GPS) kit and track the changes of the asphalt texture at the micro level. These changes are then correlated with the progression of the compaction effort. The results indicate that the Computer Vision (CV) method can very successfully identify micro variations in the asphalt texture. This is very promising because these variations can be potentially correlated with some physical properties of the asphalt layer. While this correlation study is the future work of this research, the preliminary results already contribute to highlighting the potential of CV methods to be incorporated into asphalt compaction monitoring system.

Asphalt construction; Computer Vision; Texture analysis

1 Introduction

The asphalt road is the backbone of the modern transportation system. According to the Ministry of Infrastructure and Water Management of the Netherlands, the total road traffic in 2017 was 140.8 billion vehicle Kilometers [1]. The quality of asphalt roads is of vital importance to ensure the safety of passengers and also the efficiency of transportation. However, the quality of asphalt roads is a complex parameter to control as it depends on multiple factors, including but not limited to asphalt material, production procedure, base layer condition, and the intensity of use. One, often less acknowledged, factor that significantly impacts the long-term performance of asphalt roads is the quality of the construction process. The consistent and homogenous compaction of the asphalt layer at the right temperature significantly influences the longevity and quality of roads. Considering the irreversible nature of asphalt pavement construction, it is critical to accurately inspect the asphalt pavement during the construction process to spot and fix the failures in the early stages.

In recent years, realizing that early detection of failures during the construction phase could contribute to the increased service life of road pavements while also reducing its life cycle cost by up to 37% [2], on-site monitoring during the compaction process has been taken more seriously. Makarov et al. [3] has proposed a framework for compaction guidance systems that can translate the temperature and compaction count data into clear suggestions for compaction strategies. Han et al. [4] developed a construction quality evaluation framework combining building information model (BIM) and geographic information systems (GIS), focusing on the temperature, speed, and rolling frequency during the compaction phase. Zeng et al. [5] presented a real-time asphalt pavement segregation identification algorithm based on digital imaging. However, the above-mentioned research primarily focuses on the monitoring of temperature and roller behaviours instead of the real-time monitoring of the resultant physical properties of the

asphalt layer (e.g., roughness and density). Or, in other words, are just indirect assessments of asphalt quality.

The real-time asphalt density and roughness monitoring during compaction has remained a bottleneck. Currently, the Ground-penetrating Radar (GPR) is considered to be an effective, feasible, and non-destructive tool for the real-time estimation of the density of asphalt concrete [6]. Wang et al. [7] proposed a signal-processing method for asphalt pavement layer thickness determination using GPR. However, the GPR-based method is strongly dependent on the asphalt material since the dielectric constant is essential for the AC density prediction [8]. For the real-time asphalt smoothness measurement, Chang et al. [9] introduced a laser-based system for the asphalt roughness identified from paver operation and roller compaction. Compared with existing as-build asphalt roughness measurements [10][11], this approach offers a solution for the real-time roughness measurement. However, due to the selection of the sensors, this approach is sensitive to typical events such as varying paving speeds(introducing vibration) and the environmental factors such as temperature, steam, and dust [9].

One possible method to address these limitations is to use computer vision techniques to directly assess the quality of the asphalt layer during construction. However, to the best of the authors' knowledge, the topic is not yet fully addressed. Therefore, this research aims to conduct a preliminary feasibility study of the vision-based real-time monitoring of asphalt properties. In this method, a geo-referenced image data collection system is designed. With the database built, image processing and data analysis algorithms will be introduced to correlate the change of asphalt surface texture during compaction with its corresponding physical properties. The remainder of the paper is structured as follows. In Section 2, the proposed computer vision-based asphalt monitoring framework is presented. Section 3 makes a brief explanation of a feasibility study taken in the real construction site will be introduced. Subsequently, the analysis of the results and discussions regarding the case study will be carried out. Section 4 encloses with a conclusion.

2 Methodology

A comprehensive geo-referenced data collection, image processing, and data analyzing framework is proposed in this section. The framework consists of 3 main stages, as illustrated in Figure 1. Schematic representation of the proposed framework.

In the initial stage, a data collection pipeline will be leveraged to collect geo-referenced asphalt pavement surface images. With the built dataset, an image processing algorithm will be developed, consisting of image pre-processing, segmentation, and result correction. In the last stage, the asphalt surface texture information generated from the image processing algorithm will be used as input for data analysis, where a machine learning method will be applied to make predictions on the corresponding physical properties of the asphalt pavement surface texture.

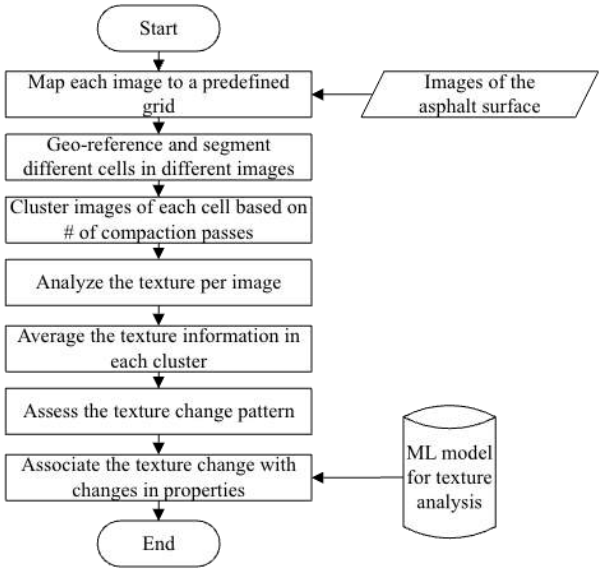

Figure 1. Schematic representation of the proposed framework

2.1 Data collection and pre-processing

The dynamic geo-referenced asphalt pavement surface texture data collection system is composed of a GPS signal receiver mounted on the top of the roller, and two cameras placed in the front of the roller and the back of the roller respectively, as illustrated in Figure 2. Schematic representation of the .

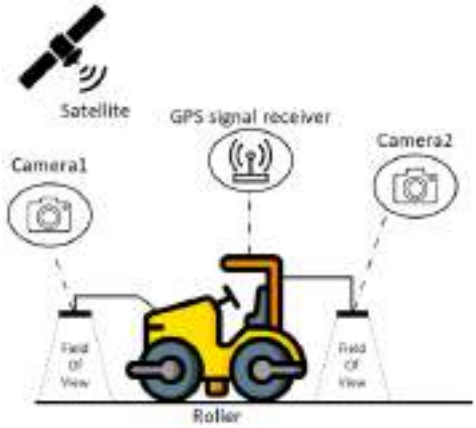

Figure 2. Schematic representation of the sensor setup

This system will take images of the asphalt surface as shown in Figure 3. The void area proportion generated

from different parameter sets . This dual-camera setup allows us to track asphalt pavement surface texture changes before and after compaction.

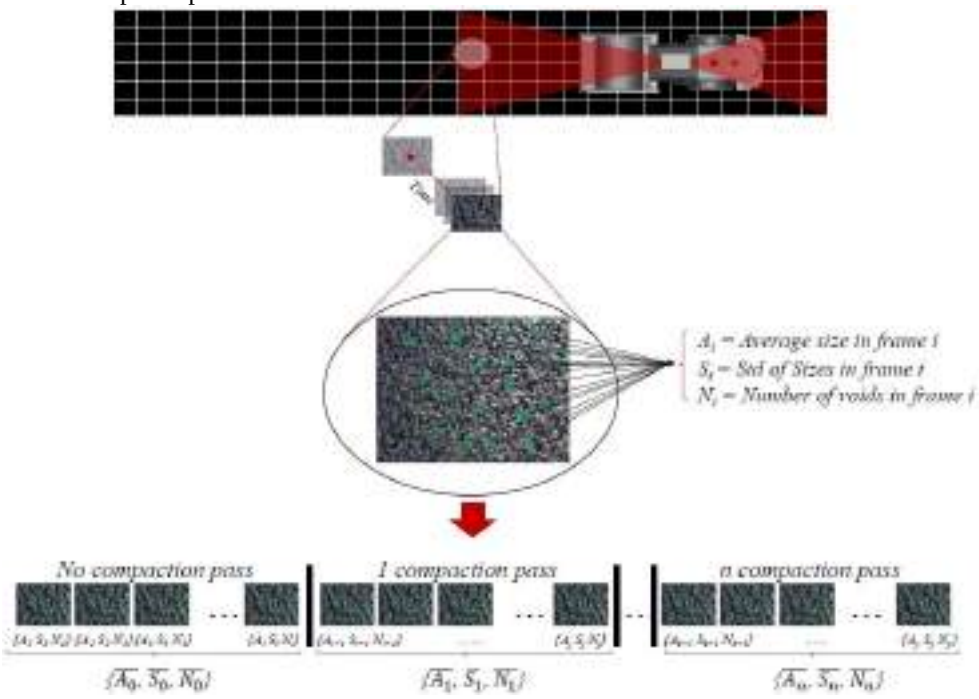

Figure 3. The void area proportion generated from different parameter sets

The raw images first need to be transformed to perspective images directly facing the surface and a compensation on the translation between the GPS receiver and the camera also need to be made. This is because the texture analysis, which is based on the shape and sizes of the voids between the aggregates, requires a uniform scale and perspective in all the images. By calibrating the camera [12], extrinsic and intrinsic parameters could be obtained. The image transformation is based on the relative orientation of the camera to the pavement surface and the translation between the camera and the GPS receiver. From the extrinsic parameters, namely the rotation matrix and translation vector, the camera's position and orientation relative to the world coordinate system could be obtained. In this phase, since the target is to convert the perspective of the camera and compensate the translation between camera and GPS signal, only the rotation matrix will be utilized and the translation vector will be replaced with a fixed translation vector between the GPS receiver and the camera. With the above-mentioned information, a homograph matrix can be computed, and with this matrix, the images captured could be projected into a perspective directly facing the surface and each image will be tagged with its rough geo-information.

Next, each raw image will be cropped into sub-images and each sub-image will be registered to a pre-defined physical grid, as shown in Figure 3. The void area proportion generated from different parameter sets. Each sub-image will be tagged with their fine geo-information. Notice that the pixel equivalent of each image is determined by (1) the installation height of the camera, (2) the orientation of the camera to the surface, and (3) the resolution of the camera[13], thus the cropped images may vary in pixel-wise sizes for different cameras.

Since the field of view (FOV) of each camera covers more than one grid, the same grid may be captured in several sequential images, and they will be clustered for result averaging. The determination of roller pass counts incorporates both image timestamps and the spatial coordinates of the roller. It is notable that sub-images that belong to the same grid from different frames will be clustered and the final output of this grid will be an average output value of all images in this cluster, as shown in Figure 3. The void area proportion generated from different parameter sets.

Sequentially, the segmentation algorithm will be conducted on the cropped images to segment the voids between the aggregates. The segmentation process is operated on each sub-image and it includes 3 steps.

(a) Brightness correction

As shown in Figure 4. Images in different lighting condition and the result of brightness correction, since

the images are captured in the natural environment, the lighting conditions could vary, and the algorithm is supposed to be sufficient to adapt to different scene illuminations.

With dynamic range compression, the images taken from different illuminated scenes are expected to produce good spectral tonal rendition and be tuned into similar brightness conditions. The Multiscale Retinex (MSR) [14] algorithm, one of the most popular and proven to be significant brightness correctness algorithms, is applied in this study. In this stage, the redundant information of the raw images such as dirt on the surface will be removed and the essential texture information (aggregate edges) will be preserved and enhanced. Figure 4 shows the result of brightness correction.

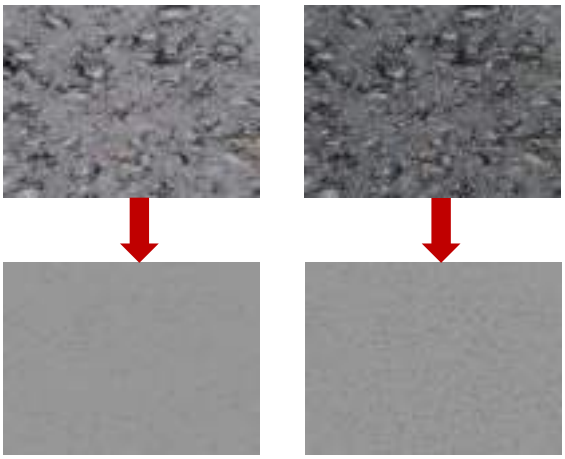

Figure 4. Images in different lighting condition and the result of brightness correction

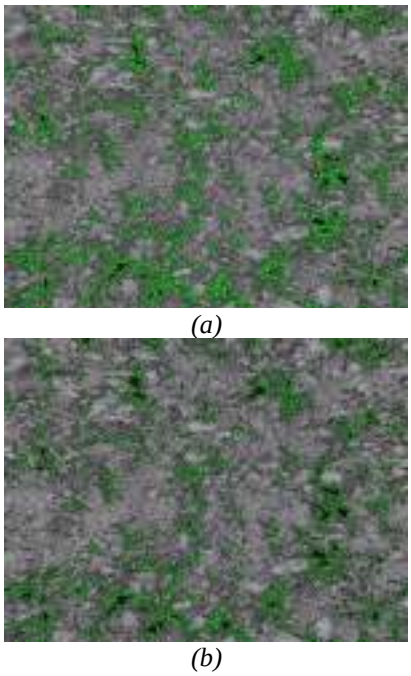
(b) Segmentation



The aggregates and the voids between them exhibit different grayscale values in the images. The voids are dark areas in the images while the aggregate areas display larger grayscale values. Considering this grayscale distribution pattern, thresholding can be applied to segment the voids. Since the raw images are corrected to a similar brightness condition, a global threshold value could be set to traverse each pixel in the images and binarize the image. If the grayscale value of the pixel is greater than the threshold value, it is considered to be the aggregate and the value of this pixel will be set to 0, otherwise, it is considered as the target voids and will be set to 255. The threshold is calculated with Equation 1.

$$threshold = mean - a * deviation \quad (1)$$

Where $mean$ refers to the mean gray value of the image, $deviation$ refers to the deviation of the gray value in the image and a refers to an experience-based parameter, which will be explained in Section 3.

(c) Segmentation result correction

The segmentation result is based on the grayscale values and small connected components can be found in the segmented results. Ideally, the fine textures in the small connected components are expected to offer detailed information on the asphalt pavement surface. However, they negatively impact the performance of texture analysis since the fine texture structure of pavement image has a marginal effect on the physical properties of the asphalt pavement (e.g., roughness) [15] but increases the computation cost of analysis. Also, some of the small connected components represent noises that affect the accuracy of subsequent processing steps. To refine the analysis and emphasize representative asphalt surface texture patterns, small and isolated regions will be removed according to their size and morphological [16] connectivity. The comparison between the initial segmentation results and the results after correction is shown in Figure 5. The contours of the segmented voids are labeled with green polygons. It is worth mentioning that the "voids" in this work refer to the void area between the aggregates on the surface, which display dark regions on the images, and they could represent the surface texture of the asphalt layer.

(a)

(b)

Figure 5. An example of the result of segmentation (a) before and (b) after correction

2.2 Data analysis

The segregated void areas will be mapped into quantified physical properties, which will be considered as a regression problem. The input of the regression

algorithm includes handcrafted features such as the quantity of void areas and the total area size of the voids, and also the high-dimensioned features generated from a pre-trained convolutional neural network (CNN). With the input, the machine learning algorithm is expected to deliver the quantified physical properties.

2.2.1 Texture analysis

The output of the image processing step is a binary image, with the void areas set to 255 and the background set to 0. The mask image, representing the features of the original image, will be serialized into a vector as the input of the machine learning algorithm.

Note that the images from each grid are clustered and their feature vectors will be averaged and then forwarded to the next step as the input feature of the machine learning algorithm.

2.2.2 Correlating texture properties with physical properties

After getting a vector as the input of the machine learning algorithm, the output of the machine learning algorithm is determined to be the corresponding physical properties of the asphalt surface area. During the training and validation stage for the machine learning algorithm, this data will be collected on-site or in a lab test. The training and validation process will follow a regular machine learning algorithm development process.

3 Experimental results and discussion

Since the core assumption of this research is that there is a trackable change in the asphalt pavement texture when the compaction happens, the preliminary feasibility validation for this research focused on the texture change detection. Two case studies were conducted in two different road construction projects in cities of Almelo and Winterswijk, the Netherlands. On each project sites, we collected data on 4 different sampling stations. The data collection station for this preliminary verification consists of a stationary camera placed on the side of the road and capturing 1 image every 10 seconds, as shown in **Error! Reference source not found.**.

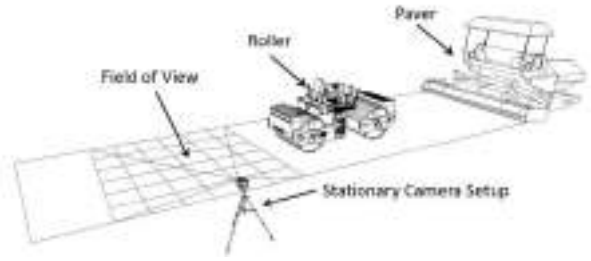


Figure 6. The experimental setup

The images captured within the compaction intervals are expected to display the same or similar pattern in texture, and images captured right before and after compaction are expected to display different texture patterns. Different models of cameras were used for each project, to assess the sensitivity to the camera model. The case studies aimed at (1) capturing the asphalt pavement surface images for the same area experiencing different rounds of roller pass, (2) extracting the surface texture, and (3) providing a quantified analysis of the texture indicating its change.

Following the steps introduced in Chapter 2.1, the total void area after each compaction was detected. As mentioned above, a few key parameters are crucial for the detection results. The sensitivity of the model to these parameters is shown in Figure 7.

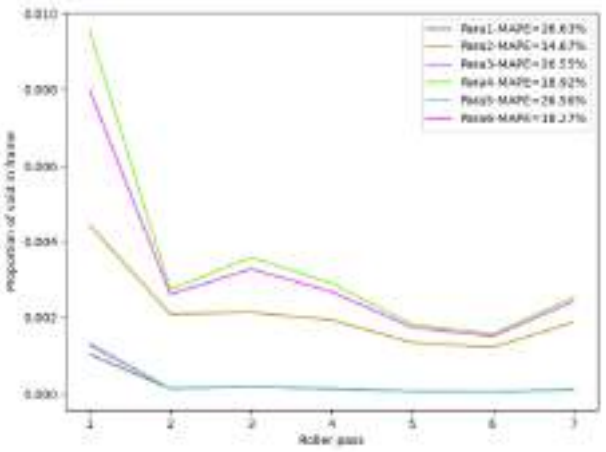

Figure 7. The void area proportion generated from different parameter sets

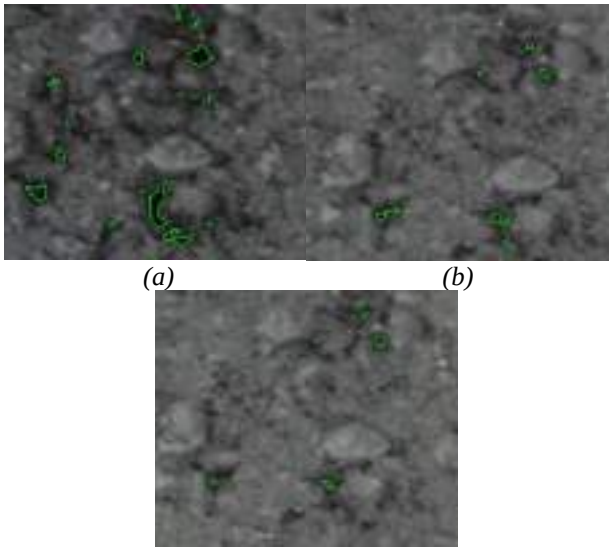
As shown in this figure, while all graphs indicate an overall negative exponential pattern, the magnitude and smoothness can vary. Given that the physical behaviour of asphalt conforms to a negative exponential trend, a negative exponential curve fitting was employed as the objective function to optimize the segmentation parameters. The mean absolute percentage error (MAPE), as indicated in Equation 2, was used for the evaluation of the fitting result.



$$MAPE = \frac{\sum \frac{|A - P|}{A} * 100}{N} \quad (2)$$

Where N refers to the number of sampling points, A refers to the actual value and P refers to the predicted value.

The result shows that the MAPE of the designed algorithm could reach 14.67% with an optimal set of parameters, which indicates that the variation of the segmented void area to the roller pass could be well-fitted

to a negative exponential function. As the assumption is that the texture of the asphalt layer surface exhibits a similar trend as some of the mechanical or physical properties of the asphalt to the roller passes, which is known to be a negative exponential pattern, this result proved that the segmentation algorithm is sufficient.

An example of the detection results of a sampled area after different roller passes is shown in **Error! Reference source not found.**. The results below is generated from the optimal parameters.

(a) *(b)*

(c)

Figure 8. An example of the segmentation results (a) right after paving, (b) after 5 rounds of compaction, and (c) after 10 rounds of compaction

Figure 9 presents the variation of the total void area in relation to the compaction passes for different test locations. As shown in this figure, there is a clear degrading pattern of the total void areas with respect to compaction passes. This can be construed as a strong indication that changes in asphalt textures are tracible and can be captured by computer vision. This clearly points to the potential that the texture analysis could be correlated with the development of different physical properties.

It is worth noting that the ranges of the total void area percentage in each frame are expected to be more or less the same, while it varies in our test. One potential reason for this variance is that the tests are done on different construction sites where different materials are used and each material has different properties. Another possible reason for this variance is that the distance between the camera and the surface is not precisely adjusted and therefore different from one station to another. At a larger distance, due to the lower resolution and the filtering strategies, some of the small voids could be undetected. Since the feasibility analysis is based on each camera in a time series, this factor does not affect the result of this experiment. However, it needs to be considered in future research when images from mobile camera (i.e., mounted on equipment) are used for analysis.

Also, during the validation, we found some factors may interfere with the image quality and lead to an unsatisfying result if the cameras are installed on the roller. The factors are (1) the water on the rollers will result in the steam and it will render the images blurry, and (2) the vibration of the roller may result in blurry images. Thus, the above-mentioned factors need to be considered when installing the camera on the rollers and extra mechanical designs such as stabilizer need to be added to the system.

4 Conclusion

This research proposed a framework for the vision-based monitoring of the asphalt properties during construction. As a preliminary validation of the idea, the asphalt pavement texture analysis has been done with a stationary camera set. The preliminary results exhibit a negative exponential pattern on the total void area of the asphalt surface as the roller passes increase. The negative exponential trend follows the theoretical trend of changes in many of physical and mechanical properties of the asphalt layer. This indicates that this method can be leveraged to correlate these properties with the changes in the texture of the asphalt during the construction. The application could be a real-time system where operators can be informed about the condition of the asphalt layer during the operation to adjust their operational strategies.

It should be highlighted that while vision-based monitoring of the asphalt condition in the operation phase (e.g., for detecting cracks and potholes) has been extensively studied, to the best of the authors' knowledge, the use of texture analysis during the construction process and the correlation of the texture change with the progression of the physical properties of the asphalt layer has not been studied.

This research will be further pursued by (1) installing the cameras on the rollers and considering the environmental interferes this may have on the images, and (2) correlating different physical properties of the asphalt layer with variation of the asphalt texture during the construction.

Abstract -

Modular Integrated Construction (MIC) currently depends on manual assembly processes, which are not only inefficient but also have safety risks. To address this issue, we propose vision-based technologies for automatic segmentation, measurement, and position estimation to aid in the assembly process in construction. Specifically, we utilize the Yolov8-seg model, which is an advanced instance segmentation tool, to segment the surfaces of the corners of the modules. These segmented surfaces are then fitted with quadrilaterals to accurately localize the four corner points. The 3D coordinates of these corners are determined by using the corresponding depth map, thus enabling precise measurements. Additionally, using the 2D coordinates of the colour map of the four corners and the actual 3D coordinates created with the center of the quadrilateral as the origin, we employ the Perspective-n-Point (PnP) algorithm for precise position estimation. The experiments show the effectiveness of the proposed methods. By integrating these vision-based techniques with construction robotics, we can significantly enhance the efficiency and safety of MiC assembly, paving the way towards full construction automation.

Computer Vision; Segmentation; Measurement; Pose Estimation; Modular Integrated Construction

1 Introduction

Modular Integrated Construction (MIC) involves the design of standardized modules, which are pre-fabricated in off-site manufacturing facilities and subsequently assembled on-site [1]. This method simplified the building process, saving project time and costs. However, the module installation process remains arduous and time-consuming. Lifting large modules requires cranes and hoists, and relies heavily on worker experience to achieve precise lifting; if workers are inexperienced, installation errors, delays, and safety accidents may occur, affecting project time and costs [2]. Due to the increasing demand for faster, safer and more efficient installations [3], the integration of new technologies such as computer vision is becoming important to improve accuracy, speed, and safety in module assembly.

Vision-based techniques have great potential to solve problems in the field of construction, offering a range of advantages that improve the overall construction process, including quality management, progress and schedule monitoring, safety enhancement, and cost reduction [4]. These vision-based methods involve advanced image processing, deep learning, 3D reconstruction, and other techniques to extract valuable visual perceptual information. Furthermore, when integrated with construction robots, these techniques—such as segmentation, measurement, and pose estimation—can significantly improve the robots' perception, enabling more efficient and automated construction.

Segmentation is extracting useful regions from an image or video frame for analysis [5]. In recent years, deep learning applications such as convolutional neural networks (CNN) have greatly improved the accuracy and efficiency of image segmentation [6]. Generally, segmentation can be divided into semantic segmentation and instance segmentation, each provides solutions for different kinds of tasks. Semantic segmentation is the categorisation of each pixel into a specific class, without distinguishing between specific objects in each class. One of the pioneering works of semantic segmentation is Fully Convolutional Networks (FCN) [7], which achieves end-to-end image segmentation by grouping each pixel into specific classes using convolutional layers rather than fully connected layers. U-Net [8], on the other hand, uses an encoder-decoder structure to be able to capture both local and global features and skip connections to fuse deep and shallow information. DeepLab [9] uses dilated convolution to increase the sensory field, which facilitates the segmentation of objects at different scales. Instance segmentation not only focuses on which class each pixel belongs to but also focuses on distinguishing different objects in the same class, which is more challenging than semantic segmentation. Mask R-CNN [10] is one of the most widely used instance segmentation models, which improves on Faster R-CNN [11]

by adding pixel-level segmentation to achieve detection and segmentation at the same time. Leanne Attard et al. [12] employed Mask R-CNN to detect and localize cracks on concrete surfaces, thereby overcoming the limitations of manual detection and significantly reducing both time and cost.

Measurement technology plays a crucial role in Modular Integrated Construction (MIC), particularly for the precise measurement of prefabricated modules. Traditional measurement methods, which rely on manual techniques, are time-consuming, labour-intensive, and subjective [13]. In contrast, vision-based methods such as binocular vision, Time of Flight (ToF), and structured light offer more accurate, objective, and reliable measurement solutions. Binocular vision simulates the human eye by using two cameras to take pictures of the same object at different angles, and by calculating the disparity of the same object in the pictures of the two cameras, thus achieving the depth measurement of the object [14]. ToF obtains depth information by measuring the time it takes for the light signal to travel from the emitting source to the target object and back to the sensor [15]. The structured light system achieves 3d reconstruction of the object by projecting a known pattern onto the target object, and the camera achieves this by capturing changes in the pattern [16]. Liu [17] uses binocular vision to measure the size of cracks in walls, preventing and treating wall defects in advance, thus enabling structural and environmental monitoring of buildings. Yu et al. [18] combined structured light with an industrial robot to stitch together 3d data, simplifying the calibration process and improving the measurement accuracy, thus enabling accurate measurement of the 3D shape of large objects.

Pose estimation is widely used in augmented reality, construction robotics, and industrial automation to enable three-dimensional reconstruction, robotic assembly, and automated construction. Pose estimation aims at obtaining the position and attitude of an object in 3D space, which is crucial for the accurate placement and installation of MIC modules. Attitude estimation methods are classified into feature-based methods and deep learning-based methods etc. Feature-based methods extract feature points such as corner points, edges, key points, etc. from images or video frames and use feature matching to estimate position and orientation. For example, the Perspective-n-Point (PnP) algorithm uses a projection model to estimate pose by extracting feature points from 2d images and matching them with actual 3D coordinates [19]. Mi et al. [20] used the PnP algorithm for 3D position measurement of the pit to achieve automated monitoring of pit displacement. Deep learning-based algorithms use CNN to predict the pose directly end to end. PoseNet [21] based on CNN directly estimates the position and orientation of the camera in 3D space from a single image without feature matching.OpenPose can extract the keypoints from a single image and supports multi-person detection. Prabesh Paudel et al. [22] used PoseNet to detect the worker's position and assess the risk based on the worker's posture to ensure safety. Deep learning-based methods require a large amount of training data to learn effective features with high computational complexity, whereas feature-based pose estimation algorithms require less data, have low computational complexity and good real-time performance.

There are also several studies that apply computer vision techniques to MIC to address challenges in the manual assembly process. For instance, Roshan Panahi et al. [23] proposed an automated assembly progress monitoring system for modular construction factories using computer vision-based instance segmentation. Zhenjie Zheng et al. [24] used Mask R-CNN in the construction process, thus enabling accurate localisation and segmentation of MIC modules, which is conducive to automated process monitoring. However, while these studies focus on segmentation and monitoring, there remains a gap in fully automating not just the detection but also the precise measurement and pose estimation of construction modules.

In this study, we aim to develop a computer vision-based framework for automated segmentation, precise measurement, and position estimation of construction components, with a focus on MIC corner surfaces. The specific objectives of this study are: (1) to achieve accurate instance segmentation of MIC module corner surfaces using the Yolov8-seg model, (2) to extract and fit segmented surfaces into quadrilaterals for identifying precise corner points and measuring the MIC corner, and (3) to implement the PnP algorithm for pose estimation by using the relationship between 2D and 3D corner coordinates.

The contributions of this study include: (1) the integration of state-of-the-art computer vision techniques to automate traditionally manual tasks in the construction industry, (2) a novel application of instance segmentation and 3D depth-based analysis to achieve precise segmentation and measurement MIC components, and (3) the pose estimation of construction components through the combined use of depth data and 2D-3D point correspondence.

The following sections of this paper is structured as follows: Section 2 details the proposed methodology, including segmentation, measurement, and the PnP-based pose estimation process. Section 3 presents experimental results and evaluates the performance of the proposed framework. Finally, Section 4 provides a conclusion, summarizing the key findings.

2 Methodology

Figure 1 shows a typical MIC module. It is notable that there is a distinctive rectangular fitting at each of the four

corners of the module. This fitting has unique geometric features and functions that not only provide additional support for the module but also facilitate quick and precise assembly. Therefore this fitting is an important feature of the MIC module. By analyzing the corner features, we can achieve the detection and positioning of the corners of the MIC module, which enables the robot to automatically identify and manipulate the MIC module and improves the automation level of the construction.

Figure 1. Typical MIC module.

To further investigate the corner feature of the MIC module, a 1:1 model of the corner shown in Figure 2 was 3D printed to investigate automated vision-based processing methods, including segmentation, measurement, and pose estimation. The model allows us to simulate and evaluate the performance of the vision system accurately under laboratory conditions.

Figure 2. 3D printed 1:1 model of the MIC module corner.

2.1 Segmentation

Considering the trade-off between accuracy and processing speed, we have selected the Yolov8-seg model for image segmentation. Yolov8 introduces several enhancements to optimize performance, including an anchor-free detection method, the C2f module, a decoupled header, and a modified loss function [25]. These improvements collectively enhance the model's speed, accuracy, and generalization capabilities. Yolov8-seg, a variant derived from Yolov8, is specifically engineered for segmentation tasks. It inherits the high accuracy and speed of the YOLO series and extends these capabilities to achieve pixel-level segmentation. The architecture of Yolov8-seg is illustrated in Figure 3.

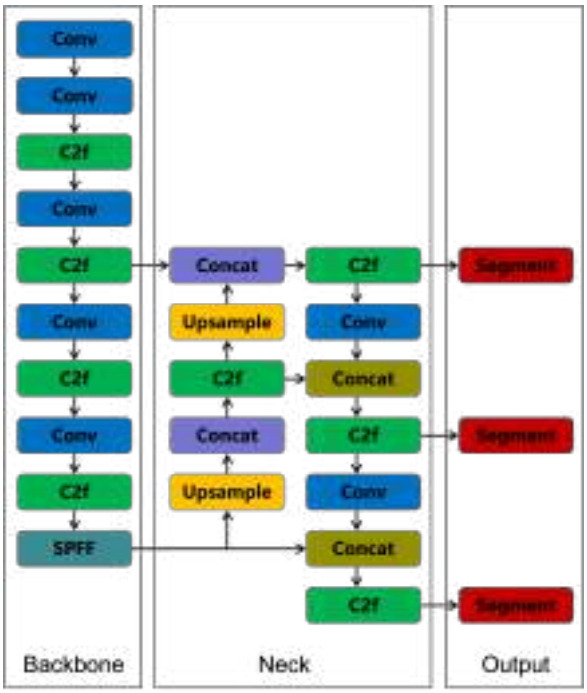

Figure 3. The architecture of Yolov8-seg.

Accurate image segmentation is essential for precise subsequent analysis. In our study, we employed the Yolov8-seg model to segment the surface of the corner model, which allows us to detect and localize the specific positions of the corner model accurately. After segmenting the image, we fit it into a quadrilateral to extract the four corner points. In this way, we can know the exact position of the four corner points in the 2D image and get the 2D coordinates of the four corner points. The segmented image and the coordinates of the four corner points provide a robust foundation for further geometric and dimensional analyses. These will subsequently be utilized for in-depth measurements and accurate pose estimation.

2.2 Measurement

The process of mapping points from a three-dimensional coordinate system to a two-dimensional image plane can be described using the pinhole camera model, which is shown in Figure 4.

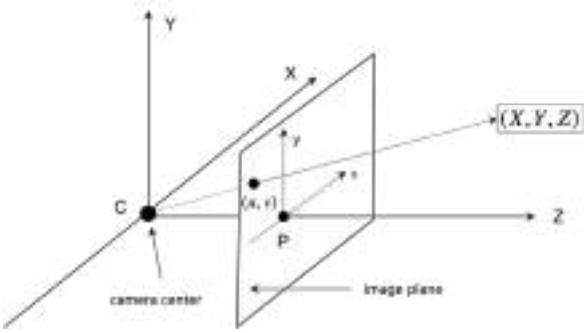

Figure 4. Pinhole camera model.

According to the pinhole camera model, the projection of a point (X, Y, Z) in three-dimensional space onto a point (u, v) on the two-dimensional image plane is described by the following equations:

$$\begin{aligned} u &= f_x \frac{X}{Z} + c_x, \\ v &= f_y \frac{Y}{Z} + c_y, \end{aligned} \tag{1}$$

where f_x and f_y are the focal lengths along the x and y axes, respectively, and c_x and c_y are the coordinates of the principal point on the image plane.

This can be further expressed in matrix form:

$$\begin{bmatrix} u \\ v \\ 1 \end{bmatrix} = K \begin{bmatrix} \frac{X}{Z} \\ \frac{Y}{Z} \\ 1 \end{bmatrix} \tag{2}$$

where K is the camera's intrinsic matrix and defined as:

$$K = \begin{bmatrix} f_x & 0 & c_x \\ 0 & f_y & c_y \\ 0 & 0 & 1 \end{bmatrix} \tag{3}$$

To accurately measure the size of the corner model, we use a depth camera. The depth camera captures both a colour map and a corresponding depth map, with the depth map providing the depth value (i.e., the z-coordinate) for the 3D points. Using the formula:

$$\begin{aligned} X &= (u - C_x) \times \frac{Z}{f_x} \\ Y &= \left(v - C_y\right) \times \frac{Z}{f_y} \\ Z &= \text{ depth value} \end{aligned} \tag{4}$$

we can accurately derive the 3D coordinates of any point from its depth map. Using the 2d image coordinates of the four corner points obtained from the segmentation result in the previous step, combined with the depth map, the 3d coordinates of the four corner points can be obtained. The actual length and width of the corner model can be obtained by calculating the distance between two neighbouring points from the 3d coordinates of the four corner points.

2.3 Pose Estimation

Since we have previously determined the actual length and width of the corner model, we can construct a 3D coordinate system for the corner model based on the actual length and width. By setting the center point of the model as the coordinate origin, we can locate the four corners relative to this origin to obtain their actual 3D coordinates. Given that we have both the actual 3D coordinates of the four corner points and their corresponding 2D image coordinates, we can employ the PnP algorithm to accurately estimate the pose of the corner model.

The PnP algorithm is widely used in computer vision to estimate the position and orientation of the camera relative to the object based on a set of 2D-3D points. PnP is an optimization problem that aims to determine the optimal rotation and translation matrices that minimize the reprojection error. This error is calculated by measuring the difference between the predicted positions of the 3D points when re-projected onto the image plane and their actual positions. The reprojection error is mathematically expressed as:

$$e_i = x_i - K[R \mid t]X_i \tag{5}$$

where x_i represents a 2D point on the image plane, X_i is the corresponding 3D point, R and t denote the camera's rotation matrix and translation vector, respectively, and K is the camera's intrinsic parameter matrix.

The goal of PnP algorithm is to minimize the reprojection error, that is:

$$\min_{R,t} \sum_i \|e_i\|^2 \tag{6}$$

This optimization problem can be solved by iterative methods, where R and t are adjusted step by step through several iterations, so as to find the minimum value of the reprojection error and the optimal R and t.

3 Experiments and Results

3.1 Dataset

We used the Intel RealSense D455 depth camera, commonly used in construction, to collect data. The D455 depth camera has two high-resolution colour and depth sensors that capture depth information through the principle of stereo vision. The intrinsic parameters of the camera are shown in Table 1 and Tabel 2 including the focal lengths (f_x, f_y), the principal point coordinates (c_x, c_y), and the distortion coefficients.

Table 1. Parameters of the colour camera

Color camera	Intrinsic parameters
f_x, f_y	391.942, 391.942
c_x, c_y	324.305, 239.027
Distortion	[0, 0, 0, 0, 0]

Table 2. Parameters of the depth camera

Depth camera	Intrinsic parameters
f_x, f_y	387.781, 387.351
c_x, c_y	325.001, 247.284
Distortion	[-0.055, 0.066, -0.800, 8.003, -0.022]

The coordinate systems of the depth camera and the colour camera are aligned through a transformation that includes rotation and translation. This alignment ensures that the data from both cameras are accurately matched. This transformation is defined by the extrinsic parameters of the cameras, represented by the rotation matrix R and the translation vector t, as follows:

$$R = \begin{bmatrix} 0.99998343 & -0.00549165 & -0.00175197 \\ 0.00548666 & 0.99998093 & -0.00283836 \\ 0.00176752 & 0.00282870 & 0.99999446 \end{bmatrix}$$

$$t = \begin{bmatrix} -0.05912773311138153 \\ 0.0003899137955158949 \\ 0.00034507890813983977 \end{bmatrix}$$

We captured a total of 1018 images under different illumination conditions and camera heights, as shown in Figure 5. These 1018 images were randomly shuffled and split into two parts: 80% as the training set to train the model and 20% as the test set to evaluate the model.

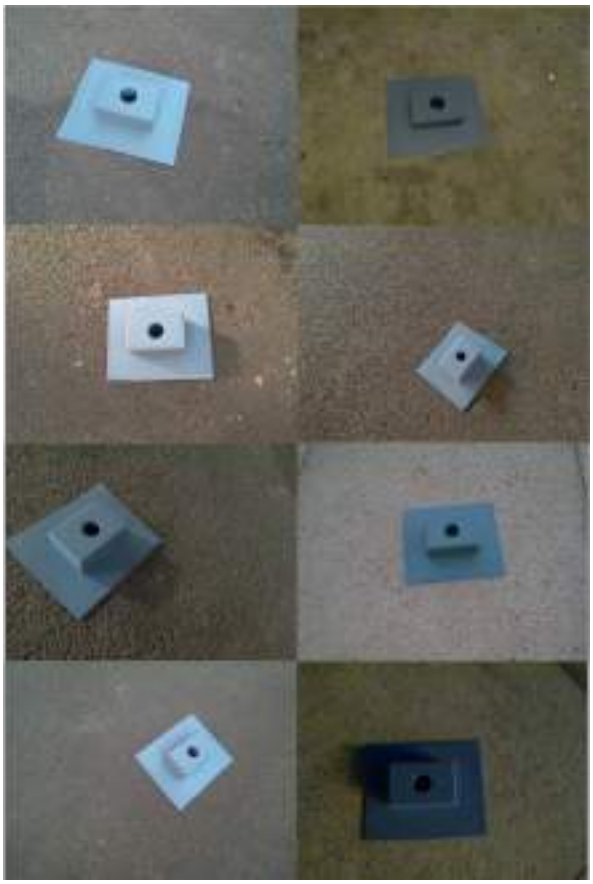

Figure 5. Image examples under different illumination conditions and camera heights.

3.2 Segmentation

We used the Yolov8-seg model for image segmentation, which enables instance segmentation by combining precise object detection and localization capabilities. The experiments were carried out using the NVIDIA GeForce RTX 4090 GPU. The input images were resized to a resolution of 640x640 pixels to standardize the input data format. We set the training with a batch size of 6 and the model was trained for 350 epochs.

To assess the effectiveness and accuracy of the model, we use a comprehensive set of evaluation metrics on the test set, including precision, recall, AP50 and AP50-95. These metrics help evaluate the model's ability to accurately detect and segment objects, providing a detailed analysis of its performance for segmentation.

After segmentation with Yolov8-seg, for each object, we get two key outputs: a bounding box and a segmentation mask. The bounding box marks the position of the object in the image with a rectangular box, which allows us to quickly detect the presence and approximate position of the object in the image. The segmentation mask provides more fine-grained output, including pixel-level categorization, indicating which pixels in the bounding box belong to the object and delimiting the object's boundaries.

Table 3 presents the results of the Yolov8-seg on the test set, indicating robust performance in the corner segmentation task. Furthermore, Figure 6 displays the segmentation result for the corner model using Yolov8-seg, clearly showing that precise and accurate segmentation was achieved.

Table 3. Experimental results of Yolov8-seg.

Evaluation metrics	Box	Mask
Precision	1	1
Recall	1	1
AP50	0.995	0.995
AP50-95	0.993	0.97

3.3 Measurement

After segmenting the surface of the corner model using the Yolov8-seg, we fit a quadrilateral to the segmented surface. The four vertices of the quadrilateral represent the

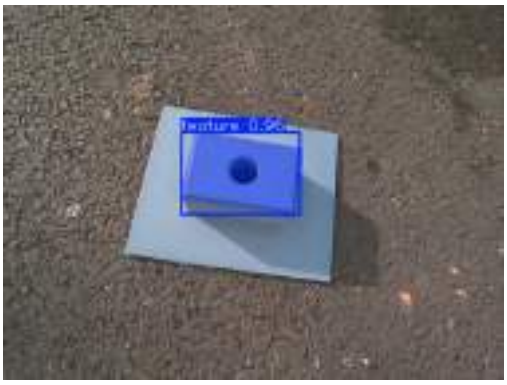

Figure 6. The segmentation result for the corner model using Yolov8-seg.

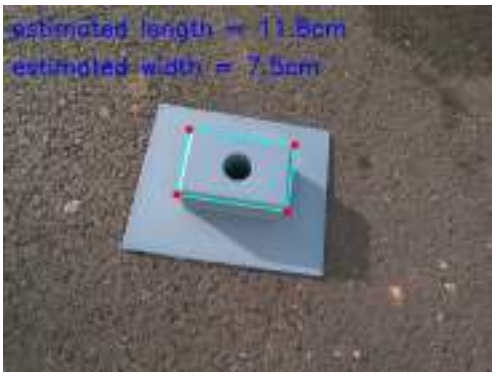

Figure 7. The measurement result for the corner model.

corners. By mapping these vertices to the corresponding depth map, we can obtain their actual three-dimensional coordinates. This enables us to measure the actual distances between the corners, thus determining the length and width of the corner model. Figure 7 shows the estimated dimensions of the corner model, with the length measured at 11.8 cm and the width at 7.5 cm. These estimations are compared to the actual dimensions, which are 12 cm in length and 8 cm in width. The test set, consisting of 204 images, was used to further validate the measurement accuracy, with the results showing that the measurement error is within 9 mm.

The measurement error can be attributed to several factors. One factor is the low resolution of the colour images, which limits the precision of segmentation and corner detection. Additionally, inaccuracies in the depth map, caused by sensor noise or resolution limitations, contribute significantly to errors in calculating the 3D coordinates of the corners. Segmentation errors from the Yolov8-seg model also play a role, as minor deviations in boundary detection can lead to slight inaccuracies in identifying the exact corner points.

3.4 Pose estimation

Once we have determined the exact coordinates and relative distances of the four corner points, we establish a coordinate system with the origin situated at the center of the quadrilateral formed by these points, which are at the upper left, upper right, lower left, and lower right, respectively. Following the segmentation process, we also acquire the 2D coordinates of these corner points within the colour map. Consequently, we can utilize the PnP algorithm to estimate the camera's position relative to the corner model surface. This is achieved by aligning the coordinate system of the corner model with the camera's coordinate system, allowing for precise calculation of the camera's orientation and position in relation to the corner model surface.

Figure 8 illustrates the results of estimating the pose using the PnP algorithm. The position of the camera relative to the surface of the corner model is described by a translation vector that quantifies the displacement of the camera to the model. The orientation of the camera relative to the surface of the angular model is represented by a quaternion. Quaternions provide a compact representation of orientations and do not suffer from the gimbal-lock problem that may result from orientation representations such as Euler angles.

To address occlusion, we consider introducing additional positioning tags, such as the Apriltag marker. When the corner features are not occluded, we simultaneously estimate the poses of both the Apriltag marker and the corner model, and calculate the relative pose deviation between them. When the corner model is occluded, we detect the pose of the Apriltag marker and use the previously obtained relative pose deviation between the Apriltag marker and the corner model to estimate the pose of the occluded corner model. Figure 9 shows pose estimation results in two scenarios. The upper image shows pose estimation when the corner features are not occluded, while the lower image shows pose estimation of occluded corner features using the Apriltag marker.

4 Conclusion

In conclusion, this study applied computer vision technology to MIC to enhance the efficiency, accuracy, and safety of the construction process. Unlike traditional construction methods, which rely heavily on manual labour and are susceptible to human error, our vision-based approach facilitates automated segmentation, measurement, and pose estimation. Specifically, we first use the Yolov8-seg model to segment the corner surfaces of modules. The

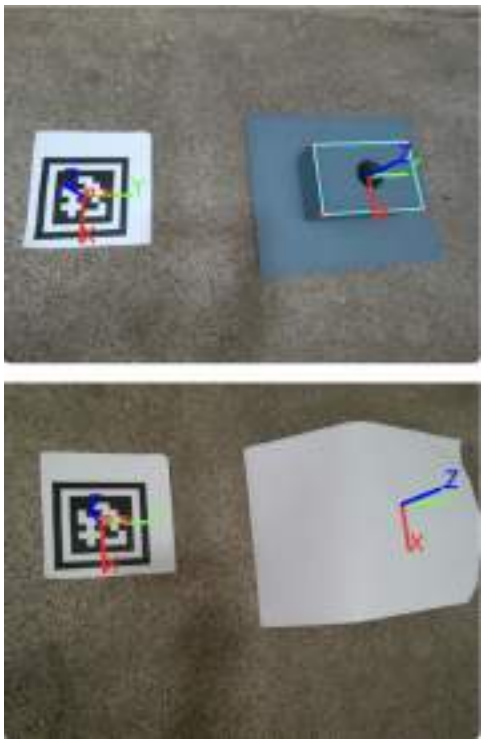

Figure 9. Pose estimation with the visible corner model (upper) and the occluded corner model using the Apriltag marker (lower).

segmented surfaces are fitted with quadrilaterals to position the four corners. By integrating the corresponding depth map, we accurately determine their 3D coordinates. Furthermore, using the 2D coordinates from the colour map and the 3D coordinates with the quadrilateral's center as the origin, we utilize the PnP algorithm for precise pose estimation. However, the 9mm measurement error is relatively high compared to the required precision in MIC. Future work will focus on algorithm optimization, addressing depth map resolution and sensor noise, and extending testing to real-world construction environments to evaluate performance under complex conditions.

Abstract -

More than 500 statutes and rules are interlinked with building codes and regulations, with 24 amendments introduced in 2023. This complex network of references, combined with frequent revisions, poses significant challenges for both legal experts and laypeople in interpreting building codes. To address this, prior research has explored the application of retrieval-augmented generation (RAG) techniques to large language models (LLMs). However, these efforts have struggled to retain contextual information due to data segmentation. This study proposes and evaluates six variants of zero-shot Chain-of-Thought (CoT) prompts, leveraging long-context window (LCW) LLMs for retrieving relevant legal texts. Among these, the prompt requiring minimal human guidance achieved 63.16% accuracy on a dataset of 171 legal interpretative question-answer (LIQA) pairs, outperforming other variants by up to 5.7%p. Furthermore, incorporating a high-level community summary improved the model's robustness to prompt variations. This approach reduced the need for extensive document hops when locating relevant provisions, narrowing the performance gap to 1.17%p. Lastly, the LCW LLM consistently referenced definition provisions, ensuring greater consistency in legal interpretation. The less the guidance, the better the performance. Less is Better!

Legal interpretation; Building code; Long context window; Multi-hop reasoning

1 Introduction

Legal interpretation involves clarifying the meaning and intent of legal texts, such as building codes and regulations, to ensure their accurate and proper application to specific cases. Understanding these codes is challenging, even for professionals, due to their complexity and frequent updates. In South Korea, more than 500 statutes and rules are intricately linked to building codes and regulations [1], with 24 amendments introduced in 2023 [2]. This complexity often requires reviewing over 400 provisions to process a single legal action such as issuing building permits [3]. The scale of this challenge is evident in the over 900,000 legal interpretation petitions related to housing and construction filed annually in South Korea [4]. Notably, a study conducted in 2017 revealed that 96.7% of handwritten petitions focused on legal interpretation issues [5].

Recent studies have leveraged large language models (LLMs) to minimize the manual effort and cost involved in legal interpretation. To enhance the capabilities of vanilla LLMs, three techniques have been commonly investigated: fine-tuning, retrieval-augmented generation (RAG), and prompt engineering. Among the three methods, RAG-based approaches are widely employed to deliver up-to-date factual information and mitigate hallucinations [1, 6, 7]. However, their performance depends significantly on the structure of the underlying database, emphasizing the need for a database designed to optimize efficient information retrieval [1]. Despite these efforts, data must still be segmented into chunks, resulting in contextual loss. This limitation can lead to the retrieval of documents that contain relevant keywords but present them within unrelated or misleading contexts [7].

To mitigate RAG's context loss, long context window (LCW) LLMs have recently gained attention. By accommodating longer input sequences, LCW LLMs demonstrate advantages in capturing relationships between pieces of information spread across extensive text [8]. However, these models still face challenges, including limitations in context length and the "lost in the middle" problem, where they tend to prioritize information at the beginning and end of the input sequence [9].

To overcome the limitations of existing methods, we propose and compare six variants of zero-shot Chain-of-Thought (CoT) prompts to identify effective strategies for utilizing a long context window in complex tasks such as legal interpretation. These variants differ in their approaches to retrieving relevant information: unguided, exhaustive, and structured search. Exhaustive search allows the model to perform unlimited recursive searches within and across statutory documents, while structured search guides the model to retrieve information based on the hi-

erarchical structure of the legal texts. Additionally, we assess the impact of providing a high-level community summary (HLCS) [10], which includes the titles of each legal provision, for all prompt variants.

For validation, we constructed the *legal interpretative question-answer* (LIQA) dataset using the Building Statutes Question Answering (QA) document published by the Ministry of Government Legislation (MOLEG) [11]. This document contains 171 QA cases requiring interpretation of legal provisions, as answers are not explicitly stated within the legal texts. The LLM identifies relevant provisions using each prompt variant to generate answers, which are then evaluated for accuracy to assess prompt effectiveness.

This paper addresses various terms related to natural language processing (NLP). *Multi-hop search* refers to retrieving information needed to answer a user inquiry through logical steps applied to the provided documents [12]. Specifically, *intra-document hop* refers to hops occurring within a single document, while *cross-document hop* involves hops between multiple documents [13]. *Contextual reasoning* is a type of reasoning task that involves interpreting a small set of factual information specific to the given problem [14]. *High-level community summary* is a summary of a group of data to understand the global structure and semantics of the dataset [10]. For Korean building codes and regulations, we adhere to the English terms provided by the official English-Korean legal terminology system [15, 16]. Additionally, the term *provision* is used throughout this paper to collectively refer to both attached forms and articles, including their sub-hierarchies.

2 Relevant Study

2.1 Retrieval-Augmented Generation

To accurately address a legal inquiry, it is essential to first retrieve the relevant provisions from a large legal corpus. Zhong [17] noted that while legal experts tend to resolve legal tasks by building well-defined rule-based or symbolic systems, NLP researchers prioritize legal information retrieval to support data-driven interpretation. Recently, RAG has gained significant attention as a method to efficiently supply task-specific information to vanilla LLMs [6].

Savelka et al. [7] assessed GPT-4's ability to explain legal terms using RAG by providing court case data that illustrated how statutory terms had been previously interpreted. Their findings demonstrated that incorporating legal information retrieval improves the quality of LLM-generated interpretations, particularly in terms of factual accuracy, clarity, relevance, information richness, and precision. Similarly, Cho and Kim [1] developed the Semantic Processing for Architecture Regulation Compliance (SPARC) model, a RAG-based framework. Their evaluations showed that the system attained high accuracy rates for general inquiries (81.8%) and moderate accuracy for complex legal interpretation cases (56.1%).

2.2 Prompt Engineering and Long Context Window

Since language models have limitations in their input sequence length, prompt engineering is aimed at utilizing the available context window as efficiently as possible. Blair-Stanek et al. [18] tested GPT-3's ability to answer statutory reasoning questions about U.S. tax codes using zero-shot, few-shot, and CoT prompting. Their findings revealed that GPT-3 exhibited incorrect prior knowledge of the U.S. tax codes. However, two-shot prompting improved accuracy by an average of 20.9%p compared to zero-shot result. Fuchs et al. [19] evaluated GPT-3.5's ability to generate a structured XML format of building regulations under four conditions: few-shot, detailed description, CoT, and self-consistency prompting. The study demonstrated that LLMs can translate regulations into structured formats without fine-tuning.

Although prompt engineering optimizes the use of a given sequence length, ensuring a large context window is crucial for long documents [20]. Previous studies have focused on developing LLMs with an expanded context window [8] or proposing frameworks to increase the amount of information that can be processed within the existing limits [20, 21]. In February 2024, Google introduced Gemini 1.5 pro, an LCW LLM capable of handling up to 10 million tokens. According to the official report [8], the model achieved over 99% recall in multimodal information retrieval tasks.

2.3 Research Gaps and Questions

While RAG enhances information retrieval in LLMs, its application in legal interpretation has several limitations. First, retrieval methods such as similarity search often fail to capture essential information due to their inability to recognize contextual relationships between predivided data chunks. For example, a retrieved sentence might contain relevant legal terminology but appear in an irrelevant or misleading context [7]. Second, addressing these retrieval failures in complex tasks requires extensive pre-processing, including the creation of a well-structured database, which is both time-intensive and costly [1].

Moreover, despite their strong performance in information retrieval, LLMs with LCW also remain imperfect. One notable issue is the "lost-in-the-middle" problem, where the model disproportionately focuses on the beginning and end of a prompt, even when the context window has not been fully utilized [22]. Additionally, vanilla LCW LLMs often perform poorly on domain-specific tasks, such as legal interpretation.

To enhance the interpretation of building codes, which demand both comprehension and the ability to parse relevant provisions from extremely long contexts, this study evaluates various types of Chain-of-Thought (CoT) prompts using LCW LLMs. The following sections present the proposed prompt designs, the implementation methods, and the experimental evaluation process.

3 Proposed Method

We propose six variants of zero-shot prompts to enable the retrieval of provisions without the need for frameworks like RAG or fine-tuning. These retrieval prompts are grouped into three categories: unguided search, exhaustive search, and structured search. Each category includes two versions—one with a high-level community summary and one without—yielding a total of six variants.

3.1 General Prompt Structure

All prompts are created based on the structure outlined in *prompting guide 101* by Google Gemini Team [23]. The guide recommends incorporating four components in a prompt: persona, task, context, and format, though including all of them is optional. The persona defines the role or perspective, the task specifies the objective, the context provides situational details, and the format outlines the desired response style. The guide also highlights the importance of using a clear verb or directive to define the task. In this paper, we propose a basic prompt structure, as illustrated in Basic Prompt, where braces denote variable or optional elements specific to the three prompt variants.

Basic Prompt "You are designed to assist users in locating legal provisions related to the Korean Building Code as they apply to inquiries. {**HLCS**} {**Context**} {**Format**}"

3.2 Prompt Variants

3.2.1 Unguided Search

The prompt used in unguided search does not include detailed CoT instructions. Instead, it provides only a command in the {Context} field. Additionally, the response format is defined as tuples within a list, as described below.

{**Context**}: "From the given files and inquiry, find all articles and attached forms related to the inquiry."
{**Format**}: "Return the law name and article or attached form number that you found as tuples in a list format. For example: [(Building Act, Article 3-2), (Enforcement Rule of the Building Act, Article 12), (Enforcement Rule of the Building Act, Attached Form 1)]. If it is not an attached form, number must include the word 'Article'. Do not directly answer the inquiry."

3.2.2 Exhaustive search

In exhaustive search, LCW LLM is guided to perform a recursive provision search, hopping between all interreferencing provisions until it encounters provisions unrelated to the inquiry. Before returning the final list, it evaluates the relevance of each provision and includes only the necessary ones. To track the multi-hop search path, results are returned in a dictionary format, where the key represents the found provision and the value represents its parent provision.

{**Context**}: "Using the given files and inquiry: 1. Identify the articles and attached forms related to the inquiry. 2. Locate other provisions that reference the provisions identified in Step 1. 3. Recursively find additional provisions that reference those identified in the previous step until provisions unrelated to the inquiry are reached. In subordinate codes, references may appear explicitly, such as 'Article 12 Paragraph 1 of the Act'. 4. From the provisions gathered, filter and return only those necessary to address the inquiry."
{**Format**}: "5. Return the results in a dictionary format, where each key is a provision, and its value is the provision that mentioned the key (its parent). Each element must be formatted as (law name, article or form number). If the provision is related to the inquiry itself, its value should be 'Inquiry'. For example: '(Building Act, Article 3-2)': 'Inquiry', '(Enforcement Rule of the Building Act, Article 28)': '(Building Act, Article 3-2)', '(Enforcement Rule of the Building Act, Attached Form 1)': '(Building Act, Article 3-2)'. If the provision is not an attached form, the number must include the word 'Article'. Do not directly answer the inquiry."

3.2.3 Structured search

In structured search, the context part is organized according to the hierarchical structure of the Korean building codes. For each Act, specific provisions necessary for its enforcement are determined by the Decree, while provisions are only incorporated into the Rule if they pertain to technical or minor matters requiring frequent updates [24]. Consequently, the search process is structured to prioritize provisions in the order of Act, Decree, and Rule. However, since some inquiry topics are not explicitly addressed in the Act, the model is allowed to initiate searches from either the Act or the Rule. The response format is the same as that used in unguided search, as described in Section 3.2.1.

{**Context**}: "Using the given files and inquiry: 1. Identify the articles and attached forms in the Act or Rule related to the inquiry. 2. Locate other provisions in Rule that reference the provisions identified in Step 1. 3. Find additional provisions in Decree that reference those identified in the previous steps. In subordinate codes, references may appear explicitly, such as 'Article 12 Paragraph 1 of the Act'. 4. From the provisions gathered, filter and return only those necessary to address the inquiry."

3.3 High-level Community Summary

For each prompt variant, two versions—one with HLCS and one without—are tested. In this study, the titles of provisions are used as summaries, as they are designed to concisely convey what each provision regulates, facilitating convenient search [24]. The HLCS prompt is provided below.

{**HLCS**}: Each article's title is provided in a text file named after the law, followed by '(Provision Title)', which can help determine relevance.

4 Experimental Design

4.1 Datasets

The dataset used to validate our prompts is derived from the Building Statutes Question Answering (QA) document, which includes 171 statutory building code interpretation cases across 21 categories, selected by MOLEG [11]. This document is well-suited for use as ground truth in evaluating the prompts because MOLEG provides standardized legal interpretation guidelines in South Korea to ensure consistency across administrative agencies' interpretations [25]. Additionally, the cases in this document require interpreting the meaning and relationships between provisions, as the answers are not explicitly stated in the legal texts.

Each case in the document is structured into four parts: the title, an inquiry, a response, and the reasoning. As illustrated in Figure 1, we developed the LIQA dataset by using the inquiry summaries as questions and compiling the corresponding ground truth answers as follows: the title served as the inquiry summary, the response as the comprehensive conclusion, and the reasoning as the basis of judgment.

4.2 Experimental Setup

Figure 1 also illustrates the experimental flow for evaluating the six prompt variants. Each variant searches and generates a list of relevant provisions for each question in the LIQA dataset. The content of the provisions in each list is then passed to the answer-generating LLM to produce the final answer. The prompt for the answer-generating LLM is shown in Response Prompt.

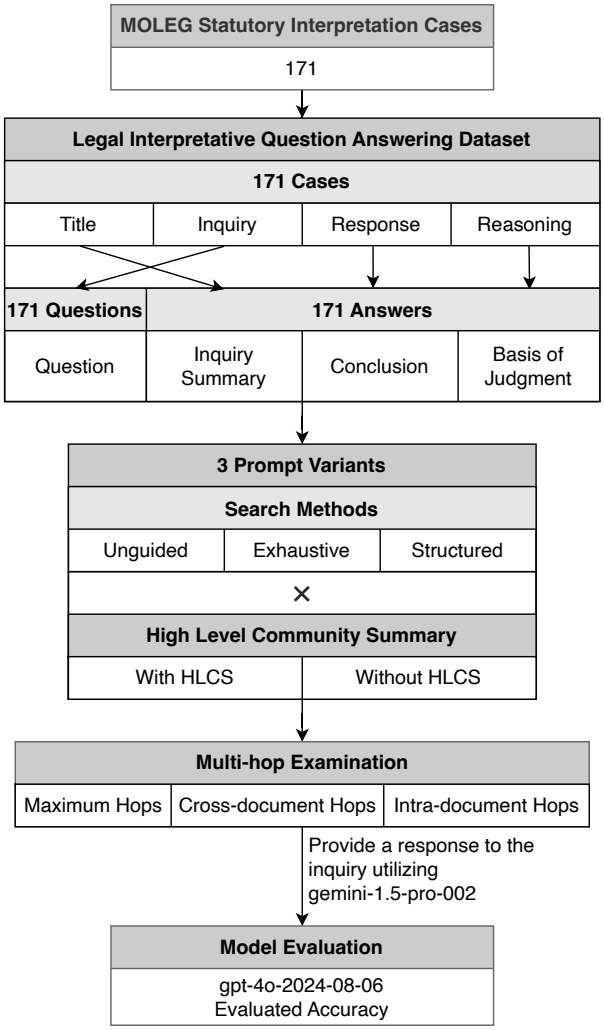

Figure 1. Flow chart of the experiment

Response Prompt You are designed to assist users in interpreting legal provisions related to the Korean Architecture Code. Your primary role is to provide interpretations of the laws as they apply to inquiries in Korean. You must analyze the legal texts in the provided documents or prompt only. The answer must consist of 3 parts: 'Inquiry Summary', 'Conclusion', 'Basis of Judgment'. The first part, 'Inquiry Summary', describes the core content of the inquiry. The second part, 'Conclusion', describes the answer or conclusion of the question. The last part, 'Basis of Judgment', contains the legal basis of the answer described in 'Conclusion'.

The proposed framework can accommodate any LCW LLM with a sufficiently large context window to handle the input data. For this experiment, we used the gemini-1.5-pro-002 model as the LCW LLM for CoT prompt processing and answer generation. To stay within context limits, provision search was restricted to the Building Act and its subordinate regulations. For hyperparameters, we followed Google AI Studio's defaults: *temperature* = 1, *top_p* = 0.95, *top_k* = 40, and *max_output_tokens* = 8192. Safety settings were disabled "threshold": "BLOCK_NONE") to prevent unintended response blocking. During answer generation, *temperature* was increased to 1.2 for enhanced creativity [26].

During answer generation, the content of the statutes is passed to the LLM as a string, retrieved via the Law Open Data Service through an Open API (hereafter referred to as LawAPI) provided by the Korean Law Information Center under MOLEG. For attached forms, however, the official PDF file of the form is provided to ensure the tabular format is preserved accurately.

The experiment was conducted on a MacBook Pro 14 (Model MacBookPro18,3) equipped with an Apple M1 Pro chip, 16 GB RAM, 10 CPU cores (8 performance cores and 2 efficiency cores), 12 GPU cores, and running macOS Sonoma 15.2. The application software used was Visual Studio Code version 1.96.2, with Python 3.11.5.

4.3 Accuracy Evaluation

The accuracy of each prompt variant was evaluated by comparing the final answer generated by the model to the ground truth answer. To ensure an efficient and fair evaluation, we employed a gpt-4o-2024-08-06 based assessment agent using the Evaluation Prompt. Q, R_H, and R_S represent a question, human response, and system response, braces indicating their variability by inquiry and prompt.

Evaluation Prompt Compare human_response and system_response for original_question. Return True if both responses reach the same conclusion or agree, otherwise return False.
original_question: {Q}
human_response: {R_H}
system_response: {R_S}

4.4 Multi-hop Examination

To trace the sequence of hops taken by the model during an exhaustive search, we instructed the LLM to return its results in a dictionary format, where the key represents the child (destination) and the value represents the parent (origin), as described in Section 3.2.2. The number of hops performed was then analyzed by converting the results into a tree format using Python code.

5 Results

5.1 Accuracy

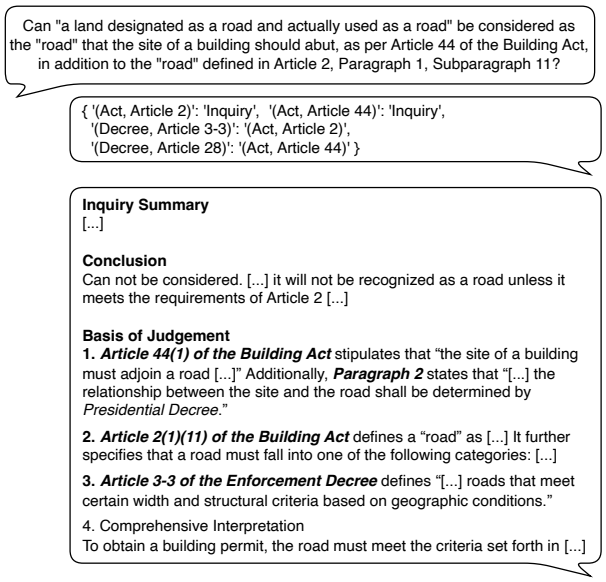

Figure 2. Example result of a Exhaustive Search + HLCS prompt.

Figure 2 depicts an example result when the exhaustive search prompt with HLCS is applied. Figure 3 presents the accuracy distribution for six prompt variants across different inquiry categories, with average accuracies represented by diamond marks and detailed in Table 1. Without HLCS, unguided search achieved the highest average accuracy of 63.16%, followed by exhaustive search at 60.82% and structured search at 57.89%. With HLCS, the accuracy gap between the prompt types narrowed, with structured search leading at 62.57%, followed closely by exhaustive (61.99%) and unguided (61.40%) search.

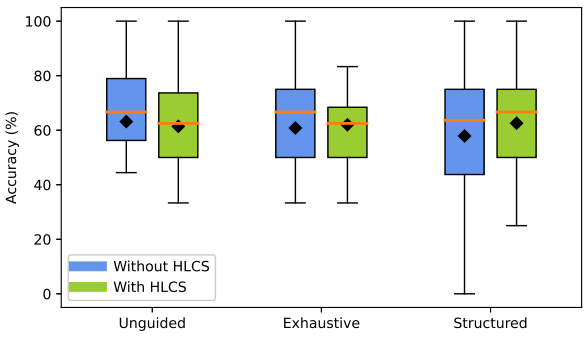

Figure 3. Comparison of six prompt variants on accuracy for each inquiry subject. Diamond marks indicate the weighted accuracy of each variant.

Table 1. Weighted average accuracy(%) of each prompt variant with and without HLCS. Ung, Exh, and Str stand for unguided, exhaustive, and structured search, respectively.

	Ung	Exh	Str
Without HLCS	**63.16**	60.82	57.89
With HLCS	61.40	61.99	62.57

5.2 Multi-hop Examination

Table 2 presents the top 5 most commonly mentioned provisions in the inquiries and the top 5 most frequently referenced provisions by the two exhaustive search prompts. Comparing the results reveals that Article 11 of the Building Act and Attached Form 1 of its Enforcement Rule are frequently both mentioned and referenced. Notably, the search prompts often referenced Article 2 of both the Act and the Rule, even though these were not explicitly mentioned in the inquiries. Article 2 in both cases contains definitions of the legal terms used in the content.

Table 2. List and count of the provisions commonly mentioned and searched. AF stands for Attached form. The number within parentheses represents frequencies (number of inquiries)

Idx	Mentioned	Exhaust / Exhaust+HLCS
1st	Act, 11 (25)	**Act, 2 (101)** / Rule, 2 (61)
2nd	Rule, AF 1 (20)	Rule, 2 (89) / Act, 2 (59)
3rd	Rule, 119 (15)	Rule, AF 1 (53 / 39)
4th	Rule, 86 (14)	Act, 11 (38) / Act, 11 (36)
5th	Act, 80 (10)	Decree, 6 (36) / Rule, 28 (30)

Figure 4 displays the percentile rank of the number of provisions referenced during exhaustive search, with and without HLCS. The plain exhaustive search referenced more provisions beyond the 97th percentile, with an average of 10.70 provisions compared to an average of 7.62 provisions for the HLCS-equipped search. Moreover, the HLCS-equipped LCW LLM performed fewer hops compared to the model without HLCS (Figure 5). The average length of the longest sequence of hops per inquiry was 2.91 for Exhaust+HLCS, which is 0.44 fewer than that of the model without HLCS (3.35). Specifically, it averaged 0.23 fewer cross-document hops (CDH) (1.62 vs 1.85) and 0.11 fewer intra-document hops (IDH) (1.22 vs 1.33) per inquiry.

Table 3 presents the average execution time of the six prompt variants for generating the list of relevant provisions. Exhaustive search took the longest time, both with and without HLCS, followed by structured search and unguided search. Meanwhile, the average prompt token count was similar across models—546K without HLCS and 556K with HLCS—since the majority of tokens came from the provided Building Act and its subordinate regulations.

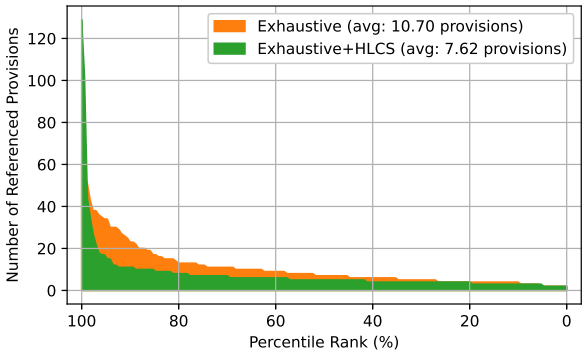

Figure 4. Comparison of the number of referenced provisions with and without HLCS across percentile ranks

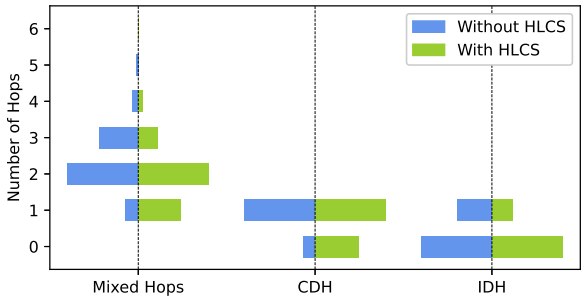

Figure 5. Horizontal bar plot illustrating the relative frequency of the number of hops taken by the exhaustive search.

Table 3. Average execution time(sec) of each prompt variant with and without HLCS.

	Ung	Exh	Str
Without HLCS	44.08	67.10	54.83
With HLCS	44.55	**83.06**	76.23

6 Discussion

When analyzing the trend in average response accuracy across six prompt variants, a counterintuitive pattern emerged: less guidance in the prompt for locating relevant provisions led to higher accuracy. Furthermore, incorporating HLCS improved the accuracy. Without HLCS, the accuracy gap between prompts reached up to 5.27 percentage points, whereas with HLCS, this gap narrowed to just 1.17 percentage points—a reduction of approximately 4.5 times. As detailed in Section 3.3, we provided provision titles as HLCS, and the results confirm their effectiveness

in legal document retrieval. However, while HLCS enhanced stability, it did not yield the highest performance, indicating that its primary effect is to ensure consistency in search results rather than directly enhancing accuracy.

HLCS's stability enhancement is further examined by the findings in Section 4.4. When the same prompt was used, the inclusion of HLCS reduced the average number of referenced legal provisions per inquiry by 3.08. Figure 5 shows HLCS reduced the length of multi-hop searches, making one- or two-hop searches predominant. Notably, the average number of cross-document hops decreased by 0.23, a more substantial reduction than the 0.11 decrease in intra-document hops. These results suggest that HLCS helps minimize unnecessary navigation and exploration across different documents. However, as shown in Table 3, using HLCS significantly increased execution time—rising by a factor of 1.24 in the case of exhaustive search—even though token usage was only 1.02 times higher. This may be attributed to the LLM repeatedly referencing the entire HLCS for each hop.

Table 2 showed that Article 2 of the Building Act and its Enforcement Decree, which are both definition provisions, were the most referenced. Exhaustive search prompt referred definition provisions in 59.1% of the inquiries. As noted by MOLEG [16], definition provisions are designed to clarify the meanings of terms within laws and regulations, ensuring their interpretation and application remain unambiguous. The frequent reference to these provisions suggests that the LCW LLM has the ability to provide consistent legal interpretations even when presented with new inquiries. Since we did not fine-tune or apply RAG with dataset-specific information, our findings may extend to other legal systems or domains.

7 Conclusion

This study designed and evaluated six prompt variants for LCW LLM-based legal interpretation, focusing on the unique challenges posed by the cross-referencing and hierarchical structure of legal texts. Notably, the exhaustive prompt aligned with the cross-referencing structure of laws, while the structured search prompt targeted hierarchical legal frameworks. Additionally, we investigated the influence of HLCS on model performance.

For evaluation, we developed the LIQA dataset, comprising 171 building code interpretation cases curated by MOLEG. Our findings revealed that providing less guidance to the model reduced the number of referenced provisions, improving response accuracy by up to 5.7%p. While HLCS helped stabilize model performance by narrowing the performance gap to 1.17%p, it did not maximize accuracy. Furthermore, the LCW LLM frequently referenced definition provisions, up to 59.1% of total inquiries, which contributed to consistency in legal interpretation.

Our research offers three key contributions. First, it demonstrates that minimizing human guidance enhances model performance when interpreting extensive and intricately cross-referenced legal data. Second, it highlights how the HLCS enhances stability across various prompt designs, reducing result variability and thereby lowering the manual effort and costs associated with LLM-based legal interpretation. Lastly, the LCW LLM consistently referenced definition provisions, contributing to more consistent and reliable interpretation results.

Future work could explore alternative LLM techniques, such as fine-tuning or RAG, to further optimize performance. Additionally, since the model typically requires fewer than three hops to locate relevant provisions, predefining the top three related provisions could help reduce token costs while maintaining high accuracy in legal interpretation tasks. Lastly, the designed guidance methods should be evaluated across various LLMs and multiple legal QA datasets to assess their generalizability, along with a qualitative comparison of the generated answers.

Abstract –

The Dutch road construction industry is transitioning from hot mix asphalt (HMA) to more eco-friendly warm mix asphalt (WMA). While WMA offers clear environmental benefits, its distinct material properties, particularly the compactability, demand different construction practices. However, limited industry knowledge hinders WMA construction planning, driving the need for automated tools for more efficient WMA construction strategic planning. This research proposed a physics-aware surrogate modelling framework to improve strategy evaluation and optimization, and enable the automative exploration of optimal construction strategies. A preliminary feasibility study demonstrated the possibility of developing a surrogate model using Random Forest to efficiently capture the temperature-dependent compactability of a WMA mixture. The industrial adoption and potential advancement of this tool, including the integration with other sensing technologies and automatic construction, to ensure high-quality pavement construction were also discussed.

Keywords –

Asphalt construction; Warm mix asphalt; Physics-based simulation; Surrogate model

1 Introduction

In the Netherlands, in response to ever-growing environmental concerns about hot mix asphalt (HMA), the road construction industry is compelled to adopt more sustainable practices, e.g., exploring alternative materials. This created a strong ambition to transition from HMA to warm mix asphalt (WMA). For instance, the Dutch road construction industry is determined to complete this shift by January 2025. Compared to HMA, WMA is produced at lower temperatures (100–140 ℃) using synthetic or organic additives. It offers notable environmental benefits, including reduced emissions, lower fossil fuel consumption, and increased use of reclaimed asphalt pavement (RAP) without compromising mechanical performance [1]. Despite the change in the material, the contractors' primary goal remains the same, i.e., ensuring the asphalt construction process quality to achieve the desirable product quality, such as optimal density. Specifically, the asphalt must be compacted within an ideal temperature window since compaction at high temperatures can cause permanent deformation and compaction at low temperatures can hinder the densification process. However, asphalt construction is widely recognised as a dynamic environment where uncertainties abound. These uncertainties, coupled with the time-sensitive nature of road construction, make achieving optimal compaction efficiency highly challenging. This often results in significant variability during construction, leading to substandard road quality.

These challenges are not unique to HMA construction but are amplified in WMA due to the substantial difference in material characteristics (particularly the different compactability) and limited knowledge about its construction. This makes it more difficult to plan explicit operational strategies (e.g., required quantity of pavers and rollers, paving speed, compaction patterns and trajectories, etc. [2]). Addressing this issue is critical, as a key incentive for contractors to adopt WMA lies in building a solid knowledge base for a stable and sustainable construction process. This would help them meet quality requirements, avoid penalties under extended guarantee periods, and support the push for sustainable road construction. To stay competitive, contractors are motivated to adopt planning tools that can optimize WMA construction strategies by embedding a deeper understanding of WMA's material behaviour into automation techniques, to enable efficient and reliable assessment and adjustments in the decision-making process of WMA construction strategies.

On this premise, this paper presents a framework of a WMA construction planning tool that can provide contractors with an efficient and explicit assessment of pavement quality regarding different construction strategies, thus advancing automation in construction strategic planning. This study revolves around a central question of how a WMA construction planning tool can be developed with the embedment of WMA's unique material features and its structural responses towards different construction strategies. A framework that applies physical modelling and physics-aware surrogate modelling was then proposed. Unlike conventional

models, it better captures WMA's compaction behaviour for more precise decision-making. The results of a preliminary feasibility analysis are presented in this paper.

The remainder of the paper is structured as follows. First, the research problem is investigated to derive the scope of this WMA construction planning tool. This is followed by a demonstration of the framework of developing such a planning tool, with a case study indicating the feasibility of the proposed framework. The paper ends with a conclusion.

2 Problem Investigation

Construction planning involves identifying explicit on-site activities and evaluating their implications [3]. Nonetheless, asphalt construction comprises a multitude of interconnected activities, resulting in considerable complexity for the effective planning of construction strategies.

Previous studies explored the development of asphalt construction planning tools, with particular attention to using simulation techniques, as simulations effectively capture construction processes and test scenarios, enabling more efficient and informed decision-making [4,5]. For instance, Dalence et al. proposed a framework integrating temporal (e.g., equipment, speed, roller passes) and spatial (e.g., trajectory, asphalt cooling rate) characteristics, where data on key factors influencing asphalt compaction is collected to generate decision variables [4]. These variables are fed into simulation models, which provide outputs such as equipment behaviours and operational feedback, facilitating strategy assessment and improvement.

Nevertheless, existing simulation-based asphalt construction planning tools predominantly rely on indirect assessment of the process quality (e.g., paver and roller output, compaction efficiency, and process consistency), where the actual structural response of asphalt mixture (which will be reflected in the pavement product quality, such as density) during the construction process are not explicitly considered. Although, intuitively, good construction process quality leads to good pavement product quality, not being able to precisely quantify the exact impact of construction strategies on the resultant structural responses of the pavement during the simulation can considerably affect the accuracy/reliability of simulation-based assessment of different construction strategies.

Therefore, understanding the interplay between mechanical and thermal characteristics during asphalt compaction is vital for precise construction planning and decision-making. However, the current body of knowledge lacks a clear understanding of the quantifiable correlation between construction quality and pavement properties. In essence, this would make the planning of WMA construction performance-based, where the most suitable on-site operations will be selected based on the resultant pavement quality and performance in other indicators (e.g., cost and productivity). In other fields, the similarity can be found in strategic planning of earth moving activities. Traditional earthwork planning focused on minimizing material transport, relying heavily on workers' experience. However, construction automation has enhanced efficiency and productivity by reducing these constraints, by optimizing operations, particularly coordinating excavators and dump trucks to maximize efficiency [6,7].

To address this limitation, advanced physical modelling is needed to capture the structural and thermal behaviour of WMA during its interaction with equipment and the environment. Two widely applied approaches are Finite Element Method (FEM) [8] and Discrete Element Method (DEM) [9]. FEM can accurately model asphalt's structural response under dynamic loads but lacks granular-level accuracy. In contrast, DEM effectively simulates contacts within granular systems and micro-mechanics. Nevertheless, DEM greatly increases the computational time. To address this, Komaragiri et al. [10], developed a simulation model using a physics engine (i.e., Bullet Physics [11]), which significantly improves computational efficiency without compromising performance. However, existing physics-based simulation models calibrated for HMA are unsuitable for WMA due to differences in material characteristics. Thus, developing physics-based models tailored to WMA is crucial for capturing its unique behaviour during compaction. Additionally, the high computational cost of physics-based models limits their use in process simulation, where analysis of multiple simulation scenarios for optimised processes is always required. One potential solution is to use data-driven techniques, such as machine learning (ML), to quantify the correlation between asphalt construction process indicators and resultant product quality indicators. In the research of Shen [12], on-site data was collected, including real-time machinery movement and asphalt cooling patterns, to capture key asphalt construction process characteristics. The data was then paired with density measurements from pavement samples to develop a dataset for machine learning model training. However, this study also highlighted critical issues, such as limited and inconsistent data availability, ineffective data management practices, and variability in data collection methods, which greatly influenced the accuracy and generalizability of data-driven approaches.

To tackle these difficulties, surrogate modelling offers a solution by approximating physics-based models with data-driven techniques, such as machine learning (ML), allowing for faster predictions without sacrificing accuracy [13]. By generating datasets from physics-

based simulations under varying input conditions, ML-based surrogate models can be developed to predict WMA's structural responses efficiently, enabling the exploration of optimal construction strategies without excessive computational expense.

3 Framework for Physics-aware WMA Construction Planning Tool

3.1 The Scope of the WMA Construction Planning Tool

To identify the scope of the WMA construction planning tool for this research context, a workshop was held with Dutch public clients and contractors in the asphalt construction sector. The workshop explored: (1) the impact of material transitions on WMA compaction, (2) factors influencing strategy formulation, and (3) the structure of the tool. The workshop identified the tool's primary functional requirement: to assess construction strategies accurately and to offer intuitive feedback on compaction quality (primarily density consistency) considering specific project characteristics.

Specifically, the proposed planning tool should begin by extracting pre-construction information, such as design data, ambient conditions, and project constraints, to define the scope of construction strategy exploration. It must evaluate strategies by assessing the resultant pavement quality. This calls for the development and integration of physics-aware models to comprehensively explore the complex system's behaviour, characteristics, and dynamics in WMA construction. The tool's output will focus on two aspects: resource allocation (e.g., equipment, materials, staffing, budgeting) and operational strategies (e.g., trajectory planning, sequencing, and equipment coordination), ensuring timely and cost-effective project execution.

Therefore, the framework of the physics-aware WMA construction planning tool can be determined, as shown in Figure 1. The rest of this chapter will provide a detailed description of each component.

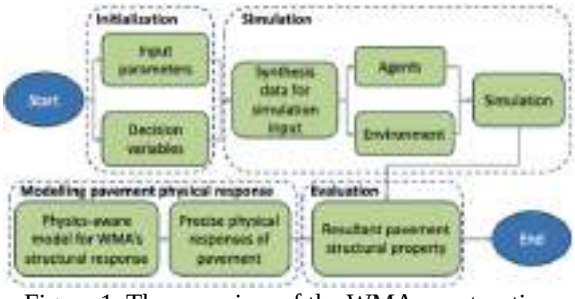

Figure 1. The overview of the WMA construction planning tool

3.2 Initialization

The initialization of the planning tool gathers input parameters and decision variables. Input parameters, which reflect fixed project characteristics, include design and engineering details (e.g., road geometry, and asphalt mixture properties) and project-specific constraints (e.g., equipment configurations), as listed in Table 1.

Identified decision variables, adjustable by decision-makers, focus on resource allocation and operational strategies, with particular emphasis on the compaction strategy in asphalt construction planning, due to its vital role in meeting asphalt pavement's functional requirements. These decision variables allow the exploration of various WMA construction strategies, as demonstrated in Table 2. The compaction strategy involves defining each roller's trajectory, determined by the length and width of the compaction section, and the number of and distance between compaction lanes (Figure 2). Additionally, the mobility of rollers is also affected by the compaction patterns, which regulate the number of compaction corridors and other rules that each roller needs to follow during compaction, especially when multiple rollers are compacting simultaneously. These compaction patterns will be pre-defined by the decision-makers as the input to the planning tool.

Table 1. Identified input parameters of the WMA construction planning tool framework

Data category	Data	Unit
Road geometry	Road width	m
Asphalt	Mixture design	-
	Production temperature	°C
	Initial density	kg/m^3
	Cooling rate	°C/min
Paver	Screed width	m
Truck	Truck capacity	m^3
	Dumping rate	m^3/min
Roller	Drum width	m
	Wheel length	m
	Compaction force	kN

Table 2. Identified decision variables of the WMA construction planning tool framework

Data category	Data	Unit
Resource allocation	Paver quantity	#
	Roller quantity	#
	Truck quantity	#
Operational strategies	Paver speed	m/min
	Roller speed	m/min
	Length of compaction section	m
	Width of compaction section	m
	Number of compaction lanes	#
	Hauling duration	hours
	Returning duration	hours
	Compaction pattern	-

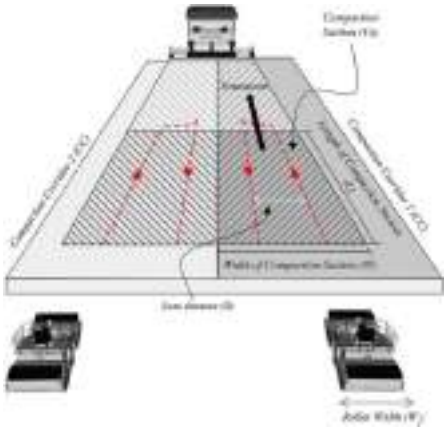

Figure 1. Asphalt compaction strategy [2]

3.3 Simulation

The collected data from the previous layer will then be fed into a simulation model to assess the corresponding impact on the product quality. Specifically, the simulation model will be informed by the previous work of Dalence et al. [4], where an agent-based simulation (ABS) model was proposed to create a context-realistic simulation of the HMA construction process. It is worth noting that despite differences in material properties, WMA and HMA share similar construction logic and workflow, making the ABS simulation model's scope a valuable reference for the WMA. This simulation model aligns closely with the functional requirements of the planning tool and operates within the same contextual framework. Given its demonstrated applicability and relevance, re-developing a new simulation model is deemed unnecessary.

The simulation, using inputs from Tables 1 and 2, defines agents, interactions, and conditions. Figure 3 shows key agents: trucks deliver asphalt, coordinating with the paver for continuous transfer. The paver operates at a set speed, signaling trucks as needed, while rollers compact within the optimal temperature window. Predefined compaction strategies are used to maintain continuity and efficiency. Furthermore, Asphalt cell agents will model asphalt's structural and thermal behavior by dividing the asphalt layer into a grid (Figure 4). Each cell cools at a set rate, while environmental conditions and contractor-provided road geometry (Table 1) define the simulation space and agent interactions.

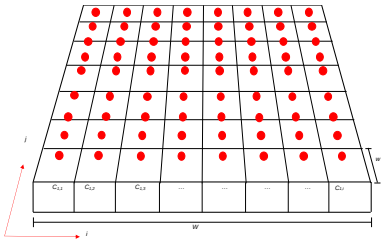

Figure 4. The asphalt pavement cell grid [2]

3.4 Modelling Physical Responses of WMA

Next, the precise physical responses of WMA during the construction process will be obtained, following the workflow shown in Figure 5.

Firstly, a generic physics-based model to accurately simulate the interaction between WMA and the compaction process will be developed. The quality of asphalt pavement is highly dependent on its bulk mechanical properties, which are determined by the contact state of the individual aggregates and the resulting skeleton structure formed between these particles [14]. During the construction process, the compaction force rearranges asphalt mixture aggregates, leading to the development of a denser skeleton structure. Meanwhile, due to the viscoelastic attributes of the asphalt binder, the mechanical properties of asphalt mixtures are also subject to change over different asphalt

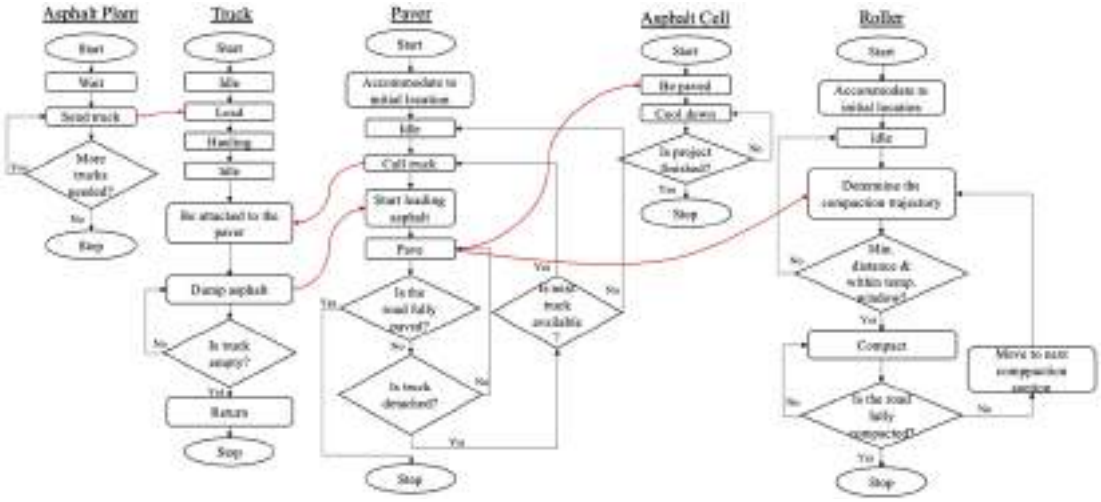

Figure 3. An overview of agents and their states [4]

temperatures. Therefore, this compaction model is expected to be able to capture the WMA's behaviour at the microscopic scale with its granular structure and can be eventually upscaled to derive the macroscopic response of the entire road pavement during compaction.

Overall, the modelling process scales from micro to macro levels. It begins with selecting a contact model to define microscopic interactions, followed by creating mesoscopic models based on WMA mixture designs, calibrated with lab tests at various temperatures. Finally, these models are upscaled to represent WMA pavement, with accuracy tested during field compaction.

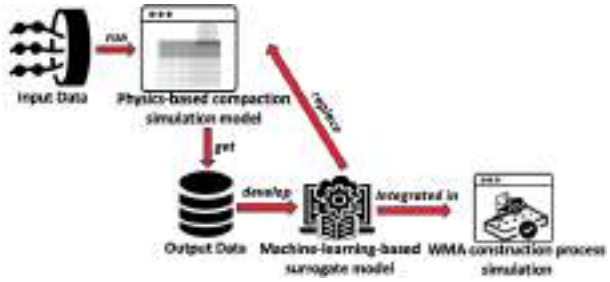

Figure 5. The overview of the WMA construction planning tool development framework

3.5 Surrogate Modelling

The physics-based compaction model will be replaced by a surrogate model to reduce computational costs in analyzing asphalt-compaction interactions. To predict structural responses based on input data, including mixture design, temperature, thickness, density, and applied compaction force.

The surrogate model development will be initiated with the data synthesis to generate a dataset, by performing simulations using the physics-based WMA compaction model under different compaction scenarios (considering different compaction forces from the roller drum and roller speed). In this step, a parametric model will be developed to streamline the data synthesis, and to rapidly construct different compaction scenarios covering the input. Next, based on the established dataset, ML models will be trained and tested, which will be used as the surrogate model to replace the original physics-based compaction model once the former is validated.

3.6 Integrating Surrogate Model into WMA Construction Process Simulation

Lastly, the developed surrogate models for WMA-roller and WMA-environment interactions will be integrated into the WMA construction process simulation model described in Chapter 3.3, to enable a more accurate evaluation of the resultant pavement product quality according to adopted construction strategies. The pavement's mechanical properties can be updated after each roller pass, based on the information including the asphalt temperature and mechanical properties (e.g., density) before compaction, and received compaction energy from the roller.

With the surrogate model, WMA construction simulation can enable automated planning using optimization algorithms like Particle Swarm Optimization (PSO) and Non-Dominated Sorting Genetic Algorithm II (NSGA-II) to generate, assess, and refine strategies for optimal density, productivity, and cost efficiency.

A field test with contractors will validate the planning tool using pre-determined engineering details and weather conditions (Table 1). Optimal construction strategies will be generated where experts from contractors will decide the strategy they will adopt on-site. Two test sections will be prepared: one following the selected optimal strategy and the other using conventional simulation-based planning tools that rely on indirect process quality assessment as a benchmark for quality and efficiency comparison.

4 Preliminary Feasibility Analysis

In this section, a preliminary feasibility study of developing such a planning tool for WMA construction following the framework proposed in Chapter 3 is conducted through a case study. It focuses on demonstrating the feasibility of developing a surrogate model, using the data generated from a physics-based simulation model (which simulates the WMA compaction process on the laboratory scale), to efficiently and accurately capture the temperature-dependent compactability of the target WMA mixture, which is key to precisely map the impact of on-site construction strategies into the resultant pavement quality in the planning tool. Therefore, this preliminary feasibility study concentrates on validating the foundational aspects of the framework and setting stages for future development.

Specifically, five gyratory compaction tests were performed on one type of WMA mixture at five different testing temperatures. Using the gyratory compaction process, the study evaluates the ability of the physics-based model to replicate key structural and thermal responses during compaction. Additionally, it demonstrates the feasibility of calibrating the model using experimental data, ensuring its relevance for future applications. This controlled environment allows for precise analysis and eliminates external complexities, making it an ideal setting for validating the proposed framework's foundational components.

4.1 Gyratory Compaction Test Scheme

Gyratory compaction, a common lab method, simulates field compaction to produce asphalt specimens for mechanical testing. The stabilized mixture in a cylindrical mold undergoes constant vertical pressure

while rotating at a set speed and angle to apply shear forces. Table 3 details the test setup, where compaction stops after 60 gyrations.

Table 3. Gyratory compaction test configurations

Configuration	Value
The internal diameter of the mould	100 mm
Minimum height of the compacted mixture	77 mm
Compaction pressure	600 kPa
Gyration angle	0.82°
Gyration frequency	1/30 Hz
Target number of gyrations	60

The WMA mixture used in the tests was prepared using the design indicated in Table 4. Specifically, this WMA mixture uses a DAT-7 additive, a surface tension reducer, to decrease its production temperature. A total of 5 samples were made. Each sample had a different temperature for performing the compaction test, ranging from 120°C to 40°C with an interval of 20°C (120°C, 100°C, 80°C, 60°C, 40°C).

The testing output is the void ratio of the specimens. The output data was collected after each gyration, to represent the densification process.

Table 4. Gradation of the WMA mixture

Sieving size (mm)	Mass percentage (%)
16 - 11	23.09
11 - 8	3.99
8 - 4	27.33
>2	34.04
Filler	7.14
Asphalt (PEN 40/60)	4.2
Additive (DAT-7)	0.21

4.2 Physics-based Gyratory Compaction Simulation

Following the methodology of Komarairi et al. [10], the gyratory compaction process was simulated using Bullet Physics engine [11]. The engine can effectively detects collisions, calculates contact forces, and updates particle positions [10,11]. Unlike DEM, which simplifies aggregates as spheres, Bullet Physics models real aggregate shapes, improving accuracy while remaining computationally efficient.

Based on the gradation in Table 4, a digital representation of the tested asphalt mixture was created using 10 3D aggregate models obtained via laser scanning (Figure 6). The number of aggregate particles was determined from the asphalt sample mass (1.4 kg) and aggregate density (2686 kg/m³). All particles were scaled to a unit size of 1 mm and adjusted according to gradation to closely match the actual specimen. For computational efficiency, fine aggregates (<2 mm), fillers, and binders were modelled as a mortar layer covering the coarse aggregates, whose thickness is calculated using Equation (1):

$$t = \frac{V_{motar}}{\sum_{i=1}^{n}(SA)_i} \quad (1)$$

where t stands for the thickness of the mortar layer, V_{mortar} refers to the total volume of the mortar, n refers to the total number of coarse aggregates, and $(SA)_i$ refers to the surface area of each coarse aggregate.

These mortar layers also provide viscoelastic contact forces, which are cohesive force in the normal direction between two contacted particles and viscous damping in the tangential direction. Equation (2) specifies the cohesive force:

$$F_c = c\gamma\sqrt{A} \quad (2)$$

where F_c is the cohesive force, c is a proportionality constant, γ is the surface tension of the mortar layer, and A is the contact area between two colliding particles. Together, $c\gamma$ represents the linear stiffness between the two colliding aggregate particles, thus can be replaced by a new parameter k, referring to the contact stiffness.

The viscous force will be simulated using linear and angular velocities [10], as specified in Equation (3) and (4) below:

$$v = v_0\eta_{linear} \quad (3)$$
$$w = w_0\eta_{angular} \quad (4)$$

where v and w stand for the linear and angular velocities of the particle after contact, v_0 and w_0 are the linear and angular velocities of the particle before the contact, and η_{linear} and $\eta_{angular}$ are linear and angular damping factors respectively.

Figure 6. An example of the aggregates

4.3 Calibration and Validation

To test the capability of the physics-based gyratory compaction model in correctly simulating the temperature-dependant compactibility of the target WMA mixture, the compaction model was calibrated using laboratory testing data described in Chapter 4.1. The primary objective is to calibrate the models to determine the corresponding values of k, η_{linear}, and $\eta_{angular}$ at various temperatures. Furthermore, this study assumes that these calibrated parameters will form three temperature-dependent functions for the target WMA mixture through curve fitting. These functions provide a continuous representation of the temperature dependency of each parameter, enabling the derivation of parameter values at any given temperature without the need for additional laboratory tests. Specifically, to validate this assumption, tests conducted at 120°C, 100°C, 60°C, and 40°C were used to calibrate the models to derive corresponding values of k, η_{linear}, and $\eta_{angular}$ and to form the temperature-dependency functions for these parameters. These functions were then used to predict

values at 80°C, where simulation outputs (i.e., the densification curve) were validated against laboratory data.

Conventional calibration of physics-based simulations requires iterative parameter adjustments and repetitive fine-tunings, making it highly time-consuming and computationally expensive. To streamline calibration, the surrogate modelling technique was also applied, where an ML model was developed to replace the physics-based gyratory compaction model. A dataset of 96 instances with varying contact parameters was generated using a full factorial design (Table 5) and simulated to pair input parameters with densification curve outputs. The densification curves were transformed into logarithmic slopes and intercepts, forming inputs for two Random Forest (RF) models: RF-A for slopes and RF-B for intercepts. After training on 80% of the data and testing on the remaining 20%, RF-A achieved an R^2 of 0.9667 and RF-B an R^2 of 0.9871. As for the computational time, using ML-based surrogate models to obtain the densification curve costs 0.003228 seconds, while running each physics-based simulation costs around 7 hours (25200 seconds).

Table 5. Levels of parameters in data generation

Parameter	Levels
Stiffness	1, 100, 1000, 10000, 100000, 1000000
Linear damping factor	0.01, 0.1, 0.5, 0.99
Angular damping factor	0.01, 0.1, 0.5, 0.99

These models facilitated calibration by solving an optimization problem to maximize the R^2 between reconstructed and actual densification curves, as defined by Equation (5):

$$maximize\ R^2 = 1 - \frac{\sum(y_i - \hat{y}_i)^2}{\sum(y_i - \bar{y})^2} \quad (5)$$

where y_i is the ith element from the actual curve, $\hat{y}_i$ is the ith element from the reconstructed curve, and $\bar{y}$ is the mean of the actual curve.

RF-A and RF-B were used to predict the values of slope and intercept to reconstruct the (logarithmic) densification curve $\hat{y}$, as shown in Equation (6).

$$\hat{y} = a + b\ln(x) \quad (6)$$

where:

$a = f_{RF-A}(k, \eta_{linear}, \eta_{angular})$

$b = f_{RF-B}(k, \eta_{linear}, \eta_{angular})$

$k \leq 1000000$

$\eta_{linear} \leq 1$

$\eta_{angular} \leq 1$

$k, \eta_{linear}, \eta_{angular} \in Z^+$

Specifically, a and b are the predictions from RF-A and RF-B respectively based on the set of input parameters $k, \eta_{linear}, \eta_{angular}$, and the three input parameters are all positive integers, whose ranges are pre-defined.

This optimization problem was solved by the Genetic Algorithm (GA), to automatically generate, evaluate, evolve, and select optimal sets of input parameters that can fit the actual densifications the best. Each iteration will start with 100 population, where the offsprings will be created with a crossover rate of 0.8 and a mutation rate of 0.2. The GA process will stop after 100 iterations.

Based on the input parameters determined through calibration, three exponential decay functions were determined accordingly, as shown in Figure 7.

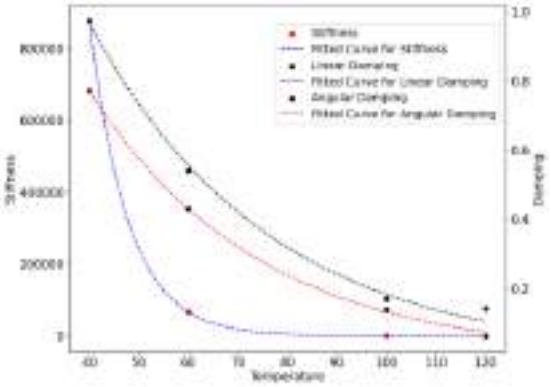

Figure 7. Temperature-dependant decay functions through curve fitting

Values of parameters at 80°C were then determined, resulting in a promising accuracy, with an R^2 score of 0.88 by comparing the obtained densification curve using RF models with the actual laboratory data at this temperature, as shown in Table 6 and Figure 8.

Table 6. Results of the validation

Temperature (°C)	Stiffness (N/mm)	Linear Damping	Angular Damping	R^2
80	5077.99	0.32	0.24	0.88

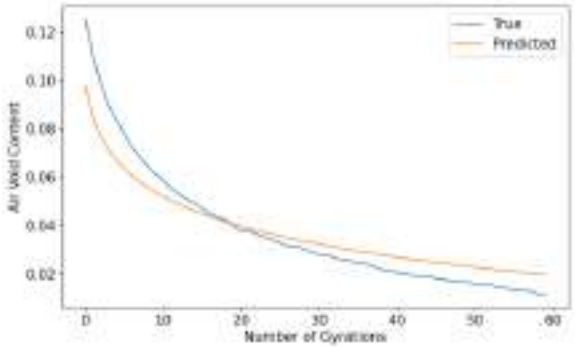

Figure 8. Plots of the validation at 80°C

5 Conclusion

This study proposed a framework for WMA construction planning that incorporates precise physical responses of asphalt, integrating project-specific data

with physics-aware models and simulations. Furthermore, a case study demonstrated the feasibility of developing and calibrating a physics-based simulation model for WMA compaction at the laboratory scale. The model effectively replicated key structural and thermal responses during compaction, capturing granular interactions and material behaviour of the WMA mixture. Calibration using experimental data enabled the derivation of decay functions for contact parameters, which were used to interpolate values across different temperatures. This approach not only ensured a focused validation of the framework but also revealed the model's capability to capture the nuanced relationships between temperature, contact parameters, and compaction dynamics. These findings affirm the foundational premise of the framework, providing a strong basis for extending its application to larger-scale scenarios. However, to validate the surrogate model demonstrated in Chapter 4, only very limited laboratory data was used for the calibration and validation, where it will be more beneficial to include more data and more mixture types to enhance its generalizability.

Additionally, while the integration of a surrogate model is part of the broader research plan, its validation is beyond the scope of this preliminary study and will be pursued in future work. Although real-world adoption of the tool remains challenging due to construction uncertainties and contractor risk aversion, the planning tool can still provide contractors with valuable early-stage planning insights, where the on-site uncertainty can be further overcome by integrating the planning tool with real-time construction data (e.g., pavement temperature, weather conditions, machinery location, etc.), enabling automated adjustments to compaction strategies based on sensor feedback. Ultimately, this would support full automation in WMA construction, enhancing efficiency, consistency, and sustainability in road projects.

Abstract -

Crew-level productivity analysis plays a crucial role in construction site management, as it provides a macro-level understanding of workforce performance. While traditional productivity measurement methods, such as work sampling, group timing technique, and five-minute rating, offer valuable insights, they rely heavily on manual observation, making them labor-intensive and prone to inaccuracy. In this study, we propose a deep learning-based framework for automated crew-level identification. The framework employs a graph-based approach that integrates visual feature similarity and spatial proximity of workers, combined with clustering algorithms, to detect and analyze worker groups. The proposed method is validated on a construction site dataset collected from a rebar installation task. Experimental results demonstrate the framework's effectiveness, achieving high accuracy in group detection with robust performance across various evaluation metrics. This work highlights the potential of automated systems to enhance construction site management by reducing reliance on manual observation and providing real-time insights into crew-level productivity.

Keywords -

Group Detection; Clustering; Image Understanding; Human Activity Recognition

1 Introduction

Labor resources play a critical role in the success of construction projects [1]. However, construction sites typically consist of distinct groups of workers collaborating to accomplish tasks. From a macro perspective, analyzing productivity at the crew level—rather than focusing on the productivity of individual workers—provides a more comprehensive view of progress tracking and performance analysis [2]. By incorporating additional contextual information such as objects or spatial locations, this analysis can help managers identify other potential causes of delays, such as inefficient material placement or work environment constraints. Therefore, understanding and monitoring crew-level productivity is essential for improving construction site management.

Traditionally, three primary methods have been used for productivity measurement on construction sites: work sampling, group timing technique, and five-minute rating [3]. Work sampling involves observing workers at random intervals to determine the percentage of time spent on productive and non-productive activities, providing insights into overall labor efficiency. The group timing technique, on the other hand, focuses on measuring crew cycle times by observing work processes at fixed intervals, which allows managers to assess the efficiency of group operations and evaluate the appropriateness of crew size. Finally, the five-minute rating is a simpler and faster approach that estimates delay times by periodically observing crew activities over short durations, such as five minutes. While these methods are effective for gathering productivity data, they rely heavily on manual observation, which is labor-intensive, time-consuming, and dependent on the experience and judgment of observers.

Recent advancements in technology, particularly the widespread deployment of cameras on construction sites and developments in deep learning and computer vision, have made automated productivity monitoring increasingly feasible. These automated systems address the limitations of traditional methods by reducing the need for labor-intensive and time-consuming manual observation. Unlike methods that rely heavily on the observer's experience and continuous monitoring, automated systems offer real-time and accurate productivity tracking. This technological shift enables site managers to focus their efforts on more strategic aspects of project management while ensuring the reliability and efficiency of data collection.

In recent studies, significant progress has been made in motion recognition for individual workers. Luo et al. [4] propose an improved CNN integrating RGB, optical flow, and gray stream data to accurately recognize and assess a single worker's reinforcement installation activity in videos. Luo et al. [5] used spatial and temporal convolutional networks with a novel fusion strategy to recognize multi-workers' actions from surveillance videos. However, these studies primarily focus on the productivity of individual workers and lack an in-depth discussion of

crew-level performance.

A limited number of studies have explored the relationships between workers and workers or workers and objects. The same author from [5] proposes a two-step method, which uses CNN to detect objects and workers and then analyzes semantic and spatial relevance between each entity [6]. Cai et al. [7] introduce a two-step classification method combining working group identification and activity recognition using LSTM networks, leveraging pre-computed positional cues (eq. bounding box overlapping) and attentional cues (eq. head pose, body orientation) to recognize construction activities with multiple entities. Although these studies successfully identify the relationships between objects in construction site images, their methods for worker group identification remain constrained by precomputed handcrafted features or site-specific rules established by domain experts. Therefore, developing an effective method for identifying and analyzing worker groups on construction sites remains a significant research challenge.

Building on these insights, this study contributes to the field by proposing a deep learning-based framework for automated crew-level identification. Unlike previous methods that rely on handcrafted features or predefined spatial heuristics, our approach dynamically integrates visual feature similarity and spatial proximity into a unified relation matrix. This enables the model to adaptively cluster workers based on real-world interactions rather than being constrained by rigid rules or single-modality input. Additionally, this method simplifies the system's deployment requirements, as it only requires image input and a person detection model, eliminating the need for manually predefined spatial constraints or external tracking devices. The framework is validated using a dataset collected from a rebar installation task on a construction site, demonstrating its robustness across diverse scenarios.

2 Methodology

In this study, our objective is to cluster workers in the scene into different groups; we combine both spatial relevance and feature relevance to represent the affinity matrix between the workers in the scene. Figure 1 shows the overview of our framework, which contains four major modules: (a) Feature Extraction, (b) Graph Construction, (c) Spatial Distance Encoding with Masking, and (d) Relational Matrix for Clustering. We will elaborate on the details of these four modules in the following section.

2.1 Feature Extraction

The purpose of this module is to extract the great information of visual feature reliance in the image for each worker. As the main goal of this research is to cluster the workers, we assume that there will be other modules to complete the object detection of workers. Therefore, the inputs of the proposed framework are the RGB image with each worker's bounding box. We first utilize Inception-v3 [8], a CNN-based backbone model combined with ROI-Align [9], to extract spatially precise feature representations for each entity.

In this study, we use Inception-v3 [8] as the feature extraction backbone. To enhance robustness and leverage prior knowledge, we initialize the model with pretrained weights from the Collective Activity Dataset [10], which has been optimized for human-centric activity recognition. This choice allows us to extract meaningful features while mitigating the risk of overfitting. Given the focus of our study on clustering methods rather than CNN architecture comparisons, we selected a well-established backbone known for its balance between efficiency and accuracy in feature extraction.

ROI-Align [9] is a region-based operation designed to extract features corresponding to a specific region of interest (ROI) from the feature maps produced by the CNN backbone. Unlike earlier methods, such as ROI-Pooling, ROI-Align avoids quantization errors by using bilinear interpolation to precisely map the input pixels to the feature space.

2.2 Graph Construction

After extracting the feature from the image, we want to calculate the affinity further according to the similarity of visual features. We can represent the individuals in any scene as a graph, where each node represents the individuals and the edge represents the connection or the relationship between these two nodes. By leveraging this graph structure, we aim to compute the visual feature affinity matrix R_E, which quantifies the affinity between features.

The graph can be denoted as $G = (V, E)$, where V represent the vertices and E represent the edges, and since we are not sure of the exact relationship in the scene in present, there might be any possible pairs of relationships between each worker, so we construct a fully connected graph; the number of vertices N is equal to the number of workers in the scene, and the number of edges is equal to $\binom{N}{2}$. To represent the relationship $e_{u,v}$ between two entities u and v, we adopt the approach introduced in [11]:

$$e_{u,v} = F_1(f_u) \cdot (F_2(f_v))^T, \quad u, v \in \mathcal{V}, \tag{1}$$

where f_u and f_v are the feature vectors of entities u and v, respectively. F_1 and F_2 are learnable linear transformations that project the feature vectors into a relational feature space. The resulting value $e_{u,v}$ represents the connection strength or similarity between u and v. The complete **feature affinity matrix $\mathbf{R_E} \in \mathbb{R}^{N \times N}$**, where N is the number

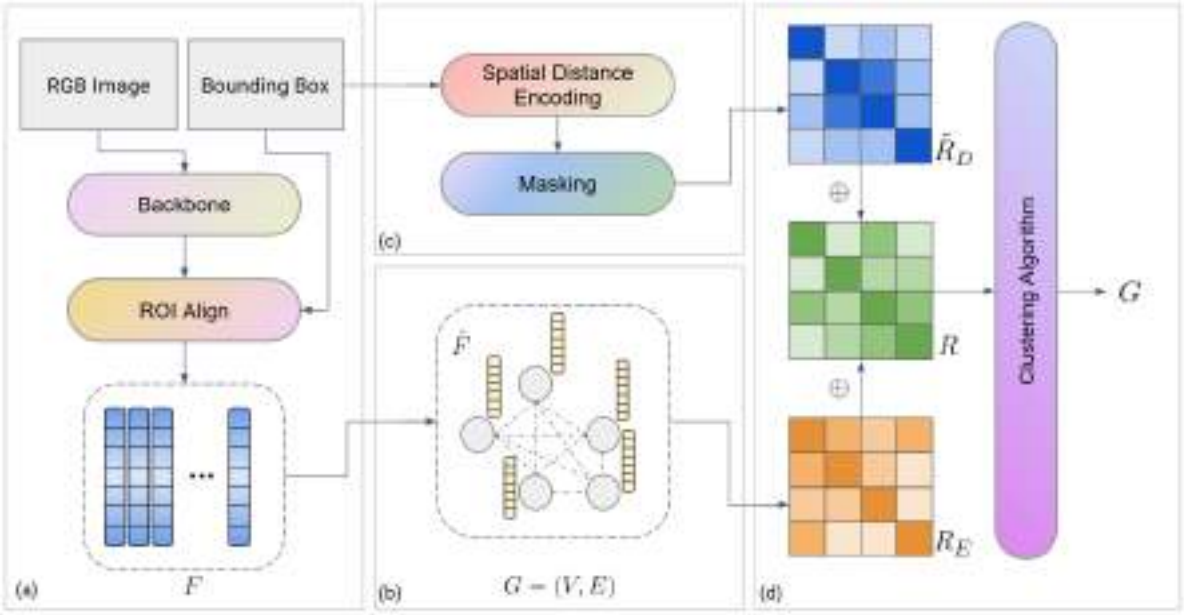

Figure 1. Overview of the Proposed Framework: Key Components – (a) Feature Extraction: extracts high-level features from RGB images and corresponding bounding boxes. (b) Graph Construction: builds a graph structure to represent the extracted features and their relationships, where nodes correspond to features and edges indicate potential connections. (c) Spatial Distance Encoding with Masking: encodes spatial distances and applies masking strategies to enhance the relevance of nearby entities while filtering out irrelevant ones. (d) Relational Matrix for Clustering: computes a relational matrix to facilitate feature grouping and clustering based on the encoded relationships.

of nodes, is constructed as:

$$\mathbf{R_E} = \left[e_{u,v}\right]_{u,v\in\mathcal{V}}. \tag{2}$$

To ensure the weights are normalized, we apply a **softmax operation** to each row of the affinity matrix $\mathbf{R_E}$. This normalization ensures that the sum of the affinity weights for each node (row) equals 1. Mathematically, this process is expressed as:

$$e_{u,v} \leftarrow \frac{\exp(e_{u,v})}{\sum_{v'\in\mathcal{V}} \exp(e_{u,v'})}. \tag{3}$$

This softmax operation converts raw edge weights into probabilities.

2.3 Spatial Distance Encoding & Masking

After we have the feature affinity matrix R_E, We also want to include the relationship between workers in space as a reference. The spatial affinity matrix R_D is computed to encode the physical proximity between entities using their Euclidean distance $D(u, v)$. It is defined as:

$$R_D(u, v) = \exp\left(-\frac{D(u, v)}{\alpha}\right), \tag{4}$$

where:

$$D(u, v) = \sqrt{(x_u - x_v)^2 + (y_u - y_v)^2}. \tag{5}$$

In these equations, (x_u, y_u) and (x_v, y_v) denote the spatial coordinates of entities u and v, typically represented as the midpoint of the bottom edge of their bounding boxes, $\alpha > 0$ is a scaling parameter that determines the sensitivity of the affinity score to the distance.

The inverse exponential function R_D ensures a smooth mapping of distances to affinity scores, where entities that are spatially close (smaller $D(u, v)$) receive higher affinity values, indicating stronger proximity-based interactions, while entities that are farther apart (larger $D(u, v)$) are assigned smaller affinity values, reflecting weaker spatial relationships.

We further apply a **masking technique** to filter out weak spatial relationships. Specifically, for each element in the spatial affinity matrix R_D, if the Euclidean distance value is smaller than a predefined threshold τ, the corresponding entry is set to zero. Mathematically, the masked spatial affinity matrix $\tilde{R}_D$ is given by:

$$\tilde{R}_D(u, v) = \begin{cases} R_D(u, v), & \text{if } D(u, v) \geq \tau, \\ 0, & \text{otherwise.} \end{cases} \tag{6}$$

Here, τ is a threshold value that controls the sparsity of the affinity matrix.

2.4 Relation Matrix

To quantify relationships between entities, we define a relation matrix R, which integrates both feature-based and spatial relationships to provide a comprehensive representation of interactions. This matrix is composed of the feature affinity matrix R_E and the masked spatial affinity matrix $\tilde{R}_D$, which represents the spatial relationships between entities based on their positions.

Finally, the combined relation matrix R integrates R_E and $\tilde{R}_D$ to capture both visual feature similarity and spatial proximity. It is calculated as:

$$R = \lambda R_E \oplus (1 - \lambda)\tilde{R}_D, \tag{7}$$

where $\lambda \in [0, 1]$ is a weighting coefficient controlling the relative importance of R_E and R_D, and $\oplus$ denotes element-wise addition of the two matrices. With the relation matrix, we can get the group division results through a post-processing method, e.g., a clustering algorithm.

To achieve robust group clustering, we employ the Spectral Clustering algorithm [12], which effectively operates on the constructed relation matrix R. Unlike traditional K-Means, which assumes spherical clusters and requires predefining the number of clusters, Spectral Clustering leverages the graph Laplacian eigenvectors to segment data based on intrinsic connectivity, making it more suitable for identifying worker groups in complex construction site scenarios. Additionally, given our method's graph-based nature, Spectral Clustering provides a more effective approach to clustering workers based on both feature and spatial affinities.

2.5 Loss Function

The loss function is designed to supervises the accuracy of group detection by evaluating the predicted relationship matrix R_{pred} against the ground-truth relationship matrix R_{gt}. Both matrices are of size $N \times N$, where N is the total number of entities. Each element $R_{i,j}$ in the matrix represents the likelihood of a relationship between entities i and j.

The loss is formulated using cross-entropy, applied element-wise across the matrices:

$$\mathcal{L}_{\text{det}} = -\frac{1}{N^2}\sum_{i=1}^{N}\sum_{j=1}^{N}\left(R_{\text{gt}}^{(i,j)}\log R_{\text{pred}}^{(i,j)} + \left(1 - R_{\text{gt}}^{(i,j)}\right)\log\left(1 - R_{\text{pred}}^{(i,j)}\right)\right). \tag{8}$$

Table 1. Average and Total Statistics for Frames and Entities

	Avg	Total
Frame	50	608
Entity	5.28	3211

where $R_{\text{gt}}^{(i,j)}$ is the ground-truth value for the relationship between entities i and j (binary: 1 if related, 0 otherwise).$R_{\text{pred}}^{(i,j)}$ is the predicted probability of the relationship between entities i and j.

3 Experiment

In this section, we elaborate on the details of our proposed dataset, the metrics used to evaluate the performance of our framework, and the results of our experiments. Additionally, we provide an in-depth discussion of the findings.

3.1 Dataset

The dataset consists of 13 videos, capturing real-world construction site activities. The videos were recorded under both sunny and cloudy conditions, ensuring coverage of different natural lighting environments. While the camera angles were not entirely consistent across all videos, the majority were captured from a top-down perspective, typically from elevated positions overlooking the construction site. To evaluate the proposed framework in general construction site, we chose to record the video during the rebar installation work item since there are a lot of workers passing between the scene and different groups of workers working simultaneously. Table 1 shows the detailed statistics of the dataset. On average, each video contains 5.2 workers per frame, reflecting realistic worker density variations. The videos were then set to a resolution of 1920×1080, and downsampled to 1fps.

For group annotation, A group of workers who interact with each other or are working on the same object will be considered a group. Figure 2 shows an annotation sample, bounding boxes of the same color in the picture with red lines between them represent that they belong to the same group.

3.2 Metrics

In this section, we discuss how to evaluate the performence of our framework; the task that our framework does can be classified as **Group Detection Task**. Following [11], we use the **Helf Matrix** [13] to evaluate the accuracy of detected groups. The Helf Matrix quantifies the overlap between a ground truth group and a discovered group using the following formula:

Figure 2. Annotation sample

$$\text{Helf Ratio} = \frac{\text{Number of individuals in the intersection}}{\text{Number of individuals in the union}},$$

the *intersection* refers to the individuals present in both the ground truth and the discovered group, while the *union* accounts for all individuals that appear in either group. If the Helf Ratio exceeds 0.5, the detected group is considered a *true detection*. By this, we can compute the *precision*, *recall*, and *F1 score*.

We also adopted the extended metrics proposed by [11]. Specifically, we evaluate the accuracy at varying thresholds by increasing the criteria from 0.5 to 1 in steps of 0.1, enabling us to plot the accuracy curve and compute the AUC (Area Under the Curve) score, referred to as IoU@AUC. Additionally, we compute the matrix IoU score (Mat.IoU) using the predicted and ground-truth binary human group relation matrices, where element-wise logical AND and OR operations are applied to measure the overlap between groups.

3.3 Network Implementation details

We used Incepction-v3[8] as a frozen backbone pretrained on Collective Activity Dataset [10], and utilize ROI-Align [9] with crop size of 5×5 to extracte features. The parameter λ in Eq. (7) is set to 0.3. The parameter τ in Eq. (6) is set to 0.7 times the width of the input image.

3.4 Training & Inference

In this study, all experiments were conducted on a workstation equipped with an AMD Ryzen 9 5950X CPU and NVIDIA RTX 3090 GPU. The workstation runs on the Ubuntu 18.04 LTS operating system. All networks in this research were implemented under the PyTorch framework. We trained the network using stochastic gradient descent (SGD) with a learning rate initially with 2×10^{-5} and decreasing to 1×10^{-5} at epoch 20. We trained the model for total 30 epochs.

3.5 Result & Discussion

This section presents the results of our proposed framework and discusses the findings. From Table 2, it can be observed that the **Precision**, **Recall**, and **F1 Score** are 64.4%, 82.7%, and 72.2%, respectively. These results indicate that the model performs well in minimizing false detections (high Precision) and capturing most of the true groups (high Recall). However, the significant difference between Recall and Precision suggests that while the model excels in identifying a wide range of groups, it may occasionally misclassify non-groups, leading to false positives. This trade-off highlights the need for further refinement to achieve better balance in precision and recall without compromising detection accuracy.

Table 2. Precision, Recall, and F1 Score (%)

Precision	Recall	F1 Score
64.4	82.7	72.2

Similarly, Table 3 provides insight into the spatial alignment of detected groups, with **IoU@0.5**, **IoU@AUC**, and **Mat.IoU** achieving 72.2%, 33.5%, and 72.3%, respectively. The high **IoU@0.5** and **Mat.IoU** values indicate that the model effectively aligns detected groups with ground truth annotations, demonstrating strong spatial consistency. However, the relatively lower **IoU@AUC** suggests that the model's performance varies across different thresholds, possibly due to challenges in handling edge cases or overlapping groups. This result underscores the importance of refining the model to improve its robustness in more complex scenarios, particularly under varying spatial conditions or occlusions.

Table 3. IoU Metrics (%)

IoU@0.5	IoU@AUC	Mat.IoU
72.2	33.5	72.3

To further analyze the results, we conducted a sensitivity analysis on the visual feature similarity R_e and spatial proximity $\tilde{R}_d$. Table 4 demonstrates that spatial proximity $\tilde{R}_d$ plays a more critical role in group detection performance. As the weight of spatial proximity increases, the performance improves, achieving the highest IoU@0.5 and IoU@AUC values of **72.2%** and **33.5%** when $R_e = 0.3$ and $\tilde{R}_d = 0.7$. However, when the model relies solely on spatial proximity ($R_e = 0$), the performance declines slightly, indicating that visual feature similarity R_e still contributes to learning individual relationships effectively. This suggests that while spatial information dominates, incorporating visual feature similarity helps the model achieve a more balanced understanding of group relationships.

Figure 3 visualizes the correct predictions. In Prediction

Table 4. Sensitivity analysis on visual feature similarity R_e and spatial proximity $\tilde{R}_d$. The highest scores are marked in **bold** and the second highest in underlined.

R_e	$\tilde{R}_d$	Group Detection		
		IoU@0.5	IoU@AUC	Mat.IoU
1		58.5	29.4	**74.1**
0.7	0.3	61.2	29.2	71.7
0.5	0.5	63.5	30.6	71.0
0.3	0.7	**72.2**	**33.5**	72.3
	1	70.6	31.5	69.7

1 (Figure 3b), the framework demonstrates its capability to effectively distinguish multiple groups within a complex scene, even when numerous workers are present and interacting across different locations. This highlights the model's ability to accurately separate groups in dense and dynamic environments. On the other hand, the result for Prediction 2 (Figure 3d) emphasizes the model's ability to correctly identify the true group despite challenges posed by spatial proximity. Specifically, although the two individuals in the upper-right corner appear close to each other, the model successfully leverages visual feature similarity to learn that the actual group consists of the two workers actively engaged in rebar installation. This underscores the model's robustness in learning semantic group relations based on contextual and task-related cues, rather than relying solely on physical distance.

However, Figure 4 highlights the incorrect predictions. The primary source of error in the upper-right corner stems from the intertwining and occlusion of two groups, making it difficult for the model to differentiate between them. Additionally, since the current model takes a single image as input, understanding group dynamics and movement becomes particularly challenging under such conditions. This limitation suggests that without temporal information, the model struggles to resolve ambiguities caused by overlapping worker interactions and visual obstructions. Beyond occlusion, we identified additional error sources: (1) Dynamic role changes, where workers temporarily move between groups, causing assignment inconsistencies; (2) Varying worker proximity, where workers working near each other but not collaboratively are mistakenly clustered together; and (3) Clothing and visual appearance similarities, where workers wearing identical uniforms and safety gear are misclassified into the same group due to similar feature embeddings. These findings suggest that integrating temporal tracking and additional contextual cues could enhance robustness in future iterations of the model.

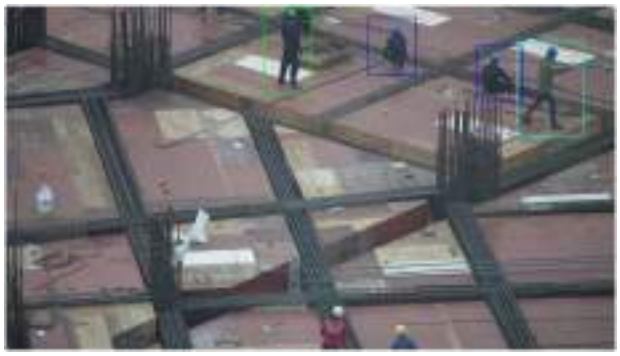
4 Conclusions

In this study, we introduced a deep learning-based framework for automated crew-level identification on construction sites. The proposed framework leverages a graph-based approach that combines visual feature similarity and spatial proximity, enabling robust detection of worker groups through clustering algorithms. By integrating these relationships into a relational matrix and applying spectral clustering, the method effectively identifies groups of workers collaborating on shared tasks.

The framework was validated on a construction site dataset collected during a rebar installation task. The experimental results showed that our method achieved high performance in group detection, with metrics such as IoU@0.5, IoU@AUC, and Mat.IoU reaching 72.2%, 33.5%, and 72.3%, respectively. Sensitivity analysis further revealed the significance of spatial proximity in improving detection accuracy, while visual feature similarity provided additional contextual support for identifying group relationships.

Despite the promising results, certain limitations were observed, particularly in scenarios involving heavy occlusion or overlapping worker interactions. These challenges highlight the need for incorporating temporal information to better capture group dynamics and movement across sequences of frames. While our dataset captures key worker interaction patterns and spatial relationships, we acknowledge that differences in construction site layouts, worker densities, and environmental conditions may influence the model's performance.

For practical deployment, cameras would be installed on nearby buildings or tower cranes to capture footage of the construction site. The recorded videos would then be transmitted to an office workstation, where the proposed system processes the data to detect and analyze worker groups. This setup enables real-time monitoring without interfering with ongoing construction activities. While the initial setup requires hardware installation and network configuration, the system significantly reduces manual observation efforts and improves productivity tracking, making it a practical and scalable solution for construction management.



Future improvements could focus on incorporating temporal analysis to enhance worker grouping consistency across frames. One approach is to implement trajectory-based tracking algorithms to maintain worker identities and analyze movement patterns over time. This would help differentiate temporary interactions from persistent group formations. Additionally, sequential modeling techniques such as RNNs or transformer-based video models could be explored to capture temporal dependencies, further refining worker clustering in dynamic construction environments.

Abstract -

Pier foundations are commonly used in locations with unstable soil or where other types of foundations are unsuitable or cost prohibitive. A pier foundation consists of vertical columns to support the structure and elevate it above the ground. Common materials for pier foundations include masonry, concrete, timber, and steel. The methods for accurate placement of pier foundations have remained relatively unchanged for decades. For simple installations, construction chalk lines are used to layout the locations of piers to ensure accurate placement and elevation. For more complex installations, surveying instruments operated by trained professionals are employed to accurately locate piers and assess correct elevation before construction. After installation, another survey may need to be performed to assess the quality of the as-built foundation. However, with the advent of terrestrial laser scanners (TLS), the means now exist for contractors to conduct their own assessments of as-built foundations. The major barrier preventing contractors from performing their own assessments of as-built foundation quality is the segmentation and analysis of point cloud data, a skill that often requires a trained user. The objective of this research is to develop a software tool (PIER: Pier Inspection and Evaluation Report) to enable automated segmentation and analysis of point clouds of pier foundations. In this paper, the automated segmentation and analysis algorithms are detailed. A mockup lay out of pier foundations was built using concrete masonry units, and the algorithms were tested to evaluate performance. Limitations of the current algorithms and future research direction are discussed.

1 Introduction

In the United States, pier foundations are often used to support a variety of building types and infrastructure. Common applications for piers include foundations for manufactured housing, site-built housing with crawlspaces, buildings constructed on unstable soil, and bridges, especially those over water. Pier foundations are unique in that they are discontinuously distributed across the footprint of the structure. As a result, the accurate placement of pier locations and elevations is critical.

Pier foundations can take the form of many shapes and sizes. An array of materials are traditionally used to construct piers (Figure 1). For example, timber, steel, cast-in-place concrete, precast concrete, and masonry are all typically used for pier foundations across diverse building types. Due to variability in materials, sizes, and shapes, methods of placement and installation can vary significantly.

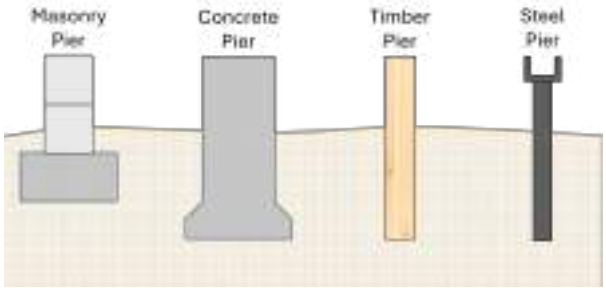

Figure 1. Types of pier foundations.

1.1 Pier foundation positioning and elevation control

The methods for accurate placement of pier foundations have remained relatively the same for decades [1, 2, 3]. For small construction sites, the layout of foundations is made using strings, chalk lines, measuring tapes, or bubble levels. Some combination of these tools is necessary to ensure squarely-set, evenly-spaced pier foundations with accurate top elevations. However, as the size of the construction site increases, the usability of these tools diminishes, and the

likelihood of user error increases. More advanced tools such as laser levels can be employed with a higher degree of accuracy to ensure that the top of each pier foundation is constructed at the correct elevation. For larger construction projects, it is common to hire a professional surveyor to measure and locate foundations prior to construction. After the construction of the foundations, it is sometimes necessary to perform another survey to determine if the as-built elevations and locations are within tolerance. Recent research has developed methods to analyze piers in challenging locations, such as underwater [4]; however these methods are not typically applicable under normal conditions in open air.

Because these tools rely on skilled labor to assess distances and read measurements, there is a chance for errors. Accurate placement of piers is critical because the structure above must be adequately supported at the correct locations. As a result, it is common to incorporate some tolerance for pier foundations so that if the placement of a pier is inaccurate to some degree, the subsequent construction is minimally affected. However, excessive errors can cause constructability issues, which can delay the entire construction schedule. For example, in a series of piers supporting an array of beams, if a pier is misplaced by more than the width of a beam, either the pier must be demolished and correctly reconstructed or the layout of the beam structure must be altered to accommodate the misplaced pier. Errors can often go unnoticed during the foundation construction process, causing significant delays in the construction timeline.

94% of construction firms report having difficulty finding workers to hire [5]. Current quality assessments of pier foundations for complex construction sites are conducted by professional surveyors, who are becoming harder to find and more expensive. The transfer of knowledge and continued development of skilled labor is necessary to ensure that construction demand can meet the growing needs of society. Digital tools can increase productivity and alleviate some of the strain on the diminishing workforce. However, for foundation layout and construction, the availability of digital tools to improve productivity is low. Some options exist on the market to automate some aspects of foundation evaluation; however, no option currently exists specifically to evaluate the quality of construction for pier foundations.

1.2 Laser scanning and point cloud segmentation

Modern laser scanning devices can collect more than 2 million points per second and are accurate at long ranges with peak range accuracy of 2 mm + 2 ppm or better [6]. These simple, easy-to-use scanners have the potential to expedite the measurement of as-built quality of construction and generate real-time guidance to correct issues. With further development, the affordability and accessibility of these devices will also add to their potential. The accompanying software with modern laser scanners can automate and simplify the process of registering multiple scans into a single frame, which is usually a time-consuming and difficult process. Laser scanners have the potential to replace manual measurement methods and tools used during the traditional process of construction if point cloud data and analysis can be streamlined and automated.

The major aspect of laser scanning that currently limits its adoption is the segmentation of point cloud data. The fastest method of scanning for most TLS is typically a full 360° scan during which every object in line of sight is measured. Once the scan is complete, the data is imported into software and the points belonging to the objects of interest (the piers in this case) are retrieved from the rest of the points. This process is called segmentation. Automated segmentation of points clouds for varying applications is a major point of interest in current research [7, 8, 9, 10]. Automated point clouds segmentation techniques exist to perform tasks ranging from prefabricated tolerance compliance assessment [11] to automated digital twin generation [12]. The segmentation process can be turned from a several-hour manual process into a few second-long automated process by incorporating automation through artificial intelligence. Previous research by the authors developed automated segmentation and analysis algorithms for the flatness and levelness of concrete slabs [6]. The current research expands upon the existing algorithms to automate segmentation and analysis of pier foundations. This paper details automated segmentation and analysis algorithms to identify and analyze the quality of construction for pier foundations.

2 Methodology

The focus of this research is the development of automated segmentation and analysis algorithms for point clouds of pier foundations. The algorithms are incorporated into a software tool called the Pier Inspection and Evaluation Report (PIER). As part of the analysis, the user is informed in real-time about differences in the top elevations of piers and misalignment of pier locations based on an assumed orthogonal planar layout. The method takes as input a dense point cloud and does not require user interaction to automatically segment points belonging only to piers and analyze the quality of construction. For the initial design of the algorithms, masonry piers were used.

2.1 Segmentation

The segmentation process is performed to identify and isolate points belonging only to piers from a dense point

cloud. This segmentation is necessary to identify and isolate pier locations before the automated analysis can be conducted. Figure 2 illustrates the steps in the segmentation procedure.

The first step is to remove points above the scanner origin. The top surfaces of piers will not be visible from the scanner unless the scanner is located at a higher elevation than all the top piers surfaces. As a result, only points below the scanner are relevant. This step helps to reduce the total number of points initially and ensure that any elements above the scanner origin are not incorrectly identified as piers. To perform this removal, the point cloud is cropped such that all points with an elevation above zero are removed from the point cloud.

It is essential to remove the points belonging to the ground around the piers. The next step consists of removing points belonging to the ground by using random sample consensus (RANSAC). RANSAC consists of randomly sampling points to generate planes and select inlier point sets that fall within a specified normal distance from that plane [13]. All points that fall within a specified distance threshold are considered inliers within the selected plane. The procedure in PIER randomly selects five points in the cloud to fit a plane. The distance threshold represents the normal distance from the plane generated and assigns points within this distance as inliers. After a specified number of iterations, the plane with the largest number of inlier points is returned as the plane representing the ground [6]. For instances where the ground around the piers is largely non-planar, the procedure may struggle to effectively remove the ground. However, it is only necessary to remove the ground around the piers to ensure there is clear separation between the points at the bases of piers and points belonging to the ground.

The next step is to prepare the point cloud data for computationally expensive algorithms. To ensure the code is not too computationally expensive and that the run time is minimized, data reduction is achieved by voxel-down sampling [14]. A grid of cubes with a specified dimension is computed. All points within each cube are averaged and reduced to a single point. In this work, a voxel size of 12.5 cm appears to be effective in reducing the point cloud while still accurately providing enough fidelity in the data for the remaining steps in the procedure [6].

Points at the edge of the point cloud are also removed to make the code run more quickly and improve robustness. To do so, convex hulls and K-D tree are used. The convex hull is an algorithm that computes the smallest convex shape of spatial data points: given $P = \{p_1, p_2, \ldots, p_n\}$, Convex Hull$(P) = \bigcap\{H \mid P \subseteq H, H \text{ is convex}\}$. The implementation of the convex hull algorithm in the Open3D library (Qhull algorithm) is used in this work [14]. In this implementation, a tetrahedron is initialized with vertices at extreme points (maxima and minima of x, y, and z). Then the remaining points outside the shape are checked and included as long as the convex property is maintained [15]. Computing the convex hull of the point cloud allows us to identify points composing the vertices or the borders of the hull. The next step is to find and remove the neighbors of these border points by using KD-Tree (k-dimensional tree) for computational optimization purposes. The K-D tree is a space-partitioning binary search tree for organizing points and enables the selection of points based on nearest neighbors [16]. Space is partitioned with an axis-aligned hyperplane. Embedded functions in Open3D easily allow the organization of the point cloud in a KD-Tree and selection of neighbors within a radius of the border points identified with the convex hull procedure to be removed.

After removing the ground and the points at the extremities of the point cloud, a density-based scan (DBSCAN) clustering method ([14] [17]) is used to identify the different clusters in order to isolate the point sets belonging to the piers. A set of filters are used to correctly identify which sets of clusters are pier foundations. The algorithm iterates through the projection of each cluster on xy plane to compare the area difference between the minimum oriented bounding box and the contour of the cluster. The minimum oriented bounding box algorithm determines the smallest rectangle at any orientation that encapsulates all points within the set [18]. The contour is computed using alpha shape: a generalization of convex hull that is capturing all vertices and allows concavity [19]. In addition, the contour area is compared with the user-specified dimensions of piers to ensure a robust selection of clusters belonging to piers. In most cases, the dimensions of the piers are normalized or easily quantified in the construction industry. The user input pier dimensions are not required but do improve the robustness of pier identification. All individual point clusters identified as piers are joined to create a single point cloud. At this stage, the point cloud includes only points that have been identified as piers and is ready for analysis.

2.2 Analysis

After segmenting the piers, labels are set based on the distance between the centroid of each pier and the origin of the point set. By using this naming convention, the identification of each pier remains consistent even if the user takes multiple scans and runs the segmentation and analysis multiple times. Labels are set as P_i. The current objectives of the analysis are to produce two plots: (1) a quantified illustration of the differences in elevations between the top surfaces of piers that allows the user to shim piers such that the top surface of each pier is at the same elevation, and (2) a quantified illustration of the

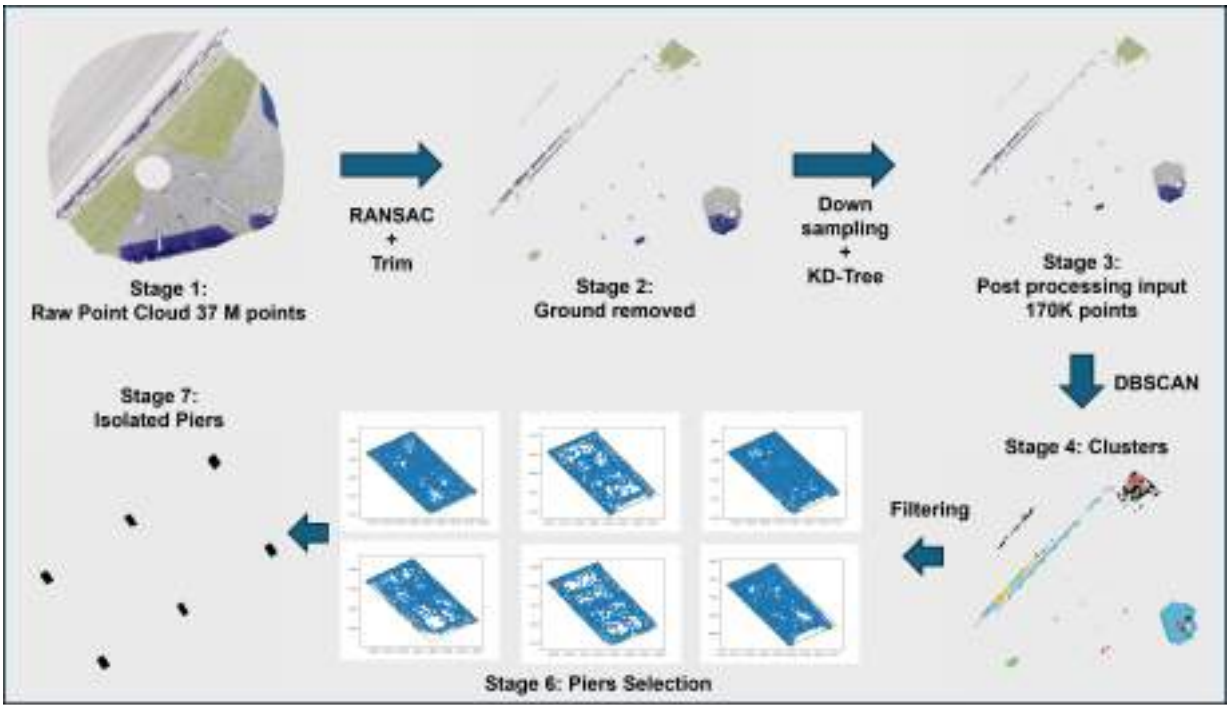

Figure 2. Steps in the automated segmentation process for pier foundations.

misalignment that informs the user about incorrect planar locations of piers.

To determine the difference in elevation between the top surfaces of piers, a point of reference must be established. The highest point of the point cloud, including only points identified as piers, is computed and referred to as h to be used as the reference. For each pier, the local maximum elevation h_i is identified, and a plane parallel to the xy-plane is created using the local maxima h_i at centroid c_i. For each of these planes, a perpendicular vector is computed, originating from the corresponding plane's centroid c_i and extending to the corresponding point where the z-coordinate matches the global maximum elevation h. This analysis results in the reported minimum distance from the top surface of the pier at the highest elevation to the top surface of each other pier as shown in Figure 3. With this information, the user can adjust piers top elevation by shimming appropriately. For example, in Figure 3, P2 is shown to be 18 cm below P6 (the datum). To correctly bring the top elevation of P2 to a uniform elevation, a shim or block with total thickness of 18 cm would need to be added to the top of the second pier. After shimming, the site can be scanned again, and the automated segmentation and analysis can be repeated to determine if the piers were correctly shimmed.

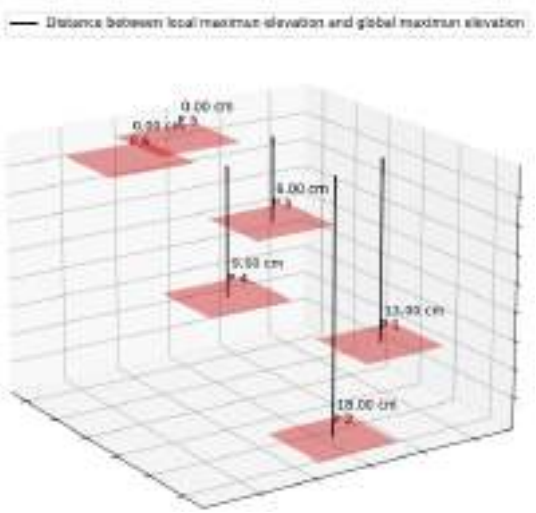

Figure 3. Elevation differences between top surfaces of piers.

During the foundation construction, the planar locations of piers need to be accurate to avoid issues with the construction of the structure above. To give corrective guidance for planar location, the automated analysis generates an illustration of planar misalignment. To generate this guidance, the total point cloud including only piers is projected onto xy plane (Figure 4). In the current development, the algorithms assume a rectangular layout of piers. The measured diagonals formed between piers at corner locations are presented to show the quality of the

rectangle produced by pier layout. If the measured distance of diagonals are substantially different, the user can know that the interior angles of the rectangle forming the layout of the piers are not orthogonal indicating an error in the construction.

Additionally, local guidance is presented to the user on how to correct the location of each pier to achieve an orthogonal rectangular layout. The contour and minimum oriented bounding box of the total point cloud including only piers are computed. For each pier, a minimum oriented bounding box is computed for all points on the xy plane. The closest point on the segment of the total bounding box from each pier extremity is given by their respective orthogonal projection (Figure 5). For example, let H be the minimum oriented bounding box of the total point cloud, and let a_i, b_i, c_i, d_i be the vertices generating the minimum oriented bounding box of the each pier P_i. For each a_i, b_i, c_i, d_i, the minimum distance between these points and H is computed and presented to the user. For example, as shown in Figure 5, the pier in the top left corner needs to be adjusted nearly 14 cm to be correctly set to create a planar rectangular layout with the remaining piers.

If the displacement between one of the points a_i, b_i, c_i, d_i for each P_i and H is less than 2 mm, it is not going to be plotted. Also if this displacement is higher than the dimension of the piers specified by the user, it is not going to be computed since it does not bring valuable information.

2.3 Limitations

In this version, the automated segmentation and analysis algorithms include some limitations. Each limitation will be addressed in future research.

First, this initial study focuses on the general performance and feasibility of the proposed algorithm for a single case study. Future research will focus on multiple demonstrations to evaluate robustness and accuracy of outputs.

The final alignment plot can be misleading if the errors are too large. Since the code is looking for the displacement needed so that all the piers are within an optimized rectangle, if large errors were made during placement, the assumption for a rectangular layout is not valid, and the algorithms generate incorrect guidance.

The number of points attributed to the piers is low compared to the remaining elements such as the ground. During the step where the ground is removed from the point cloud, a few failures occur where a pier is inadvertently removed in some instances.

In the current form, the automated analysis algorithms do not provide guidance on the levelness of the top surface of each pier. Information of the levelness of the top surface is critical to ensuring that constructability issues are not created. A feature to extract and report on the levelness of the top surface of each pier will be added to the algorithms.

In the current development, the algorithms assume a rectangular layout of piers. The measured diagonals formed between piers at corner locations are presented to show the quality of the rectangle produced by piers layout. In future developments, a digital twin is planned to be incorporated to generate guidance for complex layouts. However, in this case, alignment of the digital twin with the physical space will need to be performed to generate applicable correct guidance for users.

Due to the automated nature of the analysis procedure for correct planar rectangular layout, the algorithm assumes that the most exterior pier within the minimum oriented bounding box is the reference point. As a result, all guidance is to move the remaining piers outwards from the center of the layout. This assumption may not always be correct as a certain pier may need to be used as the reference. In future development, the user will be allowed to choose which piers should be treated as the reference point and remain unmoved.

3 Demonstration

The automated segmentation and analysis algorithms were tested on a mockup pier foundation construction located on the Oak Ridge National Laboratory site. Six masonry piers were placed in a planar rectangular layout with design dimensions of 7.5 m by 3.6 m. The mockup pier foundation was scanned using a terrestrial laser scanner.

The scan was made with a Leica MS60 which was placed in front of the piers and was set to do a 360° scan of the area to have a full view of the mockup construction site. The same scan parameters as in the previous paper [6] were used. Figure 6 shows the raw .pcd file of the scan that was loaded into the PIER digital tool. The masonry piers are clearly visible by their "shadows" cast from the laser scanning procedure.

The pier segmentation and analysis algorithms were written using Python. Table 1 shows the list of parameters and values used to analyze the mockup foundation. Voxel Size is the dimension of the voxel cube used for downsampling. The Plane Distance Threshold is the minimum normal distance between the RANSAC plane and points to be considered as inliers. Cluster Neighbor Radius is the maximum distance between points to be considered members of the same cluster. Cluster Minimum Points is the minimum number of points that a cluster must contain. KD-Tree Minimum Points is the minimum number of neighbors a point must have in order to not be considered a border point in the point cloud. KD-Tree search radius is the maximum distance where neighbors are taken into

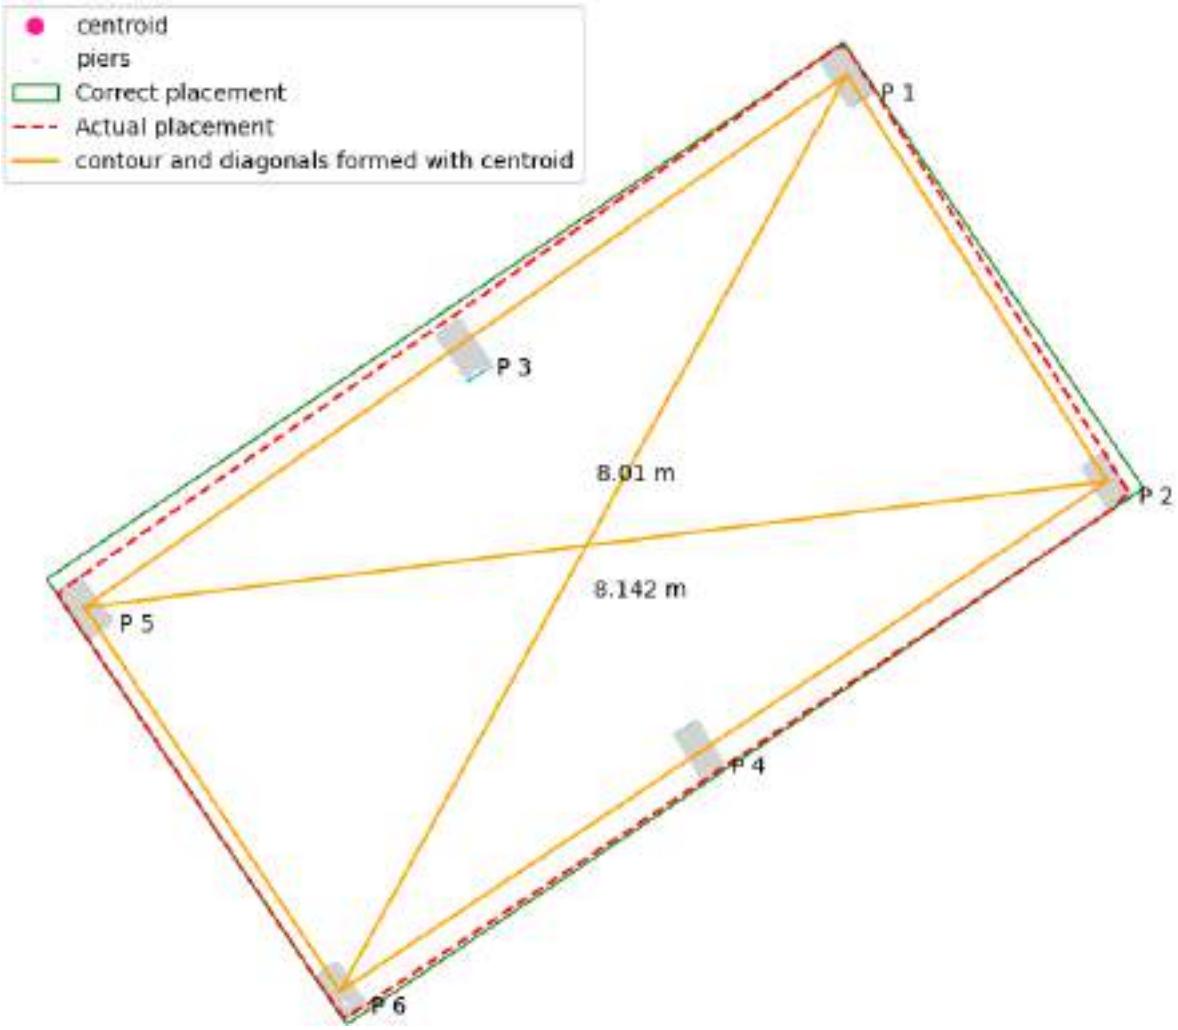

Figure 4. Planar alignment guidance for pier locations

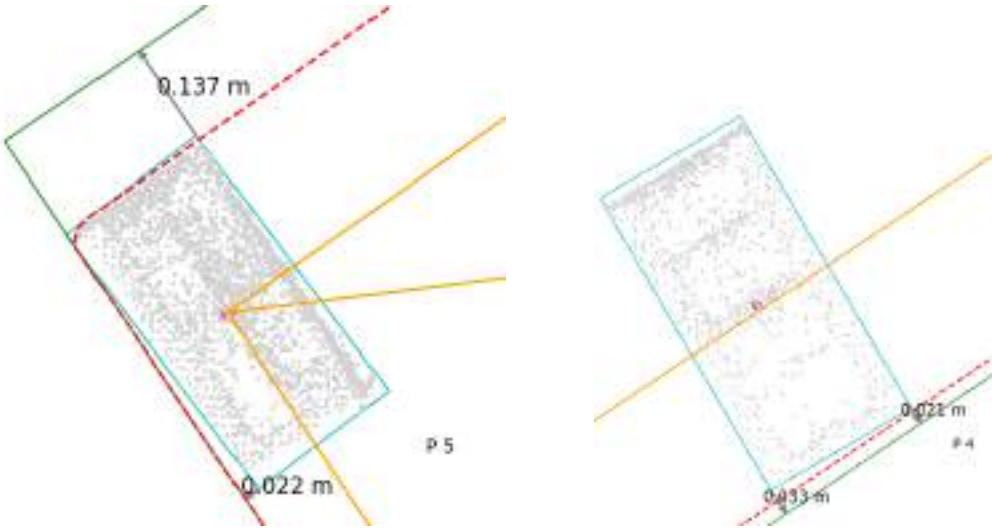

Figure 5. Local planar correction to locate each pier

Figure 6. A portion of the full-dome scan of the site with mockup pier foundations.

account.

Table 1. Parameters for the demonstration.

Parameter	Value
Voxel Size	12.5 cm
Plane Distance Threshold	20 cm
Kd-Tree Search Radius	20 cm
Kd-Tree Minimum Points	1000
Cluster Minimum Points	25
Cluster Neighbor Radius	50 cm

For the MS60 laser scanner used in this study, the single-view dense point cloud with a specified resolution was collected in approximately 45 minutes. However, many TLS scanners boast faster scanning rates and can capture point cloud data with higher resolution in a fraction of the time (3 minutes or less).

Table 2 gathers the running time for each main task required to segment and analyze the piers foundation on a standard laptop computer. Tasks before segmentation included the PCD file reading, trimming, and pre-processing with RANSAC, voxel-down sampling, and KD-Tree. The clustering by density-based scan (DBSCAN) and the cluster filtering are reported collectively within the segmentation task. Finally elevation and alignment guidance tasks represent the computation and analysis of piers elevation and placement.

The mean total run time was approximately 27.20 seconds. Most tasks within the algorithms have consistent run time except for pre-processing and segmentation. This is due to the random nature of RANSAC. Since the tests were not conducted on a flat surface, some parts of the ground may not be removed and taken into account during the segmentation which increases the computation time. Another method to identify the ground may be introduced in the future in order to address this issue.

Among 40 iterations, two runs were considered failures. One failure was due to RANSAC removing the entire collection of points belonging to a single pier. The other failure consisted of an additional element in the construction site being incorrectly identified as a pier. This variability is mainly due to the ground removal with RANSAC and the clustering method that use unsupervised machine learning, resulting in different cluster identifications between attempts. Another cause of failure is if there is an object on site that has approximately the same dimension as the piers since the algorithm is filtering the different identified clusters based on the dimension specified by the user.

Table 2. Run times. 40 iterations.

Task	Run Times (sec)			
	Min	Max	Mean	Std
Read PCD	3.77	4.11	3.89	0.09
Trim	0.01	0.03	0.01	0.01
Pre processing	4.27	5.80	5.10	0.36
Segmentation	13.06	25.25	16.33	3.08
Elevation	0.21	0.38	0.28	0.04
Alignment	1.78	1.04	1.4	0.15
Entire Procedure	23.47	36.52	27.20	3.14

4 Conclusions and next steps

Pier Inspection and Evaluation Report (PIER) is a digital tool that uses algorithms to automate the analysis and inspection of point clouds of pier foundations. Tests were conducted on masonry piers at Oak Ridge National Lab site. The results show that PIER can provide quick and accurate feedback on piers installation.

In future work, an alternative way to remove the ground to reduce the variability of the segmentation will be implemented. The selection algorithm for identifying point clusters of piers will be improved to increase robustness. Futhermore, a feature to extract and report on the levelness of the top surface of each pier will be added to the algorithms.

Additionally, future work will include research on the robustness and accuracy of the proposed methods through multiple demonstrations at construction sites where piers are being constructed. PIER will be demonstrated and verified to produce accurate results and guidance.

Abstract

Automated rebar cage assembly and quality inspection require reliable rebar recognition. Although rebar segmentation from point clouds has been extensively studied, its generalizability remains limited. One key challenge is the scarcity of real data for training the segmentation models. To address this issue, we propose, for the first time, a pipeline for generating synthetic data for the rebar point cloud instance segmentation task. Using this pipeline, we applied the state-of-the-art Oneformer3d on rebar mesh instance segmentation. The model trained on our synthetic dataset achieved 92.1 mAP in real-world experiments, showing strong synthetic-to-real transfer capability. By eliminating the need for manual data collection and annotation, the proposed method facilitates advancements in automated rebar cage assembly and dimensional quality inspection technologies.

Keywords –

Point cloud instance segmentation; Rebar Recognition; Synthetic-to-Real; Computer Vision

1 Introduction

The automation of rebar cage assembly and dimensional quality inspection has garnered significant attention in the construction industry due to its potential to enhance productivity and reduce labor costs [1]. Accurate rebar recognition is a key technology that enables the automation of the above tasks. It serves as a critical foundation for many downstream tasks, such as rebar manipulation based on pose estimation and the dimensional measurement of rebar cages.

Existing studies have extensively explored rebar segmentation from images or point clouds to accurately identify the shapes and dimensions of rebars. Depending on the type of sensor data, these methods can be categorized into image-based rebar segmentation methods and point cloud-based segmentation methods. The advantage of the former lies in the ease of data collection and annotation and lower hardware costs. For instance, Kardovskyi et al. [2] applied the Mask R-CNN to segment rebars from images, which was then integrated with stereo vision techniques to measure rebar length and spacing. Chang et al. [3] present a hybrid rebar segmentation method to enable accurate rebar dimension measurement. This method first employs Mask R-CNN to segment rebars from images, followed by mapping the segmented results into 3D space, where point cloud processing techniques are used to cluster and identify 3D rebar instances.

Compared to object segmentation from images, direct segmentation from 3D point clouds offers two significant advantages: (1) it enables end-to-end processing of point clouds from laser scanners, and (2) it leverages prior knowledge of objects' 3D shapes more effectively. Consequently, many studies have focused on rebar segmentation from 3D point clouds [4], [5], [6]. They all relied on point cloud processing techniques, leveraging prior knowledge of rebar shapes to segment point clouds from complex scenarios. For example, Kim et al. [7] proposed a method based on the line RANSAC method and circular RANSAC to efficiently identify straight rebars within rebar cages. However, relying solely on point cloud processing to identify rebars faces limitations in generalizability [3].

Deep learning-based point cloud instance segmentation has demonstrated remarkable performance in various computer vision tasks, such as indoor scene understanding [8] and industrial part dimension inspection [9]. They typically rely heavily on large quantities of annotated data for training [10]. However, such large-scale data in the context of rebar segmentation is still lacking [3], which directly hinders the advancement of rebar segmentation. Moreover, the labor-intensive and time-consuming nature of manual annotation processes further exacerbates this challenge. Wang et al. [11] proposed a synthetic dataset using BIM and Lumion 11 rendering software, which contains automatically labeled 2500 synthetic images of rebar meshes. Mask R-CNN was trained and tested on their proposed dataset, showing high accuracy of bounding

box and mask prediction. However, to the best of the authors' knowledge, no point cloud dataset specifically designed for rebar instance segmentation has been proposed. Therefore, the applicability of advanced point cloud instance segmentation networks to rebar segmentation tasks also remains unexplored.

To address these critical gaps, we first develop a synthetic data generation pipeline for generating synthetic point clouds. The pipeline simulates realistic rebar point clouds from image-based 3D reconstruction and their corresponding 3D labels, enabling the training of advanced segmentation networks without the need for manual data collection and annotation. Using the proposed synthetic dataset, we apply a state-of-the-art point cloud instance segmentation network to the real-world task of rebar mesh recognition. The feasibility and accuracy of the developed pipeline are validated through real-world experiments. Additionally, the experiments show both the applicability and limitations of the state-of-the-art method in rebar segmentation tasks.

2 Method

Point cloud instance segmentation networks typically require a substantial amount of training data to enable the model to effectively learn the visual and geometric features of target objects. Therefore, we developed an end-to-end data generation pipeline for rebar instance segmentation based on the modeling and rendering software Blender, as shown in Figure 1. This pipeline efficiently simulates 3D point clouds reconstructed using Structure-from-Motion (SfM) and Multi-View Stereo (MVS) algorithms and automatically generates labels. The proposed pipeline consists of three stages: (1) scene generation, (2) point cloud reconstruction, and (3) model training.

2.1.1 Scene generation

We first developed a parameterized modeling method using Blender and Infinigen [12]. The method can generate large-scale rebar models with diverse shapes and appearances. Specifically, Blender is used to model rebars, while Infinigen converts the parametric geometry nodes into executable code for batch processing. Figure 2 shows different rebar models generated by our method. We use Cylinder primitives in Blender to represent straight rebar segments. To simulate different real rebars, our straight rebar model supports parameters required for typical design specifications, including rebar diameter, length, bending degree, and rib type. The rib structures are created using meshes, enabling high-fidelity and geometric details.

To simulate different rebar appearances, we randomize visual parameters such as base color, metallic properties, roughness, and texture to randomize the visual appearance of the rebar models. Additionally, we use a combination of Noise Texture and Musgrave Texture nodes to simulate surface defects on rebars, such as stains and corrosion.

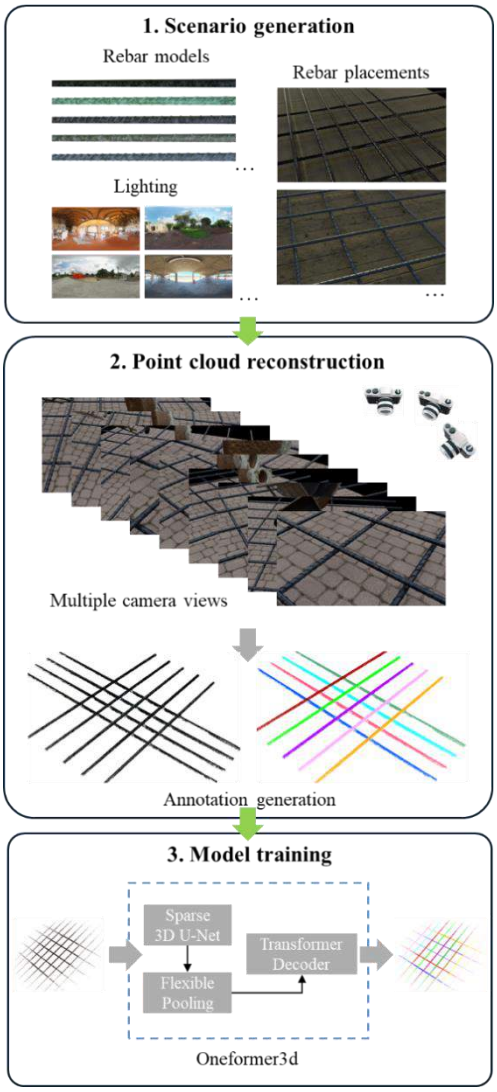

Figure 1. Proposed pipeline for rebar instance segmentation

By defining heuristic rules and graph structures, we can use automatically generated rebar models to establish various rebar cage configurations. In this study, we specify the positions and orientations of straight rebars to construct reinforcement mesh scenarios for slab production. For lighting, the approach of high dynamic range images (HDRI) is applied to illuminate the scenario. To capture a wide range of lighting conditions, 733 HDRI images are collected from the open-source asset library PolyHaven.

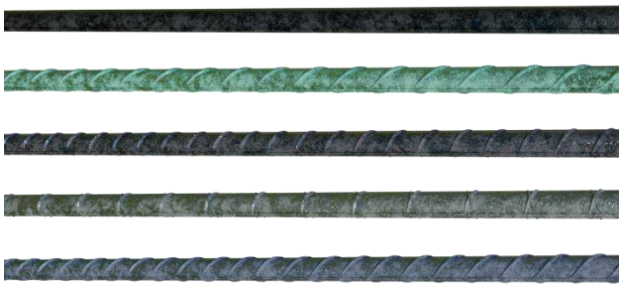

Figure 2. Examples of generated rebar models

2.1.2 Point cloud reconstruction

A straightforward method for generating point clouds from 3D scene models is to downsample the mesh directly to obtain the point cloud [13]. However, this approach struggles to effectively replicate the distribution of point clouds reconstructed from real images, leading to reduced segmentation accuracy [14]. To better simulate the point clouds derived from real image reconstruction, we sample cameras within the 3D scene and employ traditional SfM [15] and MVS [16] algorithms to generate synthetic point clouds. Blender's Cycles renderer is applied to generate photorealistic images of the scenarios. The Cycles renderer utilizes physically based ray tracing to simulate complex interactions between light, shadows, and material reflections.

To accurately label the reconstructed point cloud P_{re}, we first perform uniform downsampling on the rebar mesh model generated in the synthetic scenario, denoting it as P_{GT}. Subsequently, we align P_{re} and P_{GT} by utilizing the camera poses estimated via SfM and the ground-truth poses of the virtual cameras. Based on this alignment, the nearest neighbor for each point in P_{re} is identified in P_{GT}, allowing instance labels to be assigned to P_{re}.

2.1.3 Instance segmentation network

A SOTA transformer-based instance segmentation network, Oneformer3d [17], was used for the instance segmentation model. The method achieved the best performance on three different benchmarks (ScanNet, ScanNet200, and S3DIS), and excels in scenarios involving slender objects like chair legs, which share similar geometric characteristics as with rebars.

3 Experiment

To evaluate the adaptability and performance of the developed pipeline, a large-scale synthetic dataset was first generated. This dataset was designed to be diverse, incorporating randomized rebar models, spacing configurations, lighting conditions, camera numbers and camera poses. Based on this dataset, we trained the state-of-the-art point cloud instance segmentation model, Oneformer3d. To assess the model's syn-to-real generalization capability, real-world experiments were conducted on rebar mesh arrangements, simulating slab reinforcements that are commonly used in construction sites.

3.1 Dataset generation

Based on the proposed pipeline, a synthetic dataset containing 238 samples was reconstructed automatically, as shown in Figure 3(a-b). Each sample was annotated with detailed instance labels. The dataset was divided with an 8:2 ratio into a training set (190 samples) and a validation set (48 samples).

To evaluate syn-to-real transfer performance, we arranged slab rebar meshes to collect real-world point cloud data. A smartphone was used to capture 48 to 79 multi-angle images of each rebar placement, with a resolution of 4032 × 3024 pixels. The camera was positioned approximately 70 cm from the target. To introduce variability, we adjusted the number of rebars (8 to 14) and their placement intervals (5 cm to 25 cm), aiming to challenge the algorithm and assess its robustness under diverse spatial configurations. The final test set comprises 12 manually annotated samples. Figure 3(c-d) provides examples from our real-world test set.

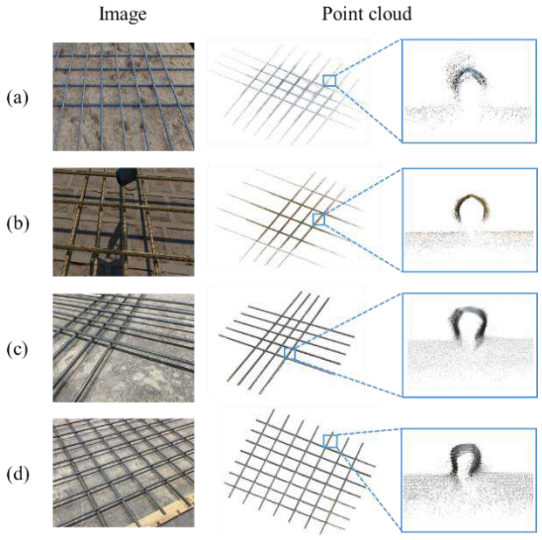

Figure 3. Examples of our synthetic training set and real-world test set: (a-b) synthetic training set; (c-d) real-world test set

3.2 Evaluation Metrics

We evaluated the performance of the 3D rebar instance segmentation using mean average precision (mAP), a standard metric in point cloud segmentation. The mAP was computed as the average precision over Intersection over Union (IoU) thresholds ranging from 50% to 95% in increments of 5%.

3.3 Training setting

All training settings of Oneformer3d are basically following the original implementation [17]. For the learning rate, we used an AdamW optimizer with an initial learning rate of 0.0001 and weight decay of 0.05. Taking computational efficiency into account, we employed a batch size of 2 and constrained the training to 160 epochs. Furthermore, we have experimentally observed that the scale diversity of the point cloud can significantly improve the sensitivity of the segmentation network to the scale of the point cloud. Therefore, we applied a larger range of random scaling, from 0.5 to 1.5, compared to the original implementation.

3.4 Results

Figure 4 illustrates the progression of the mAP on the validation set throughout training. The trend indicates that training on our synthetic dataset is stable and effective, with no signs of significant overfitting. Oneformer3d demonstrates strong segmentation performance on the synthetic dataset, achieving the highest mAP of 99.4. When evaluated on the real-world test set, the model achieved a high mAP of 92.1, indicating its ability to generalize from synthetic training data to real-world scenarios.

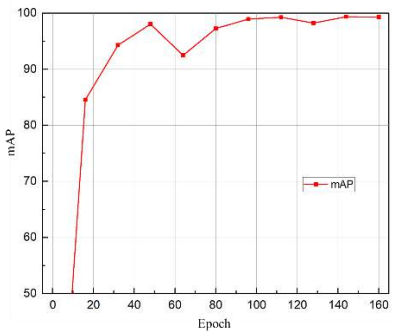

Figure 4. mAP variation with training epochs on the synthetic validation set

Figure 5 presents several results obtained from the real-world dataset. The majority of rebar outputs exhibit high segmentation accuracy with clearly defined instance boundaries However, a few cases exhibit poor segmentation performance. For instance, as illustrated by the red arrows in Figure 5(c), two rebars were incorrectly merged into a single instance. This may be attributed to the global context awareness of transformer-based models, which, in rare cases, can lead to objects with similar features being recognized as the same instance. This merged detection is also noted in indoor object segmentation [18] using a similar transformer-based model with Oneformer3d. Employing a distance-based clustering filter, such as DBSCAN[18], enhanced by shape priors, offers a potential solution to mitigate this challenge.

Additionally, missing points were observed in the segmentation results of certain rebars, as indicated by the blue circles in Figure 5(d). This can be attributed to the model's insufficient accuracy, particularly in handling incomplete edges in point clouds. This minor issue can be addressed using various post-processing techniques, depending on the downstream tasks. For instance, in the case of rebar 6D pose estimation, known geometric priors of the rebar can be utilized to accurately compute the pose even in the presence of missing points.

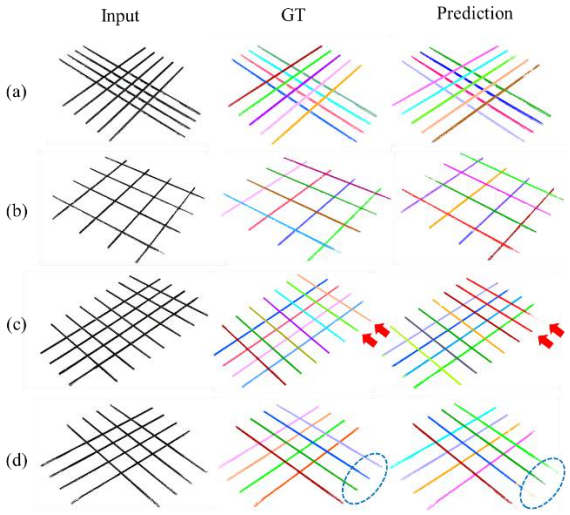

Figure 5. Examples of segmentation results on our real-world test set

4 Discussion

This study demonstrates the adaptability of synthetic data for training the rebar point cloud instance segmentation model. This validates that the approach can generate reliable rebar visual and geometric features, enabling deep neural networks to effectively learn and recognize real-world rebars. Therefore, it is expected that the proposed pipeline can automatically generate 3D data for a wide range of rebar cages. For example, as shown in Figure 6(a), our pipeline can generate complex rebar cage point clouds and annotations. Besides, the pipeline

shows promise for training networks to estimate 6D poses and 2D masks of rebars from 2D images. Furthermore, synthetic models can be integrated into physical simulations to train reinforcement learning policies for dexterous rebar manipulation in future work, as illustrated in Figure 6(d).

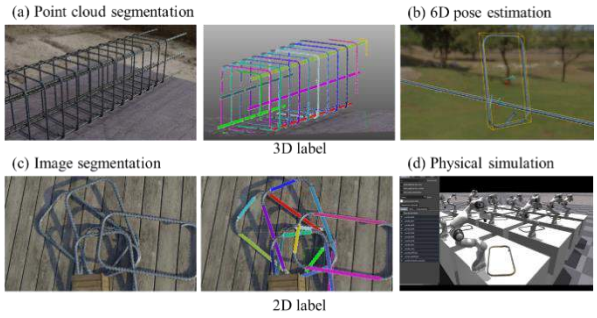

Figure 6. Our pipeline is promising to be extended in the future to: (a) 3D instance segmentation for rebar cage; (b) 6D pose estimation of rebars; (c) 2D image segmentation; (d) Physical simulation

This preliminary exploratory study has certain limitations. First, our point cloud segmentation experiments did not explicitly address the challenges posed by real-world variations, such as more complex rebar structures, occlusions, lighting conditions, and different scanner resolutions. While our synthetic dataset performs well in controlled settings, its generalization to diverse real-world environments remains an open question. Future work should focus on incorporating a broader range of 3D data that captures these variations, ensuring robustness across diverse rebar structures and scanning conditions. Additionally, while preprocessing techniques such as RANSAC [19], can effectively remove the ground, achieving end-to-end rebar segmentation in the presence of complex background interference using neural networks remains a valuable research direction.

Second, the proposed method faces challenges in achieving real-time running in practice due to the high computational cost of the point cloud segmentation network and the offline nature of the reconstruction method. In the future, adopting 3D cameras directly, combined with real-time reconstruction and lightweight segmentation or keypoint detection from 3D point clouds, will be a promising research direction. Third, future work could focus on comprehensive benchmarking to identify the optimal network architecture for rebar point cloud segmentation and facilitate model selection in real-world applications.

Finally, while this study focuses on demonstrating the effectiveness of synthetic data for rebar segmentation, a detailed ablation study on the impact of individual augmentation parameters, such as texture variations, occlusions, and lighting conditions, remains an important area for future work.

5 Conclusion

To address the challenge of lacking training data for rebar point cloud instance segmentation, we first developed a synthetic data generation pipeline. This pipeline enables high-fidelity annotated point clouds, facilitating the training of instance segmentation networks without the need for manual data collection and annotation. The adaptability of the pipeline was validated through a real-world experiment. The state-of-the-art point cloud instance segmentation network Oneformer3d trained on our synthetic dataset achieved a 92.1 mAP on the real-world test set, showing good syn-to-real capacity.

This work contributes to the advancement of automated rebar cage assembly and dimensional quality inspection technologies, paving the way for the broader adoption of intelligent construction solutions.

Abstract -

The increasing complexity and uncertainty in construction projects necessitate more efficient and adaptive construction management systems. This research studies the automation of the Last Planner System (LPS), a collaborative lean scheduling tool, by integrating predictive strategies to enhance scheduling accuracy, constraint resolution, and insights for decision-making. A conceptual framework is proposed for LPS automation while also representing the automation of LPS as an optimisation problem and determining the core aspects of LPS, such as communication management, constraint management, and planning and scheduling. This framework provides a foundation to which integration of predictive strategies in digitised Last Planner Systems is possible, focusing on process improvement, delay mitigation, and performance optimisation. A model that determines the constraint resolution duration was presented. This model used feature extraction techniques to determine constraint complexity score and preprocessed other features such as priority, location, and category to predict constraint resolution duration. The results indicated a Mean absolute error of 21.38 days (MAE) from the actual constraint resolution duration. Although the outcome and model can help in constraint management towards an automated LPS, the research identifies key limitations, including challenges in dataset quality, unfavourable sample sizes, and challenges with parsing complex textual and tabular data, highlighting areas for improvement. Future research should prioritise exploring emerging techniques, such as Table parsing (TAPAS) and Retrieval-augmented generation (RAG), to enhance the integration of data-driven strategies into Last Planner System workflows.

Keywords -

Automation, Predictive Strategies, Last Planner System (LPS)

1 Introduction

In the face of increased complexities and uncertainties of projects in the construction sector, more efficient and intuitive project controls, planning, and scheduling systems are highly sought. Pressing factors contributing to inefficiencies in existing systems include inadequate management of constraints, communication, and lack of adaptability in scheduling and project control systems [1]. However, automatically classifying constraints, intuitively classifying project communication, instantly generating insights, and detecting deviations in these systems are crucial for navigating complex and high-risk projects such that predictability is enhanced and project outcomes are favourable [1, 2, 3]. To achieve this, a more adaptive project management system (Last planner system) is considered as prototyped by Ballard [4]. While existing project control and scheduling systems have indicated significant improvement in addressing inefficiency in project implementation, there remains a substantial gap for improvement in ascertaining project status, instant generation of insights from project trends, and ensuring predictable project outcomes [5, 6]. From the first principle, a last planner system (LPS) can, therefore, be represented as a combination of constraint management system (CN), collaboration/communication system (CB), and Planning and scheduling systems (PS), where x..n is the increasing project instances of elements contained that make each system functional;

$$LPS(x..n) \rightarrow CN(x..n)+CB(x..n)+PS(x..n) \quad (1)$$

Improved efficiency in existing project control and scheduling systems depends on the integration of digitised project control and scheduling systems with other technologies and methods such as lean systems, visual simulation, BIM, artificial intelligence, AR VR, etc. [1, 5]. These integrations have been proposed as solutions to identified fundamental limitations, including unreliable schedules, unreliable data, manual processes leading to errors, and overarching challenges of delay, cost overrun, and reworks [7]. These challenges are expected for most projects, especially in complex and high-risk projects where project managers faced with trade-offs in cost, quality, time, resources, changes, etc., have to rely on tacit knowledge, experience, and intuition to make accurate decisions quickly rather than relying on insights from analysed operation data to draw conclusions and make data-driven decisions. Studies have shown that although experience and tacit knowledge are essential in managing projects, it is more reliable for businesses to find data-driven paths to making operational decisions to control current and future project outcomes [8, 9].

While predictive strategies can improve most of the existing digitised project control and scheduling systems, this study

aims explicitly to automate digital last planner systems. LPS is a lean and collaborative tool that provides short-term schedules and lookahead information that enhances planning efficiency, improves the reliability and accuracy of plans, enables the selection of alternatives, and reduces time-space conflicts on construction sites. The system pulls information from all forms of communication regarding constraints, deviations, changes, etc., to determine tasks to be scheduled within specific lookahead periods. The benefits of LPS are evident in LPS-related research sources, and an automated Last Planner System (LPS) has been proposed to exert an even greater impact on construction planning and implementation processes. [10, 11, 7, 12, 13].

As part of the contribution of this research, this study presents a streamlined flow for automating the digitised Last planner system, considering all factors which enable it to be fully functional. In achieving this aim, the study follows a procedure that allows the identification of all relevant elements and features of a last planner system, represents the system as an optimisation problem and integrate predictive strategies in one of the identified elements (constraint management). Section 1 presents a summary of the conceptualisation of the topic, and Section 2 analyses existing literature and discusses the gaps and limitations. Section 3 presents the flow for the proposed automated last planner system. Section 4 initialises a basis for integration of artificial intelligence and presents a representation of the problem mathematically. Section 5 showcases the predictive strategies and offers implementation and discussion of results. finally, Section 6 and 7 discusses the research outcomes, limitations and future works.

2 Literature Review

The last planner system (LPS) is a project control and scheduling system created in the early 90s by Glen Ballard [4]. Research highlights that LPS emerged by applying lean construction (LC) principles in construction projects. It is a system based on the need to enhance workflow reliability by field workers implementing the task specified in planning processes. Key elements of LPS identified from existing research include 1) collaborative planning, 2) constraint management, 3) hierarchy planning systems and levels, 4) pull planning, and 5) continuous improvement [1, 3, 2].

Challenges of LPS were first discussed expansively by Aslam et al., [7]. The shortcomings identified include the inability to manage project variability correctly, lack of visualisation of LPS capabilities, incorrect lookahead planning and many more [14]. However, The conceptual framework for integrated LPS included necessary features such as collaboration, constraint identification and communication methods, which led to increased collaboration, improved visualisation, risk analysis, continuous improvement, etc. The implemented digitised LPS also has shortcomings, even though it is digitised. These shortcomings include limited support and integration, lack of consistency in planning and scheduling, inadequate real-time information, data management challenges, and limited constraint management [2]. A comprehensively automated digital LPS is expected to improve efficiency in all processes and activities, enhance constraint management, allow real-time data analysis and visualisation, allow knowledge reuse and to improve collaboration and communication through streamlining processes and enhancement of information sharing.

Figure 1. Last planner transformation stages

Developing a workable automated planning system is predicated on identifying all required base elements that make the system automated, collaborative, and manage constraints. Automation, as identified in existing research, is indicated in 3 levels; the first level is research based on the digitisation of LPS systems as against the manual forms [4]; the second level is the research instances which developed linkages and union nodes for BIM and digitised LPS as an upgrade to overcome data homogeneity and enhance information sharing [15, 16, 12]; the third level is the point where predictive strategies and AI techniques are being integrated into digitised LPS platforms to aid automation and streamline processes. [2]

A review study by Agrawal et al. [1] identified several existing research where automated planning processes were categorised into master and phase scheduling, lookahead scheduling, weekly work planning and learning stage. Although the study excluded actual automation of planning and control in LPS, it systematically reviewed existing works. The research identified research works which presented automation in all three identified levels in Figure 1. Further reviews and classification of related works are summarised in Table 1.

Overall, the early research by Ballard [4] has since been transformed to become more encompassing from the manual linear scheduling methods to the digitised methods. Then, the digitised systems that link LPS with BIM are often integrated for automation, allowing for improved scheduling of activities and streamlining processes. Existing related research has focused on other specific applications and stages of projects but neglected the three core aspects of a functional LPS. This is the gap which this study seeks to cover. More specifically, automation in the Last Planner system has been applied mainly in performance evaluation. A framework or prototype of an integrated LPS system that considers all the factors and

features of an LPS system appears non-existent, motivating the need for this study.

3 Last planner system Automation

Project control and scheduling systems ensure the flow of work and control the progress and outcomes of the projects. As shown in Figure 2, a typical project will be guided by a developed master schedule, which serves as input detail to other scheduling stages, including phase scheduling, lookahead, weekly work scheduling and daily scheduling. Once the master schedule exists, LPS principles can be integrated into processes, including short-term planning and lookahead. Figure 2 contains the flow chart for logical automation of Last Planner systems.

3.1 Lookaheads

In lookahead plans or short-term plans, determining what tasks will be ready to start in a lookahead period is very important. It can be based on the probability that all tasks before this period are completed [27]. The probability of task completion can be calculated using historical productivity rates. Measuring the percentage of work completed (PPC) relative to the time spent on a similar previous task provides a more accurate estimate of productivity rates than relying on generalised project or organisational productivity rates, as suggested by Salama et al., [27]. Their method involves determining performance based on forecasted productivity rates (using linear regression) and the remaining quantity of work. However, this approach assumes that the same organisation's employees consistently perform the tasks across all projects, which is often untrue. In reality, various contractors frequently complete tasks, each contributing to different aspects of the work. This variability complicates accurately determining productivity rates, especially on-site, where numerous contractors are involved in diverse activities. Consequently, there is a pressing need to maintain detailed performance data so that individual contractors can evaluate their work completion speeds better.

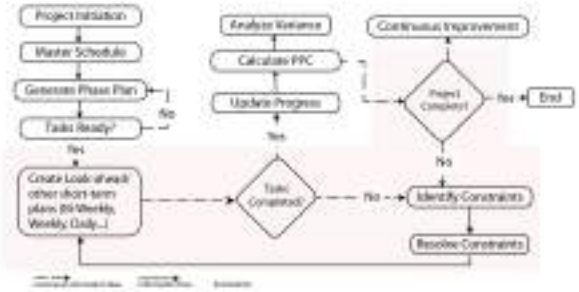

Figure 2. Proposed automated Last planner systems

4 LPS Aspects For AI Integration

As described already in equation 1, an LPS, on a fundamental basis, is a combination of three elements, which include collaboration, constraints and planning systems. This entities are further elaborated below;

AS in figure 3, the Project schedule contains a list of tasks (LT) detailing the following features: Task Name TN_1 .. TN_n, a unique identifier for each task. Location L_i .. L_n, the location identifier for each task. Trade: CT_i .. CT_n, the construction trade responsible for each task. Scheduled start and end dates: $t_{s,i}$ and $t_{e,i}$ for tasks TN_i, Duration: $D_{t,i} = t_{e,i} - t_{s,i}$, the duration of each task.

Constraint Table (CN) contains project constraints and their features: Constraint Name C_i .. C_n, a unique identifier for each constraint. Location L_i .. L_n, location identifier where the constraint exists. Trade CT_i .. CT_n, the trade associated with the constraint. Commitment start and end dates cts_i and cte_i. Constraint resolution time $D_{c,i} = cte_i - cts_i$, the time to resolve the constraint. finally, the tables LT and CN are linked through the linked task names, which associates constraints with corresponding tasks (TN_i).

Problem Definition

Given the tables LT and CN, we aims to optimize the inclusion of tasks ($TL \subset LT$) into a specified Lookahead Period (LAP). The goal is to dynamically determine an optimal subset of tasks while resolving associated constraints and efficiently allocating resources, subject to the following conditions:

- Binary Decision Variables (x_i); $x_i = 1$ if task i is included in the Lookahead Task List (TL), and $x_i = 0$ otherwise.
- Tasks left with status (ready) are well-defined for scheduling.
- All constraints are valid and removed for tasks ready for scheduling.
- The Lookahead Period is defined by the Lookahead Start Time (LAT_{start}) and Lookahead End Time (LAT_{end}).
- Tasks and constraints are resolved and aligned with resource availability and stakeholder collaboration.

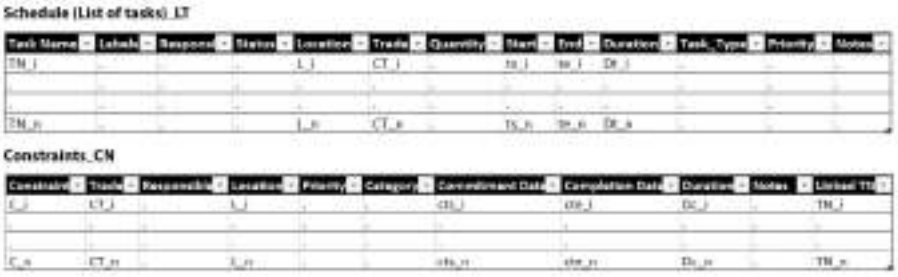

Figure 3. Standard Data-frame of the schedules and constraints entities.

Objective Function

As given in the problem definition, the objective function Z is to find the tasks TL in LT, which maximises Z.

amax Z =

$$\sum_{i \in \mathrm{TL}} w_i \cdot x_i \cdot D_{t,i} - \lambda_1 \cdot \mathrm{Pen}_{\mathrm{cons}} - \lambda_2 \cdot \mathrm{Pen}_{\mathrm{colab}} \tag{2}$$

Where w_i is priority weight for all tasks i (i.e., high = 3, medium = 2, low = 1), $D_{t,i}$ is duration of all tasks x_i, $\mathrm{Pen}_{\mathrm{cons}}$ is penalty for unresolved constraints and $\mathrm{Pen}_{\mathrm{colab}}$ is penalty for unresolved collaboration conflicts. Z is subject to the PS constraints, CN constraints, CB constraints and dynamic updates.

Schedule PS: This entity entails planning for different projects at all levels. Here, the critical dependencies, sequences, lookahead and buffers are represented accordingly.

- Task Dependency Constraint: tasks must satisfy their dependencies before being included in TL.

$$ts_i \geq te_j, \quad \forall (j \rightarrow i) \text{in dependencies.} \tag{3}$$

- Lookahead Time Period Constraint; Only tasks whose durations overlap with the Lookahead Period ($\mathrm{LAT}_{\mathrm{start}}$ to $\mathrm{LAT}_{\mathrm{end}}$) are considered

$$t_{s,i} \geq \mathrm{LAT}_{\mathrm{start}}, \quad t_{e,i} \leq \mathrm{LAT}_{\mathrm{end}} \tag{4}$$

- Lookahead Duration Constraint; The total duration of selected tasks must not exceed the Lookahead Duration (LAD)

$$\sum_{i \in \mathrm{TL}} x_i \cdot D_{t,i} \leq \mathrm{LAD} \tag{5}$$

- Buffers: This justifies the necessary lack of periods needed for selected tasks.

$$t_{e,i} + \mathrm{buffer}_i \leq t_{s,j}, \quad \forall (i \rightarrow j) \tag{6}$$

Constraints CN: This entity manages issues and emerging risks to enhance quicker constraint resolutions by teams and domains for different projects. Sometimes, tasks are usually hard-constrained. However, this component is primarily controlled by responsible persons. Sometimes, the impediment may be forced removed or managed to get the task completed. In the event of force removal or manoeuvres, the system should be updated to ensure the continuous correctness of scheduled tasks.

- Status constraint; The status constrain represents the readiness indicator for each task x_i, we introduce a binary variable R_i:

$$R_i = \begin{cases} 1, & \text{if all constraints for task } x_i \text{ are resolved} \\ 0, & \text{otherwise} \end{cases}$$

- Resource Constraint; To ensure that the selected tasks do not exceed resource limits for materials M and workers W.

$$\sum_{i \in \mathrm{TL}} x_i \cdot m_i \leq M_{\mathrm{available}} \tag{7}$$

$$\sum_{i \in \mathrm{TL}} x_i \cdot w_i \leq W_{\mathrm{available}} \tag{8}$$

- Space Constraint (S): Only tasks with available space for the job are marked ready to be scheduled. i.e available workspace $S_(avail)$ must be sufficient for the selected tasks.

$$\sum_{i \in \mathrm{TL}} x_i \cdot S_i \leq S_{\mathrm{avail}}, \quad \forall t \in [\mathrm{LAT}_{\mathrm{start}}, \mathrm{LAT}_{\mathrm{end}}] \tag{9}$$

Collaboration CB: This entity represents communication and cooperation among teams (planners, quality, design, engineering, supply chain, etc.) and domains to pre-empt and resolve potential conflicts and plan for projects to withstand emerging risks.

For a given project schedule PS, $N_i k$: Notes in LT and CN tables are associated with task x_i and constraint vector k. $CN_i k$: The k-th constraint vector in the constraint table.

The collaborative conflict for the Lookahead task list (TL) is defined as:

$$\mathrm{Pen}_{\mathrm{colab}} = \sum_{i \in \mathrm{TL}} \sum_{s} x_i \cdot (CN) \cdot \alpha(N_{i,k}) \tag{10}$$

Other than constraint CN, Each constraint type (e.g., safety, design, quality) is explicitly modelled as a separate binary

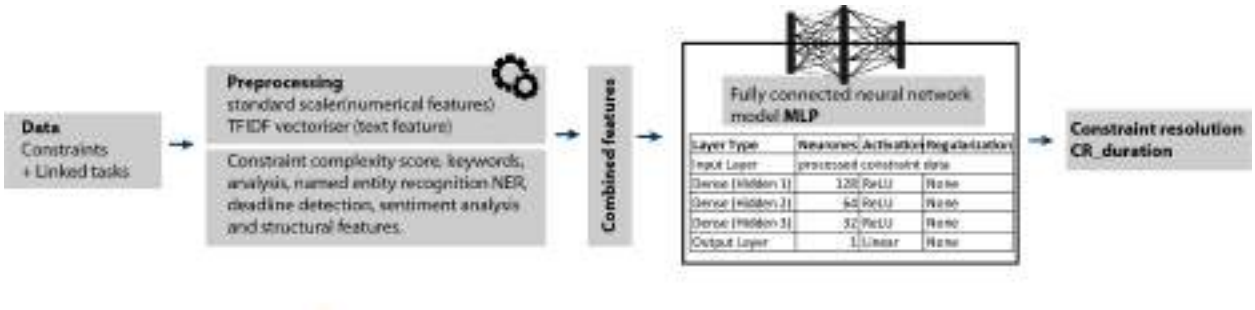

Figure 4. Model Architecture - Fully connected neural network

variable $Sf_{i,k}$ safety for task x_i:

$$Sf_{i,k} = \begin{cases} 1, & \text{if constraint of type } k \text{ for task } i \text{ is resolved} \\ 0, & \text{otherwise} \end{cases}$$

Dynamic Updates

At each time change t of a project, there are consequent changes in the amount of work completed, PPC, constraints, and communication, as these entities are not static but usually evolving. Based on this, the updated Lookahead plan must evolve. Hence, we perform rolling updates for every new iteration as the final constraint to the objective function:

$$\mathrm{LAT}_{\mathrm{start}}^{(t+1)} = \mathrm{LAT}_{\mathrm{end}}^{(t)} + \Delta T \tag{11}$$

Recompute lookahead plan task list TL dynamically. TL accuracy lies in the accuracy of the data that is fed into the process.

$$TL_{accuracy} \simeq \begin{array}{ll} Pr(y_1)=1 & \text{if upcoming tasks;} \\ CN_{x_i}=0 & \text{no constraint exist;} \\ Pr(x_n)=1 & \text{if previous tasks;} \end{array}$$

where x_n are work tasks x_i before specific lookahead interval and y_1 are WTs within the lookahead or short-term interval. The performance indication will then be the range of deviation of actuals from planned, estimated or predicted values.

5 Implementation

As illustrated in Figure 5, advanced deep learning techniques, including Table Parsing (TaPas), deep implicit layers, self-querying mechanisms, and large language model (LLM) frameworks such as Retrieval-Augmented Generation (RAG), represent pivotal architectures for enabling the digital integration and automation of the Last Planner System (LPS) [28, 29, 30, 31].

5.1 Deep learning for ALPS

Deep learning DL, a subset of machine learning, utilises advanced architectures such as Convolutional Neural Networks (CNNs) and Recurrent Neural Networks (RNNs) to process and generalise complex data with high accuracy [32]. These models, known for scalability and pattern recognition, are well-suited for enhancing project control and scheduling within frameworks like the Last Planner System as indicated in Figure 5. Also, deep implicit layers, which are an ordinary differential equation technique that is able to represent constant changes and understand multi-level reasoning as needed in an automated last planner system (ALPS), would be crucial for automation. It is noted that complex problems such as one represented in Section 4, can be crunched into a single fixed iteration formula, which can then guide LLMs to make feasibility and multilevel reasoning solutions [33].

5.2 RAG for ALPS

Retrieval-augmented generation (RAG) enhances LLMs by integrating data from external databases, enabling more accurate and context-aware outputs. RAG operates through three interconnected modules: the retriever, retriever fusion, and generator[34]. RAG techniques are particularly effective for automating text summarisation, question answering, information extraction, text classification, etc. In the context of ALPS, RAG can significantly enhance processes by enabling constraint classification, automating notifications and communication categorisation, and summarising extensive text data. This integration offers a powerful tool for streamlining complex workflows and improving project management efficiency.

Figure 5. LPS - AI integration

Figure 6. Sample of Constraints; Highlighting keywords, date and NER

5.3 Towards ALPS: Constraint Resolution prediction

The potential for improved augmentation can be significantly enhanced through the integration of predictive strategies in digitised LPS, and the aspects that this integration can impact are enormous. In terms of application, we only looked at ascertaining the resolution duration for constraints, which is an integral aspect of ALPS.

5.3.1 Data

VisiLean, a major cloud-based construction management software, supplied constraint and schedule data for major ongoing projects. Facts and details of the project are withdrawn for privacy reasons. A total of 173 constraints of a large multi-stage developmental project are contained in the dataset, and the data is framed as in Figure 3 and analysed. A sample of the constraint and notes can be seen in Figure 6.

5.3.2 Process

To build a model that predicts constraint resolution duration, we used the constraint dataset. This data was analysed using a cloud-based Python IDE called Collab. First, preliminary data preprocessing was carried out to understand the essential features needed for the model. The unnecessary columns in our dataset were dropped, and constraint resolution duration for all constraints was calculated by determining the duration between the date of constraint resolution and the date of constraint creation. As indicated in Table 2, complexity score, which depicts the difficulty level of a constraint, was determined using keywords, named entity recognition NER, deadline detection, sentiment analysis and structural features, including the length of constraints. After this, both textual and numerical columns were preprocessed. This step regularised the dataset for accurate model training purposes. The final set of features used for training these models includes TDIF vectorisation of combined textual data (Constraint title, description, notes and linked tasks), priority, and Trades. The model architecture is indicated in Figure 4. Afterwards, the created model was evaluated and accessed in the following section. The model is simplified with reduced layers, removed dropouts, and batch normalisation to allow the model to map the complexity of the small datasets fully. Epoch was set to 50, and batch size was reduced to 4 to optimise weight updates and better utilize limited data.

Table 2. Complexity score calculation

Feature	Summary
NER	This recognises named entities via SpaCy
Keywords	keywords are classified based on complexity -critical and mild
Sentiment Analysis	Scoring based on perceived negativity or positivity.
Structure	Words depicting dependencies signifies complexity eg and, but etc.
Length combined	Length of character of the combined textual data
Presence of dates	dependency, date or deadline count
Counts of keywords	Number of keywords, dependencies per constraints

6 Results

The results of the fully connected neural network model are shown in Table 3. The model predicts constraint resolution duration, and the output is explained here. The average duration error or variance for each of the test instances was determined as 23.18 days (MAE), and the standard deviations of each of the error instances in our datasets, indicating effectively the deviation of the actuals from the target variable is 30.12 days (RMSE).

Table 3. Fully connected neural network results

Model	MAE	MSE	RMSE
Neural Network (MLP)	23.18	907.22	30.12

Figure 7 indicates the results plot. These plots, the RMSE and MAE values, indicate that the model overall might not be fully capturing the patterns in the data. Although the target variable is a variable with increased variability and the dataset size is small, the model will keep improving as it is trained on more data. The model can help automate the last planner system as it will assist in pre-empting when constrained jobs can be rescheduled or included in certain lookahead

Table 4. Error comparison using other models

Model	MAE	MSE	RMSE
SVR	21.78	935.93	30.59
LightGBM	23.43	1048.46	32.38
Random Forest	24.06	1108.12	33.29

7 Discussions and Limitations

In further discussion and comparison of the results in Tables 3 and 4, it was discovered that the support vector regression SVR achieves a slightly lower MAE of 21.78 days but exhibits a comparable RMSE of 30.59 days, indicating that SVR has a lower deviation from the ideal when compared with neural network model. On the other hand, the lightGBM and random forest models display higher absolute error values (MAE: 23.43 and 24.06 days), suggesting that they are unable to map the patterns in the data as much as SVR or the Neural network model. This higher error variability is also replicated in the RMSE values, indicating that neural network models perform relatively better. Although SVR is not completely outperformed in terms of MAE by the neural network model, the neural network model maintains a competitive RMSE, signigfiying its ability to generalise despite the small dataset and variability in target

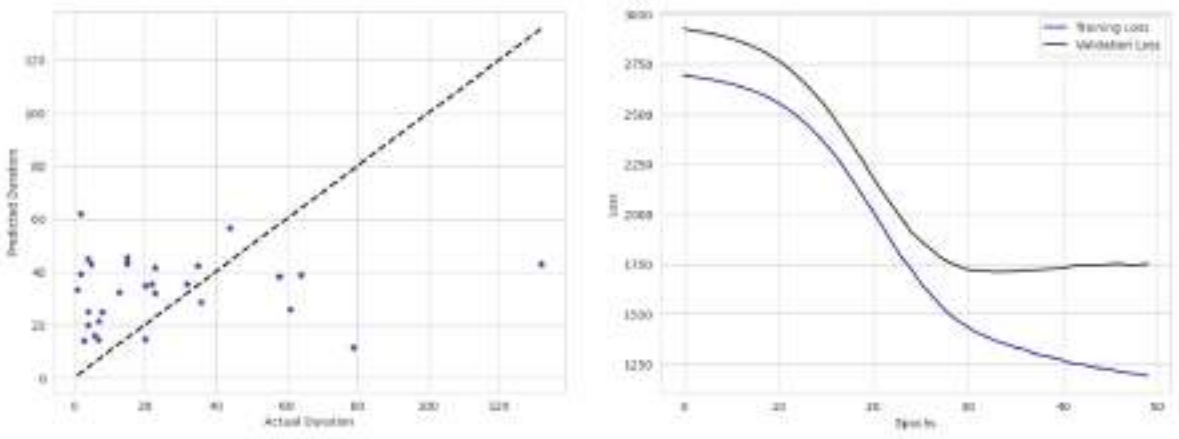

Figure 7. Plot of constraint-resolution-duration actuals and prediction compared with ideal prediction line. Validation loss and loss plot indicates the efficiency at which the model learns.

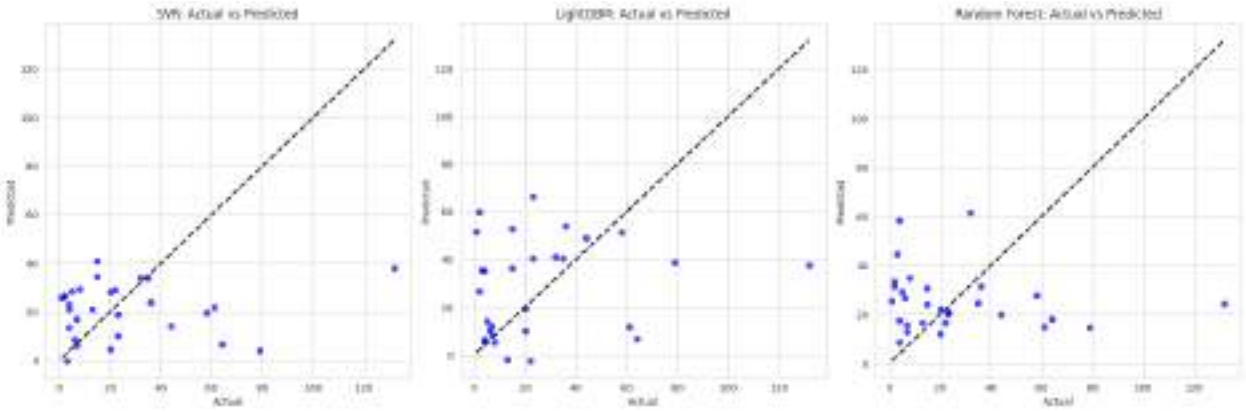

Figure 8. support vector regression SVR, LightGBM, and Randomforest Plot of constraint-resolution-duration actuals and prediction compared with ideal prediction line.

variable. Furthermore, as the dataset expands, the neural network has greater potential for improvement through training and hyper-parameter tuning. The plots in Figures 7a and 8a showcases the prediction of each constraint instance to the ideal with specific improvement in predictions especially when plots of both neural network and SVR are weighed side by side.

While this work highlighted the core aspects of LPS where automation can be applied, the potential for automated constraint management systems, automated collaborative systems, and automated scheduling systems all integrated into one system will increase the efficiency and accuracy of the Last Planner system. To initiate this ambitious research concept, the study conceptualized the system as an optimization problem, which can be reformulated into a fixed iterative equation, such as a gradient descent operation. This equation can subsequently be integrated as a constraint within a large language model (LLM) to facilitate the generation of accurate semantic queries and the determination of feasible solutions for lookahead scheduled tasks. Secondly, an analysis of constraint data of major ongoing projects to determine constraint or conflict resolution time will be handy in quick insight generation and accuracy of Lookahead tasks. However, certain limitations were evident throughout the study.

- The dataset revealed several instances where the creation_date and committed_date occurred after the completion date, presenting a distorted representation of the actual outcomes. This discrepancy primarily arises from the fact that actual data inputs are often recorded not for process improvement or performance evaluation but rather merely to fulfil reporting requirements. Such limitations hinder the model's ability to generalise effectively over the training dataset, as many data inputs exhibited either zero

or negative values for constraint resolution time.
- The available dataset was relatively small in size. In cases involving larger datasets, the model would likely demonstrate improved predictive capability regarding constraint resolution durations, thereby minimising associated errors.
- The textual data utilised in the analysis, which includes fields such as Constraint_title, Description, Notes, and Linked_tasks, exhibited a variety of named entities and structural inconsistencies. These variations complicated the analysis of constraint complexity and hindered the appropriate feature engineering necessary for enhancing model accuracy.

7.1 Recommendations and Implications for Practitioners

While the ideas presented in this research are still evolving, they can be viewed as an augmentation of the Last Planner System (LPS) rather than a complete automation of last planners. This is reflected in the title: Towards Automation of the Last Planner System. The first concept focuses on optimizing the scheduling management system to categorize the most suitable list of tasks for specific look-ahead periods while considering existing constraints and communication dynamics. Although the optimization was evaluated mathematically, the proposed LPS-AI framework suggests employing methods such as Retrieval-Augmented Generation (RAGs), TAPAS, Deep Implicit Layers, Deep Learning, and self-querying to automate the entire Last Planner System.

The second concept involves predicting constraint resolution durations. This predictive model assists in determining the period within which specific constraints will be resolved. As a result, it facilitates the scheduling of optimized look-ahead tasks by providing foresight into constraint resolution timelines. Traditionally, in the absence of such models, planners and foremen have had to replan and reschedule tasks at the beginning of each work period due to their inability to anticipate constraint resolution times, thereby losing valuable productive work hours.

Although the target variable exhibits high variability and the dataset is currently limited, the model is expected to improve as it is trained on more data. By preemptively identifying when constrained tasks can be rescheduled or incorporated into specific look-ahead plans, this model contributes to automating the Last Planner System and enhancing workflow efficiency

7.2 Future Work

Overall, the limitations are pointers to what must be done to achieve either an augmented system or a self-sufficient system that can rely on information at hand to generate accurate lookahead schedules for desired periods. The quality of the generated actual data is very important, and a structured list of possible constraints and tasks should be adhered to. This will help analysis and integration easily. While the problem is dynamic, as highlighted in the definition of the optimisation problem, constrained iterations with implicit and explicit functions would be coded into an LLM as constraints for outputs in a RAG structure to improve and augment the existing LPS. Also, improved research on table parsing (TAPAS) to map and understand complex linked tables with several rows would advance the possibility of augmentation of last planner systems.

8 Conclusion

This research highlights the potential for automating the Last Planner System (LPS) by integrating advanced AI techniques to enhance constraint management, scheduling, and collaboration. Rather than aiming for full automation, the proposed framework augments the Last Planner System by optimizing lookahead scheduling and predicting constraint resolution durations. By framing LPS as an optimization problem, this study explored the use of deep learning, Retrieval-Augmented Generation (RAG), Large Language Models (LLMs), and predictive modeling to improve decision-making and efficiency.

One key contribution of this research is the introduction of a predictive model that estimates constraint resolution durations, thereby enabling more proactive scheduling of lookahead tasks. Traditionally, foremen and planners face challenges in anticipating when constraints will be resolved, leading to frequent replanning and inefficiencies. By leveraging AI-driven predictions, this study lays the foundation for reducing uncertainty and minimizing lost productive hours.

Despite its promise, limitations such as dataset inconsistencies, small sample sizes, and challenges in complex table parsing highlight areas for further development. To overcome these challenges, future research should focus on refining the optimization representation into a constrained iterative framework, embedding implicit and explicit functions into LLM structures for better integration within RAG architectures. Additionally, improving structured data collection processes and enhancing table parsing techniques (e.g., TAPAS) will be critical in augmenting LPS capabilities.

By addressing these gaps, this research paves the way for an AI-augmented Last Planner System that enhances construction workflow efficiency, improves predictability, and ultimately transforms project planning in complex, dynamic environments.

Abstract -

Automated crack detection plays a critical role in infrastructure maintenance and safety assessment. The detection and segmentation of concrete and pavement cracks present substantial technical challenges. These challenges stem from the inherent complexity of crack morphology, environmental lighting variations, and the textural similarities between cracks and their surrounding surfaces. In this paper, we introduce a novel segmentation algorithm named EA-YOLOv8 to address two critical gaps in current crack detection techniques. The first gap involves limited spatial information utilization. To solve this, we integrate the Efficient Local Attention (ELA) mechanism into the YOLOv8 architecture's Bottleneck structure. ELA enhances spatial feature extraction without compromising computational efficiency or channel information. This approach directly tackles the challenge of precise crack localization. The second gap relates to imprecise crack boundary detection. We develop an adaptive region-specific loss (ARS loss) that specifically targets the complexities of crack edge delineation. Traditional loss functions often fail to capture the nuanced boundaries of microscopic cracks. Experimental validation of EA-YOLOv8 was conducted on the Roboflow crack dataset. Through ablation studies and baseline comparisons with YOLOv5, YOLOv8, and the latest YOLOv11, the experimental results show the superior performance of EA-YOLOv8. In terms of results, EA-YOLOv8 improved precision by 10% compared to YOLOv5 and the latest YOLOv11, and increased precision by 5% over the original YOLOv8. These experimental findings validate the theoretical framework and practical applicability of our proposed EA-YOLOv8 in crack detection scenarios.

Keywords -

Crack segmentation; YOLOv8; Efficient local attention; Adaptive region-specific loss

1 Introduction

Infrastructure has experienced extensive environmental erosion and service load increases during recent decades. These factors significantly impact structural safety throughout the infrastructure lifecycle. Concrete and pavement cracks represent fundamental indicators of structural health conditions [1]. Precise and timely crack detection remains essential for infrastructure maintenance and public safety assurance.

*Corresponding author

The advancement of inspection technologies has transformed crack detection methodologies. Manual inspection methods maintain widespread application but exhibit limitations in labor requirements, time consumption, and subjective variations [2]. The integration of optical technologies with deep learning algorithms provides enhanced automated solutions for crack detection [1, 3]. While YOLO networks have shown potential in crack detection, existing methods still struggle with fundamental limitations [4, 5].

The primary challenges in current crack detection techniques include: Crack morphology presents extreme complexity. Cracks exhibit irregular patterns with dramatic variations in width and length, making feature extraction highly difficult [2, 6]. Most existing deep learning models fail to capture the nuanced characteristics of these structural irregularities.Background and crack region imbalance creates significant segmentation challenges. Current algorithms struggle to distinguish subtle crack boundaries from surrounding surface textures. This limitation leads to inaccurate detection, especially in regions with complex surface conditions. Boundary detection precision remains a critical weakness. Existing models typically cannot accurately delineate crack edges, particularly in areas with minimal contrast or complex surface textures.

To address these critical gaps, we developed EA-YOLOv8, an advanced segmentation algorithm with two key innovations. First, we integrated the Efficient Local Attention (ELA) mechanism to improve spatial feature recognition. ELA enables more precise crack localization by dynamically distributing attention weights across different image regions. This approach overcomes the traditional limitations in feature extraction. Second, we designed an Adaptive Region-Specific Loss (ARS loss) function specifically targeting crack boundary detection challenges. This innovative loss function enhances the model's ability to differentiate crack edges from background regions during training. By focusing on the most challenging detection areas, ARS loss significantly improves edge detection precision.

Experimental validation on the Roboflow crack dataset demonstrates the substantial improvements of EA-YOLOv8. Compared to existing methods, our approach increased precision by 10% over YOLOv5 and the latest YOLOv11, and improved performance by 5% compared to the original YOLOv8. These results validate the theoretical contributions and practical utility of our method in infrastructure crack detection.

2 Related Work

Advancements in deep learning has created substantial opportunities in complex detection tasks. Its application in crack detection demonstrates extensive implementation and profound impact. The field has witnessed numerous research achievements that establish the foundation for technological progression.

N.A.M. Yusof et al. [1] implemented convolutional neural network (CNN) methodologies for concrete crack classification. Their research validated the discriminative capabilities of deep learning in crack detection applications. Liu et al. [2] developed an enhanced deep convolutional neural network incorporating deep supervision mechanisms. This approach addressed segmentation accuracy limitations in complex environments and improved fine crack detail capture. Hassan Hosseinzadeh et al. [3, 7] utilized the YOLOv5 framework for pavement crack detection and segmentation. Their methodology achieved precise crack characterization while maintaining computational efficiency, addressing practical requirements in road maintenance applications. Similarly, Yin et al. [7, 8] implemented the YOLOv3 network for automated defect detection in municipal drainage systems. Their system detected six types of defects including cracks, achieving a mean average precision of 85.37%. This work demonstrated the practical application of deep learning in infrastructure maintenance, particularly for sewer pipe inspection where thousands of kilometers of CCTV footage require analysis. Some recent research has focused on minimizing the annotation burden for sewer defect detection [9, 10]. For example, a framework utilizing weakly supervised object localization for automated sewer defect detection was developed by Yin et al. [10], achieving high localization accuracy while requiring minimal annotation effort compared to traditional supervised approaches.

Current deep learning models exhibit specific limitations in crack detection applications. These limitations manifest in edge detection precision and fine-grained segmentation capabilities, particularly when processing irregular crack morphologies and complex background conditions. Crack characteristics, including width variations, morphological complexity, and environmental interactions, present significant challenges for accurate boundary delineation and feature extraction. Addressing annotation challenges in infrastructure inspection, Yin et al. [9] applied Weakly Supervised Object Localization (WSOL) for sewer defect detection using only image-level labels. Their approach achieved mean MaxBoxAccV2 scores of 64.33% with ResNet-50 backbone and established a benchmark for weakly supervised learning in infrastructure applications, eliminating the need for labor-intensive bounding box annotations while maintaining high classification accuracy.

Research efforts focus on architectural optimization strategies to address these technical limitations. Xiang et al. [7, 11] integrated Transformer modules into YOLOv5 architecture. The self-attention mechanism enhanced long-range dependency capture and contextual understanding within crack regions, expanding model detection capabilities. Dong et al. [4, 7] incorporated the Convolutional Block Attention Module (CBAM) into YOLOv5. This modification enabled adaptive attention distribution across feature dimensions, improving crack feature focus while reducing background interference. Liu [1] enhanced the DeepLabV3+ network through Dual Attention Module integration and HDD loss implementation. These modifications strengthened feature emphasis and optimized edge detection performance, advancing crack detection methodologies.

Contemporary research demonstrates that architectural enhancement through specialized modules and loss functions represents an effective approach for performance improvement. This study implements the Efficient Local Attention (ELA) mechanism [12] and Adaptive Region-Specific Loss (ARS loss) [11] within the YOLOv8 framework. Systematic ablation experiments validate the model's effectiveness. The research provides enhanced solutions for crack detection applications, contributing to technological advancement in this domain.

3 EA-YOLOv8

3.1 Overview

To improve the performance of crack segmentation, we introduce two architectural improvements to YOLOv8. The first modification integrates the Efficient Local Attention (ELA) mechanism into the C2F module. This integration creates the C2ELA module for crack feature extraction enhancement. The second modification implements Adaptive Region-Specific Loss (ARS loss) within the segmentation component. ARS loss operates in conjunction with BCE Loss for crack boundary localization. These improvements enhance the segmentation performance of the base architecture. Figure 1 depicts the architecture of the proposed EA-YOLOv8 framework.

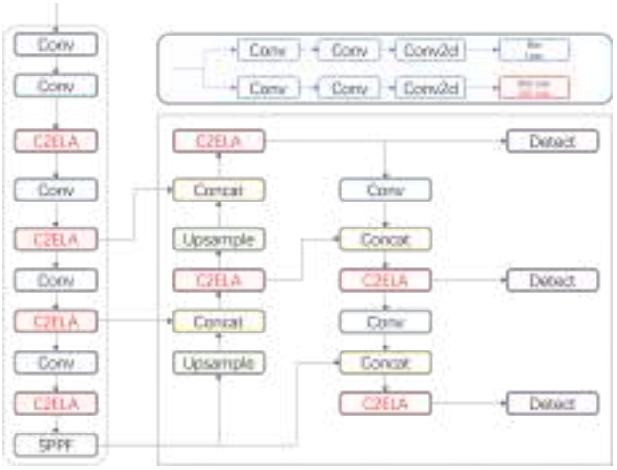

Figure 1. The network architecture of EA-YOLOv8

Figure 2. The structure of Efficient Local Attention.

3.2 Efficient Local Attention (ELA)

We introduce the operational mechanisms of ELA (Efficient Local Attention) for crack recognition in this section. Figure 2 illustrates the structural architecture of ELA. ELA utilizes strip pooling operations for coordinate information extraction. The pooling process extracts horizontal and vertical features from input feature maps. This directional processing method enables orientation-specific pattern recognition. Crack features demonstrate distinct directional properties. The coordinate extraction mechanism captures feature variations along crack extension directions. This process establishes detailed morphological analysis capabilities.

The architecture deploys 1D convolution for bidirectional positional enhancement. Unlike standard 2D convolutions that process pixels in all directions simultaneously, 1D convolution works like a signal filter that processes information along a single dimension (either horizontal or vertical). This approach is similar to how radar systems scan in specific directions to detect objects. 1D convolution has demonstrated computational efficiency advantages over 2D convolution operations, requiring fewer calculations while still capturing essential directional information. This convolution method integrates directional features and maintains spatial continuity information, helping the model "connect the dots" when detecting elongated crack structures.

ELA incorporates Group Normalization (GN) [13] for feature distribution stabilization. In simple terms, GN works like adjusting the contrast of different parts of an image separately to ensure all important details remain visible regardless of lighting conditions. Environmental factors in crack images introduce feature value variations. These factors include illumination conditions and background complexities. GN [13] executes group-based feature normalization procedures. This normalization method reduces environmental interference effects. The stabilized feature distributions support consistent pattern recognition during model training.

The integration of ELA into YOLOv8's architecture is implemented by replacing the C2f modules with our proposed C2ELA modules. The bottleneck structure in YOLOv8's C2f module performs feature extraction operations through convolutional processing and residual connections. Our implementation embeds the ELA mechanism within this Bottleneck structure according to the following steps:

- We initialize the model with pretrained YOLOv8 weights from Ultralytics.
- The bottleneck components within C2f are identified and modified to include ELA.
- Each bottleneck module processes the input through a 1×1 convolution to reduce channel dimensions.
- The ELA placement occurs after these convolutional layers but before the residual connection.
- The output from ELA is then passed through another 1×1 convolution to restore channel dimensions.
- Finally, a residual connection adds the original input to the processed features.

This architectural arrangement optimizes feature processing capabilities for crack detection. Figure3 presents the C2ELA module configuration. The structural integration combines ELA and Bottleneck functionalities, enhancing the model's ability to capture the distinctive direc-

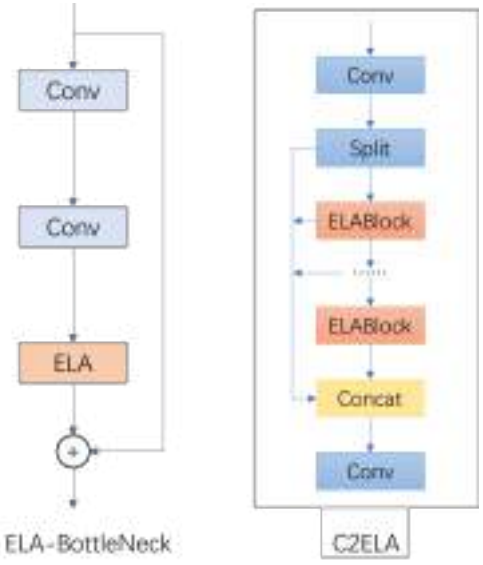

Figure 3. The structure of C2ELA.

tional patterns of cracks while maintaining computational efficiency.

3.3 Adaptive Region-Specific (ARS) Loss

We propose the Adaptive Region-Sensitive Loss (ARS-Loss) mechanism, which employs Tversky Loss [14] for sub-region computation. This approach surpasses traditional Dice Loss limitations through parameters α and β, which regulate false positive (FP) and false negative (FN) penalties. The formulation is expressed as:

$$L_{Tversky} = 1 - \frac{\sum_{i \in V} p_i \cdot g_i + \varepsilon}{y} \quad (1)$$

$$y = \sum_{i \in V} p_i \cdot g_i + \alpha \sum_{i \in V} p_i (1 - g_i) + \beta \sum_{i \in V} (1 - p_i) \cdot g_i + \varepsilon \quad (2)$$

The equation incorporates specific variables: p_i represents pixel-wise crack probability prediction, g_i denotes corresponding ground truth labels, V specifies the sub-region pixel set, and ε maintains numerical stability.

The core innovation of ARS-Loss lies in its adaptive parameters that evolve according to regional error distributions through:

$$\alpha_{\text{Adaptive}} = A + B \cdot \frac{FP}{FP + FN} \quad (3)$$

$$\beta_{\text{Adaptive}} = A + B \cdot \frac{FN}{FP + FN} \quad (4)$$

The ARS-Loss implementation follows a systematic procedure integrated with the YOLOv8 framework:

1) Forward Pass and Feature Extraction: Input images are processed through the YOLOv8 backbone and neck, generating feature maps at different scales.

2) Segmentation Head Processing: The segmentation head transforms the feature maps to produce prediction probability maps $P \in \mathbb{R}^{H \times W}$, where each pixel value $p_i \in [0, 1]$ represents the probability of belonging to the crack class.

3) Region Subdivision: Both prediction maps and ground truth labels are subdivided into a regular grid structure of 16×16×16 (width × height × channels) sub-regions. This subdivision is implemented as follows:

a. For an input of size $H \times W$, we compute region dimensions $r_h = H/16$ and $r_w = W/16$

b. Each sub-region $R_{m,n}$ covers pixels from indices $(m \cdot r_w, n \cdot r_h)$ to $((m+1) \cdot r_w - 1, (n+1) \cdot r_h - 1)$

c. The grid structure creates 256 sub-regions, enabling localized error analysis

4) Sub-region Error Analysis: For each sub-region $R_{m,n}$, we compute:

a. False Positives (FP): $\sum_{i \in R_{m,n}} p_i \cdot (1 - g_i)$

b. False Negatives (FN): $\sum_{i \in R_{m,n}} (1 - p_i) \cdot g_i$

c. True Positives (TP): $\sum_{i \in R_{m,n}} p_i \cdot g_i$

5) Adaptive Parameter Calculation: For each sub-region $R_{m,n}$, the adaptive parameters are calculated as:

a. $\alpha_{m,n} = 0.3 + 0.7 \cdot \frac{FP_{m,n}}{FP_{m,n} + FN_{m,n}}$

b. $\beta_{m,n} = 0.3 + 0.7 \cdot \frac{FN_{m,n}}{FP_{m,n} + FN_{m,n}}$

6) Sub-region Loss Computation: The Tversky loss for each sub-region is calculated using the region-specific adaptive parameters:

$L_{Tversky} = 1 - \frac{\sum_{i \in V} p_i \cdot g_i + \varepsilon}{y}$

$y = \sum_{i \in V} p_i \cdot g_i + \alpha \sum_{i \in V} p_i (1 - g_i) + \beta \sum_{i \in V} (1 - p_i) \cdot g_i + \varepsilon$

7) Total Loss Aggregation: The overall ARS-Loss is computed as the mean of all sub-region losses:

$L_{ARS} = \frac{1}{256} \sum_{m=0}^{15} \sum_{n=0}^{15} L_{m,n}$

8) Loss Integration with YOLOv8: The ARS-Loss is integrated with the standard YOLOv8 loss components:

$L_{total} = \lambda_{box} \cdot L_{box} + \lambda_{cls} \cdot L_{cls} + \lambda_{ARS} \cdot L_{ARS}$

where $\lambda_{box} = 0.05$, $\lambda_{cls} = 0.5$, and $\lambda_{ARS} = 1.0$ are weighting coefficients determined through ablation studies to balance the different loss components.

9) Backpropagation and Weight Update: During the backward pass, gradients are computed with respect to the total loss. The adaptive nature of ARS-Loss ensures that regions with higher FP receive stronger penalties for false positives (higher α), while regions with higher FN receive stronger penalties for false negatives (higher β). This region-sensitive adaptation guides the model to focus on challenging areas with imbalanced error distributions.

The implementation of ARS-Loss starts with the pre-trained YOLOv8 model (weights from Ultralytics) and modifies the loss computation module while maintaining

the original network architecture. This approach requires minimal changes to the YOLOv8 framework, making it easily applicable as a drop-in enhancement for crack segmentation tasks.

The region-sensitive methodology enhances feature discrimination capacity and crack boundary detection precision by dynamically adjusting penalties based on local error characteristics. This is particularly effective for thin crack structures where traditional global loss functions often struggle to provide sufficient gradient signals.

4 Experiments

4.1 Dataset and Implementation details

The experimental dataset consists of the Roboflow Crack Segmentation Dataset. Roboflow developed this public dataset for traffic and infrastructure safety research applications. The dataset incorporates 4,029 static images from road and wall environments. Each image contains pixel-level annotations. The image collection represents multiple infrastructure conditions and crack characteristics. The dataset supports comprehensive safety analysis tasks.

The research implementation adopts Roboflow's original data organization. The dataset division follows the provided training, testing, and validation partitions. Table 1 specifies the image distribution across these subsets.

Table 1. The dataset splitting of Roboflow Crack Segmentation dataset.

Dataset	Roboflow Crack Seg
Train	3717
Validation	200
Test	112

All experiments are conducted with an NVIDIA GeForce RTX 4070 GPU (12GB VRAM). The model is implemented with PyTorch[1] 2.4.1 framework running on CUDA 12.6. Additional libraries include NumPy 1.26.3 for numerical operations and Ultralytics for YOLOv8 implementation. All experiments are conducted with Python 3.10.14. The model initialization incorporates YOLOv8s-seg pre-trained weights from Ultralytics. The training configuration is concluded in Table 2.

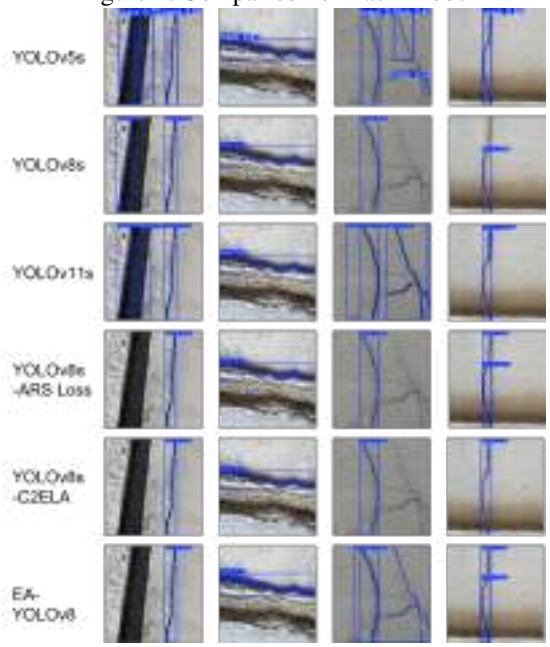
5 Results and Discussion



This investigation was executed utilizing the Roboflow dataset corpus. Our methodology encompasses a systematic evaluation between EA-YOLOv8 and preceding YOLO variants: YOLOv5, YOLOv8, YOLOv11, ELA-YOLOv8, and ARS-YOLOv8. The architectural design of ELA-YOLOv8 incorporates the ELA attention mechanism explicitly for feature extraction augmentation. The ARS-YOLOv8 framework implements the ARS loss function specifically for optimization procedures. Statistical metrics were acquired through methodological validation protocols. The empirical results, as documented in Table 3, elucidate the comparative analysis. The novel EA-YOLOv8 architecture, synthesizing the ELA attention mechanism and ARS loss function, manifests enhanced detection efficacy compared to singular-component implementations.

The experimental evaluation compares EA-YOLOv8 with the YOLOv5 baseline model. EA-YOLOv8 exhibits performance enhancements across evaluation metrics. YOLOv5 achieves baseline performance with 0.75592 precision and 0.68675 recall. YOLOv11, despite being the most recent architecture in the YOLO family, achieves 0.75672 precision and 0.69478 recall, showing only marginal improvement over YOLOv5 in crack detection tasks. YOLOv8 and its architectural variants demonstrate precision improvements. These results indicate YOLO architecture progression.

Precision defines the ratio of correctly predicted positive samples (True Positives, TP) among total positive predictions. EA-YOLOv8 achieves 0.85669 precision in crack identification. This result surpasses both YOLOv5 (0.75592), YOLOv11 (0.75672) and YOLOv8 (0.80325) baselines. The visualized results in Figure 4 column one show detection errors in baseline models. EA-YOLOv8 reduces false detections through two mechanisms. The ELA mechanism enhances directional feature extraction capabilities. The ARS mechanism enables regional attention optimization. These components reduce False Positive (FP) predictions.

Recall represents the proportion of actual positive samples correctly predicted as positive (TP). EA-YOLOv8 achieves 0.65462 recall. While this is lower than

Figure 4. Comparison of Each Model

YOLOv11's recall (0.69478), which demonstrates the highest recall among the baseline models, the third column in Figure 4 shows detection limitations in YOLOv8, ELA-YOLOv8, and ARS-YOLOv8. EA-YOLOv8 combines ARS loss regional weight adjustment with ELA feature extraction. This integration improves positive sample detection.

Mean Average Precision (mAP50) evaluates model performance in object detection tasks. EA-YOLOv8 achieves 0.70297 mAP50 ,which significantly outperforms YOLOv11's 0.65088 mAP50. The ELA mechanism extracts discriminative features. The ARS loss focuses on challenging regions. These components enhance detection accuracy across scales.

F1 score provides the harmonic mean of precision and recall. EA-YOLOv8 achieves 0.742146 F1 score , surpassing YOLOv11's 0.724428 F1 score. This metric demonstrates the effectiveness of ELA and ARS loss integration.

This research presents EA-YOLOv8 for crack detection applications. The model integrates ELA attention mechanism and ARS loss function. Ablation experiments on the Roboflow dataset validate model effectiveness. EA-YOLOv8 demonstrates performance improvements over YOLOv5, YOLOv11 and YOLOv8 baselines. The model surpasses ELA-YOLOv8 and ARS-YOLOv8 variants in precision, recall, mAP50, and F1 metrics.

6 Conclusion and Limitation

In this paper, we introduce a novel segmentation algorithm named EA-YOLOv8 to incorporate two technical innovations into the YOLOv8 architecture. First, we deploy the Efficient Local Attention (ELA) mechanism following the final convolutional layer within the Bottleneck structure of the C2f module. ELA can optimize spatial information utilization while preserving channel dimensions and computational efficiency, resulting in improved crack localization capabilities. Second, we develop an adaptive region-specific loss (ARS loss) as an auxiliary loss to specifically target the difficulties in crack boundary delineation, leading to refined edge detection results. Experimental validation of EA-YOLOv8 was conducted on the Roboflow crack dataset. Through comprehensive ablation studies and baseline comparisons with YOLOv5, YOLOv8, and the latest YOLOv11, the experimental results demonstrate the EA-YOLOv8's superior performance. Quantitatively, EA-YOLOv8 exhibits a 10% precision improvement over YOLOv5, a 10% improvement over YOLOv11 and a 5% performance gain compared to the original YOLOv8. While YOLOv11 demonstrates slightly higher recall than EA-YOLOv8, our model achieves superior precision, mAP50, and F1 scores, indicating better overall performance for crack detection tasks. These experimental results validate both the theoretical framework and practical applicability of our proposed EA-YOLOv8 in crack detection scenarios.

Research limitations require further investigation. EA-YOLOv8 recall performance remains below ARS-YOLOv8 levels. This indicates potential feature extraction misalignment between ELA and ARS loss components. ARS loss weight adjustment mechanisms may experience constraints from ELA-generated features. These interactions affect regional learning processes. Future research directions include attention mechanism compatibility analysis with ARS loss. Additional investigation of YOLOv8 detection head, feature pyramid, and SPPF module modifications may enhance crack segmentation performance. Furthermore, this study utilized only a single dataset for training and testing. Future work should incorporate multiple diverse datasets for cross-validation to better verify the model's reliability and generalizability across different crack detection scenarios.

Abstract –

The integration of off-site manufacturing with on-site construction in the Modular Construction Supply Chain (MCSC) presents significant challenges due to the differences in production methods and geographical distances. While various technologies have transformed construction practices, substantial improvements are still needed in on- and off-site coordination to mitigate delays, ensure quality, and lower costs. Blockchain-enabled smart contracts offer a promising workflow engine for enhancing process-oriented MCSC coordination. Additionally, Robotic Process Automation (RPA) holds the potential to further refine the modules within MCSC processes and automate tasks. This paper, therefore, aims to develop a new workflow engine that combines blockchain-enabled smart contracts, RPA, and related visualization technologies to address the coordination challenges inherent in MCSC. Demand-driven process modeling and smart contracts conversion with RPA actions are conducted with the MCSC coordination unit configuration, and the initial system is developed and validated in a real-world case study. Industrial requirements and feedback are collected and analyzed via questionnaires and interviews. Finally, practical implications are discussed, and the integration of RPA and AI is identified as a promising exploration for future work in MCSC coordination.

Keywords –

Smart Contract; RPA; Modular Construction; Supply Chain Coordination

1 Introduction

In dense urban environments such as Asian regions, the industrialization of construction has been significantly influenced by factors e.g., rapid urbanization and increasing sustainability demands. This context has spurred the fast development of modular construction (MC). The merging of off-site manufacturing with on-site construction in the modular construction supply chain (MCSC) presents challenges due to different production approaches and geographical separation [1,2]. These challenges include amplified delays, disjointed quality control systems, and discrepancies in accountability [3,4]. Numerous studies aim to enhance coordination within the construction supply chain at a macro level through strategies such as supplier alliance, organizational partnership, and value co-creation [5,6].

However, the effective implementation of these macro-level strategies requires a solid material and process foundation. Establishing a domain-spanning production flow and developing effective on-site and off-site coordination mechanisms are essential prerequisites for holistically improving the performance of the modular construction supply chain. A series of technological advancements provide a foundation for better process coordination in MCSC.

Business Process Management (BPM) and its process modeling standards, e.g., Business Process Model and Notation (BPMN) and Business Process Execution Language (BPEL), have been widely applied to construction information management with BIM (Building Information Modeling) models [7,8]. Recently, blockchain-enabled smart contracts have played a role in executing the process models in a traceable and semi-automated manner [9]. Meanwhile, the development of Robotic Process Automation (RPA) provides a possibility to further detail the modules within the MCSC processes and automate tasks. It comprises software agents that mimic the manual path taken by a human through integrated computer applications when performing certain tasks in a business process [10]. Currently, AI-enhanced RPA has been explored, and it shows the potential to elevate BPM from semi-automation to full automation [11,12].

Therefore, this paper aims to develop a new workflow

engine integrating blockchain-enabled smart contracts, RPA and related visualization technologies to address the coordination issues existing in MCSC. The demand analysis is conducted at the beginning with a series of industrial engagement activities. The process models and the triggering and driving mechanisms are further developed and integrated into MCSC coordination multi-terminal devices. Finally, a real-world case study is carried out to validate the proposed methods.

2 Literature Review

2.1 BPM and BPA in Construction

Business Process Management (BPM) addresses the topic of process support from a broader perspective by integrating methods of analysis (such as simulation, verification, and process mining) and connecting processes to business and societal aspects [13]. Different process languages have been gradually developed, e.g., Petri nets, Workflow nets, YAWL, and BPMN.

In construction, the supply chain process has been early modeled and decomposed from conceptual representation to process element specification using BPMN and BPEL [14]. Recently, the integration of blockchain-enabled smart contracts and workflow engines has been newly explored and developed for Business Process Automation (BPA) [9,15]. Construction supply chain coordination and payment automation were frequently taken as use cases and application examples [16].

Robotic Process Automation (RPA) is an emerging automation technology in BPA that uses robots to partially or fully automate simple or complex repetitive tasks [17]. These robots, for example, process transactions, manipulate data, and communicate with other digital systems or agents [11]. Therefore, RPA and smart contract-enabled workflow engines can work together in a complementary way when deploying and monitoring automated processes. RPA automates a specific set of tasks, while smart contract-based workflow engines automate the flow among tasks and rule-based decision-making in each logical branch [9].

2.2 MCSC Coordination

The development of information technologies to improve visibility, enable coordination, and promote performance through information sharing in the construction supply chain is a continuously explored topic. The applications of blockchain-enabled smart contracts in conventional construction supply chain management mainly concern aspects including procurement, inventory management, traceability, sustainability, cross-border logistics, etc. [18].

In the general construction supply chain research field, regarding boundary-spanning interdependence, the off-site and on-site domains and domain-spanning processes and activities underneath have been analyzed [3]. In MCSC, the domain-spanning effect shows great importance. The typical MCSC process-oriented scenarios, including production, logistics, and business processes, have been identified as critical application areas [19]. The use of blockchain-enabled smart contracts and automation technologies as an MCSC coordination enabler is still in the early phase. According to a systematic review, currently, only about 18% of studies in modular construction practically implemented digital tools and applications [20]. It also indicated that the on-site and off-site fragmentation is a critical issue for MCSC and requires more digital solutions [20].

3 Methodology

3.1 Top-level Design for MCSC Process Collaboration and Automation

Smart contract generation necessitates accurate process models (e.g., in the BPMN format). Establishing such process models requires clear specifications of each participant's responsibilities and requirements, combined with BIM models, plans, and real-time site information. In different scenarios, the process participants and task complexity may vary. The MCSC process encompasses complex tasks and many participants, including the contractor, client, designer, and suppliers. Process splitting and subprocess modeling can be performed to simplify highly complex processes.

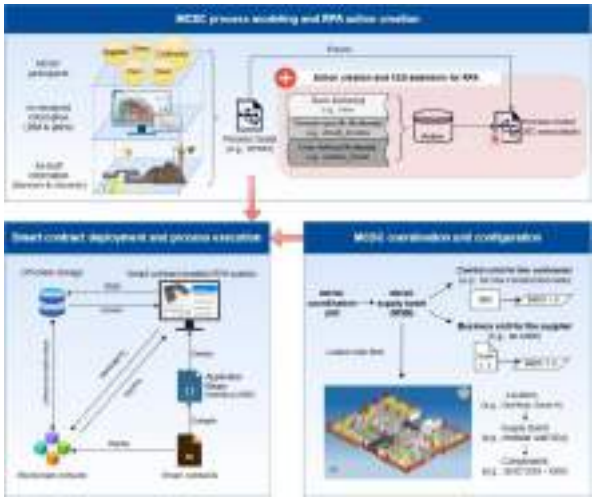

Figure 1. The framework of MCSC process coordination and automation

Because the initiation of tasks in the MCSC process is affected not only by the participants but also by as-

designed and as-built information, process modeling and automation can be conducted by combining BIM and IoT applications. Figure 1 shows the details of the top-level design of the MCSC coordination framework.

There are three key aspects that form the foundation of MCSC coordination: 1) demand-driven process modeling and smart contracts conversion with RPA actions; 2) MCSC coordination unit configuration from a managerial perspective; and 3) blockchain-enabled smart contracts deployment and MCSC process automation.

3.2 MCSC Process Modeling and Conversion

The industrial opinions were collected from a survey with 146 questionnaires and a series of interviews with practitioners involved in MCSC. Regarding the functionality of smart contract and RPA-enabled coordination systems or tools, the majority of respondents recognize that these tools ensure the authenticity of construction supply chain data (with 94% of respondents assigning high scores), traceability (with 81% of respondents assigning high scores), and automation capability (with 96% of respondents assigning high scores).

In the demand analysis of MCSC coordination, the majority of respondents identified the following key needs: preventing supply delays, interacting with suppliers to control progress and costs, obtaining quick responses from suppliers, planning and controlling inventory based on production activities, implementing more automated supply management systems, and ensuring traceability.

Based on industrial requirements, this study modeled the MCSC process using precast components as an example, as shown in Figure 2.

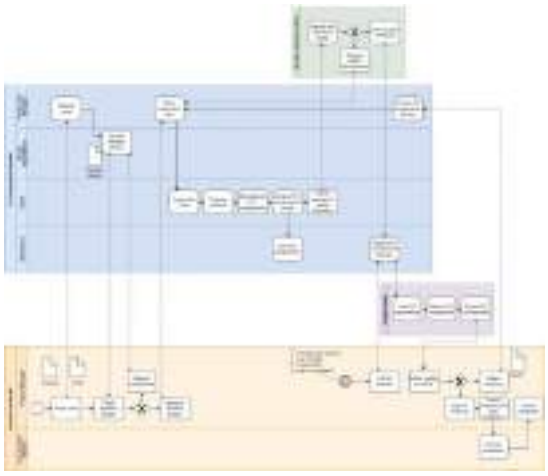

Figure 2. MCSC process model example

In this process model, all essential schedules and quality control gateways are set, and the information flow among the contractor, precast component supplier, logistics service provider, and quality inspection unit are modeled.

Based on the process model, blockchain-enabled smart contracts can be generated using our previously developed generation method [9], as shown in Figure 3. Smart contracts work as the global workflow engine for process execution and flow automation, which can provide traceable reports of the execution records.

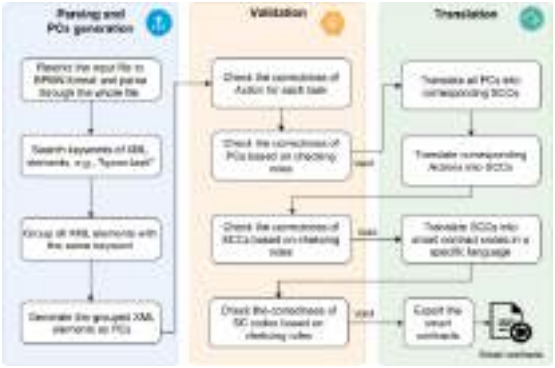

Figure 3. Smart contract generation method (permission obtained)

Meanwhile, a series of RPA actions were defined for internal task automation. To conform to the context of MCSC, RPA actions are defined in three levels: general (basic level for general purpose), domain-specific (e.g., logistics, payment, warehouse and construction), and user-defined (customized level under the requirements of a specific user).

Some manual actions can be replaced with fully or semi-automated RPA actions using smart contracts and blockchain (e.g., a “pay” RPA action), where the smart contracts are used as robots to realize RPA. Other manual actions, which cannot be simply executed via smart contracts (e.g., “check progress” action or “tracking” action), can be transformed into RPA actions by further integrating other devices or agents (e.g., sensors).

3.3 MCSC Coordination Configuration

MCSC Supply Batch (MSB) is defined as the smallest element within the coordination framework, which helps facilitate interactions and processes across different stages and parties in the supply chain, as shown in Figure 4. The attributes of MSB can be generated from predefined templates and integrated IFC properties from the BIM model.

The configuration of MCSC coordination with the basic unit, i.e., MSB, is shown in Figure 4. The defining and planning of MSB are based on project decomposition and a location-based perspective. A construction project can be decomposed from division work, sub-division work, and sub-item work, into construction tasks, and the MSB is linked to a construction zone, which contains a

series of construction tasks following the sequence. The location-based perspective [21] is for better collaboration to provide the MCSC participants with a BIM model view. This project decomposition and a location-based perspective is mainly for the construction and project management side, e.g., the contractor, client, and consultant.

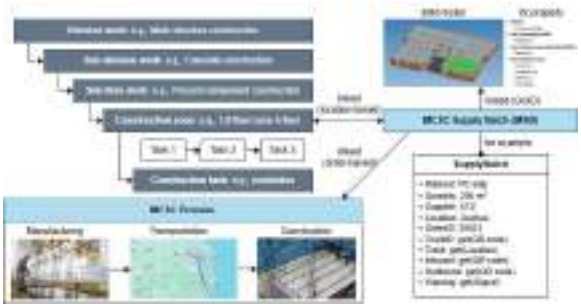

Figure 4. The basic unit of MCSC coordination

Another essential perspective is the order-based perspective, which is mainly for the supply side, e.g., the suppliers and logistics service providers. The order can be generated automatically after the contractor sets up the MSB in the system. The supplier can prepare the delivery and related documents according to an MSB order or link the MSB order to an existing purchase contract. All automatically collected data (e.g., sensors), semi-automatically collected data (e.g., QR code), and manually input data (e.g., mobile device or computer) can be linked to the MSB unit. Therefore, the life-cycle process of an MSB from off-site to on-site can be easily tracked and monitored. With inbound and outbound functions, the as-built information of MSB can also be tracked and shown in the BIM model view.

3.4 MCSC Process Automation

The MCSC process can be executed through semi-automatic operations by authorized personnel and predefined automatic triggers. Figure 5 shows the MCSC coordination process execution with RPA actions.

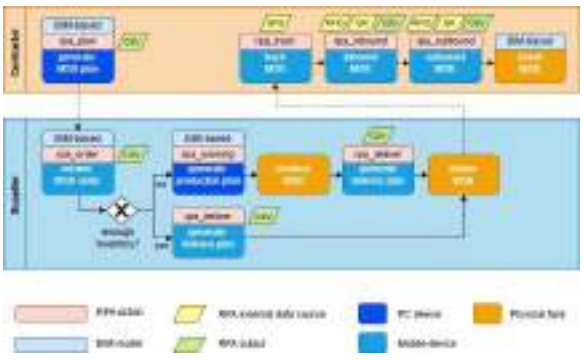

Figure 5. MCSC coordination process execution with RPA actions

In the initiation stage, an MSB plan can be generated with BIM models (components selection) and schedules, including the MSB name, construction zone, and required date. The quantity and associated components can be extracted from the IFC properties. The generation process can be semi-automatically executed using the rpa_plan action. For example, a CSV document of the MSB plan can be automatically created with manual adjustments on quantity unit and required date.

When the supplier receives the MSB plan, the rpa_order action will automatically convert it into an order so that it can be better understood from a business perspective, which also can be a part of a purchase contract.

When there is enough inventory, the supplier can confirm the MSB order and provide a delivery plan with a planned arrival date and other essential information including related staff account information. The rpa_deliver can automatically create a CSV document and send it back to the contractor. This situation is common in practice when a series of MSBs belong to one purchase contract. However, when the MSB is an ETO or MTO-type material or equipment, the production process is required, and the rpa_warning action will calculate if there will be any potential production delay according to real-time data.

After the supplier delivers the MSB, the rpa_track action can update the transportation location automatically, integrating GPS data, while the rpa_warning action will also calculate if there will be any potential transportation delay.

When the MSB arrives, the rpa_inbound action will automatically generate an inbound receipt according to previous WSB data and related staff account information to better assign responsibility. When the MSB is taken for use, the rpa_outbound action will automatically generate an outbound record and assign as-built information, such as construction zone, material requisitioner and outbound clerk.

All manual operations can be performed using mobile devices, except MSB planning and production planning, which are usually integrated into existing PC systems.

The overall workflow is deployed on the blockchain network, and all tasks and gateway decisions will be recorded into transactions to ensure traceability. The automation mechanism of blockchain-enabled smart contracts has been introduced in our previous study [9]. Meanwhile, the status of internal task RPA actions can also be recorded and ensured via the blockchain network.

4 Implementation

This study applied the initially developed system to a project in Nanjing South New Town in China, one of the smart construction pilot projects in Nanjing city,

covering commercial, office and residential areas, to test the proposed blockchain-enabled smart contracts and RPA integrated method.

The demo system of the blockchain-enabled smart contracts for precast components supply coordination is shown in Figure 6.

Figure 6. The demo system of the precast components supply coordination

Based on the further requirements from the project managers and communication with suppliers, the first version of the MCSC system has integrated the MSB concept and RPA actions. In this project, the MCSC coordination is not only about the precast components but also includes the prefabricated decoration components, for example, wood flooring materials and decorative wall aluminum plates. An example of the user interface of this system translated into English is shown in Figure 7.

Figure 7. Example interface of MCSC coordination system in case project

In this case, an example of MSB is "Building B Zone A 3rd floor slab", of which quantity amount is 200 m^2, and the required arrival date is 2024-09-01. This MSB was assigned to the process model and triggered by predefined conditions and manual decision input in the process model, which was displayed using the BPMN standard in the interface, while on the backend, it was deployed on the blockchain in the form of smart contracts.

In this project, the B/S system was mainly applied for the main contractor to plan, generate, and track the MSBs. The planning of MSBs is the most difficult step since it guides all the following data collection, tracking and warning. Therefore, in this project, the MSBs were defined and planned by a small group of one project manager, one construction manager, and one researcher. The supplier only used mobile devices to receive MSB orders and deliver MSB products. All the logistics processes utilized GPS devices for tracking, and the inbound and outbound processes used QR codes, which are attached to each MSB and scanned by the on-site staff and construction workers' phones.

The tools and system provided solutions to issues such as on- and off-site process fragmentation, information silos, data redundancy, untimely logistics tracking and untraceable.

During this project execution, several issues arise, such as a lack of understanding of new technologies, especially among material suppliers with low levels of information technology adoption. Distinguished by the abstract, on-chain coding mechanisms, smart contracts differ fundamentally from more visually intuitive technologies like BIM or Virtual Reality (VR). This often requires significant effort and time for communication and system adjustments. This is one of the key reasons for choosing mobile devices on the supplier side. Most experienced project managers have no problems with the B/S system and can easily deal with BIM elements. Meanwhile, most MCSC participants are not familiar with BPMN tools, and sometimes, additional UI design is required to simplify the process models for better coordination.

5 Conclusion

Given the practical issues of the modular construction supply chain and industrial requirements, this study proposed a blockchain-enabled smart contract and RPA-integrated method to improve process coordination. Three key steps are elaborated: 1) modeling processes driven by demand and converting them into smart contracts with RPA actions; 2) configuring the MCSC coordination unit from a managerial viewpoint; and 3) deploying blockchain-enabled smart contracts and automating MCSC processes. A real-world project validation provided positive results from both technical and managerial perspectives.

Further work can be improved in several aspects. First, the process models and RPA actions can be decomposed into process pattern base and RPA action base for more flexible assembly for various scenarios. Second, the deployment and execution of the smart contract can be optimized by adopting advanced blockchain or other encrypted database technology. Third, practical training and tool usability are essential for better MCSC

coordination practices, and the design of systems based on unrealistic assumptions should be avoided. Additionally, the integration of RPA and AI will be a promising research topic in future MCSC coordination.

Abstract

Chilled water-cooling systems are essential for maintaining optimal building temperatures in commercial applications, such as hospitals, where precise temperature control is critical for patient care. Accurately estimating cooling tower fan speed is vital for energy efficiency and operational optimization. Traditional physics-based models often require iterative solving techniques, such as Newton-Raphson, leading to high computational costs and slow performance. This paper presents an alternative approach using symbolic regression to develop a data-efficient, explicit model for predicting cooling tower fan speed. Trained on just 72 hours of data, the model was validated on three separate periods: the first week immediately after training, the following week, and another week approximately two months later, achieving R^2 values of 0.92, 0.87, and 0.83, respectively. The inference speed is nearly instantaneous, as the model eliminates iterative calculations, making it well-suited for real-time applications. Using commonly available system parameters, the model enhances both computational efficiency and energy management. Results demonstrate its potential to improve HVAC system performance, reduce energy consumption, and support sustainable building operations, offering a scalable solution for practical deployment in commercial cooling systems.

Keywords –

HVAC, Cooling Tower, Simulation, Symbolic Regression

1 Introduction

Efficient cooling is essential for maintaining optimal environmental conditions in commercial buildings, particularly in facilities like hospitals where temperature control is critical for patient care [1]. Cooling towers, as integral components of chilled water-cooling systems, play a crucial role in rejecting heat from the system. Accurate estimation of the cooling tower's fan speed is vital, as it serves as a proxy for estimating power consumption through the application of the affinity laws, which describe how fan power scales with changes in fan speed. This relationship can be leveraged in simulations to optimize control variables for the condenser water loop, thereby enhancing the cooling system's performance [2]. By balancing the power consumption between chillers and cooling towers, it is possible to minimize the overall energy consumption of the chilled water system, leading to improved operational efficiency and reduced operational costs [3, 4, 5].

Traditionally, physics-based models (also known as gray-box models), such as Merkel-based models, have been employed to simulate cooling tower performance [6]. These models rely on a combination of fundamental physical principles and empirical data, providing robust options for system analysis and power estimation. However, they do not offer a direct output for fan speed, necessitating the use of iterative search methods like the Newton-Raphson technique to solve for fan speed [2]. This requirement for iterative solving introduces complexity and computational inefficiencies, rendering these models less suitable for real-time applications where rapid and responsive control is necessary.

In contrast, data-driven models (or black-box models) present a promising alternative by utilizing machine learning techniques to learn the relationship between input parameters—such as temperature, flow rate, and environmental conditions—and output variables like fan speed directly from data. While data-driven models can achieve high accuracy, they often suffer from limitations in generalization capability, particularly when operating outside the range of the training data. Additionally, these models typically require large datasets for effective training, which can limit their applicability in scenarios where data availability is constrained or where dynamic, real-time system responses are needed [7].

The motivation for this research lies in overcoming the limitations of both gray-box and black-box approaches by developing an interpretable and data-

efficient model using symbolic regression (SR). Symbolic regression provides a unique methodology that automatically discovers mathematical expressions to describe the relationships between input and output variables [8]. Unlike traditional machine learning methods, SR generates transparent, closed-form mathematical models that are both interpretable and computationally efficient [9]. This makes SR particularly suitable for real-time control strategies, as the resulting models eliminate the need for iterative numerical solutions required by gray-box models while avoiding the black-box nature and data dependency of conventional machine learning techniques.

2 Objectives of the Study

The primary objectives of this research are as follows:

1. Develop a data-efficient explicit model for cooling tower fan speed using symbolic regression, incorporating key input variables such as wet-bulb temperature, inlet and outlet water temperatures, and water flow rate, while minimizing the need for large datasets.
2. Improve simulation speed and computational efficiency by providing an explicit, direct model for fan speed estimation, thereby eliminating the need for iterative solutions required by traditional physics-based models and enabling faster real-time decision-making.
3. Leverage symbolic regression to create an interpretable and generalizable data-driven model that performs well with limited data and can be adopted in real-time applications, offering a practical and computationally efficient alternative to black-box models that typically require large, extensive datasets.

By addressing these objectives, this research aims to present a data-efficient, computationally efficient, and interpretable approach for estimating fan speed in chilled water-cooling systems. This advancement has the potential to enhance energy optimization, improve real-time control mechanisms, and offer a practical solution for systems with limited data, thereby contributing to more sustainable and cost-effective building operations.

3 Literature Review

Cooling towers are critical components of HVAC systems, responsible for rejecting heat from processes or buildings to the atmosphere. Their operational efficiency and energy consumption depend significantly on the control of fan speed, which in turn determines the leaving water temperature. Accurately predicting this temperature is essential for improving energy efficiency and ensuring optimal performance [3, 10, 11]. To model the leaving water temperature, three primary methods have been developed over the years: the Merkel method, the Poppe method, and the enthalpy-driven effectiveness-NTU method [6]. These models have served as the foundation for cooling tower analysis and control strategies.

The Merkel method, first proposed in 1925, simplifies the cooling process by assuming a constant Lewis factor (the ratio of sensible to latent heat transfer coefficients) and neglecting the evaporation losses of water. It integrates the heat and mass transfer equations along the height of the cooling tower to estimate the leaving water temperature [6]. While this approach has been widely adopted for its simplicity and ease of implementation, it fails to capture the complex interactions between heat and mass transfer that occur in real operating conditions, particularly under varying ambient and operational parameters.

The Poppe method improves upon Merkel's assumptions by considering the simultaneous and coupled heat and mass transfer processes inside the cooling tower. Unlike Merkel's method, the Poppe approach does not assume a constant Lewis factor and accounts for variations in the air and water enthalpy. This method provides higher accuracy in predicting the leaving water temperature, particularly in scenarios where Merkel's assumptions lead to discrepancies [12]. However, the Poppe model requires solving a system of coupled nonlinear differential equations, which makes it computationally intensive and less suited for real-time control.

The enthalpy-driven effectiveness-NTU method provides a more flexible and systematic framework for predicting the leaving water temperature. By introducing the concept of heat exchanger effectiveness, this method evaluates cooling tower performance using enthalpy as the driving force. It allows for improved accuracy in capturing cooling tower dynamics under varying conditions compared to traditional methods [2]. Despite its advantages, the enthalpy-driven method still involves solving nonlinear relationships, which can pose challenges for real-time optimization and control strategies. Another, simpler model was proposed based on Merkel’s theory and the effectiveness-NTU method. This model was developed through energy balance and heat-mass transfer analysis [13].

For a closed-loop cooling tower leaving water temperature control strategy, the fan speed must be set to its optimal value to maintain the optimal leaving water temperature. However, if the desired leaving water temperature setpoint deviates from this optimal condition, determining the appropriate fan speed requires solving

the governing equation numerically. Equation (1) illustrates this relationship [2]:

$$T_{CWS} = f_T(T_{CWR}, T_{WB}, M_{CW}, SPD, K_d'A) \quad (1)$$

where T_{CWS} is the leaving water temperature, T_{CWR} is the entering water temperature, T_{WB} is the ambient air wet bulb temperature, M_{CW} is the water mass flow rate, SPD is the fan speed, and $K_d'A$ the design moisture transfer coefficient.

Solving for SPD under these conditions requires iterative numerical techniques such as the Bisection method or Newton-Raphson method, which are widely used for solving nonlinear equations. These methods, while effective, are computationally demanding and time-consuming, especially for real-time applications where fast control responses are essential [2, 3]. Similarly, for closed-loop approach temperature control, the fan speed must also be determined iteratively if the approach temperature setpoint differs from the optimal value. These computational requirements can lead to delays in control responses, limiting their feasibility for real-time applications [3]. Thus, while the Merkel, Poppe, and enthalpy-driven NTU methods provide robust frameworks for cooling tower performance prediction, their reliance on computationally intensive numerical solvers introduces significant overhead during closed-loop control.

To overcome the computational challenges associated with traditional models, data-driven approaches have gained increasing attention. Data-driven methods utilize operational data to identify complex system dynamics and provide real-time predictive models. Among these approaches, symbolic regression (SR) has emerged as a powerful technique for deriving explicit and interpretable mathematical expressions from data [8, 9]. SR identifies relationships between variables without relying on predefined model structures, enabling the discovery of closed-form equations that can directly describe the behavior of cooling towers, including fan speed and leaving water temperature.

Although symbolic regression has been applied successfully in other areas of HVAC systems, such as building thermodynamics [14] and gray-box modeling of air conditioning systems [15], its application to cooling tower modeling remains underexplored. [14] used SR to model building energy dynamics and demonstrated a 16.1% reduction in peak power through a predictive control framework. [15] applied SR for gray-box modeling of unitary air conditioning systems, achieving high accuracy in predicting cooling capacity and coefficient of performance (COP). [16] further showcased the potential of SR for indoor temperature forecasting, reducing model complexity while improving computational efficiency. These studies highlight SR's ability to capture nonlinear dynamics effectively while providing explicit and interpretable solutions, making it a suitable candidate for real-time applications.

In this research, we address the limitations of traditional cooling tower models and propose a symbolic regression-based model to predict cooling tower fan speed as a function of the leaving water temperature, entering water temperature, water mass flow rate, and wet bulb temperature. Unlike traditional methods, which require iterative numerical solutions to determine fan speed for a given setpoint, our approach formulates an explicit and interpretable model derived directly from operational data.

The proposed symbolic regression (SR) model eliminates the need for computationally intensive techniques, such as the Bisection method or Newton-Raphson iterations, which are typically employed to solve the governing nonlinear equations. By generating closed-form expressions, the SR model enables faster and more efficient inference, making it particularly well-suited for closed-loop control strategies. This capability allows for real-time adjustments of fan speed to maintain desired leaving water temperature or approach temperature setpoints. Furthermore, the resulting SR model is computationally efficient and highly interpretable, providing clear relationships between key operational variables—leaving and entering water temperatures, wet bulb temperature, and water mass flow rate. This facilitates real-time optimization of cooling tower performance, overcoming the bottlenecks inherent to traditional numerical approaches while ensuring robust and accurate control of cooling tower operations.

4 Methodology

4.1 Case study and Data Collection

The primary case study for this research is a hospital located in the Greater Vancouver area, within ASHRAE climate zone 4. This hospital is one of the busiest in the region, providing comprehensive care across multiple specialties, including trauma, cardiac, neurosurgery, high-risk obstetrics, neonatal intensive care, and acute mental health services. The diverse range of services necessitates a robust and efficient cooling system to maintain optimal environmental conditions, which are critical for patient care. The hospital's central cooling plant, comprising chillers and cooling towers, is responsible for meeting the facility's substantial cooling demands.

Data for this study were collected from the central cooling system of the hospital over a five-month period, from May 1, 2024, to September 30, 2024. However, only 72 hours of data, specifically from July 8th to July

10th, were utilized for training the models (see Figure 1). This subset consists of 288 data points, sampled at 15-minute intervals, capturing the system's dynamic behaviour. Representing approximately 2% of the total collected data, these 72 hours were carefully selected to include a wide range of operational conditions, such as fluctuations in outdoor temperature, humidity, and cooling demand. This ensures a diverse and representative dataset that effectively captures the cooling system's performance across different operating states.

The collected variables include leaving water temperature (T_{CWS}, in °C), entering water temperature (T_{CWR}, in °C), condenser water mass flow rate (M_{CW}, in L/s), dry-bulb outdoor air temperature (OAT, in °C), relative humidity (RH, in %), and cooling tower fan speed (SPD, in %). The fan speed during this period varied, with a lower bound of 33.3%, and its operational range was crucial for evaluating the system's performance.

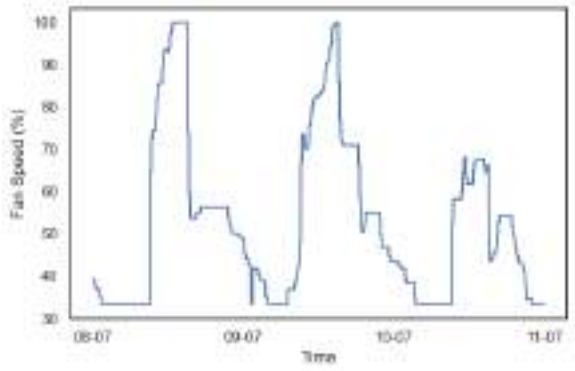

Figure 1: Cooling tower fan speed dataset used for model training

4.2 Data Pre-processing and Feature Engineering

To ensure the quality and relevance of the data for modeling, several pre-processing and feature engineering steps were undertaken. Wet-Bulb Temperature was calculated using both Relative Humidity and Air Temperature based on the formula provided by [17]. This additional feature was included to better capture the thermodynamic conditions affecting the cooling tower performance.

The raw dataset underwent a series of filtering criteria to remove unreliable or irrelevant measurements. First, instances where the fan speed (SPD) was below 33.3% were discarded to eliminate periods of suboptimal operation. Additionally, data points with a wet-bulb temperature below 10°C were excluded to focus the analysis on conditions where cooling demands are more significant. Measurements where the condenser water supply temperature (T_{CWS}) exceeded the condenser water return temperature (T_{CWR}) were also removed, as such scenarios are physically implausible and likely indicative of sensor errors or operational issues.

Further, any records where the condenser water mass flow rate (M_{CW}) fell below 50 L/s were filtered out to ensure the dataset only included stable and efficient operating conditions. Finally, rows containing NaN values in any of the input or target variables were discarded to maintain data integrity and avoid computational issues during model training.

After the pre-processing steps, a total of 283 data points remained, reflecting the impact of the filtering criteria in removing unreliable or irrelevant data. This cleaned dataset was subsequently split into training and testing subsets, with an 80-20% division, respectively. The split was performed without shuffling to preserve the temporal sequence of the data, which is critical given the time-series nature of the dataset. For modeling, the fan speed (SPD) was designated as the target variable, while the remaining variables were selected as the input features. This structured and pre-processed dataset provided a robust foundation for the subsequent symbolic regression modeling and analysis.

4.3 Symbolic Regression Modeling with PySR

The modeling process was conducted using Python, leveraging the PySR package [18] for symbolic regression. Symbolic regression is a data-driven approach that searches the space of mathematical expressions to find models that best fit the data. Unlike traditional regression methods that require predefined forms of the model, symbolic regression explores a wide variety of possible equations, offering both accuracy and interpretability [8].

PySR employs a genetic algorithm-based approach to evolve mathematical expressions, optimizing them to minimize the error between the predicted and actual values. The underlying computational engine utilized Julia, a high-performance programming language, to enhance the efficiency and scalability of the symbolic regression process. This integration allows for rapid evaluation of numerous candidate models, facilitating the discovery of optimal or near-optimal symbolic representations of the target variable.

In this study, the symbolic regression was configured with specific hyper-parameters to guide the model generation process. The binary operators included in the search space were addition (+), multiplication (*), subtraction (-), division (/), and exponentiation (^). The loss function was set to L2DistLoss(), which corresponds to the mean squared error between the predicted and actual fan speeds. Model selection was based on accuracy to ensure that the generated models achieved high predictive performance.

To accelerate the training process, several performance settings were enabled. The multithreading setting was activated to utilize multiple CPU cores, improving computational efficiency. The fast_cycle setting was set to False, which prevents the batch over population subsamples algorithm, designed to speed up the cycles by approximately 15%, but at the risk of being less algorithmically efficient. The turbo setting was also False, as it refers to the experimental use of LoopVectorization.jl, which speeds up the search evaluation but may not support certain operators and does not work with 16-bit precision floats. Finally, the bumper setting was turned off; this experimental feature uses Bumper.jl to speed up the search evaluation, though it also does not support 16-bit precision floats. These configurations were carefully chosen to strike a balance between computational efficiency and model accuracy, ensuring that the symbolic regression process remained robust, scalable, and suitable for generating interpretable models for cooling tower fan speed prediction.

4.4 Model Training and Validation

The training phase involved fitting the symbolic regression model to the training dataset using the specified hyper-parameters and performance settings. The model was trained to identify the mathematical relationship between the input features (T_{CWS}, T_{CWR}, T_{WB}, and M_{CW}) and the target variable (SPD). This relationship can be mathematically represented in the following general form:

$$SPD = f_{SPD}(T_{CWS}, T_{CWR}, T_{WB}, M_{CW}) \quad (2)$$

Once the model was generated, its performance was evaluated using two key metrics: R-squared (R^2) to measure the proportion of variance in the target variable that is predictable from the input features and Root Mean Squared Error (RMSE) to provide an absolute measure of the prediction error in the same units as the target variable.

To assess the model's generalizability, validation was performed on an independent dataset comprising two weeks of subsequent data. This validation step was crucial to ensure that the symbolic regression model maintained its accuracy and reliability when applied to new, unseen data. The performance metrics on the validation set provided an indication of the model's robustness and its potential applicability in real-world cooling system optimization.

Overall, the methodology combines rigorous data collection and preprocessing with advanced symbolic regression techniques to develop an accurate and interpretable model for predicting cooling tower fan speed. The use of PySR and its efficient computational backend facilitates the discovery of optimal mathematical models that can enhance the understanding and control of cooling system operations.

5 Results

5.1 Symbolic Regression Model

The best-performing model derived through symbolic regression is represented by the following mathematical expression:

$$SPD = 0.707M_{cw} + \frac{0.707M_{cw}}{T_{WB}} - \frac{13.2M_{cw}}{T_{cwr}} + T_{cwr}^{\frac{0.764T_{WB}}{T_{cwr}-9.71}} - 13.5 - M_{cw}^{-0.878M_{cw}} \quad (3)$$

This equation provides a direct relationship between cooling tower fan speed and the key input features: wet-bulb temperature, condenser water supply temperature, condenser water return temperature, and mass flow rate of condenser water. The model is interpretable and captures the nonlinear interactions among the input variables.

5.2 Performance Evaluation on Test Data

The model's performance was first evaluated on the designated test dataset, comprising 20% of the data selected from the initial 72-hour training period. The following metrics were obtained:

- R^2 score: 0.8881
- RMSE: 3.9325

These results indicate that the model captures a significant portion of the variability in the fan speed while maintaining low prediction error. The R^2 score of 0.89 demonstrates high predictive accuracy, while the RMSE of approximately 3.93 reflects the model's strong ability to estimate fan speed with minimal deviation from the actual values.

5.3 Performance Evaluation on Validation Data

To assess the model's generalization capability, it was validated on an independent dataset across three separate periods: the first week after training (July 11th to 18th), the following week (July 18th to 25th), and an additional week nearly two months later (September 1st to 8th), demonstrating its credibility and robustness.

For the week of July 11th to 18th, 2024, the model achieved an R^2 of 0.92 and an RMSE of 3.76, demonstrating its strong predictive accuracy and robustness in estimating fan speed. The time-series plot (Figure 2) illustrates a close alignment between actual and predicted values, while the scatter plot (Figure 3) confirms a strong correlation, with most points closely

following the diagonal reference line, indicating minimal prediction error.

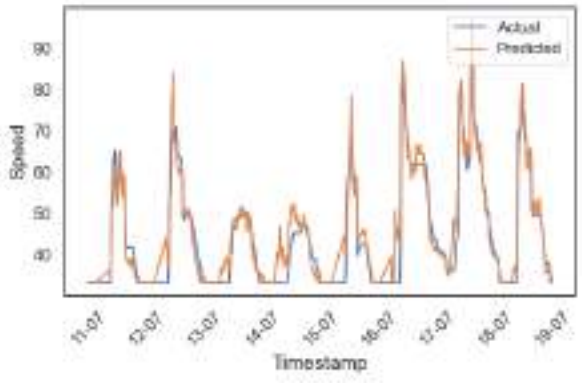

Figure 2 Time series plot of actual versus prediction values for first week of validation data

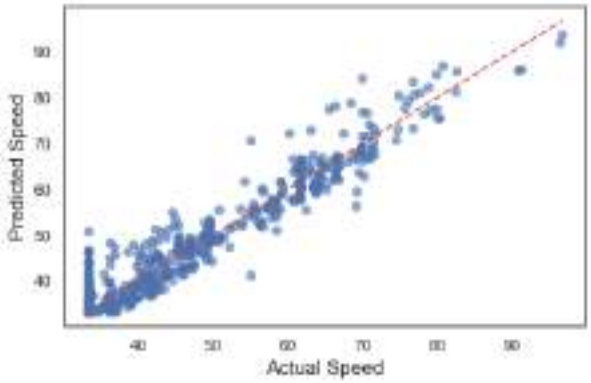

Figure 3 Scatter plot of actual versus prediction values for first week of validation data

For the week of July 18th to 25th, 2024, the model achieved an R^2 of 0.87 and an RMSE of 3.82, maintaining strong predictive performance and consistency in estimating fan speed. The time-series plot (Figure 4) illustrates a close match between actual and predicted values, while the scatter plot (Figure 5) confirms a strong correlation, with most points aligning along the diagonal reference line. The slight decline in R^2 suggests minor operational variations, yet the model continues to generalize well, reinforcing its reliability in diverse conditions.

To evaluate the performance and generalizability of the model, it was further validated on an independent dataset covering the week of September 1st to 8th, 2024, achieving an R^2 of 0.83 and an RMSE of 6.20. While the slight decline in R^2 suggests some operational variations, the model remains effective in capturing key system dynamics. The time-series plot (Figure 6) shows strong alignment between actual and predicted values, while the scatter plot (Figure 7) confirms a consistent correlation, reinforcing the model's reliability in predicting fan speed under varying conditions.

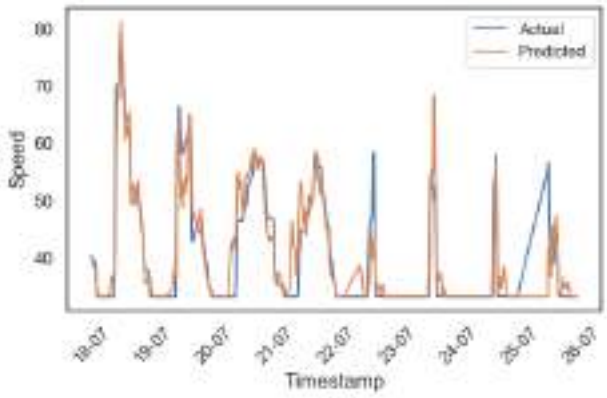

Figure 4 Time series plot of actual versus prediction values for second week of validation data

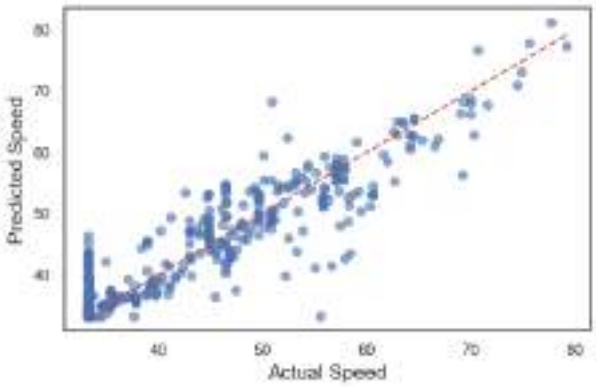

Figure 5 Scatter plot of actual versus prediction values for second week of validation data

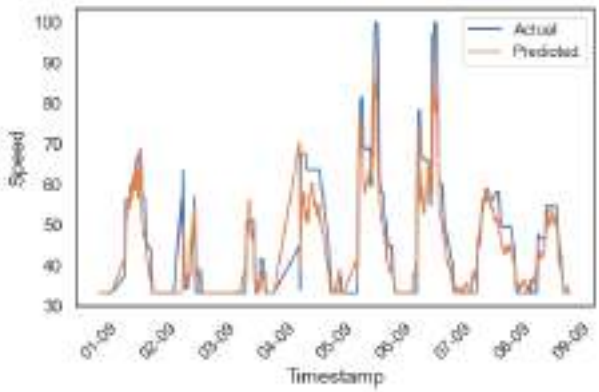

Figure 6 Time series plot of actual versus prediction values for third week of validation data

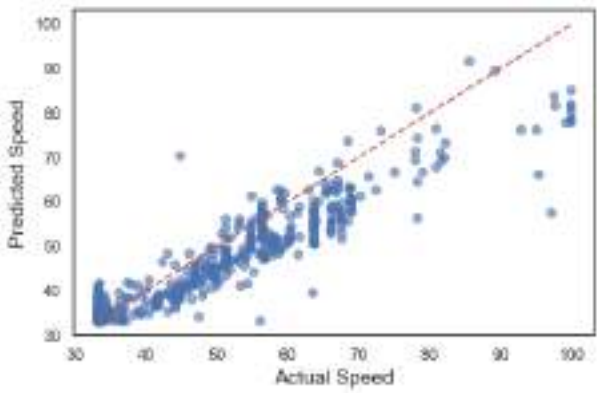

Figure 7 Scatter plot of actual versus prediction values for third week of validation data

6 Discussion

On the test dataset (20% of the training period), the model achieved an R^2 score of 0.8881 and an RMSE of 3.9325, capturing nearly 89% of the variance in fan speed with minimal prediction error. Further validation confirmed its generalizability. During the first validation week (July 11–18, 2024), the model achieved an R^2 of 0.9206 and an RMSE of 3.7566, demonstrating strong agreement between predicted and actual values. For the second validation week (July 18–25, 2024), the model maintained an R^2 of 0.8676 and an RMSE of 3.8246, despite slight variations likely caused by operational changes. A third validation nearly two months later (September 1–8, 2024) resulted in an R^2 of 0.8349 and an RMSE of 6.1975. While the R^2 declined slightly over time, the model remained effective, confirming its robustness under changing conditions.

The symbolic regression model eliminates the need for iterative numerical methods, such as Newton-Raphson, which are computationally intensive and impractical for real-time applications. By generating explicit mathematical expressions, the model enables fast inference, allowing real-time adjustments to cooling tower fan speed to maintain desired operating conditions.

Beyond computational efficiency, the model supports practical energy optimization strategies for chilled water plants, where balancing chiller and cooling tower operation is critical to minimizing total energy consumption. Cooling tower fans consume energy, but their operation influences chiller efficiency; optimizing only one component in isolation may lead to suboptimal system performance. The proposed model can be integrated into real-time optimization frameworks to determine the best trade-off between chiller and cooling tower energy use, reducing overall power consumption while ensuring adequate cooling.

With its fast inference capability, the model enables real-time control adjustments based on changing conditions, preventing excessive cooling tower fan speeds that could increase energy use unnecessarily. Its explicit equations provide a direct relationship between key operational parameters, making it suitable for predictive control applications where chiller load and cooling tower operation are jointly optimized for efficiency.

The model's interpretability also facilitates decentralized control, where cooling tower fan speed is adjusted at the local level rather than relying on a central controller. This reduces communication delays and computational overhead while improving responsiveness to system dynamics. In large-scale systems with multiple cooling towers, localized optimization enhances overall performance, leading to energy savings and improved reliability.

By integrating the model into smart HVAC control platforms, facilities can automate real-time energy management strategies to optimize cooling performance while reducing costs. This scalable approach makes the model applicable to hospitals, commercial buildings, and industrial facilities where precise control and efficiency are essential.

In summary, the symbolic regression model provides a practical, real-time solution for cooling tower control. By balancing chiller and cooling tower energy use, it enhances system-wide efficiency, offering a valuable tool for intelligent HVAC management in energy-conscious applications.

7 Conclusions

This study demonstrated the effectiveness of symbolic regression for predicting cooling tower fan speed in central chilled-water systems. The SR model achieved high accuracy, strong generalization, and computational efficiency across test and validation datasets. By producing explicit and interpretable mathematical models, it overcomes the limitations of traditional physics-based approaches and data-hungry black-box techniques.

The proposed model offers a practical and scalable solution for real-time optimization and decentralized control of cooling systems, facilitating improved energy efficiency and operational performance. Future work will focus on enhancing the model's adaptability to dynamic system changes and integrating it into broader energy management frameworks to further optimize large-scale cooling operations.

Abstract –

The rapid development of digital twin technology has opened new avenues for infrastructure management, particularly for addressing vegetation encroachment risks near power lines. This paper builds upon our previous work in LiDAR-based proximity detection by proposing a framework for creating digital twin for vegetation management near power distribution networks. The framework leverages the RandLA-Net model for semantic segmentation of power lines, poles, and vegetation followed by clustering and rule-based thresholding for data refinement. Detecting vegetation encroachment is achieved through KDTree-based spatial analysis, ensuring efficient identification of risk zones. The segmented and processed point cloud data is then transformed into detailed 3D models, forming the basis of the digital twin, which can be enhanced in the future by adding advanced semantic attributes and predictive tree growth models, enabling proactive vegetation management. The methodology is demonstrated through a case study, highlighting its potential to enhance operational efficiency and the resilience of power distribution networks.

Keywords –

Digital Twin, Computer Vision, 3D Point Cloud, Power Lines, Semantic Segmentation, Vegetation Management

1 Introduction

Vegetation encroachment near power lines is a critical issue that threatens the reliability and safety of power distribution networks. Approximatively 40% of the distribution outages are caused by vegetation. Power outages often happen when vegetation is exposed to severe weather conditions [1]. Traditionally, vegetation management has relied on manual inspection, which is labor-intensive, time-consuming, and often limited in accuracy and frequency. This highlights the need for automated solutions capable of delivering accurate, consistent, and cost-effective monitoring. Advancements in sensing technologies, such as Light Detection and Ranging (LiDAR), and machine learning algorithms have significantly improved vegetation management processes [2]. LiDAR's ability to capture high-resolution 3D spatial data enables precise detection of vegetation and its proximity to power lines, surpassing the capabilities of traditional 2D imaging or visual inspection. However, the vast volume of data generated by LiDAR systems presents computational challenges, particularly in efficiently segmenting and classifying power lines, poles, and vegetation. Semantic segmentation models have been pivotal in overcoming these challenges, offering high-accuracy classification of large-scale point clouds [3].

On the other hand, digital twin technology provides a novel framework for addressing these challenges by enabling the creation of dynamic virtual replicas of vegetation and power distribution networks. Digital twins integrate real-world data with advanced modeling and analytical capabilities, offering several benefits, including the potential to model the dynamic behavior of trees, such as growth patterns, movements under loads, and responses to environmental factors like wind [4, 5]. This capability is further enhanced by incorporating additional attributes such as tree type and age, allowing for predictive and adaptive management strategies. Additionally, digital twins facilitate improved asset management for utility poles and power lines by integrating attributes like material type, age, and condition, enabling comprehensive and data-driven maintenance planning.

In our previous work, we demonstrated the application of RandLA-Net for vegetation segmentation and proximity detection, achieving improved accuracy and operational efficiency [6]. Building on this work, the present study advances these efforts by developing a digital twin for vegetation management near power

distribution network. By leveraging 3D models derived from LiDAR data, this study aims to enhance the identification and management of vegetation risks near power lines. The proposed framework integrates refined segmentation, clustering methods and proximity analysis, supporting proactive maintenance strategies and real-time operational insights. The contributions include an integrated framework for accurate risk detection, a digital twin with 3D models, and a scalable solution that can be used for improving the resilience of distribution networks, as well as for managing the assets of these networks. The paper is structured as follows: Section 2 reviews existing works on digital twins based on point cloud analysis. Section 3 describes the proposed framework. Section 4 presents the implementation of the framework. Section 5 discusses findings and future directions, while Section 6 concludes the paper and outlines potential areas for further research.

2 Related Work on Digital Twins Based on Point Cloud Data

Digital twins can be used for assessing risks and managing vegetation near power lines. These models leverage point cloud data to create detailed 3D models, enabling precise monitoring of spatial relationships between trees and infrastructure.

Surface reconstruction is a critical step in translating raw point cloud data into usable 3D models. Techniques such as Delaunay triangulation and KD-tree (k-dimensional tree) indexing, as highlighted by Glumova and Filinskih [7], have proven effective for generating high-quality meshes from unstructured data. Similarly, Ismail et al. [8] explored methods like Poisson Reconstruction and Ball Pivoting Algorithm, focusing on their adaptability and simplicity for applications like building modeling in digital twins. Tagarakis et al. [9] emphasized maintaining geometric accuracy during mesh generation, which is vital for capturing intricate details like tree branches critical for proximity assessments. Chen et al. [10] proposed integrating dynamic simulation data to enhance mesh precision, offering better insights into environmental interactions and vegetation growth.

Alignment of point cloud data with pre-existing models is facilitated by advanced matching algorithms. Zhang and Li [11] utilized simulation tools such as Blender and the Grove plugin to model tree growth under various environmental conditions, ensuring accuracy through comparisons with LiDAR-derived ground truth. Gobeawan et al. [12] extended this by introducing species-specific growth models, precisely aligning these models within spatial constraints derived from point clouds to represent biological and structural tree characteristics effectively.

Digital twins offer continuous monitoring and risk assessment capabilities for power line management. Buonocore et al. [13] demonstrated their use in predicting vegetation growth and simulating environmental impacts, such as weather events, to mitigate risks.

Kim et al. [14] introduced a framework integrating semantic segmentation, geometric processing, and data export into CityGML, streamlining the generation of accurate indoor models from point clouds. Other researchers, such as La Guardia and Koeva's [15] developed interactive 3D web navigation model. Wu et al. [16] proposed a precision alignment method for CAD data to enhance digital twin applications in urban and industrial contexts. Agapaki and Brilakis [17] proposed a deep learning approach for matching point cloud clusters with CAD models. Li et al. [18] developed GRNet framework for 3D object detection and demonstrated the potential of digital twins in diverse infrastructure scenarios. While digital twins have been proposed in urban modeling, existing studies lack an integrated framework that combines LiDAR-based segmentation with digital twin modeling for vegetation management.

3 Proposed Framework

This study extends our prior work [6], where we developed a computer vision framework for managing vegetation near power lines, employing the Random Sampling in Large-scale Point Cloud Analysis Network (RandLA-Net) [19] for semantic segmentation of large-scale 3D point clouds. This framework also included post-processing techniques such as Density-Based Spatial Clustering of Applications with Noise (DBSCAN) [20] for object isolation and rule-based thresholding to filter urban elements and mitigate noise. Furthermore, a proximity detection method was utilized to assess potential risks by analyzing spatial relationships between vegetation and power lines in urban settings. Building on this framework, the current study enhances and integrates these processes into a comprehensive digital twin framework tailored for vegetation management near power distribution networks. The extended framework advances the previous work by creating detailed, dynamic 3D models of power lines, poles, and vegetation using LiDAR data. These models facilitate continuous monitoring and risk assessment, aligning with the concept of a digital twin. Figure 1 shows the proposed integrated framework, where the segmentation and post-processing pipeline serves as the core data processing engine, while the new components enable the generation of the digital twin for enhanced decision-making and management capabilities.

(1) Semantic Segmentation: The RandLA-Net model [19] is employed for segmenting LiDAR point clouds into key classes such as power lines, poles, and

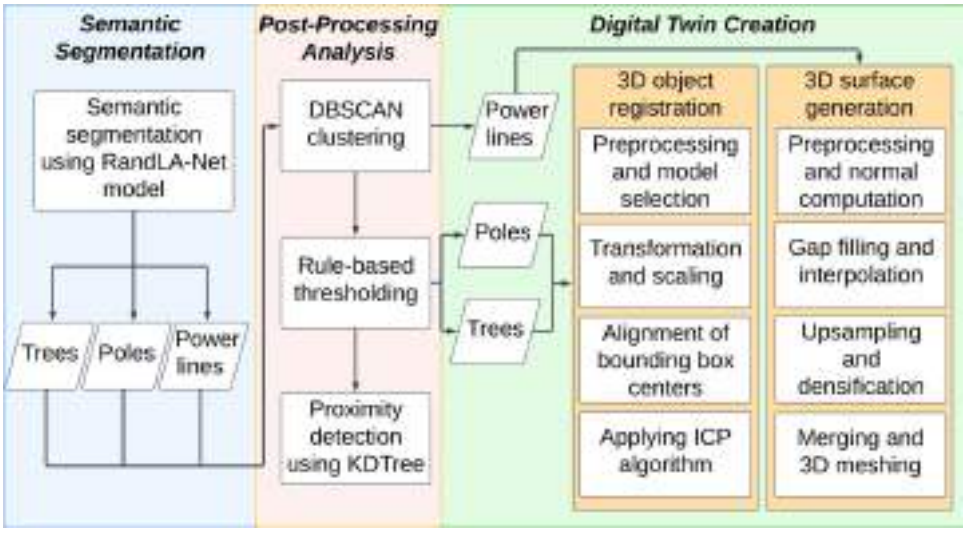

Figure 1. Proposed framework

vegetation, leveraging its efficiency in processing high-density data. This model is chosen for its ability to achieve high accuracy on large-scale datasets, including its notable performance on the Toronto-3D dataset, where it demonstrated superior overall accuracy compared to other methods. RandLA-Net employs random point sampling for downsampling, significantly reducing computational overhead while preserving critical geometric details within the point cloud. Its architecture integrates innovative components, including a local feature aggregation module, comprising local spatial encoding and attentive pooling, which effectively captures complex local structures. Additionally, its use of shared Multilayer Perceptrons (MLPs) and dilated residual blocks enhances both processing speed and scalability, enabling it to handle up to one million points per iteration efficiently. To evaluate the model's performance, the Intersection over Union (IoU) metric is utilized, providing a robust measure of the overlap between predicted and ground truth classifications for each class.

(2) Post-processing: Following the segmentation process, the output data undergoes a series of post-processing steps to enhance its accuracy and utility. DBSCAN algorithm is employed to identify clusters within the segmented point cloud, leveraging its capability to detect clusters of varying shapes and densities without requiring predefined cluster counts. Key parameters, such as epsilon and minimum samples, are carefully tuned to suit the complex structure of urban environments, ensuring sensitivity to variations in density and distribution. Complementing DBSCAN, rule-based thresholding is applied to further refine the output, using class-specific thresholds, such as height and point count, to isolate critical features like trees and poles while effectively filtering noise and irrelevant data. To evaluate proximity risks, that could cause the encroachment of vegetation on power lines, a K-Dimensional Tree (KDTree) structure is used for efficient spatial querying. This approach allows for rapid identification of the nearest tree to each power line, leveraging the KDTree's capacity for efficient multi-dimensional space queries. Proximities are then compared against safety thresholds to flag potential hazards. However, the current proximity detection and risk assessment rely on static conditions, which limits their ability to account for dynamic environmental factors such as wind, tree movement, or weather changes.

(3) Digital Twin Creation: This study employs a systematic approach to construct a seamless representation of power lines, poles, and trees from segmented point cloud data, using Python for 3D data handling and analysis. For power lines, the process begins with importing the segmented point cloud, representing discrete points corresponding to power line geometry. To estimate normal vectors and curvature at each point, a k-nearest neighbor (KNN) search algorithm (K=10) is applied, balancing efficiency and accuracy in densely populated regions. Normal vectors are calculated by fitting a plane to the nearest neighbors, with curvature derived from deviations of neighboring points from the fitted plane, enabling precise modeling of intricate power line geometries. To address data gaps in the segmented point cloud, Radial Basis Function (RBF) interpolation is used for its effectiveness in reconstructing missing points while ensuring smooth, continuous outputs. Additionally, upsampling is employed to achieve uniform point density, enhancing the resolution and accuracy of power line representation.

For poles and trees, segmented point cloud data are aligned with reference 3D models sourced from libraries like Sketchfab [21] and CGTrader [22], assuming all

(a) Examples of poles 3D models

(b) Examples of trees 3D models

Figure 2. Poles and trees libraries

trees belong to the Honey Locust species, which is common in Canada. Figures 2 (a) and (b) show examples of the poles and trees libraries, respectively). The Iterative Closest Point (ICP) algorithm is used for alignment, iteratively refining transformation parameters (translation, rotation, and scaling) to minimize discrepancies between the segmented objects and reference models. Bounding box centers of segmented objects and reference models are aligned for accurate spatial placement, while a scaling step is included to adjust for size differences by computing and applying appropriate scaling factors based on bounding box dimensions. This process involves initializing alignment parameters, applying an initial transformation matrix, and iteratively refining alignment to ensure better matching of the model, location, and size.

4 Implementation

The implementation of the proposed framework builds upon the methodologies discussed earlier, extending the capabilities established in previous work to realize a comprehensive digital twin system for vegetation management near power distribution networks. The process was executed in the following stages:

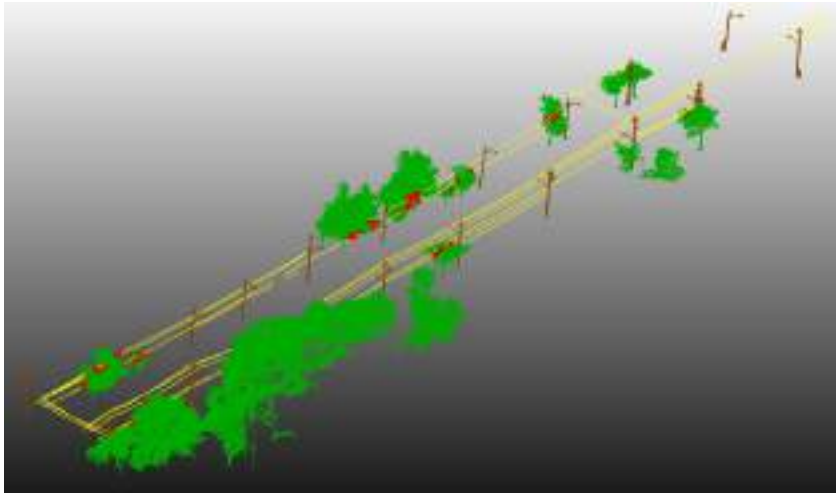
(1) Data Acquisition: This study utilized the Toronto-3D dataset [23], a high-density point cloud dataset collected via Mobile Laser Scanning (MLS) along a one-kilometer stretch of Avenue Road in Toronto, Canada. The dataset, consisting of approximately 78.3 million points with an average ground point density of 1,000 points per square meter, is particularly suited for capturing intricate details of urban environments. Each data point includes attributes such as XYZ coordinates, LiDAR intensity, RGB reflectance, GPS time, scan angle, and class labels, which classify features like roads, trees, poles, power lines, and buildings. The dataset's high density and comprehensive labeling make it ideal for semantic segmentation tasks in this study. Preprocessing steps involved grid subsampling at a 0.06-meter resolution to balance data volume and feature retention. Additionally, projection indices were generated to map processed results back to the original dense point cloud, ensuring consistency and accuracy. These preparations provided a well-structured dataset optimized for semantic segmentation and further analysis. Figure 3 shows point cloud data of a sample area.

(2) Semantic Segmentation: The RandLA-Net model was trained and optimized using the Toronto-3D dataset, focusing on the segmentation of vegetation, poles, and power lines. The training process involved dividing the dataset into sections for training and testing, with three sections designated for training and one for evaluation. The model underwent 100 epochs of training using the Adam optimizer with an initial learning rate of 0.01, which decreased by 5% per epoch to improve convergence. A batch size of 4 was selected to balance computational efficiency and training performance.

Training was conducted over 124 hours and 33 minutes on a workstation equipped with an NVIDIA RTX A6000 GPU and a 48-core CPU, ensuring high computational power for processing the dense point cloud data. However, the inference time takes about 10 minutes. The model incorporated geometric features along with RGB

Figure 3. A sample area of point cloud data

and intensity attributes to enhance segmentation accuracy. To ensure optimal model performance, various configurations of RandLA-Net were tested on the Toronto-3D dataset. This involved systematically exploring different combinations of hyperparameters to evaluate their impact on classification and segmentation accuracy. The best-performing configuration from these tests was selected and utilized in the subsequent stages. The test results demonstrated high IoU scores for individual classes, achieving 97.05% for trees, 87.44% for power lines, and 82.33% for poles, ensuring reliable classification for the target features. This robust performance underpins the digital twin framework by providing precise and detailed semantic segmentation of the urban environment.



(3) Post-Processing: In the post-processing phase, DBSCAN clustering was utilized to refine the segmented point clouds by identifying and isolating critical features based on spatial density and predefined thresholds for height and point count. Parameters such as epsilon (maximum distance between samples) and the minimum number of samples were carefully calibrated to align with the attributes of the Toronto-3D dataset. Clusters exceeding specific thresholds, such as a height threshold of 8 meters for poles or a minimum point count of 500 points for vegetation, were retained, while irrelevant features and noise were filtered out. This approach ensured that significant urban elements were clearly distinguished for further analysis. To assess proximity risks, KDTree spatial queries were employed to calculate the distances between vegetation and power lines in a 3D space. These distances were compared against a safety threshold (e.g., 1 meter) to identify hazardous tree regions encroaching on power lines. These flagged areas were then prioritized for risk management, supporting effective vegetation maintenance and infrastructure safety. Figure 4(a) shows the post-processed semantic segmentation result, highlighting hazardous tree areas (red points) within the safety perimeter of power distribution lines.

(3) Digital Twin Development: For the utility lines, the implementation of the methodology was carried out using Python and its specialized libraries for point cloud processing. Segmented point cloud data was imported, and a KNN algorithm was applied to compute the 10 nearest neighbors for each point. Normal vectors were calculated by fitting a plane to these neighbors, and curvature was estimated by measuring deviations from this plane. To ensure continuity in the utility lines, RBF interpolation was employed to fill gaps in the point cloud. This process created a seamless structure by reconstructing missing data points. An upsampling step was then applied to increase point density in sparse regions, enhancing the model's resolution and uniformity. Finally, the segmented sections were integrated into a single, cohesive representation, ensuring geometric continuity.

The process for poles and trees involved aligning segmented point cloud data with reference 3D models using Python. Reference models were imported, and alignment began with the initialization of parameters based on approximate geometry and spatial data. A transformation matrix, incorporating rotation, translation, and scaling, was applied for preliminary alignment. The ICP algorithm was then used to iteratively refine these parameters, minimizing alignment errors and ensuring a precise fit. To ensure spatial and size accuracy, the bounding box centers of segmented objects and reference models were aligned, and a scaling factor was applied based on a comparison of their bounding box dimensions. Finally, the geometrical attributes of the created 3D objects are added to these objects. Figure 4(b) illustrates the digital twin model integrating the 3D models of trees, poles, and utility lines derived from the point cloud data.

5 Discussion

Digital twins offer a dynamic, continuously updated virtual representation of power lines, poles, and

(a) Post-processed result of semantic segmentation, highlighting hazardous tree areas near power lines

(b) Digital twin model

Figure 4. Digital twin model based on point cloud data

vegetation, that can be a part of a federated digital twin at the urban level. The work presented in this paper is limited by the fact that the digital twin developed so far is static. However, by integrating diverse data sources, including point clouds, GIS data, satellite imagery, and real-time weather updates, the digital twin can be further developed to provide a high-fidelity, dynamic model for vegetation management near power distribution networks. A critical advantage of this digital twin lies in its ability to simulate and predict how various factors, such as vegetation growth and adverse weather, affect overhead power lines. This predictive capability can be bolstered by deep learning (DL) algorithms, which enable accurate forecasting of vegetation dynamics, offering actionable insights for proactive management [24, 25]. Key attributes such as tree height, canopy spread, and species types are indispensable for evaluating risks to power infrastructure. Tree height helps identify potential threats from vegetation of comparable or greater height than poles, while canopy spread highlights horizontal encroachments even from distant trunks. Species type offers further context, enabling growth pattern predictions and customized maintenance strategies. Incorporating these attributes into the digital twin enhances risk assessment, providing utility managers with a robust framework for mitigating vegetation-related hazards.

Furthermore, this digital twin can integrate weather simulation to assess and address compound risks, such as the interplay of high winds and dense tree canopies, which exacerbate outage probabilities. By analyzing historical weather data and integrating live forecasts, this digital twin can dynamically update risk profiles, enabling timely interventions like proactive pruning or operational adjustments to minimize disruptions. This real-time adaptability transforms network management

from reactive to preventive, which can optimize resources [4, 5]. Moreover, this digital twin fosters organizational collaboration by serving as a centralized platform that unifies data across departments. This shared understanding of network conditions enhances communication and aligns teams toward common objectives, such as reliability and resilience. The capacity to simulate the outcomes of various vegetation management strategies, such as modified pruning schedules or low-maintenance species planting, supports sustainable practices that balance operational demands with environmental considerations.

While the creation and maintenance of digital twins require an initial investment, their unparalleled benefits justify the effort. Unlike static models, they provide not only visualization, but also actionable intelligence for strategic planning. For example, predictive growth models informed by species-specific data and environmental conditions (e.g., climate, soil) allow precise forecasts of tree encroachment on power lines. Adopting digital twins also opens avenues for sustainable vegetation management. By optimizing trimming schedules and employing selective pruning techniques, they minimize carbon emissions associated with vegetation maintenance. While traditional methods focus on clearing immediate risks, digital twins enable long-term planning that preserves larger trees while maintaining network safety. This approach aligns utility management goals with environmental stewardship, enhancing biodiversity and urban air quality [26, 27].

6 Conclusions and Future Work

This paper presents an integrated framework for computer vison-based digital twin for power distribution network management, focusing on vegetation management and risk assessment. The framework leverages the RandLA-Net model for semantic segmentation of power lines, poles, and vegetation, coupled with post-processing techniques such as DBSCAN clustering and rule-based thresholding to refine data outputs. Proximity detection using KDTree spatial analysis ensures precise identification of hazardous zones. The processed data is utilized to generate accurate 3D models, forming the foundation of a digital twin. By addressing key challenges such as data segmentation and geometric refinement, the framework enhances proactive vegetation management strategies and contributes to infrastructure resilience. The study demonstrates the potential of integrating computer vision and point cloud data processing techniques for developing digital twins for vegetation management near power distribution networks. The proposed framework effectively combines semantic segmentation, clustering, and proximity analysis to provide detailed 3D models for risk assessment and maintenance planning. The results highlight the scalability and reliability of the approach, offering a practical solution for improving vegetation management and infrastructure safety. These findings represent a significant step toward leveraging digital twin technology for utility management, with potential applications across a wide range of urban and industrial systems.

While the proposed framework offers significant advancements, several limitations remain. The framework has been tested primarily on the Toronto-3D dataset, which may not capture the diversity of urban and rural environments. Future work should involve testing on datasets with varying complexities and characteristics to enhance generalizability and robustness. Additionally, the RandLA-Net model and post-processing techniques, such as DBSCAN clustering and KDTree queries, require substantial computational resources. Optimization efforts are necessary to enable real-time processing and scalability for larger networks, especially in resource-constrained settings.

Beyond these points, as explained in Section 5, additional limitations include incorporating real-time and multi-source data streams, predictive vegetation growth modeling, and sustainability practices. Addressing these topics will be essential to fully realize the potential of the proposed framework for comprehensive risk assessment and more resilient power distribution systems.

Abstract –

Panelized construction is an offsite construction approach that offers enhanced design flexibility and cost-effective assembly. Despite these advantages, it faces challenges due to a fragmented supply chain (SC) and transportation coordination issues that can lead to cost overruns and schedule delays. To address these challenges, this study introduces a transportation planning method that leverages Just-In-Time principles and hybrid multi-agent simulation to align factory and onsite operations across multiple projects through integrated transportation procedures. These procedures categorize SC flows into: (1) a dispatching flow, which manages trailer loading and dispatch readiness; and (2) a reverse flow, which ensures the timely retrieval of empty trailers to maintain continuous production. These flows form the core of an innovative resource coordination strategy that dynamically allocates resources, including trailers and trucks, to ensure an uninterrupted supply of panels from factory to sites. The validation results using operational data from a residential panel manufacturer illustrate the model's effectiveness in coordinating SC operations and resources. The model successfully adapts to fluctuating onsite demands and aligns transportation operations with delivery dates, matching real operational timelines. The model also manages limited production capacities efficiently and ensures precise trailer dispatch, effective truck assignments, and timely retrievals of empty trailers from different sites. The proposed simulation-based planning model provides an integrated and automated solution to improve SC performance, supporting efficient multi-production lines and multi-project operations in panelized construction.

1 Introduction

In panelized construction, floor, wall, and roof panels are produced in a factory-controlled environment and then transported to project sites for final assembly [1]. This approach provides several advantages compared to volumetric modular construction, such as easier handling of prefabricated components (since the components are smaller and lighter), a higher degree design flexibility, and reduced crane capacity required for onsite assembly [2]. However, the adoption of panelized construction faces challenges with respect to supply chain management (SCM), integrated planning, transportation logistics, and storage constraints (both at the factory and on site). These issues can disrupt the coordination between production, transportation, and onsite assembly, leading to increased project costs and extended schedules [1–3]. To address these challenges, efficient transportation planning is essential. Transportation planning facilitates the integration of factory production lines with project sites and manages the delivery of loaded trailers to sites and the return of empty trailers to the factory (i.e., distribution and reverse logistics). The transportation process bridges factory and onsite operations by ensuring the timely delivery of panels to project sites—a vital function for maintaining the continuous progress of onsite activities. Disruptions in transportation operations, such as delays in trailer distribution or inefficiencies in reverse logistics, can lead to idle resources and delays in onsite schedules. Moreover, factory production may be interrupted due to the unavailability of empty trailers (which are needed for loading manufactured panels). Thus, effective transportation planning is crucial for minimizing supply chain (SC) operational time and costs while enhancing the performance of both factory and project site operations.

Studies on offsite construction (OSC) transportation planning and logistics have primarily focused on individual aspects of the SC, often addressing either factory operations or construction site requirements [4,5]. While some studies

have considered integrated planning [6], these have not accounted for the unique transportation challenges in panelized construction, particularly the coordination of individual panels produced in multiple production lines, the various trailer types, operational-level planning of SC tasks, and just-in-time (JIT) delivery (as opposed to using intermediate storage space between factory and site).

Existing studies have explored methods for optimizing transportation in OSC contexts such as ready-mixed concrete, precast components, and modular construction [7–10]. These works have addressed diverse topics related to transportation planning in OSC, including optimal vehicle routing and the development of stacking plans [11,12]. However, the unique needs of panelized construction, such as integrating distribution and reverse logistics and the treatment of trucks and trailers as separate units performing distinct tasks, have not been accommodated in these studies.

These limitations highlight the following critical gaps in the literature: (1) existing studies have not considered the needs of factory and project sites simultaneously, which is essential for integrated SC operational performance; (2) reverse logistics, a key component of panelized construction, has not received adequate attention (with this gap resulting in inefficiencies in trailer utilization and delays in production schedules, ultimately disrupting the SC flow); and (3) existing studies have typically assumed the availability of sufficient onsite storage, which is unrealistic for panelized construction projects (in which, ideally, JIT delivery is employed to address limited space and assembly sequencing requirements). Additionally, prior studies, such as Hsu et al. (2018) [6], have focused on truck-based transportation planning while overlooking the need to manage trailers separately from trucks (which, in turn, introduces additional coordination challenges, as trailers have distinct dispatching and returning operations that directly affect SC efficiency).

To address these gaps, the present study develops an integrated transportation planning framework tailored to panelized construction. The aim underlying the framework development is to coordinate factory production with onsite requirements, ensuring efficient trailer distribution and return operations while minimizing idle time for both transportation fleets and construction resources. Unlike previous approaches, this framework encompasses trailer prioritization based on onsite assembly sequencing and crane availability, ensuring efficient resource allocation and uninterrupted SC flow. By aligning transportation operations with factory production and onsite requirements, the proposed framework enhances SC performance, reduces project delays, and improves overall SCM efficiency.

2 Methodology

As illustrated in Figure 1, the proposed framework consists of the following four steps: (1) define SC operational objectives and constraints; (2) develop integrated transportation procedures; (3) design and build the simulation model; and (4) conduct model validation and output evaluation. The first step identifies goals such as synchronizing factory production with onsite schedules and minimizing delays, inventory, and inefficiencies. In the second step, a dispatching flow is established to ensure timely trailer loading and dispatch based on onsite requirements, along with a reverse flow for the efficient retrieval of empty trailers as a means of maintaining production continuity. In the third step, Agent-based Modeling (ABM) is implemented in the simulation model to represent factory production lines, trailers, trucks, and onsite operations. Moreover, discrete-event simulation (DES) is used to model workflows inside the agents, and GIS integration is used as a shared agent environment, facilitating resource agent movement (e.g., truck movement) within the SC. The model incorporates a GIS city map, enabling agents to navigate SC locations—factory and project sites—positioned using geographic coordinates. Agents move along transportation routes, with travel times determined based on real distances, speed limits, and road network constraints. This GIS functionality supports route selection and scheduling by incorporating distance-based travel times and automatically determining the shortest route for transportation resources, ensuring a realistic representation of transportation planning. Finally, the robustness and accuracy of the model are ensured through verification using artificial datasets and validation using real operational data to evaluate JIT adherence, resource utilization and efficiency, operations timelines, and synchronized SC performance.

To efficiently integrate transportation operations with other SC activities involved in the production and onsite assembly stages, integrated transportation procedures for SCM in panelized construction are first developed. These procedures constitute a systematic approach to managing a multi-unit fleet of trucks and trailers during a typical working day. This approach also defines critical decision points such as trailer prioritization, onsite sequence checks, and operational constraints (e.g., panel delivery dates, truck availability). Unlike traditional truck-based approaches, this method treats trailers as independent transportation units requiring distinct dispatching and returning operations. By dynamically prioritizing trailer dispatch based on onsite assembly sequencing and crane availability, the method enhances resource utilization and minimizes SC waste (i.e., resource idle time). By aligning transportation with production and onsite demands, these procedures ensure adherence to JIT delivery principles.

Figure 2 presents the developed pseudocode, which captures these transportation procedures in detail through two primary flows-dispatching flow and reverse flow.

(1) Dispatching flow—managing the fleet by checking loaded trailer availability and panel delivery dates, prioritizing trailers that contain panels required earlier in the onsite sequence, and ensuring trailers are assigned to sites with idle cranes to reduce waiting times. This trailer prioritization strategy prevents bottlenecks and ensures cranes remain productive, improving overall SC performance. Dispatching flow also assigns trucks for dispatch, and verifies sequence readiness at the site before delivery. Once dispatched, trucks deliver the loaded trailers to the project site and return to the factory for subsequent tasks.

(2) Reverse flow—retrieving empty trailers during a truck's return from dispatch or through an independent retrieval process triggered when the factory's trailer buffer falls below a threshold. This mechanism prevents production disruptions from trailer shortages and maintains fleet circulation, enhancing SC efficiency.

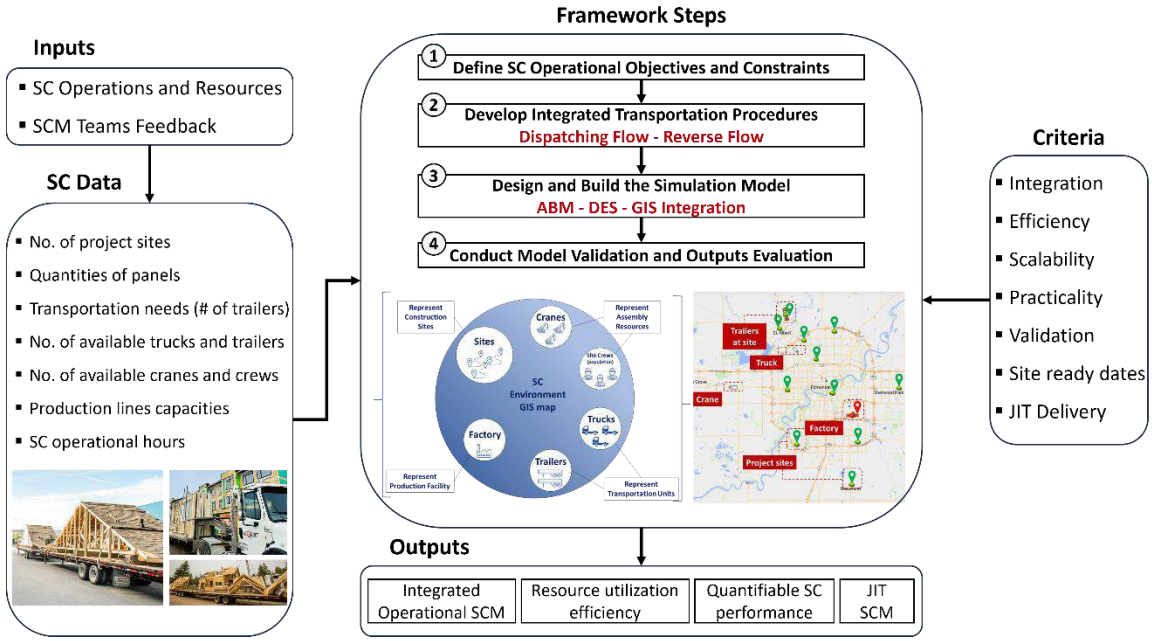

Figure 1. Overview of the research framework

The developed transportation procedures serve as the foundation for the development of the simulation's governing logic, ensuring seamless coordination between factory, transportation, and onsite operations. The simulation model integrates SC operations by leveraging ABM and DES to plan transportation-oriented panelized construction processes. This simulation models SC resources and entities as agents communicating and executing tasks based on specific production and logistics requirements within a predefined planning period. Figure 3 presents a sequence diagram illustrating the interactions among key agents: (1) the factory, which processes production and logistics requests, assigns production lines, manages trailers, trucks, cranes, and crews, and dynamically coordinates both dispatching and reverse flows; (2) the project site, which generates logistics requests, monitors deliveries, completes the onsite assembly, and manages the marking and release of empty trailers for retrieval; (3) trailer and truck, which facilitate the transportation of panels to project sites and the retrieval of empty trailers to the factory; and (4) crane and crew, which execute onsite tasks synchronized with production and transportation progress.

The simulation model outlines two primary transportation operations: (i) dispatching operations, initiated when production is completed, panels are loaded into trailers, and the panel delivery date comes due (based on the simulation time); and (ii) returning operations, activated post-onsite assembly, where trailers are marked as empty, and the factory assigns trucks for retrieval. In the developed simulation model, the factory agent plays a pivotal role in managing logistics operations to ensure the completion of all SC activities. The factory agent receives production requests (i.e., information about the quantities of panels and the location of the delivery site) and logistics requests (i.e., information about the crane type required and the number of crews) from project site agents. Based on these requests, the factory agent ensures the assignment of cranes and crews before establishing any dispatching to sites.

The factory agent processes the requests received using DES models that depict production lines and logistics workflows. These DES models actively communicate with truck and trailer agents by monitoring the behavior charts (i.e., statecharts) that show their operational status within the SC. Figure 4 illustrates the

statecharts of trucks and trailers, depicting their state transitions during key operations such as loading, dispatching, and returning. These charts detail the interactions and transitions for trucks and trailers, and they are dynamically updated as the simulation progresses. Trailers progress through three primary states: (i) (AtFactory), representing empty trailers available for loading; (ii) (TrailerLoaded), indicating trailers loaded and delivered to construction sites; and (iii) (TrailerUnLoaded), referring to trailers that have completed their deliveries and are awaiting return to the factory. To minimize delays and support uninterrupted production, the factory agent ensures the prompt return of trailers, following the reverse flow procedures outlined in Figure 2.

Similarly, trucks transition between two states: (i) (TruckAvailable), indicating readiness for new transport assignments; and (ii) (TruckUnavailable), signifying active dispatch or return operations. By incorporating the transportation procedures, agent requirements, and statecharts reflecting resource operational conditions, the simulation achieves seamless and efficient transportation cycles throughout the planning horizon.

3 Implementation and Results

To evaluate the proposed integrated transportation procedures, a case study was conducted using operational data from ACQBUILT, an Alberta-based prefabricated panel manufacturer. The case company produces floor, wall, and roof panels in a factory-controlled environment and transports them to project sites for assembly. Despite advancements in production automation, the case company's SCM remains manual, lacking integration between production and onsite operations. It relies on push planning, producing panels early regardless of onsite delivery dates, resulting in excess inventory and inefficiencies. The proposed transportation procedures ensure timely delivery of panels by bridging factory and onsite operations. A simulation model was developed to test the proposed procedures under realistic conditions in order to demonstrate their ability to connect factory production, transportation, and onsite assembly for efficient SC performance.

To assess the effectiveness of the proposed framework, several verification and validation steps were conducted. Test cases using artificial datasets were developed to confirm agent interactions and workflows, ensuring the procedures functioned as intended. Additionally, the movement of transportation resources on a GIS map was visually checked to verify that trucks were traveling to the required destinations while adhering to operational hours and taking the shortest available route. Real operational data and project details from April, 2021, was also used to validate the ability of the proposed framework to align with actual production progress and meet onsite requirements. During April, 2021, panels for 35 distinct home construction projects needed to be produced, transported and assembled on site. These projects varied in design complexity, panel sizes, and panel quantities, leading to differences in transportation scheduling, trailer allocation, and onsite

sequencing. The proposed framework manages variations through independent project site agents, each autonomously handling its panel orders, trailer arrivals, and resource coordination based on project-specific parameters. This structure ensures that each site dynamically adapts its logistics based on actual SC conditions, supporting multi-project scalability. With respect to the case implementation, the simulation model used the same production capacities and SC resources as those established by the partner in reality for the same period (April, 2021). While predefined factory capacities, working hours, and resource availabilities serve as operational constraints in the proposed framework, the scheduling process itself is automated. The framework dynamically extracts actual job details and available resources from the enterprise resource planning system (ERP) and updates scheduling parameters accordingly. A dedicated user interface (UI) extracts data and integrates it into a built-in database (DB) within the simulation that structures SC configurations and job details. These automated updates ensure that each scheduling horizon reflects the latest available data without requiring manual intervention beyond predefined constraints. To ensure data reliability, extracted datasets undergo a structured verification process before integration into the simulation model. Before integration, extracted data is validated in structured Excel files to flag inconsistencies. Missing values either are corrected through cross-validation with ERP records or are replaced with default estimates based on historical data to maintain scheduling feasibility.

The purpose of the validation was to evaluate the performance of the proposed framework against operational data for manufacturing, delivery, and onsite assembly. Metrics such as delivery times and adherence to JIT delivery were used to assess the successful coordination of SC processes. Expert feedback further confirmed the practicality of the generated SC operational plans and the effectiveness of the developed model in minimizing delays in dispatching and returning operations and enhancing resource allocation, thus achieving integrated SC performance. It should be noted that, given its structured database architecture and ERP-based data extraction, the framework can be adapted to other OSC companies with similar SC structures, ensuring flexibility in different operational environments.

The first verification step was to ensure that the model accurately manages production operations in response to onsite demand. The factory agent should be able to receive and record all required panel quantities and then manage production according to factory procedures. Moreover, the factory agent should adhere to internal constraints (e.g., production line capacities and operational days). For instance, as shown in Figure 5, on April 15, 2021, a peak daily request of approximately 20,000 sq ft was recorded, exceeding the production line's capacity of 12,000 sq ft/day. Despite the high demand, the model ensured that production remained within capacity by deferring excess quantities to subsequent operational days. Non-operational days, such as April 11, 18, and 25, were accurately represented with zero production, reflecting compliance with predefined factory capacities. Another verification aspect was to ensure model accuracy in terms of the total quantities received from the sites being equal to the total amounts produced by the factory at the end of the planning period. As shown in Figure 5, cumulative quantities confirmed that the wall production line successfully fulfilled all orders received, with the cumulative received and produced quantities reaching the same number, 168,680 sq ft, by April 28, 2021. These results underscore the model's ability to dynamically adjust production to meet varying demands while maintaining efficiency and strict adherence to operational constraints.

After verifying the production performance, the focus shifted to evaluating the transportation procedures to confirm their effectiveness in seamlessly linking production and onsite activities. The factory uses two types of trailers: flatbed trailers for loading floor and roof panels and vertical trailers for wall panels. In the model, "TA 1-TA 35" represents flatbed trailers while "TA36-TA55" refers to vertical trailers. As shown in Table 1, the model assigns trailers based on panel type and initiates dispatching operations efficiently. For instance, Trailer 38 was loaded with Wall0 on April 12 at 10:51. However, Truck 1 was assigned (and dispatching occurred) on April 15 to ensure delivery on the same day panels were required on site, with arrival at the site on April 15 at 5:39 and assembly completed by 8:30. As this example demonstrates, the model was found to adhere to JIT principles, ensuring trailers and trucks arrive onsite before assembly begins and promptly return empty trailers after assembly. Regarding returning operations, there are two notable patterns: daytime returns to meet immediate factory needs and end-of-day returns for flexibility. Dispatching operations are prioritized to ensure timely delivery to sites and to maintain continuity in onsite assembly activities by avoiding crane idle times.

Finally, the model's ability to manage the assembly of the same number of jobs completed in reality was validated by comparing assembly quantities between actual SC performance and simulated results. Although daily assembled quantities were found to fluctuate, the model completed all assembly operations on the same day as the actual schedule (April 30, 2021). Additionally, the total cumulative quantities (58,600 sq ft) in reality were the same as in the simulation, demonstrating the model's accuracy in completing all necessary onsite tasks. These results validated the model's ability to synchronize dispatching, onsite activities, and trailer returns, ensuring JIT delivery and maintaining alignment across the SC.

4 Conclusion

This study introduces a simulation-based framework designed to address the complex challenges of SCM in panelized construction. It integrates production, transportation, and onsite assembly using JIT delivery principles and hybrid multi-agent simulation, enabling synchronized SC operations. The proposed framework develops integrated transportation procedures that plan dispatching and reverse flows in the SC, emphasizing coordinated operations and resource allocation.

The contributions of this study are as follows. First, a synchronized transportation planning framework tailored to panelized construction is proposed. This framework uniquely addresses the dual objectives of improving factory and onsite operations by considering trucks and trailers as distinct entities with different tasks. By integrating distribution and reverse logistics with JIT, it resolves inefficiencies in trailer utilization, mitigates delays, and aligns transportation flows with onsite needs, enhancing overall SC performance. Second, a detailed approach to simulation of SC workflows, including dispatching and reverse logistics, is developed. The model captures interactions among trailers, trucks, cranes, and crews to address limited onsite storage and improve resource allocation. By focusing on actionable strategies, such as adhering to onsite delivery dates, the framework provides practical insights for mitigating SC disruptions. Third, a practical simulation-based SCM approach is proposed that enables the automated generation of SC plans, ensuring dynamic coordination between production, transportation, and onsite assembly. It also addresses SCM challenges such as onsite storage constraints by applying JIT, ensuring minimal waste and efficient resource utilization. Moreover, the proposed transportation planning procedures introduce an algorithmic innovation by integrating rule-based

heuristics for trailer prioritization, dynamically aligning dispatching and retrieval decisions with onsite SC conditions to improve resource allocation and minimize idle time. Additionally, the framework supports operational decision-making, empowering stakeholders to test various SCM scenarios, thereby ensuring adaptability to onsite-specific challenges and constraints.

While the case study presented herein demonstrated the framework's ability to coordinate multi-project operations, handling logistics for 35 distinct sites with varying resource requirements, future research could be undertaken to further validate the model's scalability by applying it to a more diverse project environment, such as multi-manufacturer settings or projects with different types (e.g., commercial projects). Moreover, the model's application could be expanded to assess its adaptability to additional logistical constraints and SC configurations.

Furthermore, while the proposed simulation model effectively coordinates transportation and production using predefined decision rules and heuristics, further enhancements could be made by incorporating optimization-driven decision-making. The integration of metaheuristic algorithms (e.g., genetic algorithms) could further improve resource allocation by, for instance, optimizing the balance between owned and rented transportation resources, ensuring cost-effective fleet management while maintaining operational flexibility. Additionally, stochastic factors could be incorporated improve the model's ability to account for uncertainties in SC performance, particularly fluctuations in transportation availability, onsite demand variations, and operational constraints. These advancements could contribute to further reductions in operational costs and scheduling delays while improving overall SC resilience. The framework could also be extended to evaluate alternative transportation methods, such as rail, ship, or autonomous vehicles, by introducing corresponding agents into the simulation model. This extension would allow for the impact of different transportation strategies on the efficiency and cost-effectiveness of the SC to be analyzed. Furthermore, sustainability metrics could be integrated to evaluate the environmental impact of different transportation strategies, providing insights into reducing carbon emissions and improving the sustainable performance of SC operations.

Abstract

This paper presents a novel image-based indoor localization approach that leverages semantic segmentation techniques by combining synthetic images generated from building information modelling (BIM) and deep learning (DL) methods. Unlike traditional image-based methods that compare overall visual features, our approach focuses on stable building components—such as floors, ceilings, walls, doors, and windows—that remain largely consistent over time. To enhance localization accuracy, we introduce a new similarity metric based on the intersection-over-union (IoU) ratio for each building component. This metric accounts for the spatial distribution of building elements, allowing for more robust comparisons between semantic masks derived from real-captured images and those generated from synthetic BIM models. The method reduces the dependence on detailed BIM models, enhancing reliability by focusing on the geometric and semantic consistency of key building elements. The feasibility of the approach is demonstrated through a case study with an institutional building, showcasing promising localization performance despite low-fidelity BIM models.

1 Introduction and Related Works

Accurate indoor localization plays a crucial role in enabling a wide range of applications such as facility management, disaster response, and navigational assistance in complex indoor environments [1]. In recent years, various indoor localization methods have been developed, such as dead reckoning approaches with inertial sensors and piloting approaches using range-based signals [2-3]. However, these methods have their own constraints. For instance, range-based signals such as Wi-Fi, Bluetooth, and ultra-wideband signals are highly susceptible to environmental interference (e.g., walls) and require additional deployment of hardware infrastructure within buildings. Inertial measurement unit (IMU)-based methods suffer from cumulative drift errors, leading to decreased positioning accuracy over time [4]. In contrast, image-based localization methods offer a promising alternative, as they have a lower reliance on specialized hardware and can provide discrete, location-referenced measurements [5].

Traditional image-based indoor localization methods typically incorporate an offline database collection and an online image retrieval process [6]. During offline collection, various views of indoor environments need to be captured to establish an image database along with the associated locations and orientations. Subsequently, the online image retrieval is performed to leverage a real-captured query image to search the database for the most visually similar match, from which the position can be inferred. Nevertheless, the database collection process demands extensive preparatory work, and the effectiveness of the database may be affected over time when the indoor environment evolves, and the visual characteristics of certain areas change significantly [7].

To reduce the manual effort in data collection, recent research has explored building information modelling (BIM) to generate synthetic images in an automated and controllable manner. For instance, Ha et al. [8] generated the BIM-rendered images and then utilized a convolutional neural network (i.e., VGG 16 [9]) to measure the similarity between the real-captured images and the BIM-rendered images for indoor localization.

Similarly, in the study by Acharya et al. [10], the authors used 3D indoor models to generate rendered synthetic images and perform similarity comparison on a modified GoogLeNet-based deep convolutional neural network architecture (i.e., PoseNet [11]). These studies showcase the benefits of BIMs for image database collection, such as rapid image generation and customizable camera configurations like positions, orientation, and focal lengths. Despite these advantages, these BIM-derived methods have their limitations. To ensure the effectiveness of the similarity calculation between the real-captured and BIM-rendered images, these methods rely heavily on the high fidelity of BIM models, such as the inclusion of furniture, fixtures, and decorations. Such a prerequisite, in turn, requires certain human efforts to maintain the similarity of visual appearance continuously and meticulously. Any discrepancy, caused by insufficient detail in modelling or significant changes in actual environments, can severely degrade the positioning accuracy.

To address these challenges, this study proposes a semantic segmentation-oriented indoor localization approach by leveraging synthetic BIM image generation and deep learning (DL) techniques. Instead of comparing the holistic visual similarity of environments, the proposed approach concentrates on fundamental building components, i.e., floors, ceilings, walls, doors, and windows, since these components usually remain stable regardless of the interior changes and thus provide robust referencing patterns for similarity computation. In this way, the approach reduces the dependency on the highly detailed BIM models. The objectives of this study are: (1) to create an automated approach to generate the semantic masks of BIM-rendered images and real-captured images for similarity computation; (2) to develop a semantic segmentation-oriented similarity metric to implement image retrieval; and (3) to investigate the feasibility and quantify the performance of the proposed approach using a real-world case study. The detailed method development and validation are discussed in the following sections.

2 Methodology

The proposed approach consists of three key stages, including BIM-based synthetic image generation, DL-based image segmentation for real captures, and similarity-based image retrieval. Fig. 1 illustrates the architecture of the proposed approach.

2.1 BIM-based Synthetic Mask

In this study, fundamental building components (i.e., floors, ceilings, walls, doors, and windows) are prioritized since they generally maintain stable geometric and spatial relationships over time. In contrast, furniture and decorative elements may sometimes change and thus offer less reliable features for image matching. Specifically, the relative positions and proportions of these building elements can provide persistent features to enhance similarity measurements. Therefore, this study intends to generate semantic masks to exploit both the semantic and geometric information contained in each captured view.

To construct a database of semantic masks, BIM models are selected as they offer accurate geometries of the target environment and allow flexible configurations for camera deployment. A custom plugin is developed via the Revit API [12] to automate the placement of virtual cameras within the BIM environment for capturing various interior views. Specifically, the cameras are positioned at predefined intervals along two

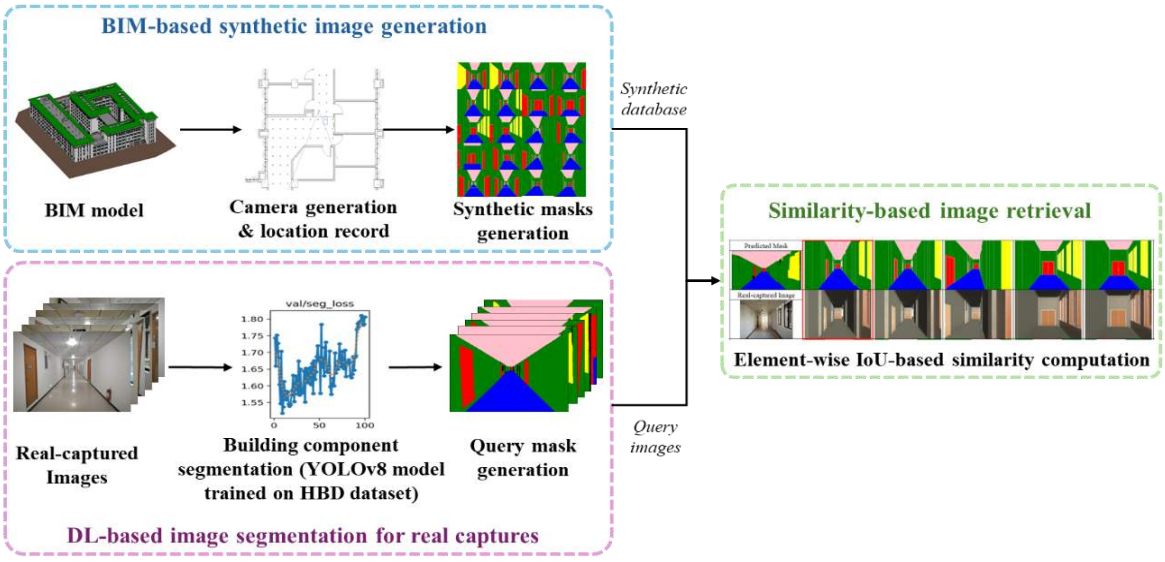

Figure 1. The architecture of the proposed approach

axes, and the boundaries of interior spaces are used to exclude any out-of-bound camera placements. From each camera's position, four axis-aligned orientations are recorded to ensure comprehensive interior coverage. Moreover, camera parameters such as height, image resolution, and dots-per-inch (DPI) can be further customized to produce images with suitable sizes and qualities.

Once the virtual cameras are configured, each building component type within the BIM model is assigned a distinct rendered color to generate component-specific semantic masks. This process involves filtering each target component into a collection and then overriding its graphical properties to establish consistent color coding. Through these steps, synthetic semantic masks from various camera views are generated, along with the corresponding positions and orientations, together constituting the reference database for image retrieval.

During the large-scale semantic mask generation, certain images may lack sufficient spatial features (such as the cases where cameras are placed too close to walls) and provide limited values for image matching. To address this, a filtering process is introduced to enhance the quality of the synthetic BIM-based mask database. The filtering criterion is to retain images that simultaneously include both the ceiling and the floor classes to ensure sufficient semantic and geometric patterns are covered in the masks across various capturing views. In this way, the less distinguishing semantic masks are removed by filtering to enhance the referential quality of the database.

2.2 DL-based Image Segmentation for Real Captures

After preparing the offline database, it is also necessary to process real-captured images and create corresponding masks that have consistent classes with the synthetic BIM masks. To do so, this study employs supervised learning techniques to classify and delineate the building components within images. Specifically, an off-the-shelf image segmentation model, YOLOv8 [13], is adopted as it enables rapid inference speed while maintaining good recognition performance. To align with the classes in the synthetic BIM masks, this study selects the HKU building image dataset (HBD) as the training material since it comprises large-scale annotated images of both building interiors and exteriors, covering all the interested building components [14]. Given the scope of this study, a subset of HBD containing only the interior scenes is utilized, yielding 1,780, 224, and 231 images for training, validation, and testing.

The training process is performed using a computer with configurations of Intel i9-14900HX CPU, NVIDIA GeForce RTX 4060 laptop GPU, and 8 GB GPU memory. After 300 epochs, the training and validation losses plateau, and the training process is terminated. As a result, the best-performing model with the highest validation is subsequently deployed for real-world predictions. The segmentation performance on the test set is summarized in Table 1, which indicates the model obtains moderately high segmentation accuracy. The segmentation of ceilings and floors performs relatively well, probably due to their fixed positions and shapes within images. In contrast, the segmentation result of windows is less effective because of the limited training materials (731 instances in total in the interior scenes of the HBD dataset [14]) and their various appearances.

Table 1. Building component segmentation results on the test set

Class	Images	Instances	mAP^{50}	mAP^{50-95}
Wall	228	554	0.829	0.670
Door	183	315	0.938	0.868
Window	34	94	0.741	0.540
Ceiling	190	213	0.915	0.776
Floor	215	237	0.945	0.866

2.3 Similarity-based Image Retrieval

Last, similarity-based image retrieval is implemented to match the real query images and the BIM-based image database to calculate the most similar pair and acquire the camera positions for indoor localization. Specifically, both the BIM-derived synthetic masks and the real-captured semantic mask are utilized for comparison. These semantic masks effectively capture the composition of the architectural elements, where their spatial arrangement and proportions help characterize the interior layouts. In general, two images deemed similar would exhibit analogous distribution and counts of building elements, occupying comparable proportions and locations within each image. Based on this pattern, this study designs a similarity metric using the element-wise intersection-over-union (IoU) ratio to reflect the overlaps between the real and synthetic masks. The similarity metric focuses on the five fundamental building components to compute the class-balanced IoU values. For each class c_i in the class set C, the pre-class binary masks are generated for the real and synthetic masks, as shown in Equations (1) – (2). Next, a pre-class IoU (IoU_{c_i}) is calculated to quantify the overlap between these corresponding binary masks. Given that the spatial distribution of door and window elements usually provides more distinguishable cues to describe the location-aware context than the other classes, this study assigns different weights w_{c_i} to each class. As a result, the overall similarity metric s is derived by aggregating these weighted IoU values into a single score, as shown

in Equations (3) – (4).

$$R_{c_i} = \{(x,y)|R(x,y) = c_i\}, \quad c_i \in C \tag{1}$$

$$S_{c_i} = \{(x,y)|S(x,y) = c_i\}, \quad c_i \in C \tag{2}$$

where $C = \{c_1, c_2, \ldots, c_n\}$ is the set of semantic classes, R and S is the real mask and the synthetic mask, and R_{c_i} and S_{c_i} are the pre-class binary real and synthetic masks that include the pixel locations labelled as a class c_i.

$$IoU_{c_i} = |R_{c_i} \cap S_{c_i}|/|R_{c_i} \cup S_{c_i}| \tag{3}$$

$$s = \sum_{c_i \in C} w_{c_i} IoU_{c_i} \Big/ \sum_{c_i \in C} w_{c_i} \tag{4}$$

where the default weights of the door, window, wall, floor, and ceiling classes are empirically set to 0.325, 0.325, 0.15, 0.1, and 0.1.

By comparing the real and synthetic masks, the similarity metric identifies the image pairs whose semantic layouts most closely resemble one another, thereby determining the best candidate for indoor localization.

3 Case Study

3.1 Experiment Setup

To validate the feasibility and localization performance of the proposed approach, a real-world case study was carried out. The experiment was conducted in an institutional building at the University of Macau, China, where a publicly accessible corridor area was selected as the testbed. The corridor area is an L-shaped space with a length of approximately 175 meters. Both the fundamental building elements and the furniture and decorative elements (e.g., garbage bin, water dispenser, and poster board) exist inside the corridor area. The floorplan layout of the testbed is displayed in Fig. 2.

The proposed approach was applied to the corridor area for indoor localization. First, the LOD 200 BIM model of the institutional buildings was employed to construct the offline database. This BIM model contained fundamental building components, while other furniture and decorative components were not created due to the considerable efforts required. This study then leveraged the custom plugin to generate a set of virtual cameras, where the camera interval was set to 0.914 meters (3 feet), resolution was set to 640×480 pixels, and the DPI was configured at 600. The camera interval was determined through an iterative testing process. Initial experiments with smaller intervals yielded excessive redundancy in the image database, as numerous virtual cameras generated highly similar images with negligible variation. In contrast, larger intervals substantially reduced the size of the reference database, but this came at the cost of increased localization errors due to inadequate image coverage. Therefore, a moderate interval was determined via trial-and-errors to balance the database size and the localization accuracy.

Subsequently, 616 virtual cameras were generated, covering 2,464 capturing views, with cameras oriented

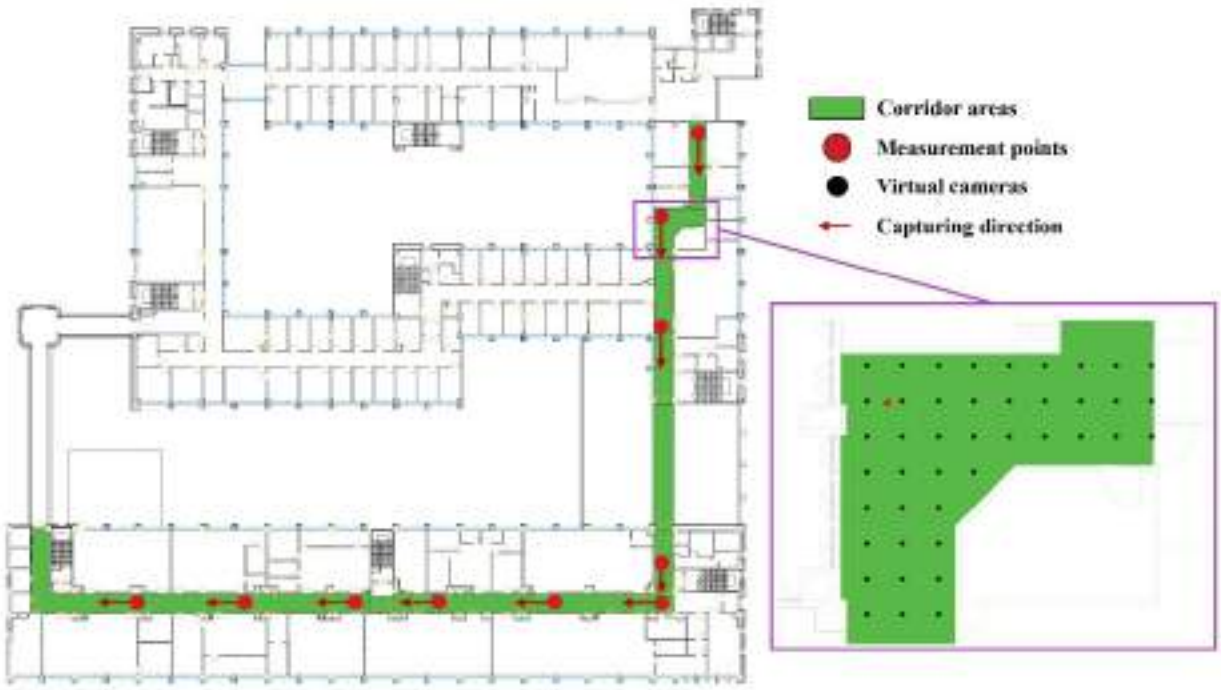

Figure 2. Virtual camera deployment and the measurement points in the testbed BIM model

along the four directions of the X and Y axes. After filtering, 1,005 semantic masks remained as the reference data in the offline database. Fig. 2 shows the deployment of the virtual cameras in the BIM model.

Next, this study conducted a pedestrian walk inside the indoor environment. During the walk, ten measurement points were selected to capture real photos along the walking direction. Additionally, their relative locations were recorded manually using a tape to form the ground truth data. In this study, a digital camera equipped with a mobile device (Xiaomi Mi 13 [15]) was utilized to capture the real photos. Fig. 2 shows the locations of the measurement points in the BIM model. These photos were then performed segmentation predictions to generate the masks of building components. Last, the mask of each measurement point severed as the query images to match with the offline database. The most similar pair was calculated based on the class-balanced IoU metric.

For comparison, this study selected the method proposed by Ha et al. [8] as the baseline approach. The baseline approach leveraged BIM models to generate realistic rendered images and then utilized convolutional neural networks to extract visual features from images for similarity computation. Accordingly, we generated the BIM-rendered images of the corridor areas and took the fourth convolutional block of the ResNet50 model [16] built on the Keras framework [17] to characterize the image features. Subsequently, the cosine similarity metric was employed for image retrieval.

To perform quantitative analysis, this study introduced two indicators to compare the accuracy of the proposed and baseline approaches. The first indicator is the system error, which measures the deviation between the actual positions and its nearest reference points in the offline database. This system error reveals the inherent impact of the interval spacing of the virtual cameras in BIM on localization accuracy. The second indicator is the top10 range accuracy, which comprehensively quantifies the image retrieval results in terms of both location proximity and mask similarity. The traditional top10 accuracy only considers whether the nearest reference point of the query image exists in the first ten search results or not, without accounting for other reference points that also lie near the actual location. Hence, the top10 range accuracy addresses this limitation by incorporating two parts, i.e., a positioning score and a sequencing score.

The positioning score (p_i) gauges whether the matched reference lies within an acceptable distance (i.e., a specified radius) from the actual position and further quantifies their proximity, as shown in Equation (5). The positioning score ranges from 0 to 1, where a value closer to 1 indicates that the matched reference point is closer to the actual location. The sequencing score (q_i) calculates the relative similarity of each matched result using the IoU metric, as shown in Equation (6). Consequently, the top10 range accuracy (t_{10}Acc) is determined by selecting the maximum product between the position score and the sequencing score among the first ten retrieved results (Equation (7)).

$$p_i = \begin{cases} (r - d_i)/r, & \text{when } d_i \le r \\ 0, & \text{when } d_i > r \end{cases} \quad (5)$$

$$q_i = s_i / s_1 \quad (6)$$

$$\mathrm{t_{10}Acc} = \max_{i \in [1,10]} \{p_i \times q_i\} \quad (7)$$

where d_i is the distance between the i-th matched reference point and the true location, r is the radius of the acceptable range (i.e., 2 meters in this study), and s_i is the IoU metric obtained from Equation (4).

3.2 Experimental Results and Performance Evaluation

After the experiment, the results of the case study are calculated accordingly. For the system error, the results indicate that an average deviation of 0.38 meters exists between the actual locations and their nearest reference points. This error indicates that due to the camera interval configuration, the proposed approach reaches approximately decimetre-level accuracy in the best scenarios, which should meet the requirements of most pedestrian indoor navigation applications.

Next, the results of the top10-range accuracy for the two approaches are summarized in Table 2.

Table 2. Top10 range accuracy of the two approaches

Measurement point	t_{10}Acc	
	The proposed approach	The baseline approach
1	0.88	0
2	1	0
3	0.77	0.95
4	0	0
5	0.54	0.54
6	0.54	0
7	0.51	0
8	0	0
9	0.33	0.34
10	1	0
Average	0.57	0.18

Specifically, the results demonstrate that the proposed approach achieves an average t_{10}Acc of 0.57, showing a moderate level of performance for indoor localization. Fig. 3 illustrates more details about the image retrieval results, revealing that the IoU metric can identify highly similar mask images for all measurement points. However, the range accuracy is sometimes

constrained when multiple images exhibit high resemblance across different locations. Comparatively, the first three measurement points which contain all five building components would result in relatively higher accuracy, given that these images provide richer semantic and spatial details. On the other hand, the rest measurement points only incorporate a reduced set of components (i.e., floors, ceilings, walls, and doors), which may result in similar patterns across various locations and thus sometimes yield suboptimal matches.

By contrast, the baseline approach produces less satisfactory results, leading to an average t_{10}Acc of 0.18. The relatively low accuracy could be attributed to the inconsistent visual features between the BIM-rendered images and the real-captured images. Particularly, the BIM models include only fundamental building components painted in default colours, which significantly differ from the actual indoor environment in terms of visual fidelity. Therefore, the baseline approach may become ineffective when applied to low LOD BIM requirements.

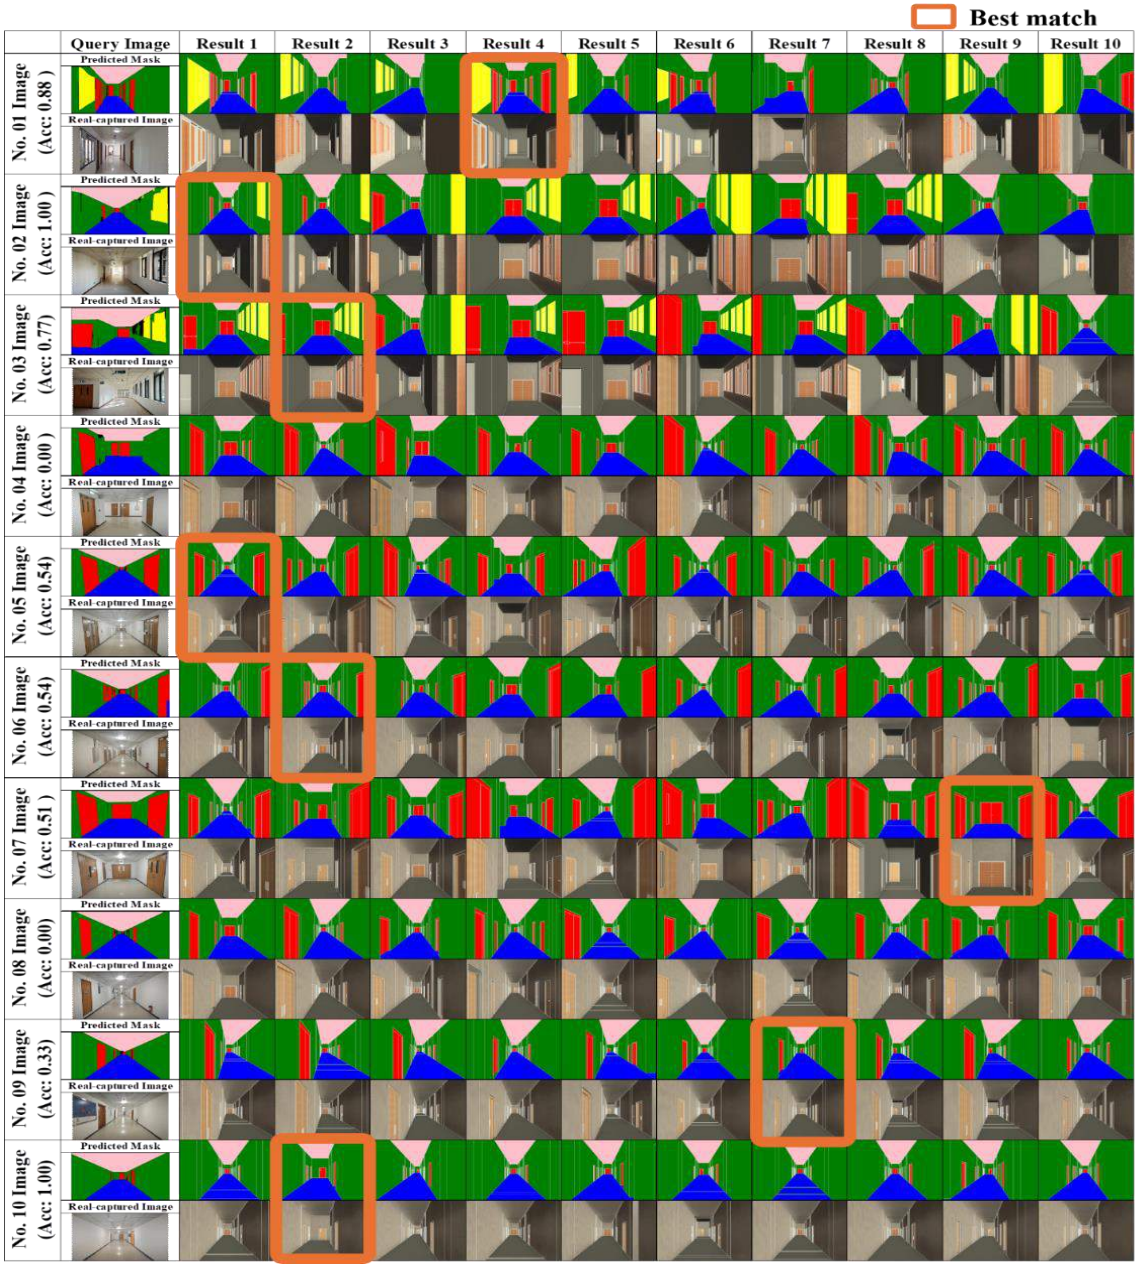

Figure 3. Image retrieval results of the proposed approach.
Note: Queries with no box-selected images indicate that the best match is absent from the top10 results

4 Discussion and Conclusion

This study presents a novel image-based indoor localization approach by integrating BIM synthetic data generation and building component semantic segmentation. Through the development and evaluation of the proposed approach, the benefits and limitations are identified. Specifically, the approach concentrates on the fundamental building components and generates semantic masks for both offline BIM database construction and online image querying. The benefits of this approach are multi-fold. First, it operates effectively with relatively low-fidelity BIM models, thereby minimizing the manual effort required for detailed modelling or continuous updates. Only essential building components are required, which enables greater applicability for real-world uses. Second, it provides a more robust performance against environmental changes. Prior methods often rely heavily on visual fidelity between BIM models and real-world environments, making them vulnerable to discrepancies in actual conditions. By contrast, the proposed approach makes use of the spatial and semantic information of those static building components, which offers consistent patterns for feature matching over time.

Compared to traditional localization methods such as IMU-based tracking or Wi-Fi fingerprinting, the proposed image-based approach offers advantages in measurement mechanisms and ease of deployment. The accuracy of IMU-based methods is gradually affected by cumulative drift errors, which require additional recalibration. Range-based approaches (e.g., Wi-Fi signals) may suffer from environmental interference and often rely on additional infrastructure, such as multiple access points, beacons, or specialized sensors, which may not be readily available in all environments. By contrast, the proposed approach determines the user's locations using independent capturing and similarity matching, which does not incur any accumulated errors. In addition, the approach provides position references using stable architectural features extracted from images without the need for extensive sensor deployments. This makes the approach scalable to large-scale indoor environments.

The result of the case study indicates that the top 10-range accuracy of the proposed approach achieves moderate performance (0.57), which significantly outperforms the conventional baseline approach (0.18). Moreover, the result also discloses that the top 10-range accuracy varies across different measurement points. When positioning with various surrounding features like distinct combinations of windows and doors, the proposed approach results in a better performance. It is because these divergent environmental features provide a more distinguishable image pattern in the segmentation mask to separate it from others in the image database. However, the proposed approach may struggle in common corridor scenes, where repetitive features like similar doors and walls occur and confuse the image retrieval results.

Several limitations are also identified and require further investigation. First, the parameters of virtual camera deployment, such as orientation directions, camera spacing intervals, and focal lengths, are set empirically in the present study, which needs to be optimized by systematic experiments to better understand how they affect localization accuracy and computational efficiency. Second, the current approach only considers discrete measurements using individual image captures, which makes localization accuracy highly susceptible to segmentation errors. Incorporating continuous measurements with probabilistic models could mitigate this issue and offer a more robust solution. Third, the case study reveals that the proposed approach may become less effective when applied to locations with similar spatial patterns of building components. To address this, additional essential elements (e.g., mechanical, electrical, and plumbing components) could be included in the segmentation process to enhance feature distinguishability. Finally, future work should validate the method across diverse interior environments to confirm its generalizability and practical applicability. Specifically, the present study is still in the proof-of-concept stage to investigate the feasibility and performance of the proposed approach for BIM-based indoor localization. In the future, the approach should be further integrated into self-developed prototypes or existing software to empower different applications such as facility management and emergency response. Such integration has the potential to assist various practitioners, including facility managers, construction engineers, and emergency responders, in enhancing operational efficiency and decision-making. Besides, systematic comparison to existing approaches using open datasets is needed to quantify its performance and identify its utilization and potential challenges.

To conclude, this study demonstrates the potential of leveraging spatial and semantic details of fundamental building components in capturing views to develop an efficient and reliable approach for indoor localization. At the same time, follow-up research is still needed to fully exploit the advantages of the approach and broaden its adoption in more complex indoor environments.

Assessing the Efficacy of Virtual Reality Site Visits to Enhance Remote Learning Experiences for Civil and Construction Engineering Students

Samira Mirhasani[1], Jared Bosch[1] and Joseph Louis[1]

[1]School of Civil and Construction Engineering, Oregon State University, Corvallis, Oregon, United States
mirhasas@oregonstate.edu, boschja@oregonstate.edu, joseph.louis@oregonstate.edu

Abstract –

Remote construction engineering education can provide immense benefits to students and colleges by removing time and cost hindrances that currently prevent enrolment. However, replicating the hands-on experiential learning provided by traditional in-person site visits poses significant challenges for remote students due to accessibility barriers. These barriers include limited access to physical construction sites and the inability to engage in peer-to-peer interactions common in in-person settings. This research aims to bridge this gap between remote and in-person students of construction engineering by studying the potential of virtual reality site visits on undergraduate education for civil and construction engineering students. Thus, the study developed and deployed a virtual site visit using the discrete event simulation software ConStrobe and game engine Unity, accessible through WebGL on smartphones. Participants experienced both in-person and virtual site visits and engaged with the simulation to complete classwork tasks such as calculating equipment productivity for the Heavy Civil Construction Management course. Data was collected using surveys and analysed to assess their understanding and engagement. Initial findings suggest that virtual simulations effectively complement traditional site visits by improving students' understanding of construction concepts, particularly productivity and equipment interaction. However, some students reported challenges such as feeling overwhelmed, emphasizing the need for enhanced user guidance. These insights provide guidance for construction instructors and curriculum designers aiming to integrate virtual simulations into the classes, offering an accessible and effective tool to support experiential learning for remote learners.

Keywords – Virtual Reality Site Visits, Remote Education, Experiential Learning, Construction Education

1 Introduction

The evolving demands of construction management education necessitate innovative approaches to deliver experiential learning, especially in remote and hybrid settings. The shift toward remote education, accelerated by the COVID-19 pandemic, further highlights the need to address issues of student engagement and experiential learning. Studies, such as those by (Neisler 2020), indicate that remote students often struggle with motivation due to a lack of hands-on experiences and peer interactions. In response, (Park et al. 2020) recommend the use of virtual spaces and tools to replicate the serendipitous interactions and moments of engagement that occur in in-person settings. On the other hand, traditional in-person site visits are invaluable for providing hands-on exposure but pose challenges related to accessibility for remote students.

Thus, the goal of this research is to explore the use of virtual reality to enhance remote learning by providing in-person student experiences of construction site visits and peer interaction through virtual reality platforms. This research will implement virtual reality site visits for students in the Heavy Civil Construction Management course and collect student feedback and data about its use to answer the following research questions: (1) Can virtual reality site visits improve student experience for remote students? (2) Can virtual reality site visits measurably improve student understanding compared to site visits?

By addressing these questions, the study assesses whether and to what extent virtual simulations can replicate in-person construction site visits and serve as a robust learning tool. The findings contribute to the development of scalable, sustainable, and inclusive learning tools in construction management education, aligning with broader goals of accessibility.

2 Literature Review

Remote learning technologies, such as virtual site visits, are increasingly used in construction education, providing accessible and cost-effective alternatives to traditional methods (Jaselskis *et al.* 2012). During the COVID-19 pandemic, remote teaching broadened accessibility but highlighted challenges in maintaining educational quality and hands-on skills acquisition (Martínez-Muñoz *et al*. 2021). These challenges underscore the need for innovative solutions like virtual simulations to bridge gaps in accessibility, engagement, and comprehension while addressing technological and pedagogical challenges. This section explores the use and approaches of virtual simulations in construction education.

2.1 Use of Virtual Simulations in Construction Education

Virtual simulations are transforming construction education by bridging theoretical knowledge and practical application. They have been effectively applied in safety training (Ismail *et al.* 2021), immersive learning for specific construction phases (Salman 2023), and onboarding programs (Belaroussi *et al.* 2023). Studies demonstrate their role in enhancing comprehension, engagement, and problem-solving skills across topics like highway engineering (Seifan *et al.* 2020), railway transportation (Eiris *et al.*, 2022), and steel structure assembly (Salman 2023).

Virtual scenarios also support construction management education by reinforcing principles such as project planning and safety compliance (Shojaei *et al.* 2023) and enabling hands-on practice in scheduling *(Ilbeigi et al*. 2024) and post-disaster assessment (Humayoun *et al.* 2024). Despite these advances, research on their application in customized heavy civil construction management topics remains limited, which this study aims to address.

2.2 Variance of Simulation Approaches

The degree of immersion and type of simulation significantly impact virtual learning outcomes. Visualization methods range from 2D displays to immersive 3D environments (Shojaei *et al.* 2022), allowing educators to tailor experiences based on subject complexity and learner proficiency. Custom VR platforms, like those by Eiris et al. (Eiris *et al.* 2022) and Elgewely et al. (Elgewely *et al.* 2021), explore innovative teaching methods that enhance student engagement. However, immersive tools like head-mounted displays (HMDs) and CAVE systems (Wang *et al.* 2024) offer high levels of engagement while presenting challenges related to comfort, accessibility, and cost, particularly in large or remote learning settings (Lucas 2018). In contrast, web-based platforms such as Mozilla Hubs® (Eiris et al. 2022) offer greater accessibility for devices like smartphones and tablets. However, allowing diverse hardware use, ranging from phones to laptops and HMDs, can result in inconsistent user experiences and technical challenges, such as varying device capabilities and a lack of experimental control. Additionally, cybersickness with immersive systems can be another issue (Eiris et al. 2022), whereas WebGL-based platforms mitigate this problem and ensure consistent performance across devices.

This study adopts a simpler approach, avoiding immersive technologies like 360-degree images, which can sometimes overwhelm students. Instead, the simpler visualization was tailored to meet specific course learning outcomes. The implementation relied on a web-based simulation accessed primarily through smartphones, ensuring affordability and consistency across devices. This standardization minimized variability caused by diverse hardware setups and provided an equitable learning experience for all students. By prioritizing accessibility, simplicity, and alignment with educational objectives, this approach demonstrates the potential of virtual simulations to effectively enhance remote learning in construction education.

3 Research Methodology

This research examines differences in student perceptions of experience and understanding between real-world and virtual simulation environments. Key steps include 1. Development of Survey Questions 2. Real-World site visit, 3. Development of virtual site visit, 4. Data collection, and 5. Data analysis. Figure 1 shows research methodology workflow.

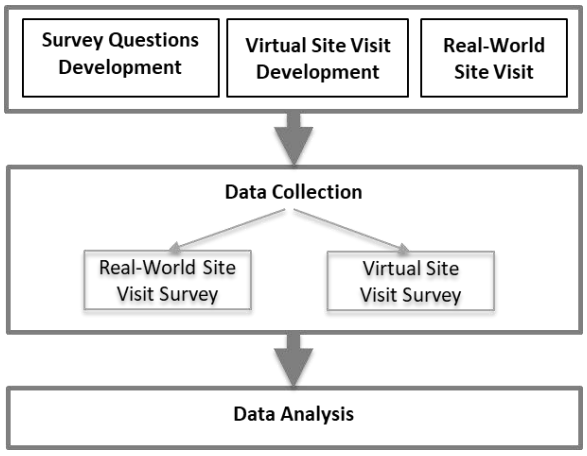

Figure 1. Research Methodology Workflow

3.1 Development of Survey Questions

The development of survey questions to evaluate the impact of virtual simulations is grounded in a diverse range of scholarly sources. For instance, (Yuan Sun et al. 2022), Kamińska et al. (2022), and (Wen et al. 2023) provide frameworks and insights that inform the design of assessment tools. These studies emphasize the importance of crafting questions that capture both qualitative and quantitative aspects of the learning experience, such as engagement, comprehension, and ease of use.

To ensure relevance, survey statements were derived from major topics covered in the CEM441/541 class, such as equipment productivity (both individual and collaborative performance), factors influencing productivity, cost implications of equipment usage and maintenance, and the importance of selecting appropriate machinery to optimize efficiency and minimize costs. The survey comprised two main parts: the first included statements derived from literature-based questions to evaluate students' learning experience. The second focused on CLO #6 (“Develop an estimate for a project using production and costs from a real-world project”) and CLO #7 (“Critically analyze a heavy civil operation and suggest alternatives”), assessing students' understanding of operational and productivity concepts. The post-virtual simulation survey also included five open-ended questions for deeper insights. Tables 1 and 2 categorize statements related to experience and understanding, respectively.

Table 1. Real Site Visit and Virtual Simulation Experience Statements

No.	**Experience Statements**
1	I have a clearer sense of the complexity of a worksite
2	Seeing the activity clarified concepts discussed in class
3	I learned something about site processes that was not discussed in class
4	Questions I had, or unclear concepts, were clarified.
5	The atmosphere/environment was overwhelming and made it difficult to learn
6	The experience was more engaging than I expected
7	The experience captured and held my attention
8	The experience was a valuable part of my learning process
9	I am more comfortable identifying interdependence of site activities
10	The experience provided me enough time to feel fully engaged with material presented
11	I felt like I could ask questions and receive satisfactory answers
12	I felt present and involved in the learning process
13	The experience aligned with my expectations
14	Peer interaction was an important component of the experience
15	I felt like my presence was disruptive to the work process

Table 2. Real Site Visit and Virtual Simulation Understanding Statements

No.	**Understanding**
10	Understanding factors that can improve equipment production (Improving
4	Identifying improvements to maximize equipment production
12	Ability to describe what swell and shrinkage factors are, how they apply to soil volume, and the effect of swell and shrinkage on site production
1	Estimating material to be excavated (either cut of fill)
11	Understanding of how soil is converted from a bank state to a loose state and the effect
14	What a fill factor is, and how it relates to the type of soil being moved or loaded, and its effect on production
3	Estimating cost of equipment
6	Estimating cost per unit of material moved
8	Optimizing equipment pathways for maximum productivity
9	Causes for delays, long lines, and long wait times
19	Understanding how cycle times relate to matching of equipment, and causes of delays, and bunching/queueing
13	Understanding of grade and rolling resistance, and their influence on production
7	Calculating ideal ratio of pieces of equipment (trucks: excavators or pushers: scrapers)
15	Understanding the importance of selecting the proper equipment
16	Describing different pieces of equipment and what they do
17	Understanding how efficiency relates to heavy equipment production
18	Describing how different factors affect efficiency (operator skill, visibility, blade adjustment factor, etc.)

3.2 Real Site Visit

The in-person site visit was a critical component of this study, providing students with firsthand exposure to real-world applications of concepts discussed in class. This visit allowed participants to observe an active construction site, engage with ongoing activities, and experience the complexities of heavy civil engineering projects in a controlled environment. Figure 2 illustrates multiple pieces of equipment working together to excavate and haul earth. Also, it highlights the impact of an unbalanced ratio of excavators to trucks, resulting in idle equipment.

Figure 2. Left Image: Excavator idle, and right image: Excavator and truck working in tandem

3.3 Virtual Site Visit

The virtual environment, developed using simulation tools and visualization techniques, enables students to observe and analyze critical concepts in heavy civil construction, including equipment productivity, operational delays, and system efficiency. The details of the simulation and visualization are explained in the following sections.

3.3.1 Simulation

The discrete event simulation (DES) was conducted using ConStrobe (Construction Operations Network Simulation for Time and Resource-Based Evaluation) (Louis 2025) to simulate real-world construction activities. The simulation focused on earthmoving operations, including activities such as loading, hauling, dumping, and returning. Fixed timings were used for loading and dumping activities, while uniform timings, representing variable durations, were applied to haul and return activities. The simulation involved one loader and four trucks per cycle. Figure 3 illustrates the simulation model, with various shapes representing activities like loading and hauling, along with their respective timings. Links within the model define system functions and the sequence of operations.

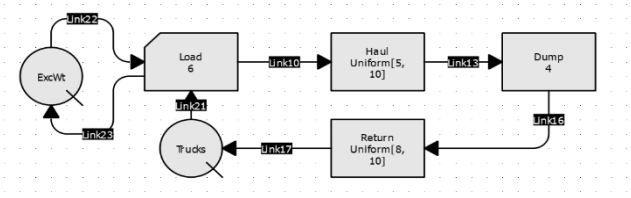

Figure 3. DES in ConStrobe Software

As seen in Figure 3, a model is created to represent earthmoving operations on a construction site. From this model, a text file is created which is exported from ConStrobe and used as input to create an animation in Unity, a game engine.

3.3.2 Visualization

To make the simulation more comprehensible for students, it was visualized using the Unity game engine. The simulation exported a trace file containing commands such as CREATE, TIME, MOVE, SETOBJCELL, and DYNUPDATECELL, which were used to generate animated visualizations.

Unity's versatility allows for exporting simulations in various formats, including desktop applications (.exe), mobile apps, and WebGL. For this study, WebGL was chosen due to its compatibility, ease of use, and ability to run in any web browser without requiring additional software installations or powerful hardware, such as head-mounted displays (HMDs) or high-performance computers. Most students accessed the visualization on their smartphones, while a few opted to use laptops. For homework, students accessed the simulation via a QR code linked to the WebGL platform, where they calculated cycle times for trucks and loaders.

The animations illustrated key earthmoving activities, including loading, hauling, dumping, and returning. Students could identify trucks by their assigned colors and interact with the simulation using features such as pause/play controls for timing calculations, touch navigation for exploration, and a reset button to restart the simulation from the initial camera angle. The visualization provided an opportunity for students to observe various scenarios in earthmoving operations as the simulation's time clock progressed. These scenarios demonstrated essential course concepts, such as bunching and queuing, variable timing, idle loaders, and waiting trucks, offering a dynamic and engaging learning experience. Figures 4–7 showcase examples of the visualization environment encountered by students.

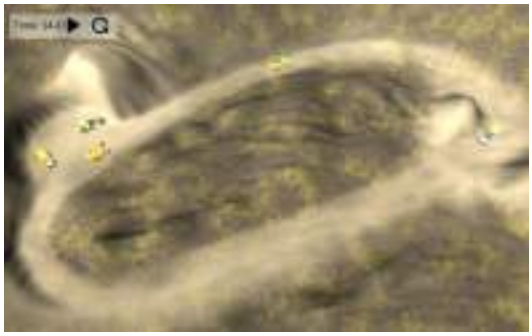

Figure 4. Scenario 1: Blue truck dumped, green hauling, red waiting to load, yellow is idle.

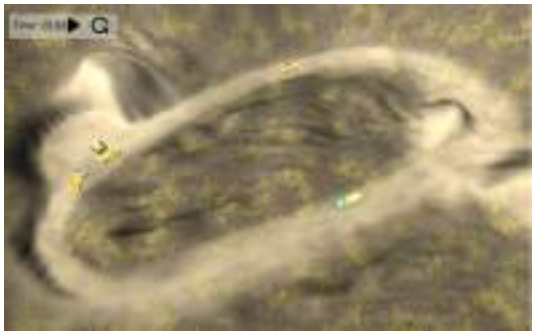

Figure 5. Scenario 2: Blue truck waiting, green returning, red hauling, yellow loading.

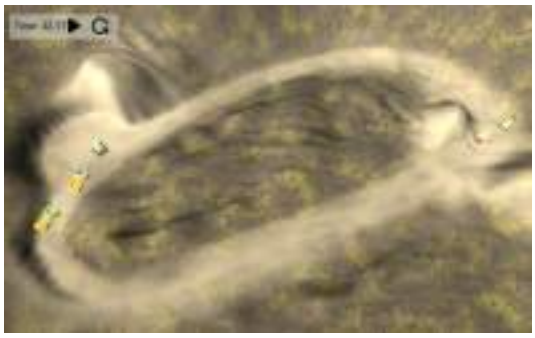

Figure 6. Scenario 3: Bunching in both loading and unloading areas.

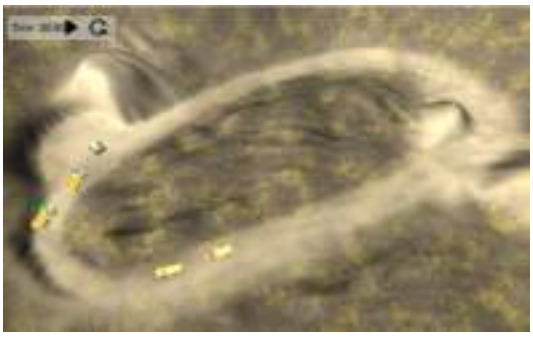

Figure 7. Scenario 4: Yellow truck overtaking red one, showing different timing.

3.4 Data Collection and Analysis

This study compared the educational impact of in-person construction site visits and virtual simulations on students' experience and understanding. Surveys were administered digitally via Qualtrics to all participants. A baseline survey was collected after the in-person site visit, followed by a post-virtual simulation survey. For post-virtual survey, participants engaged with the virtual simulation via a QR code through a WebGL platform on smartphones or laptops, completing tasks such as analysing equipment productivity and calculating cycle times(Figure 8). The surveys were identical except for 5 open-ended questions included at the end of the post-virtual simulation survey. Response options for questions evaluating experience were scored on a 5-point Likert-type scale: 1 = Strongly disagree, 2 = Somewhat disagree, 3 = Neither agree nor disagree, 4 = Somewhat agree, 5 = Strongly agree. For questions assessing understanding, the scale ranged from 1 = Not knowledgeable at all, 2 = Slightly knowledgeable, 3 = Moderately knowledgeable, 4 = Very knowledgeable, to 5 = Extremely knowledgeable. Responses were automatically recorded to the Qualtrics web portal. A total of 46 responses were collected, providing valuable insights into the educational effectiveness of virtual site visits. It is important to note that the analysis is based on a single course with 46 responses, which limits the generalizability of the findings.

Initial feedback indicates that virtual simulations improved students' understanding of key construction concepts, including equipment productivity, optimal ratios, and delay management. The simulation effectively enhanced comprehension of dynamic and complex topics compared to in-person visits. However, students' experiences showed mixed results, with some finding the virtual environment overwhelming or misaligned with expectations, emphasizing the need for improved user guidance and interface design.

Future work will involve detailed statistical analysis to compare paired ordinal responses and further evaluate the educational impact of the two methods.

Figure 8. Students working on homework using visualization

4 Findings and Discussion

This study successfully developed and deployed a virtual site visit using Unity and WebGL to enhance students' understanding and experience of heavy civil construction concepts. The visualization allowed students to explore key topics, including equipment productivity, cycle times, queuing, and delays, in a structured and accessible environment. Students accessed the simulation via a QR code, enabling them to interact with the visualization and apply course concepts through homework tasks, such as calculating cycle times and equipment productivity by observing earthmoving operations. Initial feedback from surveys indicates that the virtual simulation provided valuable insights into construction operations and effectively complemented traditional in-person site visits. While most students found the simulation engaging and informative, some reported challenges, such as feeling overwhelmed or unsure of what to expect, highlighting areas for improvement in interface design and user guidance. Future work will analyze the survey data in detail to assess the educational impact of the virtual simulation compared to in-person site visits and to identify further opportunities to enhance the virtual learning experience. Additionally, future research will incorporate objective performance metrics, such as pre- and post-simulation assessments, to provide a more concrete measure of learning effectiveness.

5 Conclusion

This study demonstrates the potential of virtual simulations as an effective and accessible alternative to traditional in-person site visits in construction management education. Virtual simulations enhanced students' understanding of key concepts such as equipment productivity, optimal ratios, causes of delays, and overall production efficiency. Compared to traditional in-person site visits, virtual simulations provide a controlled, tailored learning environment that simplifies dynamic, abstract processes and allows for deeper conceptual comprehension.

These advantages make virtual simulations particularly valuable for remote learners who may lack access to physical construction sites, bridging gaps in hands-on learning opportunities. While virtual simulations successfully replicated and, in some areas, surpassed the learning outcomes of in-person visits, areas for improvement remain. Students reported challenges, such as feeling overwhelmed, or uncertain about what to expect, emphasizing the importance of pre-simulation preparation, such as tutorials or demonstrations, to improve alignment between expectations and experiences. Furthermore, virtual simulations proved particularly beneficial in teaching concepts reliant on dynamic visualizations, such as cycle times and delay analysis, highlighting their potential as a complementary tool to traditional methods.

As remote and hybrid education continues to grow, virtual simulations offer a promising pathway to enhance accessibility and inclusivity while maintaining the quality of experiential learning. Future research should focus on tailoring simulations to specific educational objectives and optimizing learning environments for better accessibility and usability. With thoughtful implementation and continued refinement, virtual simulations hold the potential to transform construction management education, ensuring an optimized balance between virtual and in-person learning experiences. Despite these promising results, the study's scope was limited by its single-course design and sample size. Future research should validate these findings across multiple courses and larger, more diverse student populations, explore the scalability and practical implications of virtual simulations.

Abstract

Visual inspection of civil infrastructure assisted by Unmanned Aerial Vehicles (UAVs) witnessed significant improvements due to the rapid development of drone-mounted cameras and sensors. In visual inspection, accurate pose estimation of the collected images is a pivotal task that enables registering images to pre-existing 3D scenes of the structure to identify the geometric relationship between the scene and the image. This allows for localizing regions of interest or defects in these images. In this work a novel image pose estimation technique is proposed to improve images pose estimation and registration of drone-collected images. The proposed method utilizes a 3D base Structure from Motion (SfM) model and pre-calibrated poses of base images to facilitate the registration and pose estimation of new query images via feature-based pose estimation framework. The method leverages deep-based feature matching to generate dense 2D correspondences to simultaneously generate the 2D and 3D correspondences needed to execute the perspective-n-point solver and accurately estimate the pose. The proposed approach was tested against drone-collected images of cell tower and the image registration efficiency was evaluated through ROI localization in the registered images.

Visual Inspection; Asset Management; Image Localization; Telecommunication Cell Tower

1 Introduction

Condition assessment of large and hard-to-access infrastructure is a complex task and often requires trained technicians to employ time- and resource-extensive techniques for physical inspection [1]. The rapid development in UAVs and their associated sensors has led to a wide range of applications in condition assessment of civil infrastructures [2]. However, UAVs (e.g., drones) can be considered a multifunctional data acquisition system. Hence, robust inspection algorithms are required to leverage and fuse the various data types that drones can acquire to make sure of the acquired data.

A widely adopted application of drones in condition assessment of civil infrastructure involves utilizing them to capture high-resolution images, which are then used to construct SfM models of the structure. For example, in bridge inspection, SfM models enhanced damage quantification [3], crack identification and visualization [4], and risk assessment and management [5]. Xiao et. al. utilized a deep learning-based point cloud segmentation algorithm to assist ROI extraction and crack identification in bridges [6]. For large highway truss structures, Yeum et. al. proposed autonomous ROI localization algorithm, and ROI classification algorithm [7]. Visual inspection using drone images was also implemented for crack and rust identification within ROIs extracted from monopole tower images [8] and produce a health index of power transmission tower [9].

In visual inspection, determining the 6 degrees of freedom (DoF) pose of the image (3 for translation and 3 for rotation) enables establishing a geometric relationship between a 3D scene of the structure and the images. In the SfM framework, the simultaneous 3D reconstruction of a scene and pose estimation of images are core processes. This is typically achieved by extracting correspondences between 2D keypoints across multiple images and solving for camera poses and 3D points simultaneously. This implies that in case of visual inspection that involves constructing SfM model using large volume of images, the images are registered automatically as a natural product of the 3D reconstruction.

On the other hand, the inspection process for civil infrastructure typically does not involve constructing an SfM model; instead, it primarily relies on visually analyzing high-resolution images of the structure, collected from specific targeted regions of interest (TRIs). Hence, SfM-enabled pose estimation is not possible and in case the inspector needs to estimate the pose of these images, then a pose estimation technique should be employed that works on single image, or image sequences [10].

Image pose estimation is an extensively explored

topic in the field of computer vision. A critical review by Xu et al. categorized pose estimation methods into two main categories: structure feature-based localization methods and regression-based pose estimation methods [11]. In structure feature-based methods, a 3D scene of the structure is employed to enable building correspondences between 2D points in a query image (image to be localized) and 3D points from the scene to enable estimating the pose of the image. Regression-based methods employ convolutional neural networks and deep neural networks to regress the pose of RGB images (e.g., PoseNet [12])

Structure feature-based methods are widely used due to their robustness and accuracy [11]. The 2D-3D correspondences in this method are typically established by matching distinctive features from a 2D query image with a database of 3D points, each associated with corresponding feature descriptors. Establishing these 2D-3D correspondences enables the estimation of the camera's position and orientation relative to the scene using a geometry constrain solver (e.g., Perspective-n-Point [13]).

A major drawback of this approach is the assumption that a database of descriptors is available and associated with the 3D points of the scene. However, the outputs of commercial 3D reconstruction and SfM platform does not typically involve image feature descriptors. Hence, a computationally intensive step is needed to establish the descriptors database for all base images. Another drawback related to the database of features descriptors is that the same feature extraction and description method should be used for both the base and query image to ensure consistency and accuracy [14]. Accordingly, if the feature extraction and description algorithm used in building descriptors database exhibits poor performance in matching image pairs with significant change in image environment (e.g., perspective, scale, or illumination), then finding proper number of matches between database and query images might not be possible.

On the other hand, assuming that a database of descriptors is established, if the 3D point cloud (SfM model) of the structure is not dense enough, then establishing high-quality correspondences between the database of descriptors and the query image's descriptors cannot be achieved.

To overcome the aforementioned drawbacks, an efficient structure feature-based image pose estimation approach is proposed to enable registering query images to the 3D scene without the need for database of descriptors and that can perform well in registering query images captured with significant variations in scale, perspective, zoom level, and background visibility compared to the database images.

The proposed algorithm leverages deep-learning-based local feature matchers to build dense 2D-to-2D matches between database images with known calibrated image poses and the query image. Then, the dense matches are used to simultaneously determine the 2D features and the 3D corresponding points, needed to estimate the pose. To estimate the image pose, a perspective-n-point solver within a Random Sample Consensus (RANSAC) framework was implemented.

The proposed approach was implemented on drone-collected cell tower images to test the accuracy of the approach in estimating the position and rotation of query images of the cell tower. The reliability of the proposed method was evaluated by utilizing the projection matrix calculated from the estimated pose in localizing regions of interest (ROIs) in the query images.

2 Methodology

2.1 Overview of the Technique

UAV-based inspection of civil infrastructure involves building SfM model from a large set of sequentially captured images of the structure. The process of 3D reconstruction outputs 3D map of the structure (hereafter, base model) along with calibrated camera poses (hereafter, base images).

In many cases, inspectors collect few images (hereafter, new images) around a specific TRI of high importance and the number of images might not be enough to build an SfM model. Hence, a reliable method is needed to enable registering these images and extract their poses without the need for a 3D reconstruction step. Registering the new images enable building the geometric relationship between the 3D scene and the new images which, in return, enable retrieving information from these images. To allow registering any new image to the base model, a pose estimation approach is proposed.

The approach, shown in Figure 1, starts with a base image that clearly shows the TRI where the inspector needs to perform a focused inspection by collecting new images around that region with varying camera angle, distance from the region, zoom level, or perspective. Prior to registering the new images, a vital step is to enable the inspector to retrieve the closest image relative to the base image the inspector started with. A geometry-based closest image retrieval algorithm is proposed, and it retrieves all the closest images within an applicable pre-defined criteria set by the inspector. From the set of retrieved images, the inspector can select the image with the clearest view and highest details of the all the ROIs that needs to be inspected.

The main enhanced step of this paper is to propose a registration approach that addresses the limitations of existing methods discussed in Section 1. Unlike conventional algorithms, the proposed method enables registering new images of hard-to-access infrastructure

with a pre-existing SfM model, even if created by commercial SfM platforms that lack 3D-associated feature descriptors or depth maps, without relying on such data. This broadens the applicability and utility of the registration process.

For registering the new image and in addition to the base image the inspection started with and the new image that was selected from the pool of retrieved closest images, the concept of shadow image is proposed. Shadow image is another image from the set of base images that is adjacent to the original base image. To automate the process of selecting the shadow image, the proposed algorithm extracts the shadow image by bringing the image next in sequence relative to the original base image (base images are collected sequentially). The poses of the original base image and the shadow image are known from the SfM output. What keeps missing is the pose of the new image.

The foundational step for registering the new image in the proposed approach is extracting dense 2D-to-2D correspondences between the three images: the original base image, the shadow image, and the new image. From the dense correspondences, the common extracted matching features in the three images are retained. Since the poses of the original new image and the shadow image are known, then a direct triangulation is performed on the common matched features between these two images and a 3D point cloud is generated. Moreover, from the common correspondences of the three images, the 2D-to-2D matched features between the original base image and the new image is extracted. The aforementioned steps simultaneously generate the 3D points and their corresponding 2D projections in the new image and these 2D-to-3D correspondences are then fed to a PnP solver to solve the geometric constrain relationship and estimate the 6 DoF pose of the image.

An important outcome of registering the new image to the SfM model is the ability to calculate the new image's projection matrix, which, in turn, facilitates the retrieval of ROIs from the new image. In this study, retrieving ROIs means allowing the inspector to select an ROI from the original base image, and the algorithm autonomously identifies and retrieves the corresponding ROI from the registered new image. The selection of the ROI is achieved in this study by enabling the inspector to simply draw a bounding box around the ROI in the original base image and to retrieve the same ROI form the new image. Hence, interacting with the 3D model to select the ROI points and project the ROI on the new image is not needed. More details provided in the subsequent sections explaining the details of the approach.

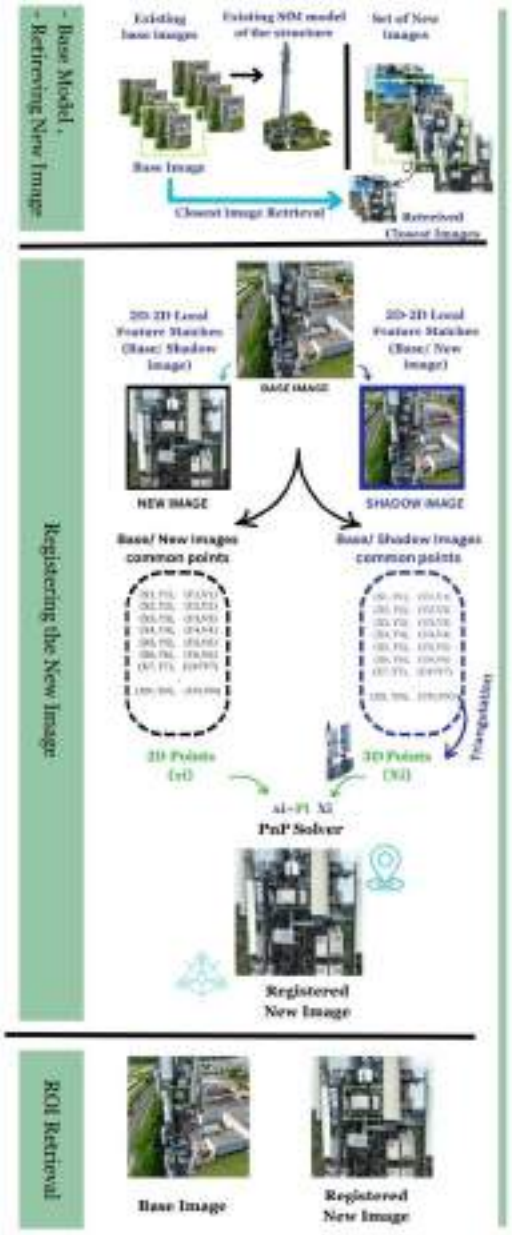

Figure 1. Proposed methodology overview

2.2 Base SfM Model

The SfM technique has been widely adopted for its ability to create accurate 3D scene reconstructions. SfM establishes correspondences from overlapping images to concurrently calibrate unknown camera parameters (intrinsic and extrinsic) while reconstructing the 3D scene. Since SfM can construct the scene and calibrate the extrinsic (position and rotation) of each camera (image), SfM technique was utilized to extract the poses of the base images.

Building high-quality SfM model requires feeding

large number of properly overlapping images to the 3D reconstruction algorithm. SfM quality depends on the quality of features matches across the sequenced images. Hence, employing high-resolution camera to collect the images is necessary to ensure reconstruction quality.

In this work, since the algorithm is implemented on a hard-to-access structure (cell tower) a commercial drone equipped with high-resolution camera was used to collect the images needed for the 3D reconstruction. The images were collected along a pre-defined path designed using a drone mission planning software to ensure the systematic overlapping of the collected images.

2.3 Retrieving Closest New Image(s)

Traditional image retrieval algorithms rely on a database of precomputed image descriptors linked to set of database images. Distance between descriptors in the new and database images are computed and the images with the highest correspondences are retrieved. However, these approaches are computationally demanding and depend on predefined descriptors databases, which may not be available and also, cause potential mismatch.

For UAV-based inspections, drones equipped with sensors like GPS, IMU, and compass typically record and associate metadata or exchangeable image file format (EXIF) data such as camera position, altitude, and heading angle with each collected image. Accordingly, A fast trigonometry-based retrieval algorithm leverages images metadata was developed to efficiently retrieve closest images without relying on complex feature-based methods.

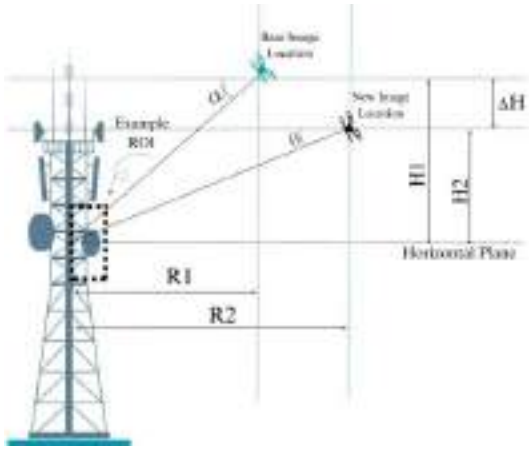

Figure 2. Image Retrieval Illustration

Figure 2 illustrates the proposed technique for retrieving closest new image(s) using a single base image. In the shown illustration, for an arbitrary ROI, a base image is assumed to be captured at a distance (R1) from the ROI with camera pitch angle (α). For the same ROI, a new image is assumed to be captured at distance (R2) from the ROI with camera pitch angle (θ) and looking at the ROI (the main region to be inspected is expected to be near the centre of the image). Subsequently, relative altitudes between base camera and ROI horizontal plane (H1) and between new camera and ROI horizontal plane (H2) and the calculated difference in altitude (ΔH_{calc}) can be calculated as follows:

$$H1 = R1 * \tan(\alpha) \quad (1)$$

$$H2 = R2 * \tan(\theta) \quad (2)$$

$$\Delta H_{calc} = R1 * \tan(\alpha) - R2 * \tan(\theta) \quad (3)$$

The trigonometric relationships in Equations (1-3) form the foundation for EXIF-based image retrieval algorithm. To retrieve the new image(s) closest to the base image, the algorithm starts by reading the heading angle for the base image and all the new images. New images with similar heading to the base image are retained and remaining images are ignored. Then, for the base image and all retained new images, the algorithm will read the longitude, latitude, altitude, and camera pitch angle of each image and calculate (R1), (R2), (H1), (H2), and subsequently, the actual altitude difference (ΔH_{actual}) between the base camera and new camera. Simply, closest images can be filtered by selecting new images with (ΔH_{actual}) close to (ΔH_{calc}). To filter images, either by heading or by ΔH similarity, the inspector can set threshold for the tolerance of the heading or the altitude differences. With higher tolerance, images with larger change in perspective might be retrieved, and vice versa.

This algorithm aims to enhance the speed and quality of UAV image retrieval for images with GPS information. In the case of operating the drone in GPS-denied zones, the conventional content-based image retrieval algorithm can be used to retrieve the closest image.

2.4 New Image Registration

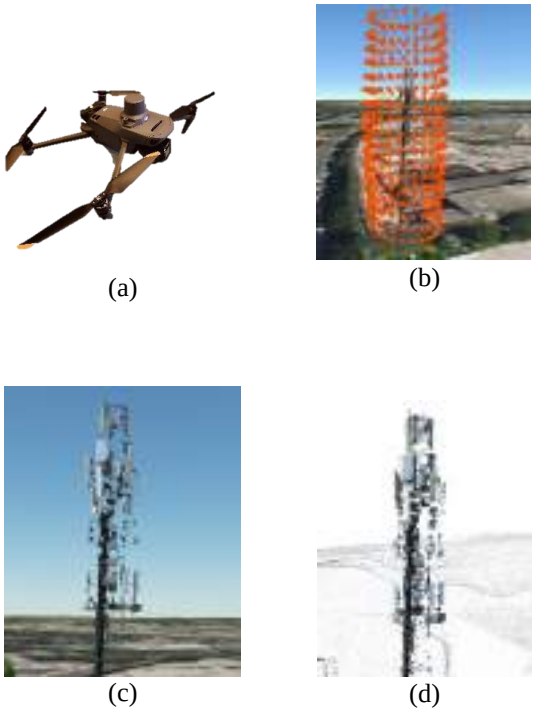
This study introduces improved approach for image registration that leverages state-of-the-art deep learning-based feature matching algorithms to simultaneously construct the 3D scene points and the 2D corresponding points of the new image without the need for pre-defined database of feature descriptors.

As discussed in the "Overview of The Technique" section, three images are utilized to enable registering the new image: base image, its associated shadow image, and a retrieved new image. Robust feature matchers are required to ensure extracting dense matches between the base, shadow, and new image even if the new image was captured under challenging conditions compared to the base image. Deep learning-based feature matching algorithms are employed to ensure accurate and dense feature extraction, even in challenging conditions like varying lighting, perspective, and scale [15].

Accurately estimating pose of the new image enable

calculating the projection matrix. Then, the algorithm can retrieve ROIs selected from the base images and localize the same ROIs in the query images.

3 Experimental Validation



To validate the proposed approach, a lattice telecommunication cell tower in Waterloo (Ontario, Canada) was selected for testing the proposed algorithm. A cell tower was selected for validation as it is type of large and hard-to-access structures that requires systematic and frequent inspections due to its significant and importance as a vital telecommunication infrastructure. The selected tower contains multiple components with highly overlapping wiring and equipment. The cell tower height is approximately 47 meters, with a base width of around 5.5 meters and a width of 4 meters at the location of the tower components.

3.1 Base Cell Tower SfM Model

To construct the base model, we used a commercial DJI Mavic 3 Enterprise drone to capture high-resolution images of the cell tower for the purposes of building high quality SfM model. The drone comprises dual cameras: wide-view camera for regular images, and tele camera with 7x optical zoom. Moreover, the drone is equipped with RTK-GPS. Accordingly, with each collected image, the set of extracted EXIF data contain information needed for executing the various steps of the proposed algorithm. The open-source tool, ExifTool [16], was used to retrieve EXIF data for each image.

To build high quality SfM model, a set containing large number of high-quality and overlapping images of the cell tower was collected. For better results, the collected images should be sequenced and capturing the different components of the cell tower at different perspectives. To ensure systematic collection of images, a commercial software, Drone Harmony [17], for flight path planning and autonomous drone mission was utilized. The planned flight path for image collection was a helical path with a proper pitch distance between helix turns that ensures proper vertical overlap of images. The horizontal overlap of images is guaranteed as the drone is always directed towards the centre of the cell tower. The result of image collection step was a set of 409 images fully covering all the regions of the cell tower. The collected images were then fed to an SfM platform to 3D reconstruct the cell tower.

Different open-source and commercial SfM platforms were tested to create a 3D model of the tower and the platform with the highest quality was selected. In our study, a commercial SfM platform, One3D [18], was utilized to build the base SfM model. The software yielded a 3D reconstruction with relatively high quality compared to other tested platforms. The platform outputs the position and rotation of each camera which allows constructing the projection matrices of all base images.

Figure 3: Base model 3D reconstruction (a) DJI Mavic 3D used in this study, (b) collected images and helical flight path (c) generated textured mesh (d) generated point cloud

3.2 Retrieving Closest Cell Tower Image

To validate the proposed image retrieval algorithm, a set of new images were collected at a different day and with different perspectives. New images were collected using wide-view camera and tele camera (7x zoom). In the post processing stage, the images were placed in the same folder directory of the base images to prepare for autonomous image retrieval.

As shown in Figure 4, the algorithm was able to successfully retrieve set of closest images relative to the base image. The algorithm retrieved the images taken with the wide-view camera and the tele camera. As shown in Figure 4, the base image was selected on the basis that the region to inspect located approximately at the center of the image, as shown within a bounding box in (a), the retrieved images clearly show that the main region of the base image is clearly shown in the retrieved images shown in (b). The inspector can retrieve more images by increasing the tolerance of heading and difference in altitude discussed in section “2.3 Retrieving Closest New Image(s)”.

Figure 4: Image Retrieval Algorithm Outputs. (a) base image, (b) example retrieved closest images.

3.3 Image Registration Output

The first step in this approach is to select local feature matching algorithms that can build dense 2D-to-2D common correspondences between base and shadow image and between base and new image. By common correspondences we mean features that are shown in the base, shadow image, and new image, simultaneously.

Three state-of-the-art deep learning-based detector-free local feature matching algorithms were employed in this study to build the dense correspondences: Efficient LoFTR [19], RoMa [20], and AspanFormer [21]. The RoMa model creates feature pyramids by integrating coarse-level features with fine-tuned specialized features, using classification-based loss for global matches and robust regression loss for fine-tuning to improve correspondence accuracy. Efficient LoFTR is an extension to LoFTR (Local Feature Matching with Transformers) algorithm. It enhances LoFTR by refining attention mechanisms and incorporating a two-stage correlation layer to enhance efficiency and accuracy in feature matching. AspanFormer is another transformer-based algorithm that employs a hierarchical attention structure and adaptive attention spans to dynamically focus on relevant regions. This adaptive design ensures accurate feature matching across varying scales and challenging scenarios. Each algorithm approaches the feature matching problem from a different perspective. Hence, in this study, the three algorithms were cascaded together to build dense correspondences that are spread across the TRI. Figure 5 shows the results of common features between the base and shadow and between base and new image. It worth noting that all features captured in the non-overlapping regions in the three images were discarded to reduce outliers and that feature that are not common in the three images were excluded.

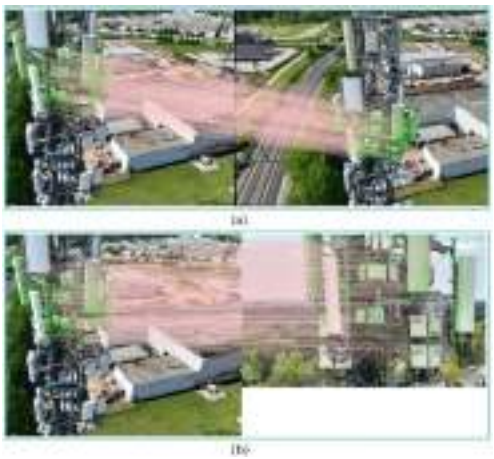

Figure 5: Feature Matching Output. (a) base image with shadow image, and (b) base image with the new image.

To build the 2D-to-3D correspondences required to localize the new image, the common features between the base and shadow images, show in Figure 5 (a), were triangulated to generate the 3D scene points and the common features between the base and new image, shown in Figure 5 (b) were extracted as the 2D projections.

The PnP algorithm was employed to minimize the reprojection error of a geometric constrain relationship. For PnP solver, and in addition to the 2D-3D correspondences, the intrinsic matrix **K** for the camera is needed and was acquired by calibrating the drone camera in the lab using camera calibration board. Additionally, a PnP solver type should be specified. For this study, the Efficient PnP solver (EPnP [22]) was implemented within a Random Sample Consensus (RANSAC) framework, in order to handle outliers.

To test the proposed algorithm, the estimated camera position of the new image should be compared to ground truth values. However, since new images have unknown ground truth values and base images have known calibrated poses, 10 base images were selected from the pool of base images and were treated as new images to evaluate the localization approach. Table 1 shows the absolute distance between actual and estimated camera positions.

Table 1. Evaluation of Image Localization Approach

Images ID	Error in Camera Position	Error in Camera Rotation (degrees)
1	0.066	0.739
2	0.022	0.180
3	0.090	0.078
4	0.075	0.544
5	0.078	0.094
6	0.061	0.685
7	0.017	0.314
8	0.041	0.089
9	0.094	0.371
10	0.064	0.620

It can be shown from Table 1 that the average error in camera position is around 0.06 m and the average error in rotation vector is 0.37°. This implies that the proposed dense feature matching-based camera pose estimation approach can accurately and reliably register new images.

In addition to the 10 base images, the whole dataset was tested to investigate the ability of the methodology to register images with different view angles and perspectives. The average mean error in camera position was found to be 0.069 m and the mean error in rotation vector was found to be 0.41°.

For the case of cell tower, and due to the fine and complex details on the structure, the image resolution was kept high during the feature matching process. This is needed to ensure building robust correspondences that guarantees high registration accuracy. High resolution images increase the inference time for deep learning-based matchers. In our experiment, an NVIDIA GEFORCE RTX 3080 GPU with 12 GB VRAM was used. The inference time for each pair takes ~2.5 seconds using AspanFormer, ~7 seconds using EfficientLOFTR, and ~9 seconds using RoMA. This inference time makes this method not compatible with real-time applications. However, the method is designed to enhance offline visual inspection and ROI retrieval from new images.

3.4 Localizing ROIs in New Cell Tower Images

Once the new image is localized, the inspector can map ROIs from base (old) images to new images to track and assess the condition changes of the ROI. In this paper, and to avoid the need to interact with the 3D scene of the structure to identify the ROI, the algorithm is designed so that the inspector selects an ROI in the base image and the features within that ROI and their corresponding features in the shadow image will be selected and triangulated using both images' projection matrices. The 3D points of the ROI are then projected back in the new image using the calculated projection matrix estimated using during image registration. Figure 6 presents different examples of ROIs selected in the base image (with the letter B in the corner) and the corresponding ROI retrieved from the new image (with the letter N). The last column in Figure 6 (with letter Z) is for zoomed retrieved ROI.

It worth mentioning that for this example the new image was selected from the set captured by the tele camera with 7x zoom. This reflects the robustness of the algorithm in localizing images and retrieving ROIs even in challenging scenarios and severe change in perspective, illumination, and scale. Figure 6 illustrates two main advantages of the proposed approach: 1) select ROIs within the region of focused inspection and retrieve the same ROI with clear details to assess condition inspection and temporal changes (as shown in first three rows of Figure 6), and 2) Inspect changes in asset dismantling or installation on the cell tower as shown in the last row where the retrieved ROI shows the change in asset installation on the selected region.

Figure 6: ROI retrieval results. First column for selected ROI in base image (B). Second column for retrieved ROI from the new image (N). Third column for zoomed in view of the ROI (Z).

4 Conclusion

This study introduces and validates an innovative method for enhancing image localization and pose estimation by leveraging state-of-the-art feature matching algorithms. Key contributions in this study include:

1. An efficient image registration method that overcomes the limitations of existing methods that require database of feature descriptors associated with 3D scene points.
2. Simplified metadata-based image retrieval algorithm for drone-collected images.
3. Accurate ROI retrieval, allowing inspectors to select ROIs on a base image, and automatically retrieve and localize the same ROI in the new image, without the need to interact with the 3D reconstruction for ROI selection.

The image localization algorithm achieved an absolute error in camera position of around 6 cm. Tests on new images from a 7x optical zoom camera shows the performance of the algorithm even in challenging scenarios of image environment. This approach significantly improves UAV-based inspections of large and hard-to-access infrastructure, offering broad applicability for diverse structures.

Abstract –

The management of complex civil infrastructures must adopt the principles of complex systems, focusing on identifying and modeling emergent behaviors for effective decision-making and predictive insights. Current methods face limitations in cross-scale and cross-domain analyses: process-based models are confined to single domains and fail under uncertainty, while data-driven approaches lack explainability, risking misaligned human-machine decisions. This work addresses this challenge by employing expert-elicited Bayesian Networks (BNs) to enhance the interpretative capabilities of Digital Twins (DTs) of civil infrastructures. BNs enable the modeling of expert knowledge regarding significant cross-domain and cross-scale relationships within complex systems, contextualizing data to develop knowledge and explicitly identify emergent system configurations. A case study focusing on the behavior of a reinforced concrete bridge pier under varying scenarios demonstrates the methodology. Qualitative testing validated the BN model's ability to reflect potential system behaviors and provide predictive insights. This study serves as a foundational step toward the development of civil infrastructure DTs with interpretative and decision-support capabilities. The presented knowledge development process facilitate the recognition of patterns that would otherwise remain undetected or be recognized only following time-consuming expert knowledge integration processes missing operational and emergency response needs.

1 Introduction

Large-scale civil infrastructures such as road infrastructures are complex systems [1] featuring nonlinear, interdependent interactions among numerous components across different domains and scales. Each component, though autonomous, influences the behavior of others, often resulting in dynamic equilibrium or instabilities that cannot be deduced by merely combining the rules governing individual components. This is not only due to the mathematical intricacy of the problem but also because of the extreme variability in outcomes that can arise from minimal changes or insufficient definition in input data.

Based on the principles governing complex systems, it is evident that the ability to identify and model their emergent behaviors must serve as the foundational basis for any decision-support tools aimed at forecasting within these systems. The contextualization of all the available heterogeneous information on the system (e.g., structural analyses and traffic flow) through cross-domain and cross-scales agent-based modeling becomes essential to develop knowledge [2] about the system and support meaningful high-level diagnosis [3]. It concerns the integration of observations (data) into a model in which both their consequences and potential causes are propagated.

Digital Twins (DTs) of complex civil infrastructure systems must include data contextualization procedures. A DT operates as a virtual shared representation of the physical system and its heterogeneous parts, aligned with it through both virtual and human agents, also exploiting real-time acquired data. This synchronization permits the perception of the system's true state, highlighting aspects that may be difficult to measure directly in the physical context. A DT of a complex system should allow for the observation of its behaviors and, crucially, the early detection of impending changes through the recognition of emergent behavior, potentially allowing for the anticipation of effects via forward simulations across time horizons that are commensurate with the system's inherent instability, typically of a short duration.

With that in mind, in this work we adopt Bayesian Networks (BNs) as a core modeling approach for data contextualization, also in accordance with the concept of human-centered digital systems. This paper therefore introduces the critical transition from information to knowledge through the use of expert-elicited BNs within

a civil infrastructure DT framework. BNs are thereby intended as a superstructure of agent modeling that allows data contextualization to explicitly identify emergent system configurations for diagnostic and prognostic purposes.

2 Background

Probabilistic inference involves making conclusions about uncertain events using existing probabilities. This approach is based on probability theory, where results are not certain but rather defined by different levels of probability. Probabilistic inference enables the representation of uncertainty and the forecasting of outcomes or choices based on the likelihood of specific results. Bayesian inference is a method of probabilistic inference that involves using Bayes' theorem to adjust the probability estimate of a hypothesis as additional evidence or data is obtained. Bayes' theorem is rooted in Bayesian inference as it explains the connection between conditional probabilities. It is asserted that the probability $P(H|D)$ of the hypothesis H given the data D, is directly related to the prior probability of the hypothesis, $P(H)$, and the likelihood of the data given the hypothesis, $P(D|H)$:

$$P(H|D) = \frac{P(D|H)P(H)}{P(D)} \quad (1)$$

In this context, the prior indicates our assumptions about the hypothesis before observing the data, while the posterior shows a revised belief following consideration of the evidence.

BNs are a class of probabilistic graphical models representing a set of variables and their conditional dependencies through directed acyclic graphs [4]. BNs are well-suited for modeling expert knowledge in situations where uncertainty is prevalent. The concept of subjective probability, which underpins Bayesian theory [5], is rooted in modern probability theory. Unlike classical probabilistic approaches, which rely on frequentist assumptions, Bayesian probability incorporates beliefs and subjective interpretations (e.g., decision-making under uncertainty). BNs therefore excel at interpreting micro-level evidences at a macro scale by identifying patterns within system's state transitions. BNs can also enable abductive inferences at a macro level, while offering the whole range of inference capabilities. Therefore, BNs present a versatile and robust approach to modeling the behaviors of complex systems [3] overcoming many limitations of traditional process-based algorithms, and purely data-driven methods as shown in Table 1. Expert knowledge-based BNs effectiveness lies in a set of key strengths that allow them to fully invert the traditional inferences logic and adapt to complex scenarios:

- explainable inferences: BNs are explicit models enabling human-computer shared awareness,
- expert knowledge-based: BNs are uniquely positioned to leverage expert knowledge, transforming experience and intuition (subjective probability – beliefs) into structured conditional probabilities,
- flexibility with input data: BNs can process partial or incomplete data,
- multi-domain and multi-scale variables,
- bidirectional inferences: BNs can perform causal (deductive) and diagnostic (abductive) inferences,
- data-driven compatibility, which helps prevent the introduction of biases caused by the subjectivity of expert knowledge

Building on the strengths of BNs this study integrates them into a DT framework for civil infrastructure diagnostics.

Table 1. Analysis of different modeling methodologies for diagnostics of civil infrastructures.

Models	Features
Knowledge-based	Multi-domain and scale variables Explainable inferences Handle uncertainty
Process-driven (physics-based)	Explainable inferences Single domain Cannot handle uncertainty
Data-driven	Multi-domain and scale feature Non-explainable inferences

3 Methodology

It is essential to conceptualize the DT not merely as a conventional simulation tool or as a simplistic virtualization of physical systems, although these aspects are certainly included. The DT possesses significant interpretative and decision-making implications, both from the service (operation and maintenance) and proactively resilience (disasters) management perspectives. The interpretive and decision-making features of a DT, as occurs in the human world, require high-level knowledge about the system under observation. This is necessary to produce meaningful and effective diagnoses. However, high-level knowledge is typically not readily accessible without substantial computational efforts or through human experts. Therefore, DTs must develop knowledge (Figure 1) starting from low-level data and information [2]. AI models can contribute to knowledge development on multiple levels. It must be said, however, that while at a low level data-driven and process-driven models prove useful, at a higher level of the pyramid there is a risk in

the former of parallelized human-computer decision-making and in the latter a lack of multi-domain and multi-scale contextualization. Therefore, within the broader framework of a civil infrastructure DT, BN models are hereby intended to serve as high-level multi-scale and multi-domain data contextualization systems.

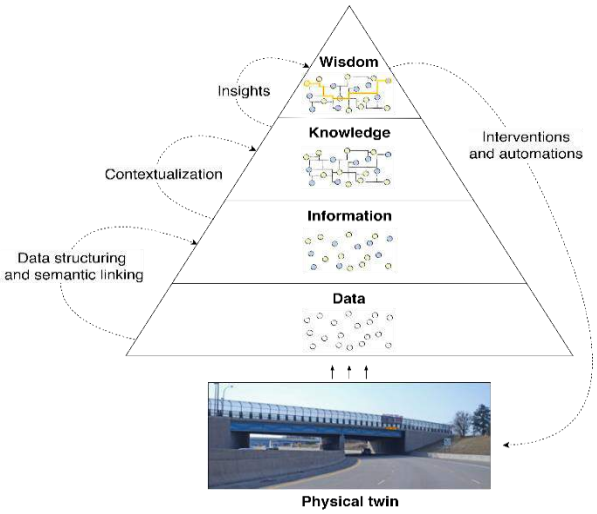

Figure 1. DT's knowledge development processes.

The proposed DT framework builds on a web-based Information Management Framework (IFM) integrating BN models that, by contextualizing a pool of significant evidences and observations through the elicitation of expert knowledge, is used as a bottom-up diagnostic framework for discovering patterns and supporting decisions. Data is collected and can describe events, observations, output from analytical models (e.g., system dynamics, discrete-events simulations, or further agent-based sub-models), real-time sensor data and design and survey data.The IFM taken as reference, and hereafter also generally referred to as DT platform, has been built to support the management processes of assets or systems of heterogeneous assets. It integrates knowledge graphs and unstructured data through a microservice-based architecture with backend and frontend services. The DT platform's backend service acts as an orchestrator of microservices, including a graph database, a document management system, data extraction, integration and query services, a REST API interface and a message broker. The BN models can be integrated with the DT platform as web-based microservices, enabling real-time inferences (Figure 2).

A Bayesian inference service was therefore developed using the Hugin Expert API REST web service [6]. It provides a Bayesian inference process server that can be queried via REST API calls to provide evidence to the network or retrieve the beliefs of nodes of interest after propagating the evidence. BN models can either be loaded or created directly within the web service by instantiating nodes and relationships through the Hugin REST API.

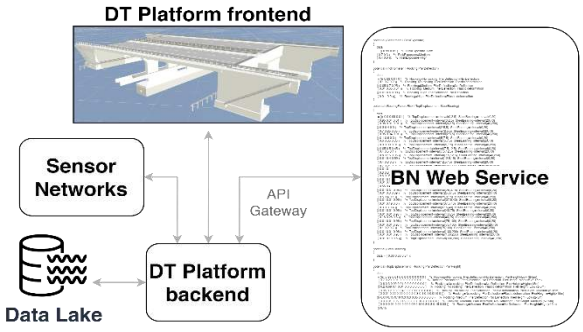

Figure 2. Schematization of the DT platform integrating the BN web service as a virtual sensor.

3.1 Case study implementation

To demonstrate the methodology, this section presents the development of a BN model representing the behaviors of a Reinforced Concrete (RC) bridge. The bridge is considered to have a simply-supported span scheme (Figure 3a). Specifically, the model focuses on the representation of high-level reasoning about the behavior of a single bridge pier, which under different actions is subject to different amplitudes of displacement at its top (Figure 3b), and may experience varying levels of bearing failure. The case study is not properly a large-scale complex infrastructure system by itself, but rather a significant part of it, given the number of multi-domain variables that influence its behavior. This case study is selected for its comprehensibility, facilitating the discussion and giving an understanding of the proposed approach along with its applicability and scalability to wider civil infrastructure systems. Key considerations include the following:

- expert knowledge was elicited to identify key variables, states, and interactions across scales and domains through five iterative 3-hour consultation session among the authors of this paper. .
- the model includes both static data (e.g., design information or data from surveys) and dynamic inputs (e.g., data from inspections, such as newly identified damages, analytical models like acceleration data analysis, or sensor data such as tilt values from inclinometers). This flexibility extends to real-time data integration,
- the BN can be updated with new evidence as it becomes available, ensuring its significance and accuracy over time,
- the BN model was integrated with the DT platform as explained in Section 3 and its output can directly

feed virtual agents as well as trigger actions from human experts,

- scalability and modularity: the network lies on a "plug-and-play" architecture, allowing for expansion and integration with other networks through loose connections, where significant. This modularity enables the development of multiple networks tailored to address further multi-domain and multi-scale interactions,
- for testing purposes, the BN was modeled using Hugin Expert [6] and exported as a HKB file.

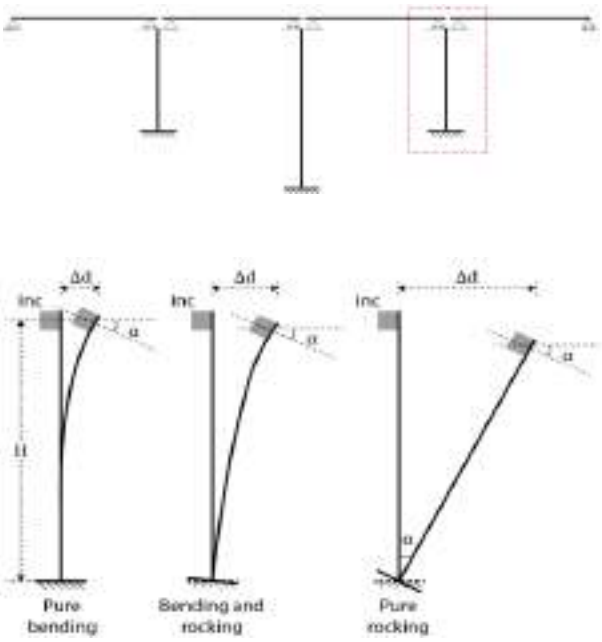

Figure 3. Structural scheme of the bridge pier taken as reference for the case study. The same inclination (α) causes different top displacements (Δd) depending on the pier's behavior.

3.1.1 Analysis of significant variables

An analysis of the significant variables was performed following the *Italian guidelines for existing bridges - classification and management of risk, safety assessment and monitoring* [7]. Given the quantity of the variables involved, a study has been performed to consider only those most appropriate for the purpose of the model presented: variables describing dynamic evidences (e.g., sensor readings or field inspection findings), context conditions (e.g., design data), and behaviors or phenomena (e.g., bending and rocking of piers, or bearing failure). The list of variables considered in the proposed model is shown in Table 2. It is not exhaustive of all possible variables, whose integration within the present model would go beyond the scope of this work. Therefore, the following key assumptions have been made:

- the model schematizes the behavior of a single circular pier of diameter $\boldsymbol{\emptyset}$ and height $\boldsymbol{H}$ in the longitudinal direction of the bridge. The pier is modelled as a fixed-base beam element free to longitudinally move at the top, involving its bending deformability (Figure 3b),
- the bearing can be either a steel or a neoprene support device (Figure 3a),
- the bridge is equipped with accelerometers, and a tilt sensor is positioned at the pier top to measure inclination α (Figure 3b),
- measurements of the relative displacement between the deck and the bearing (Δd) could be measured with displacement transducers. In some case, it might not be available,
- top displacement is caused by bending and/or rocking of the pier in the longitudinal direction.

Since the objective of this research is to validate the digital twinning methodology, these assumptions were necessary to define a specific use case. However, they do not constrain the model's updating with additional variables, limit its application scope and scalability, or compromise the network's effectiveness as a framework for contextualizing data and perform system diagnoses. Additional nodes (variables) and edges (relationships) can be modeled to capture currently omitted variables, interactions and system behaviors.

3.1.2 Model definition

The bridge pier system is described through the modeling of the variables presented in Table 2 as nodes of the network (Figure 4), and through the expert elicitation of conditional probabilities (arcs) in the Conditional Probability Tables (CPTs), which define the relationships between variables. For what concerns the variables, their states were discretized based on values deemed significant for the purposes of the model. For example, continuous variables like inclinometer readings were discretized into three ranges to simplify probabilistic modeling while capturing key behavioral thresholds that correlate with varying damage severities. Regarding the CPTs, an example is provided in Table 3. The table should be read as follows: in a scenario with "No rocking" and "No bending", the bridge pier is most likely (99%) experiencing a low level of inclination (0-0.005 rad). The probabilistic quantification of the network is achieved by specifying the CPTs for each node. For initial nodes (those without parent nodes), this quantification is assigned as prior probabilities. These priors are derived from statistical considerations when available, or by assigning equal probability to each interval into which the variable's domain is divided in cases of total uncertainty. The network's development

reflected the paradigm that effects are conditioned by their causes. Therefore, the BN was designed with a hierarchical structure where variables that represent potential dynamic evidences $\{\alpha, B_d, g\}$ are conditioned by the variables representing phenomena and behaviors $\{R_v, S_f, D_p, \theta, \Delta d, B_{f1}, B_{f2}\}$ that act differently depending on the context condition variables $\{R_e, FT, Ag, K_y, \phi, H, AR, B_s, B_n\}$. The complete model is illustrated in Figure 4.

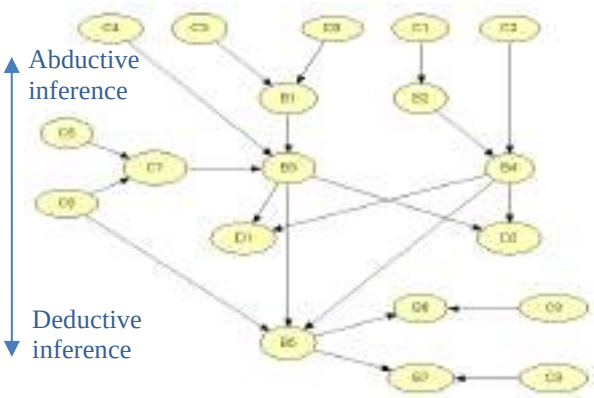

Figure 4. Visualization of nodes (variables) and relationships within the developed BN.

3.1.3 Model validation

Validating an expert-elicited BN involves determining whether the analysis accurately represents the specific concepts it is intended to model for its designated purpose. As a reflection of a mental construct designed to address possible consequences, which may or may not occur, a direct comparison between the BN's model outputs and observations from the real-world system is not feasible. In the context of this study, a comparison with historical data would be inconclusive given the little quantity of available data. However, validation can extend beyond comparisons with observed data by evaluating the internal consistency and logic of the model. Such approaches are widely applied in social science research, system dynamics modeling, and expert-driven BN modeling. A range of specific tests can be performed to assess whether the model meets predefined criteria [5]. Among those, predictive validity tests for BNs can be considered to encompass both the model behavior and the model output. Of particular relevance to establishing confidence in the predictive validity of BNs are Behavior Sensitivity Tests such as the Qualitative Features Tests (QFT). In this test the model response is evaluated in terms of a qualitative understanding on how the system is believed to respond under certain conditions and the sensitivity of the variables. This also helps unearth potential biases introduced by the modeler during the expert knowledge elicitation phase, including those caused by subjective judgment. The QFT is performed by triggering certain states of the BN-variables as inputs, and by inspecting the corresponding model response. The QFT test was performed in this study to qualitatively evaluate the BN and its consistency. Further testing will be performed in future developments, especially to assess the potential bias introduced by the heavy reliance on expert knowledge [5]. In this work, the test was conducted by two domain experts, distinct from those who contributed to the BN modeling phase. The experts have a grounded background in civil engineering with field experience related to the inspection and safety evaluation of existing bridges, obtained by conducting numerous back-office inspections and assessments following the requirements of state-of-the-art Condition Rating Systems [7]. The small validation sample size stems from the specificity of the developed model, which requires civil engineers with proven and established experience in the field of reinforced concrete bridge monitoring and inspection. This may partially limit the comprehensiveness of qualitative validation. However, this limitation does not impact the results of this research that aims at validating a digital twinning methodology. It is part of the future developments of this research to expand the validation sample by including a larger number of domain experts in the validation phase.

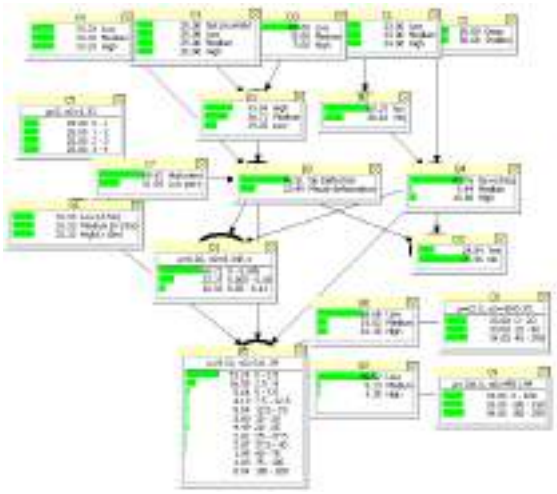

Table 2. Variables used to describe the bridge pier system under consideration.

Variable	Symbol	Node	Evidence from	Discretization
Inclinometer	α	D1	Inclinometer sensor data	{0-0.005, 0.005-0.05, >0.05} [rad]

(S6)

Figure 5. Tested scenarios (S1 to S6). Input variables for each scenario are highlighted in red.

Table 4. QFT results.

Test ID	Plausibility assessment
S1	The model schematizes a general conditions in which higher risks are not very likely, which demonstrates a good degree of generalization.
S2	A deep foundation implies a lower chance of rocking. Evidence of bending damage at the base of the pier implies a flexural plastic deformation even though the bridge was designed with appropriate standards. The inclination observed is therefore only given by bending, causing a medium level of displacement at the top of the pier (Δd). A steel bearing would experience extensive damages with high probability. Of interest is also the abductive reasoning process related to the potential causes of such damage: the beliefs of earthquake intensity grew in its *Medium* and *High* states compared to the baseline.
S3	The height of the pier is considered to be *Low (2-5m)*. The measured inclination angle therefore is most probably caused by rocking instead of bending. It implies that the belief of the state *No* of the *PiersBaseDamage* variables is higher than 85%. The significant inclination angle implies a *High* level of rocking. Nevertheless, the displacement on top seems to be not much influenced. This is plausible since the pier is low and displacement Δd grows along with the pier's height H. The believed displacement Δd would be critical in case of steel bearing causing at most moderate damages.
S4	Non-significant tilt angle is observed, bending and rocking effects are strongly believed to be absent. It implies that the displacement on top of the pier is low. Low or no risks for the bearings.
S5	Extremely significant tilt angle is observed, the model is predicting a combined bending-rocking scenario. Bending is more likely than rocking. Indeed the probability is higher, since there is a 50 % chance that rocking is not present. Displacement on top of the pier correctly increases and becomes significant. High risk of failure for the steel bearings, whereas for the neoprene ones additional evidences are required.
S6	Assuming that the displacement has been measured in a range between 20-25 mm, a low pier is 100% experiencing a significant rocking effect. The reason behind that could be the exposure of the pier and its foundation type, which are respectively believed to be most probably *High* and *Shallow*.

3.1.4 Querying the model

The model was integrated with the DT platform as explained in Section 3. The BN was then queried via the REST API service for testing the following processes:

- loading the developed BN model,
- assigning and propagating evidence after new observations,
- retrieving the beliefs of nodes of interest after evidence propagation.

Table 5 shows an example of a test query aimed at retrieving the a posteriori belief of one of the states of Node B5 after evidences in Nodes D1 and C6 are triggered in Scenario n. 5. The Response Body shows a belief of 14.09% for a top displacement in a range from

40 to 75 mm, which corresponds to the one outlined in Figure 5 (S5).

Table 5. Example of a query to the BN model.

Get the a posteriori belief of Node B5 {40-75 [mm]} in Scenario n. 5

4 Conclusions

This study aims at enhancing the management of complex civil infrastructures by integrating expert-elicited Bayesian Networks (BNs) with Digital Twins (DTs), offering a robust and scalable approach to modeling multi-scale and -domain emergent behaviors.

While the traditional process-based and data-driven models prove useful for data processing, this study offers a solution to the problem of developing high-level knowledge in DTs by endowing them with interpretive value. This is achieved through the development and integration of predictive and explainable BN models. BNs model expert knowledge, enabling the contextualization of heterogeneous multi-domain and multi-scale data (e.g., sensor data streams, observed damages, and design specifications) that are otherwise analytically non-integrable. This contextualization process, capable of assimilating significant new evidence as it arises—even in real time—facilitates the recognition of dynamic system configurations relevant to operational and emergency management needs. In this way, the proposed DT framework functions as a diagnostic and prognostic tool for civil infrastructures, including large-scale systems. It digitizes and accelerates the traditionally slow processes of expert knowledge integration.

The efficacy of this approach was demonstrated through a case study focusing on the dynamic behaviors of reinforced concrete bridge piers. A BN was modeled eliciting the authors' knowledge. The model was first integrated with a web-based DT platform through its REST API interfaces and then validated through Qualitative Features Tests conducted with two external domain experts.

The capacity to bridge human expertise with DT-based diagnostics ensures a cognitive human-machine collaboration that enhances a shared understanding of system behaviors, reflecting the concept of collective intelligence that characterizes complex systems.

Future developments will focus on the extension of the BN model, on its further validation through additional qualitative and quantitative testing and on the integration of the BN web service with the platform backend through a message broker. This would ensure seamless push communication between the service and the backend of the DT platform enabling real-time queries.

Abstract –

Effective monitoring of aging bridges is critical for ensuring their safety and maintenance. This study introduces a framework for on-site autonomous aerial bridge monitoring using sensor fusion and SLAM (Simultaneous Localization and Mapping). The proposed method utilizes a lightweight LiDAR sensor and a mini PC onboard a drone to generate real-time 3D semantic maps and flight waypoints. YOLOv8-based image segmentation is employed to identify bridge components, achieving a mean Average Precision (mAP50-95) of 86.6% across test data. Segmentation requires less than 10 milliseconds per frame, while processing LiDAR point clouds takes less than 1 second per frame. Waypoint generation based on the semantic map is completed in under 3 seconds. These results demonstrate the framework's capability to deliver precise and reliable on-site monitoring. This system provides a significant advancement in autonomous aerial bridge inspection by enabling efficient and real-time operation.

Keywords –

Autonomous Drone; Bridge Monitoring; Semantic SLAM; Sensor Fusion

1 Introduction

The need for rapid and precise monitoring of aging bridges has become increasingly critical, and drones have been demonstrated as effective tools for this purpose in various studies [1]. Particularly, autonomous drone navigation minimizes errors caused by subjective human judgment and ensures consistent data quality, making it a promising technology. However, traditional drone-based inspections often rely on predefined flight paths and manually generated waypoints, which can lead to incomplete coverage and inefficiencies in dynamic environments. Additionally, many existing approaches depend on pre-built 3D models, which are often unavailable for aging infrastructure or may become outdated due to structural modifications.

Simultaneous Localization and Mapping (SLAM) is a core technology in autonomous navigation, enabling robots or drones to perceive their surroundings and estimate their position while simultaneously creating a map. SLAM can be categorized into Visual SLAM and LiDAR SLAM. Visual SLAM uses cameras to extract features and reconstruct 3D environments, but its performance degrades in environments with poor lighting or limited texture. On the other hand, LiDAR SLAM generates dense 3D point clouds, offering precise distance measurements and real-time mapping capabilities [2], making it particularly advantageous for large-scale infrastructure inspection.

For autonomous bridge monitoring, maps should include semantic information in addition to geometric data. To achieve this, 3D semantic segmentation techniques can be applied, using either traditional or learning-based approaches. Traditional methods are computationally efficient but lack generalization and accuracy, while learning-based methods provide high accuracy but require significant computational resources.

In this study, a drone equipped with a lightweight LiDAR sensor and a mini PC is utilized to generate high-precision maps in real time, eliminating the need for pre-existing models and enabling adaptive waypoint generation based on continuously updated spatial information. By integrating semantic information with LiDAR SLAM, the proposed approach enhances scene understanding, allowing drones to differentiate bridge components and optimize flight paths accordingly. Camera-LiDAR sensor fusion is employed to achieve fast and accurate 3D bridge segmentation, enabling autonomous navigation with improved structural awareness.

As shown in Figure 1, the proposed method comprises three stages. First, bridges are identified using image segmentation based on deep learning. Second, semantic SLAM is performed by assigning classes to bridge point clouds through camera-LiDAR sensor fusion. Finally, waypoints are generated to provide autonomous flight paths. This approach enables effective aerial monitoring even for aging bridges without pre-

existing 3D models.

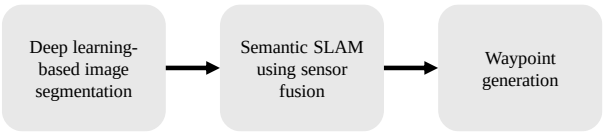

Figure 1. Overview of proposed method

2 Related Works

Most existing studies on waypoint generation and path planning for autonomous drone navigation rely on pre-existing 3D models, such as point cloud, CAD, or BrIM/BIM models. Bolourian and Hammad [3] utilize BrIM/BIM models to define key observation points and apply ray-tracing-based visibility analysis to optimize drone flight paths. Zhao et al. [4] employ a two-stage optimization approach, first determining waypoint locations using genetic algorithms and then refining camera poses through a greedy algorithm to maximize coverage efficiency. Phung et al. [5] model drone path planning as a traveling salesman problem (TSP) and solve it using discrete particle swarm optimization (DPSO), optimizing waypoint sequences to minimize flight distance while ensuring complete coverage. Lin et al. [6] integrate 2D satellite maps for flight planning, enabling flexible data collection missions.

While these methods effectively plan drone flight paths, many aging bridges lack accurate 3D models, and structural changes due to maintenance or disasters may render existing models outdated. To overcome these limitations, some studies have explored on-site mapping approaches that do not rely on pre-existing models. For instance, Narazaki et al. [7] focuses on the rapid post-earthquake inspection of reinforced concrete railway viaducts, specifically targeting damage assessment of columns. To achieve this, their approach generates waypoints based on a progressively built sparse point cloud, enabling drones to autonomously inspect structural elements. While various mapping methods, including SLAM, were considered, their experiments primarily relied on Structure from Motion (SfM) for 3D reconstruction. SfM requires acquiring a sufficient number of images before generating a usable model, which introduces a delay and limits real-time waypoint generation.

This study introduces a real-time LiDAR SLAM-based approach that generates high-precision 3D maps and enables drone-based waypoint generation without relying on pre-existing models. By leveraging LiDAR-generated point clouds with semantic information, our method ensures accurate localization and detailed structural representation, enabling drones to operate based on continuously updated spatial information. This approach facilitates efficient aerial monitoring even for aging bridges without pre-existing 3D models, providing a reliable framework for autonomous navigation in environments where structural changes from maintenance or disasters may render existing models inaccurate or obsolete.

3 Methodology

3.1 Deep Learning-based Image Segmentation

Accurate identification of bridges is a prerequisite for monitoring using autonomous drone navigation. However, processing 3D point clouds in real-time during drone flight is challenging due to computational resource limitations. To address this, the proposed method utilizes deep learning-based image segmentation and sensor fusion to recognize bridges. A real-time deep learning model segments image data captured by the drone's camera into superstructure and substructure. The

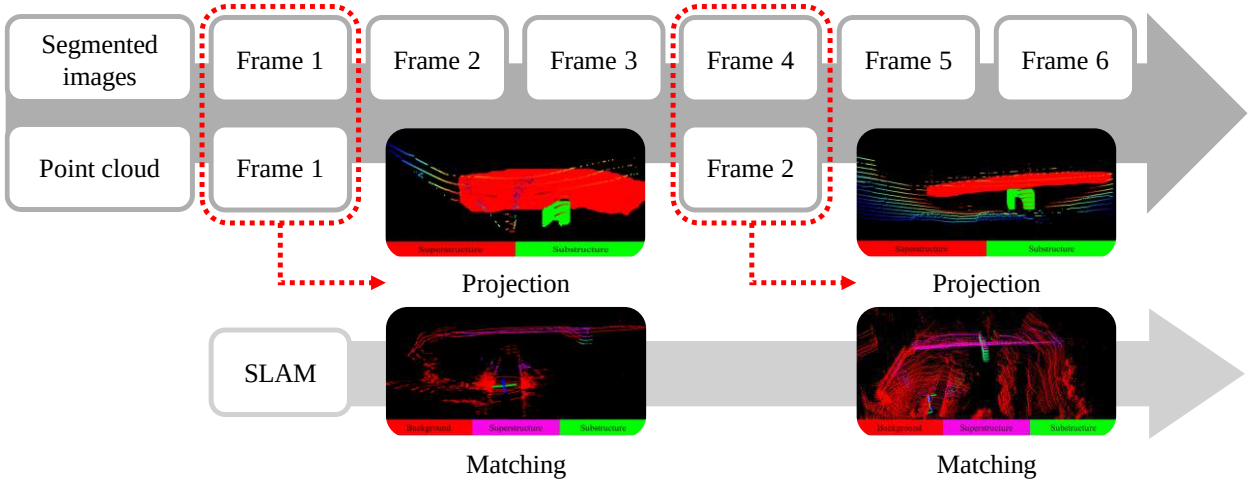

Figure 2. Process of semantic mapping using sensor fusion and SLAM

segmentation results are then used to assign classes to point clouds within the camera view, enabling the system to differentiate between bridge components effectively. This classification is crucial for optimizing waypoint generation and ensuring accurate inspection of critical structural elements.

3.2 Semantic Mapping Using Sensor Fusion and SLAM

To project 3D point clouds acquired by LiDAR onto images, precise calibration between the LiDAR and the camera is required. Calibration aligns the camera's 2D images and the LiDAR's 3D data within the same coordinate system. This involves estimating the camera's intrinsic parameters to correct distortions and matching features between LiDAR point clouds and camera images to calculate the transformation matrix (extrinsic parameters). In this study, a target-based approach using a checkerboard was employed to perform feature matching between the point clouds and images. The checkerboard provides reliable and consistent feature points, ensuring high calibration accuracy.

Once alignment is completed, the segmented images are projected onto the point clouds. The timestamps of the images and point clouds are compared to find the closest frames for matching. Since the number of images is typically greater than that of point clouds within the same duration, the nearest image to each point cloud is selected. Points within the camera's field of view are projected onto the image, and the class of the corresponding pixel is assigned to the points. This ensures that each point in the cloud is semantically labeled with a category, such as superstructure or substructure, and is subsequently utilized in the SLAM and waypoint generation processes. Figure 2 shows the process of semantic mapping in this study.

The LiDAR-Inertial SLAM algorithm integrates data from LiDAR and the Inertial Measurement Unit (IMU) to achieve high-precision real-time localization and map generation. The IMU compensates for motion between LiDAR frames, while LiDAR matching corrects the IMU's drift. This fusion ensures stable performance even during fast movements, rotations, or vibrations of the drone. In this study, calibration between the LiDAR and the drone's IMU was conducted to obtain the transformation matrix, aligning the classified point clouds with the IMU data to generate a real-time semantic SLAM map.

3.3 Waypoint Generation

The generated semantic SLAM map is processed to extract bridge point clouds, which are used as the basis for waypoint generation. First, the point cloud is downsampled to reduce computational load, and noise is removed to enhance the quality of the extracted data. Then, the RANSAC algorithm is applied to extract vertical planes of the bridge, which represent key structural elements such as piers or deck. These vertical planes are critical for determining the spatial boundaries of the bridge and for planning inspection routes.

Second, XY histograms are generated for both superstructure and substructure points, and empty bins around the structure are identified. The center of these bins is used to define the X and Y coordinates, while the Z coordinate is added considering the structure's height to define 3D waypoints. The use of histograms ensures that the generated waypoints are distributed evenly around the structure, optimizing the drone's flight path. This process enables the drone to plan flight paths for efficiently inspecting the superstructure and substructure while maintaining consistent coverage of critical areas.

4 Experiment

4.1 Implementation Details

As shown in Figure 3, the data acquisition platform was built by equipping a drone (DJI Matrice 300 RTK) with a mini PC (Intel NUC) and a LiDAR sensor (Velodyne VLP-16). The camera, LiDAR, and the drone's built-in IMU data were transmitted in ROS (Robot Operating System) message format and stored as bag files. Each message included a timestamp, which was utilized for matching point clouds with images. Data collection was conducted at two bridges in South Korea. Image segmentation was performed in real-time using YOLOv8 [8].

YOLOv8 offers models of various sizes: nano, small, medium, large, and x-large. In this study, YOLOv8n (nano model), which is suitable for real-time processing on CPUs, was selected. The model was pretrained on the COCO dataset and fine-tuned using images captured by the drone camera. Of the total 1,032 images, 722 were used as training data, and 310 as testing data. Figure 4 illustrates an example of annotations.

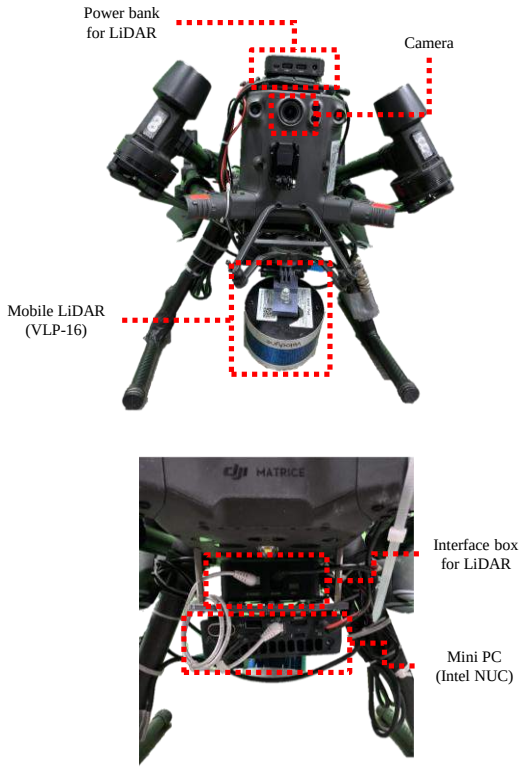

Figure 3. Hardware configuration

The LIO-SAM [9] algorithm was employed for SLAM, organizing sensor data into graph structures and optimizing them to achieve precise localization and mapping. The IMU data was utilized to compensate for the drone's motion, ensuring accurate alignment and consistency within the generated point cloud map. For waypoint generation, it was assumed that the bridge points were sufficiently accumulated on the map, with the initial flight performed using GPS-based or manual control. The map was used for waypoint generation once the bridge points exceeded 100,000 in number.

Semantic mapping, waypoint generation, and the training and testing of the YOLOv8 model were performed on a computer running Ubuntu 18.04 with an Intel Core i7-10700KF CPU and an Nvidia GeForce RTX 3090 GPU.

4.2 Experimental Results

Table 1 and Figure 5 present the quantitative results of image segmentation and examples of segmented images, respectively.

Table 1. Quantitative result of image segmentation

Class	mAP(50-95)
Superstructure	88.1%
Substructure	85.1%
All	86.6%

Figure 5. Visualization of segmented image

The segmentation results achieved an overall mAP(50-95) of 86.6%, where mAP(50-95) refers to the mean Average Precision calculated over IoU (Intersection over Union) thresholds ranging from 0.50 to 0.95 at 0.05 intervals. This metric provides a comprehensive evaluation of the model's detection performance, considering both loose and strict matching

criteria. The slightly higher accuracy for superstructure (88.1%) compared to substructure (85.1%) suggests that superstructure features may be more distinctive or easier to identify in the captured images. This highlights the robustness of the YOLOv8 model in recognizing bridge components under varying conditions, though substructure classification still has room for improvement.

Figure 6 shows the projection of point clouds onto images using the transformation matrix obtained through camera-LiDAR calibration, as well as the generated semantic SLAM map. This figure confirms that the LiDAR data has been accurately projected onto the image and that class information is being appropriately incorporated during the mapping process. The process of waypoint generation are visualized in Figure 7.

In waypoint generation, the bin size of the XY histogram was set to 2 meters, considering the size of the drone and its distance from the bridge. Similarly, the Z-axis interval was also set to 2 meters. Waypoints were initially generated at the midpoint height of the structure, and additional waypoints were generated above and below, considering the structure's height. The generated waypoints were verified against the structural geometry to ensure complete coverage of critical areas. Figure 8 shows the generated waypoints on the SLAM map.

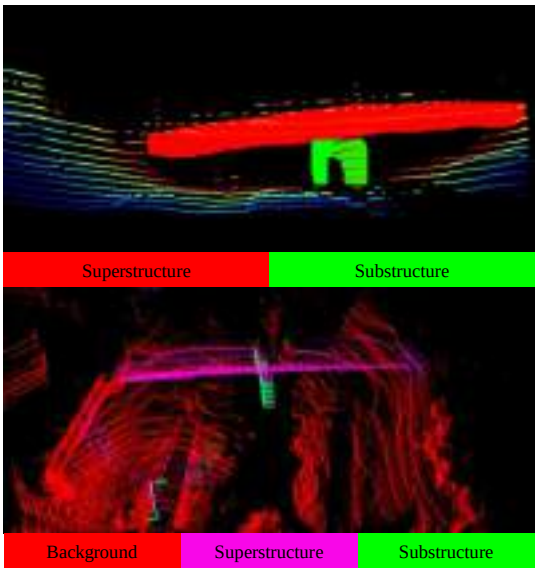

Figure 6. Visualization of projection and mapping

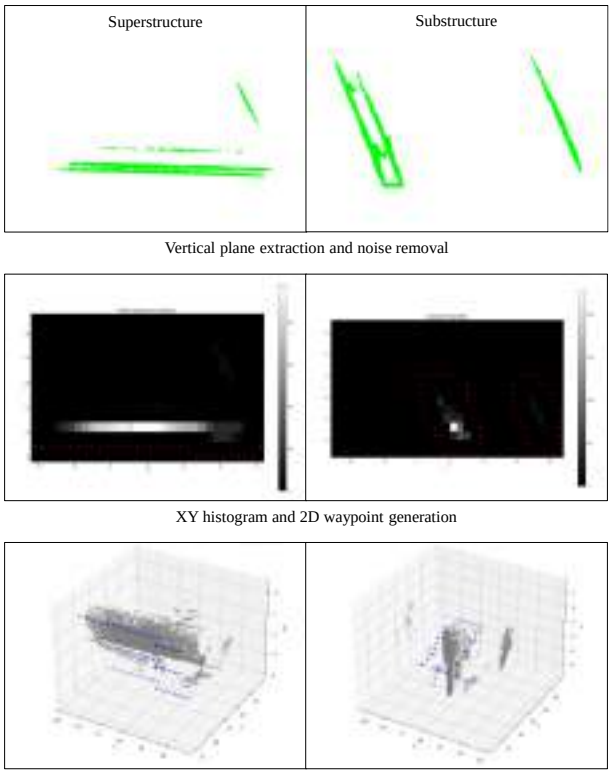

Figure 7. Visualization of waypoint generation result

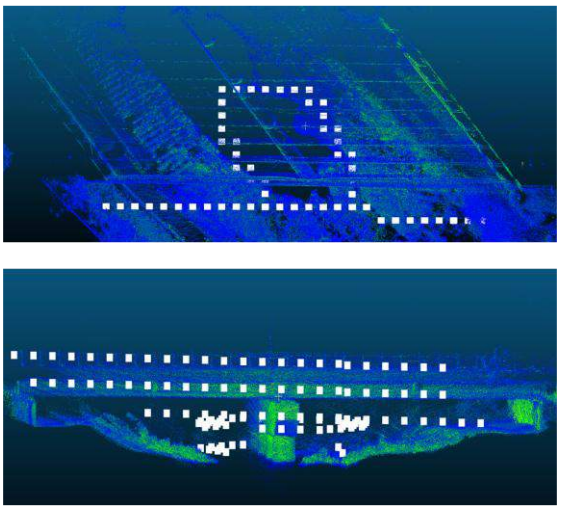

Figure 8. Visualization of generated waypoints on the SLAM map

To validate the effectiveness of the generated waypoints, a coverage evaluation was conducted using the whole bridge point cloud acquired through manual flight. The number of bridge points covered from each waypoint was measured, considering the LiDAR sensor's field of view (FOV). The visibility assessment incorporated a vertical FOV of 30° (-15° to 15°) and a horizontal FOV of 360°. Additionally, the detection

range was limited to a maximum of 10 meters to exclude excessively distant points.

In this experiment, coverage was calculated based on a voxel-based approach. The space was divided into voxels of 0.5m size, and only those containing a certain minimum number of points were considered occupied. Using this information, a ray-casting technique was applied at each waypoint to evaluate visibility. During the ray-casting process, if the line of sight from a waypoint was blocked by bridge components (e.g., girders, decks, or columns) or other obstacles acting as occluding elements, the obstructed area was considered not visible and thus not covered.

As summarized in Table 2, 144 waypoints were generated for Bridge 1, covering 119,956 bridge points, which accounts for approximately 41.21% of the total 291,064 points. Similarly, 113 waypoints were generated for Bridge 2, covering 133,837 bridge points, corresponding to 30.19% of the total 443,280 points.

Table 2. Coverage of bridge point cloud from waypoints

Bridge	Way points	Covered points	Total points	Coverage ratio (%)
1	144	119,956	291,064	41.21
2	113	133,837	443,280	30.19

These results demonstrate that the generated waypoints can effectively serve as an initial exploration path, even with data acquired only from one side of the bridge. The coverage ratios of Bridges 1 and 2 indicate that despite being derived from a limited initial map, the waypoints provided visibility to a significant portion of the bridge structure. As the drone follows these waypoints, it progressively captures more of the bridge, accumulating additional information about the structure. This allows for the continuous refinement of waypoints, enabling a gradual expansion of coverage until the entire bridge is mapped.

The execution time analysis in Table 3 demonstrates the feasibility of on-site processing. Image segmentation requires only ~10 milliseconds per frame, making it highly suitable for on-the-fly data processing during drone flights. Point cloud processing, which includes projection and semantic labeling, takes ~1 second per frame, reflecting efficient handling of LiDAR data. Waypoint generation is completed in ~3 seconds, ensuring that the overall process from image capture to waypoint planning is achieved within ~4 seconds. This performance supports the system’s applicability for on-site operations, allowing for timely and autonomous bridge inspection.

Table 3. Execution time for each process

Process	Time
Image segmentation	~10 milliseconds
Point cloud processing	~1 second
Waypoint generation	~3 seconds
Total	~4 seconds

5 Discussion

The experimental results demonstrate that unmanned and autonomous monitoring of bridges is feasible even in the absence of prior information. The proposed method achieved real-time and highly accurate bridge detection through deep learning-based image segmentation, while sensor fusion and SLAM facilitated the rapid creation of a 3D map containing the necessary bridge information for waypoint generation. The overall processing time was sufficiently short, confirming the method's applicability for on-site operations. However, the proposed method has certain limitations that require further improvement in future research.

First, the process of incorporating image segmentation results into the point cloud needs refinement. Currently, the segmentation result of the single image closest to the point cloud's timestamp is used. If the selected image's segmentation is inaccurate, the error could propagate to waypoint generation. To address this, multiple images could be utilized simultaneously, leveraging only regions identified consistently over a certain number of images, or by evaluating the reliability of segmentation results and selectively incorporating them.

Second, the waypoint generation process requires additional research. This study generated waypoints based on an initial map containing over 100,000 accumulated bridge points, but this map can be continuously updated during the drone's flight. Since the initial map was created using data collected from only one side of the bridge, the opposite side and substructure may not have been sufficiently represented. As the drone collects new data while following the initial waypoints, a dynamic approach could be employed to update the map and generate additional waypoints. For instance, after the drone passes a certain number of waypoints, the map could be updated to reflect new areas, and waypoints could be dynamically generated for further exploration.

Finally, it is essential to ensure the generalizability of the proposed method. While this study demonstrated meaningful results by applying the approach to two bridges, further validation is needed across a wider range of bridge types and environmental conditions.

Addressing these improvements would enable the proposed method to evolve into a more robust and accurate drone-based bridge monitoring system, adaptable to various environments.

6 Conclusion

This study proposed a drone-based monitoring system to address the absence of 3D models and structural changes in aging bridges. By integrating YOLOv8-based image segmentation and camera-LiDAR sensor fusion, bridge point clouds were segmented in real time, while LiDAR-Inertial SLAM enabled stable localization and continuous 3D map generation. The generated semantic SLAM map facilitated waypoint planning, allowing the drone to autonomously inspect bridges. The experimental results demonstrated that the proposed method enables adaptive bridge monitoring and autonomous flight even with limited prior information.

This study focused on adapting and integrating existing techniques into a unified system specifically designed for drone-based bridge inspection. By combining LiDAR SLAM, semantic segmentation, and waypoint optimization, the proposed framework overcomes challenges such as occlusions, real-time adaptability, and the lack of pre-existing 3D models. This integration ensures flexible and efficient coverage of bridge structures, highlighting the practical applicability of this approach in real-world scenarios.

Future research will focus on enhancing waypoint generation by incorporating multi-frame segmentation results and refining real-time map creation and path planning. Additionally, validating the system across a diverse range of bridge types will help assess its generalizability. Further optimization efforts will aim to ensure stable operation in resource-constrained environments, enabling more efficient deployment in large-scale infrastructure monitoring. This study contributes to the advancement of autonomous drone technologies for ensuring the safety and maintenance of aging bridges, demonstrating that existing algorithms can be effectively tailored to meet the specific demands of structural inspection.

Abstract –

Hand-Arm Vibration Syndrome (HAVS) results from prolonged exposure to hand-held vibrating tools, such as jackhammers, drills, and grinders. Construction workers frequently use these tools for extended periods and are therefore prone to developing HAVS over time. HAVS can affect the vascular, neurological, and musculoskeletal systems of workers, leading to both short-term and long-term disability. Despite its severity, HAVS is often under-reported due to a lack of awareness and delayed detection. Existing methods for detecting HAVS primarily focus on assessing the vibration levels of hand-held equipment rather than the condition of the exposed workers. This study proposes a machine learning tool to assess the hand and arm conditions of construction workers exposed to vibrating equipment. The tool is capable of analyzing hand drawings to detect hand tremors, an early symptom of HAVS. This innovative approach offers a potential solution for the regular monitoring of construction workers' health, enabling early detection and management of HAVS symptoms.

Keywords – HAVS; Machine Learning, Construction Workers Health; Hand Tremor

1 Introduction

The construction industry is one of the most hazardous industries around the world in terms of both fatal and non-fatal injuries. Global reports estimate approximately 60,000 fatal injuries take place within the construction industry around the world [1]. In the United States alone, approximately 200,000 non-fatal injuries and illnesses take place every year and the number go significantly higher when it comes to global injuries in the construction industry [2].

Since construction is a labor-intensive industry, the health and safety of construction workers become significantly important. A major factor affecting the health and safety of these workers is the physical demanding and hazardous nature of their work environment, particularly their reliance on heavy, hand-held machineries such as jackhammers, drills, and grinders to complete tasks [3]. These tools are heavily used in the industry for works such as demolition, drilling, cutting, etc. These tools generate intense vibrations due to their high speed and powerful mechanical operations which are then transmitted to the hands and arms of the workers.

Depending on the equipment type and specifications, the level of vibration can range from moderate to extreme. Studies show that approximately 1.2 million workers in the United States are potentially exposed to hand-arm vibration syndrome risks and among them 500,000 are construction workers [4]. To make things worse, often these tools generate more vibrations than the manufacturers declare. The Hand-Arm Vibration Database [5] on the Physical Agents Portal website collected a total of 4,913 field vibration measurements from 2,897 pieces of equipment and compared their field values with the manufacturer-declared values. This database shows that in the majority of cases, the field values are significantly higher than the declared ones [5]. Exposure to these tools with higher vibration rates and longer duration can cause significant damage to the construction workers' health. Over time, these vibrations can damage soft tissues, nerves, and blood vessels, particularly when workers are exposed for extended periods without adequate breaks or protective measures [6-8]. Additionally, weather conditions, particularly cold and wet environments, significantly worsen the risk of HAVS for construction workers [9]. Cold weather constricts blood vessels, increasing susceptibility to Vibration White Finger (VWF), while wet conditions reduce grip efficiency, amplifying strain on hands and arms [10]. These factors, combined with prolonged outdoor exposure, heighten workers' vulnerability to developing HAVS over time.

Despite these eminent dangers, HAVS is often under-reported or undetected in the construction industry due to the intermittent nature of symptoms. Studies suggest that workers wait more than 3 years after symptom onset before seeking any treatment related to HAVS and

approximately 9 years before receiving a proper assessment [11]. Workers also tend not to report the early symptoms due to lack of awareness. Hence, it is necessary to assess HAVS among the workers regularly, especially those involved in hand-held heavy machinery usage.

This paper proposes a machine learning tool that can assess the workers' hand tremor condition by analyzing their hand drawing. The tool is trained on Parkinson's disease patients' dataset and can analyze the condition of the construction workers' tremor condition and characterize them as HAVS.

2 Hand-Arm Vibration Syndrome (HAVS)

Hand-Arm Vibration Syndrome (HAVS) is a progressive condition caused by continuous exposure to vibration from tools and machinery [12, 13]. It is characterized by symptoms such as tremor, tingling, numbness, reduced grip strength, and loss of fine motor skills, and can affect the vascular, neurological, and musculoskeletal systems [6, 14]. At advanced stages, HAVS can lead to chronic pain and permanent loss of hand function, severely impairing a worker's ability to perform tasks and maintain their livelihood [15, 16]. Vibration exposure can also exacerbate other musculoskeletal disorders, creating compound health risks. Beyond its physical toll, HAVS has economic consequences for both workers and employers, including increased healthcare costs, compensation claims, and decreased productivity [17, 18].

HAVS has been reported across different industries such as manufacturing, mining, forestry, automotive etc. where workers operate vibration-intensive equipment. The prevalence of HAVS among workers regularly exposed to vibration averages 50% and increases over time if corrective measures are not implemented [19]. Studies have shown a high prevalence of HAVS in specific occupational groups, such as foundry workers, where up to 47% of exposed workers may have advanced stages of the syndrome [12].

While HAVS is a concern in different industries, it is particularly prevalent and severe in the construction industry [20]. Workers in the construction industry are regularly exposed to vibrating tools such jackhammers, concrete saws, angle grinders, pneumatic drills etc. The construction environment exacerbates HAVS risks due to prolonged tool usage, lack of awareness, and inconsistent implementation of safety measures [21, 22]. Studies suggest that up to 63% of the construction workers may be affected by HAVS to some extent [23]. In Europe, it is estimated that one in four workers are exposed to either hand-arm vibration or whole-body vibration [24]. In the United States, an estimated 1.45 million workers use powered tools that generate hand-arm vibration, with the prevalence of HAVS ranging from 6% to 100%, with an average of about 50% [25].

3 Point of Departure and Research Objectives

In order to prevent the severe health consequences of HAVS, early detection and intervention is crucial. HAVS detection involves evaluating workers' physical symptoms, functional impairments, and their exposure history [26-29]. There are clinical and technological approaches to detect HAVS among workers. For example, the Vibrotactile test evaluates the level of sensitivity of the mechanoreceptors in the hand [30], while the Thermal Aesthesiometry test assesses the sensitivity of thermal receptors in the hand to changes in temperature [31]. There are other tests such as the Purdue Pegboard test [32], Grip Force Measurement test [33], Cold Provocation test [34] etc. that assess the patients' level of sensitivity and fine motor skills in hands. Although these assessment methods are clinically effective, these strategies can be applied only when the workers self-report some of the symptoms of HAVS. However, in many cases it has been observed that workers often overlook the early symptoms and do not self-report the symptoms [7, 11, 35, 36]. By the time they report their symptoms, it is often too late.

In recent times, researchers have come up with some strategies to detect potential HAVS among construction workers by measuring the level of vibration in hand-held equipment. For example, studies demonstrated the technical feasibility of using the integrated microphone and accelerometer from commercial smartwatches in identifying the level of vibration the hand-held tools generate [25, 37, 38]. However, these methods only assess the hand-held tools' level of vibration rather than the condition of the workers' hands and arms due to the exposure to these vibrations. Additionally, these tools heavily rely on data collected through sensors in smart watches. It is often observed that these sensors collect a lot of noise from surroundings due to the dynamic nature of construction activities.

To address these issues and detect HAVS symptoms among construction workers, this research proposes a machine learning tool that can analyze the hand-drawing of construction workers and assess the condition of their HAVS in real time and continuously over a period. The tool is easy to use and does not require any wearable sensors. The tool can analyze the hand-drawing of workers, especially those exposed to vibrating tools for a longer duration and detect any vibrating syndrome such as tremor in their hands.

4 Methodology

4.1 Development of the HAVS Assessment Tool

Our methodology for developing the HAVS assessment tool is rooted in the motivation of detecting various diseases, such as Parkinson's disease, from hand drawings. Despite originating from distinct causes and affecting different parts of the nervous system, HAVS and Parkinson's disease share similarities, particularly in their effects on motor function and the nervous system. One of the common symptoms for both diseases is hand tremors. Although the causes for hand tremors differ, their effects are indistinguishable. Consequently, given the apparent scarcity of datasets dedicated to HAVS detection, our proposed machine learning model is trained using datasets primarily created for detecting Parkinson's disease [39]. The dataset primarily consists of drawings of wave and spiral shapes, both from healthy individuals and patients affected with Parkinson's. Spiral drawings, in particular, are highly effective in recognizing hand tremors of both resting and active types associated with Parkinson's. This is because tremors cause drawn lines to become relatively uneven and wavy compared to smooth spirals drawn by healthy individuals. As HAVS primarily involves hand arm vibration, it can also be associated with tremoring hands, making this approach particularly useful.

The Hand Arm Vibration Syndrome (HAVS) detection framework proposed in this study can be divided into three distinct modules which will be described in the following subsections sequentially. Figure 1 describes the structure of the proposed system.

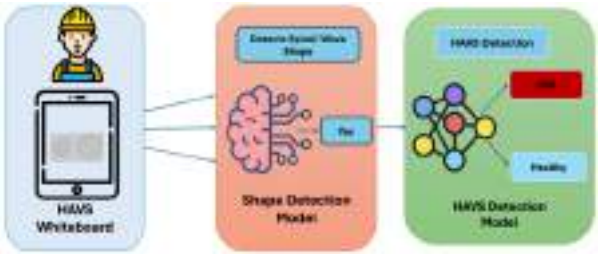

Figure 1. Proposed HAVS System Architecture with three modules.

4.2 HAVS-Whiteboard

To facilitate the collection of drawings from construction workers, a standardized online virtual drawing board is essential. While numerous virtual drawing tools are available, a dedicated tool is necessary to create a compact system that is entirely independent of any third-party application. This system must ensure the privacy and security of construction workers' sensitive information from various malicious inference attacks, such as Health Attribute Inference Attack and Personality Inference Attack, as it is shown that drawing-based inference attacks allow unauthorized intruders to accurately predict the personality and health condition of the concerned individual [40]. We envision to develop the HAVS-Whiteboard as a mobile application.

The data collection process in the HAVS-Whiteboard system begins with initialization of an empty data structure to store all the drawing-related information. Each stroke, defined as the continuous movement of the pen from contact to lift-off, is assigned a unique identifier to ensure proper segmentation of the data. This enables the system to differentiate between individual drawing actions. A sample HAVS-Whiteboard interface is demonstrated in Figure 2.

When a user starts drawing (pen-down event), the system captures the starting position of the pen on the canvas (x, y coordinates), the pressure applied, and the precise timestamp of the interaction. This starting point is the beginning of a new stroke, and a unique stroke ID is generated. As the user continues to draw (pen-move event), the system records data points at regular intervals. Each data point includes the pen's current position, the pressure applied, the angle of the pen, and the timestamp. Additionally, the speed of the pen's movement is calculated in real time by dividing the distance between two consecutive points by the time elapsed between them.

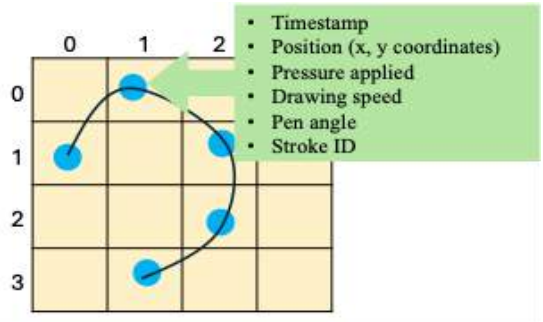

Figure 2. Data collection on HAVS-Whiteboard interface.

When the user lifts the pen (pen-up event), the stroke is finalized, and the system compiles all the captured data for that particular stroke. This process repeats for every new stroke. The collected data is securely stored and includes attributes such as timestamp, position, pressure, speed, pen angle, and the corresponding stroke ID.

In our current implementation, the HAVS-Whiteboard, a Python-based standalone application, captures the (x,y) coordinates and timestamp information. We plan to continue enhancing the application by implementing additional features, which we intend to utilize for data collection from construction workers. Our discussion of the subsequent modules of the architecture is focused on the current state of the implementation.

4.3 Disease Detection Model

Our detection model is built upon the concept of training a deep convolutional neural network model using Spiral and Wave images of the aforementioned dataset. Convolutional Neural Networks (CNNs) unlike the traditional machine learning models like SVM, Random Forest etc does not require manual feature extraction and remarkably effective for identifying hierarchical features like textures, edges etc from images while at the same time showing increased resiliency towards noise and distortions. But the problem arises from the fact that, training a deep CNN model is a tough nut to crack due to the requirement of high quantity of task related quality which is pretty difficult to ensure for each task. This seemingly unsolvable dilemma can be solved by a process which is commonly known as Transfer Learning. Transfer Learning involves finetuning a pretrained model, which has been trained on a large dataset, for a particular task. In this work, we used a pretrained deep CNN model called MobileNetV3Large which has been trained on ImageNet dataset and finetuned for our HAVS detection task. Figure 3 below illustrates the architecture of the HAVS detection model.

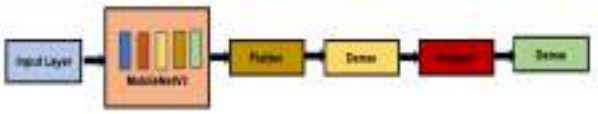

Fig 3. Block Diagram of Detection Model

4.4 Shape Recognition Model

As our proposed detection model is solely trained on Spiral and Wave images, while deploying this very HAVS detection system in real-life scenarios, there remains always a distinct possibility of users generating drawing other than Spirals or Waves. In these types of cases, how robust our detection system may be, it is bound to face failure. So, for uninterrupted operation of the detection model, it must be ensured that only related Spiral and Wave images are forwarded to that system discarding any other shapes. That's where the concept of using Shape Recognition Model comes from. It will primarily work as a filter whose very purpose will be to protect the detection model from unwanted shape images. In this work, we used the same DCNN model called MobileNetLargeV3 that we used for detection task using Transfer Learning. The difference lies in the fact that we finetuned this MobileNetLargeV3 with a dataset to detect whether the input image shape is Spiral or Wave.

MobileNetV3 is an open-source lightweight deep CNN model which has been primarily designed for producing efficient inference results in resource constrained devices such as Smartphones, Embedded Systems and IoT devices. It uses depth wise convolution which separates simpler convolutions into two distinct categories - Depthwise Convolution and Pointwise convolution which reduces the computational cost while still maintaining significant accuracy. Our particular version of MobileNet which is MobileNetV3 uses a squeeze-and-excitation module which helps module to focus on most informative feature channels while ignoring the less relevant ones thus improving its performance over the baseline one. Figure 4 presents the block diagram of the MobileNetV3 architecture, highlighting its key components such as depthwise and pointwise convolutions, bottleneck blocks, and the squeeze-and-excitation module, which collectively enable efficient and accurate feature extraction. As we want to focus on deploying this model in future on edge devices for real time use by the users, this model with its lightweight architecture, less susceptibility to noise and requirement of less computational power becomes a natural choice for the proposed HAVS detection system.

Figure 4: Block Diagram of MobileNet Architecture

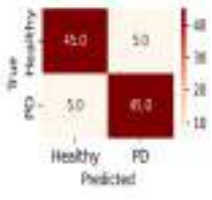
5 Experimental Setup and Result Analysis

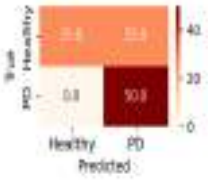
The entire experiment was implemented in Python using Pytorch framework for training and testing the model and NVIDIA's A100 GPU. Different performance metrices starting from Accuracy, Confusion Matrix, Precision, Recall and ROC-AUC curve have been used for evaluating the performances proposed Shape Recognition and HAVS detection model.

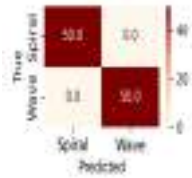
Confusion matrix is a tabular summary of model's predictions compared to actual outcomes which is widely used for evaluating model's performance. Table 1 describes the confusion matrix for both HAVS detection and Shape Recognition Model.

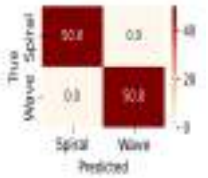
From Table 1, it is clearly visible that our modified finetuned MobileNetV3Large based Shape Detection model performs exceptionally well for both Healthy and Parkinson/HAVS categories where it is nearly perfect while correctly predicting Spiral and Wave Shapes. This Shape detection model works as a gateway to the detection mechanisms, it's highly accurate performance suggests its reliability as a filtering tool. In the case of HAVS model, it is evident that it's ability to differentiate between Healthy and Parkinson/HAVS drawing is significantly better for Spirals compared to Wave drawings where it produces some False Positives.

Table 1. Category Specific Confusion Metrices









HAVS Detection Model		
	Spiral	Wave
Shape Detection Model		
	Healthy	Parkinson/HAVS

Table 2 demonstrates the category specific results of other metrices such as Accuracy, Precision, Recall, F-1 Score which are usually generated from confusion matrix for both models.

Table 2. Category Specific Results of Performance Metrices.

		Accuracy	Precision	Recall	F-1
HAVS Detection Model	**S**	0.83	0.82	0.87	0.84
	W	0.93	0.93	0.93	0.93
Shape Detection Model	**H**	1.00	1.00	1.00	1.00
	P	1.00	1.00	1.00	1.00

Here S=Spiral, W=Wave, H=Healthy and P=Parkinson/HAVS.

From the above table, it can be observed that the shape recognition model works perfectly for both categories, HAVS model performs well especially for Wave drawings but there are areas of improvement to be done.

6 Discussion

The development of a HAVS assessment tool leveraging machine learning and existing Parkinson's datasets represents an innovative approach to address the challenge of limited HAVS-specific data. By using Spiral and Wave drawings as a means to detect hand tremors, the study successfully demonstrates the potential of integrating this tool as a method of continuous monitoring of hand-tremor development among construction workers. The integration of a custom-built virtual drawing tool i.e., HAVS-Whiteboard, enhances data security and privacy, addressing critical concerns in real-world applications.

Another finding of this research is the effectiveness of transfer learning with MobileNetV3Large in achieving robust performance on both Shape Recognition and HAVS Detection tasks. The Shape Recognition model displayed near-perfect accuracy, acting as a reliable filter to ensure only relevant input reaches the detection model. However, while the HAVS Detection model performed exceptionally well on Wave drawings, its slightly reduced accuracy for Spiral drawings reveals areas requiring further refinement. This discrepancy highlights the importance of feature representation in the input data, as Spiral patterns may involve subtler tremor-induced variations compared to Wave patterns.

Additionally, the study underscores the importance of implementing a lightweight architecture for edge deployment. MobileNetV3's efficiency, low computational overhead, and resilience to noise make it a natural choice for resource-constrained environments, such as construction sites.

The inclusion of multiple performance metrics ensures a comprehensive evaluation of the proposed system. However, analyzing false positives and negatives reveals opportunities for improving the model's ability to differentiate between Healthy and HAVS-related cases, particularly in complex scenarios. Furthermore, the reliance on Parkinson's datasets introduces potential biases, necessitating the collection of HAVS-specific data to enhance generalizability and reduce overfitting to Parkinson's-like features.

7 Conclusion

The study presents the development of a machine-learning-based tool designed to detect Hand-Arm Vibration Syndrome (HAVS) among construction workers. This innovative tool utilizes drawing patterns, captured through timestamps and (x, y) coordinates of drawing, to identify potential symptoms of HAVS.

While the current proof of concept has been validated using simple spiral and wave-like drawings, future iterations of the tool will incorporate additional features to enhance accuracy. In the next phase of development, we will expand the dataset by collecting real-world drawing samples from construction workers who are exposed to hand-held heavy machinery and integrating richer data, such as pressure, speed, and pen tilt. This will enable us to fine-tune the model and improve its reliability in identifying HAVS among construction workers.

The findings highlight the potential of machine learning to revolutionize occupational health monitoring by providing a scalable, efficient, and accurate tool for

early detection of HAVS symptom. The integration of such tools can significantly improve the well-being of workers, reduce the burden of health-related risks, and enhance safety outcomes in high-risk industries. With further refinements and real-world validation, this framework can serve as a foundation for broader applications in health diagnostics and safety monitoring.

Abstract – Crack detection in concrete structures is a critical component of infrastructure health monitoring, as cracks pose significant risks to structural integrity. Traditional manual inspection methods, while effective, are resource-intensive, time-consuming, and prone to human error. Automated crack detection using vision-based techniques has become a focal point of research, aiming to enhance accuracy, efficiency, and consistency in inspections. Deep learning (DL) methods have revolutionized crack detection by enabling end-to-end systems that automatically learn from data and perform pixel-level segmentation. This study provides an overview of recent advances in deep learning-based crack recognition, highlighting the mainstream detection methods, and revealing ongoing challenges including the need for large and diverse datasets, the development of lightweight models for real-time performance, and model generalization across diverse conditions.

Keywords –
Crack Detection; Deep Learning; Computer Vision; Infrastructure Health Monitoring

1 Introduction

Civil infrastructure, such as buildings, bridges, and dams, develop defects over time due to material weathering, cyclic loads, environmental factors, and natural hazards. In concrete structures, cracks are the most common defect which can degrade structural integrity. Therefore, early detection of cracks is crucial to prevent catastrophic damages, making regular visual inspections critical for safety and timely maintenance planning. However, traditional manual crack inspections rely on specialized equipment, and skilled professionals, and often disrupt regular operations, making the process resource-intensive, costly, time-consuming, and prone to human error. To address these challenges, automated vision-based crack recognition methods have become a focal point of research, aiming to provide efficient, cost-effective, and consistent inspection methods.

Early efforts in vision-based crack recognition relied on digital image processing techniques, however, these techniques demonstrated limited efficacy in handling the complex and irregular geometries of cracks, as well as the varying illumination and background noise in real-world images. The introduction of machine learning (ML) provided a more adaptive approach, allowing algorithms to recognize patterns from image data and improve detection accuracy. Nevertheless, ML algorithms rely on manual feature engineering, making the process time-consuming and difficult to scale to more complex environments, which limits their broader application.

The advent of deep learning (DL), particularly Convolutional Neural Networks (CNNs), has revolutionized crack detection, enabling models to automatically learn features from data without manual intervention. CNN-based methods have shown superior performance in crack segmentation tasks, to identify cracks at the pixel level, overcoming the limitations of traditional image processing and ML algorithms. In addition, the introduction of Vision Transformers (ViTs) has enabled deep models to capture global and long-range dependencies, further enhancing the ability to detect cracks in complex backgrounds and under varying conditions. This has led to a shift in focus toward deep models capable of segmenting cracks with higher accuracy, robustness, and speed.

This study aims to provide an overview of the recent advancements in automated crack recognition, with a focus on deep learning-based methods that have revolutionized the field through their accuracy, scalability, and ability to handle complex patterns in diverse scenarios. Challenges introducing potential future directions for research and development are also explored and discussed.

2 Background

Over the past two decades, image-based crack detection has been a critical and active research area for achieving efficient and reliable automated inspections

[1,2]. Crack recognition, which involves identifying cracks in digital images or videos and quantifying their dimensions (i.e., length and width), is being extensively studied within the fields of image processing and computer vision. By definition, images are composed of pixels, which can be represented as numerical matrices, where the dimensions of the matrix are determined by the resolution of the image, and the values within the matrix represent the color or intensity of each pixel. This matrix representation enables the application of various mathematical and computational operations for tasks such as object detection and segmentation [3]. Crack detection involves highlighting pixels representing the crack, which can be analyzed at three levels: image, region, and pixel [4]. At the image level, images are classified based on whether they contain cracks (image classification) [5]. At the region level, cracks are identified and localized with bounding boxes (object detection). At the pixel level, segmentation identifies the exact boundary of cracks by highlighting pixels that represent the crack area (Figure 1) [1,6]. The goal of crack recognition is not only to detect cracks but also to measure their dimensions, where researchers explore various approaches to improve accuracy and robustness in crack segmentation. However, crack detection is challenging due to the irregular geometry and non-rigid topology of cracks, which vary in shape and size [7]. Additionally, images captured by inspection devices, such as UAVs, present diverse conditions including variations in illumination, noise, motion blur, and background complexity. For years, digital image processing techniques were explored for crack detection, however, due to their limitations remained impractical.

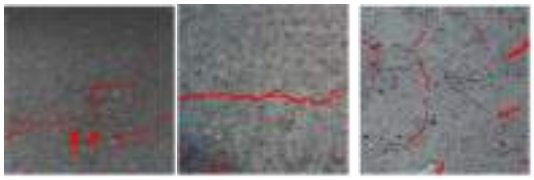

Figure 1. Examples of crack segmentation

The advent of learning-based and data-driven approaches has transformed the field, specifically Deep Learning (DL) become the mainstream approach for handling complex and high-dimensional data. The key innovation is the model's ability to automatically learn features from raw data and complete tasks without the need for manual feature engineering (Figure 2) [8]. In the field of computer vision, DNNs, especially Convolutional Neural Networks (CNNs) and Vision Transformers (ViT), have consistently outperformed traditional image processing techniques. This advancement has led to a paradigm shift in crack recognition research. The focus of many studies has been on deep models that offer faster and more generalized crack detection, where the model learns to extract features from inspection images autonomously and can identify cracks at the pixel level, a process known as semantic segmentation. Given the multi-scale nature of cracks, which can appear in different sizes within an image, and their non-rigid changing forms, several network architectures have been explored to address these challenges.

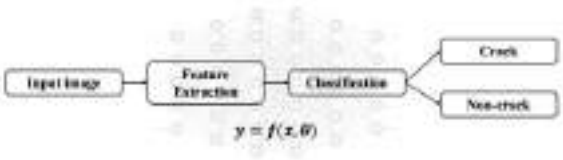

Figure 2. Representation learning by deep neural networks

3 Methodology

This review is based on a systematic content analysis of the existing literature on crack recognition. In the preliminary phase, relevant research papers were collected from databases, including Google Scholar, Scopus, ScienceDirect, and Web of Science, and using backward and forward snowballing techniques.

The keywords "concrete" AND "crack" AND ("segmentation" OR "detection"), "concrete" AND "crack" AND ("segmentation" OR "detection") AND ("measurement" OR "quantification"), and "deep" AND "crack" AND "detection" AND "quantif*" were used to search for the publications. The asterisk (*) wildcard was applied to include variations such as "quantify" and "quantification" in the search results.

During this phase, the collected papers were screened based on their abstracts, focusing on studies employing deep learning methodologies for crack detection. Only the most relevant studies were selected for an in-depth review. The analytical findings from this review were synthesized into a conceptual framework, as illustrated in Figure 3. Overview of the sections and subsections of this study . The remainder of this paper is structured according to the sections outlined in Figure 3. Overview of the sections and subsections of this study .

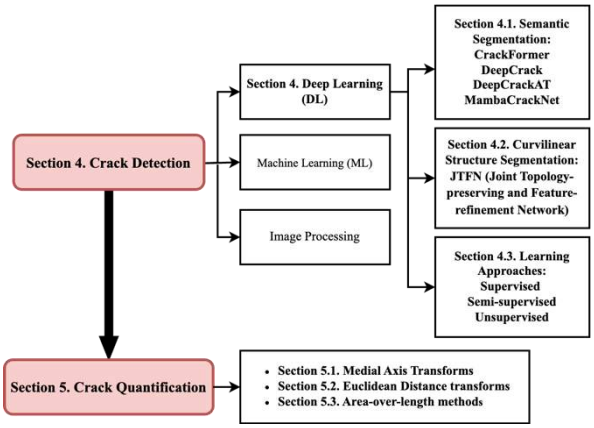

Figure 3. Overview of the sections and subsections of this study

4 Deep Learning-based Crack Detection

This section discusses various crack detection methods based on deep neural networks, with a summary of the selected studies provided in Table 1.

4.1 Semantic Segmentation

Convolutional Neural Networks (CNNs). The work by [9] introduced an early attempt at end-to-end crack segmentation using deep neural networks (DNNs), proposing a Fully Convolutional Network (FCN)-based semantic segmentation model trained on 500 concrete crack images of size 227×227 pixels. While the model outperformed Otsu's method with a 90% F1-score and precision in extracting crack paths, it failed to quantify crack dimensions due to noisy crack-like artifacts in the segmented images, a limitation stemming from the hierarchical processing of FCNs. In FCN, detailed information often from early layers is lost, which is crucial for crack detection as it requires both low-level and high-level features for fine details and semantic context, respectively. Additionally, the inductive bias of CNNs toward local feature extraction limits their ability to capture global contextual information, reducing their effectiveness in distinguishing cracks from complex backgrounds, such as material imprints.

To overcome these limitations, researchers have explored various mechanisms in designing crack segmentation models. These include dilated convolutions for enlarging the receptive field without losing resolution [10], attention mechanisms for focusing on relevant features [11−13], and Vision Transformers for capturing long-range dependencies in the data [14–19]. For instance, [20] presented a deep multi-scale crack feature learning model, named DeepCrackAT, based on an encoder-decoder architecture employing dilated convolution and attention mechanism. The model was trained on two datasets including 1440 images of masonry cracks and 2736 images of concrete and wall cracks, all resized to 224×224 pixels in size. The final model achieved 76.67% F1-score and 64.44% mIoU, nevertheless, it had limitations in segmenting cracks with significant variations in width.

Vision Transformers (ViT), introduced by [21] in 2020, employ self-attention mechanisms to capture global patterns and long-range dependencies. Demonstrating strong generalization capabilities, researchers have leveraged ViTs to enhance model robustness in new scenes and to improve crack detection in complex backgrounds [14]. For instance, [22] addressed the challenge of detecting fine-grained cracks by proposing a transformer-based segmentation network, CrackFormer. The model adapts SegNet architecture, introducing novel self-attention modules with 1×1 convolutional kernels to capture efficient contextual information across features channels, and efficient positional embeddings. New scaling-attention modules are also proposed to suppress non-semantic features and sharpen semantics when combining encoder-decoder outputs. Their comparative results demonstrated CrackFormer's superiority in multi-scale analysis of pavement crack images with higher performance and fewer floating-point operations (FLOPs).

Vision transformers, however, are dependent on large data and are computationally expensive. Therefore, researchers have proposed more efficient hybrid architectures combining convolutions and transformer operations. For instance, [18] proposed a dual-encoder network fusing Transformers and CNNs to capture local and global context information in crack inspection images with complex backgrounds. The model was trained on the Crack3238 dataset and achieved 76.44% F1-score and 78 FPS, which was higher than that of other networks in the comparative analysis.

Vision Mamba is a state-of-the-art high-performance computational framework that incorporates bidirectional state-space models for data-dependent global visual context modeling and position embeddings for location-aware visual recognition [23]. It is designed for efficient and precise data processing, offering scalability and flexibility for diverse applications. In a recent study, [24] proposed a hybrid architecture, MambaCrackNet, combining Mamba and CNN approaches to improve fine crack segmentation accuracy while reducing misdetections of background stains. Comparative experiments on two crack datasets demonstrated MambaCrackNet's superior performance over conventional segmentation models. Nevertheless, the model has a large number of learnable parameters due to the addition of two feature processing paths, leading to increased model complexity and slower inference speed.

Additionally, the Mamba module imposes restrictions related to input image size and the handling of extra spatial dimensions, which can limit the model's flexibility and adaptability in crack detection applications.

4.2 Curvilinear Structure Segmentation

Another approach in crack detection is curvilinear structure segmentation. These methods focus on identifying elongated, narrow structures such as cracks, blood vessels, roads, or rivers in images [25]. Preserving continuity, connectivity, and shape while minimizing false detections are the emphasis of these methods. Early approaches relied on edge detection and hand-crafted features, while modern techniques leverage deep learning models including CNNs and U-Nets, incorporating multi-scale feature fusion and global context modeling. Despite advances, challenges such as fragmentation, noise sensitivity, and scalability remain [26,27].

4.3 Learning Approaches

The studies on crack detection can also be categorized based on their learning approaches, including supervised, semi-supervised, and unsupervised learning methods. Supervised learning approaches have been widely studied in the literature. However, one of the challenges in crack detection is the lack of large-scale annotated datasets, hindering the full employment of deep learning models to achieve robust and generalized models. The most large-scale crack detection study is [28], which recently introduced OMNICRACK30K, a comprehensive collection of decentralized crack segmentation datasets, aimed at establishing a sustainable benchmark. Therefore, to address the challenge of large-scale labeled datasets, some studies investigated semi-supervised learning methods to leverage both small-scaled annotated data and largely available unlabelled datasets. [29] introduced a semi-supervised framework for crack segmentation on concrete and asphalt surfaces. The framework involves three stages: 1) supervised learning with different fractions of labeled data (2%, 10%, 14%, 20%, and 25%) using transfer learning, 2) consistency regularization for stability between original and perturbed images, and 3) self-training with pseudo-labeling and retraining the model from scratch on the expanded dataset for two times. According to the results, despite using only 2% of the data as labeled data, the model's performance (mIoU) was only 2.6% to 4.7% lower than using 100% of the labeled data, showing the effectiveness of the semi-supervised approach with limited annotations.

Furthermore, a novel representation learning framework was introduced by [30]. Addressing the ambiguity of marginal non-crack regions in crack segmentation, this study proposed a clustering-inspired representation learning framework (CIRL) consisting of two phases, where in phase 1, marginal non-crack regions are localized by introducing an Ambiguity-aware segmentation loss (Aseg Loss) to learn prediction variances. Next, to prevent the disturbance of marginal non-crack during model training, in the second phase, a Clustering-inspired loss (CI Loss) was proposed for ambiguous pixels based on the idea that features that are located close/farther in feature space should have consistent/inconsistent prediction. Their comparative analysis of their CIRL with other state-of-the-art crack segmentation models and loss functions showed the superiority of CIRL on four different datasets.

Table 1 Summary of the selected studies on crack detection

Category	Ref.	Model	Approach	Dataset	Performance	Advantages	Limitations
CNN-Based Approaches	[9]	FCN-based semantic segmentation	Supervised	500 concrete crack images (227×227)	90% F1-score	Early work on end-to-end crack segmentation, Outperforms Otsu's method	Fails to quantify crack dimensions, loss of crack details
	[20]	DeepCrackAT (Encoder-Decoder + Dilated Conv + Attention)	Supervised	1440 masonry, 2736 concrete/wall cracks (224×224)	76.67% F1-score, 64.44% mIoU	Captures multi-scale features	Struggles with variable crack widths

Vision Transformer-Based	[22]	CrackFormer (Transformer + SegNet)	Supervised	Two pavement crack datasets (CrackTree260, CrackLS315), one stone crack (Stone331)	Higher accuracy with lower FLOPs (88% average precision)	Multi-scale analysis, effective contextual learning	Computationally expensive
Hybrid Approaches	[18]	DTrC-Net with a Dual-encoder (Transformer + CNN)	Supervised	Crack3238	76.44% F1-score, 78 FPS	Balances local and global feature extraction	High computational cost
	[24]	MambaCrack Net (Mamba + CNN)	Supervised	CCSD (458 high-resolution concrete crack), CD (776 pavements/building walls cracks)	Higher performance than conventional models	Improved fine crack detection	High parameter count, slower inference
Curvilinear Structure Segmentation	[26]	JTFN (Joint Topology-preserving and Feature-refinement Network)	Supervised	concrete/pavement cracks (Crack500, CrackTree260,), 40 retina images (DRIVE), 1160 Road cracks	84% F1-score	Preserves connectivity and shape	Fragmentation, noise sensitivity
Learning Approaches	[29]	U-Net	Semi-supervised framework (transfer learning + pseudo-labeling)	Concrete & asphalt datasets (2%-25% labeled)	mIoU only 2.6%-4.7% lower than fully supervised	Effective with limited labels	Dependence on pseudo-labeling quality
	[30]	JTFN + CIRL	CIRL (Clustering-inspired representation learning)	Concrete/pavement cracks (CrackTree260, Crack500, CrackSeg5K), retina images (DRIVE)	Outperforms state-of-the-art methods on ambiguous crack pixels	Reduces marginal non-crack disturbances	Computationally intensive due to the clustering algorithm

5 Crack Analysis

As the literature review revealed, most studies have focused on enhancing crack detection models, while only a few have addressed methods for crack analysis (i.e., width measurement). This aspect is challenging, as high-quality crack segmentation is crucial for reliable and accurate measurement, especially considering variations in crack inspection images, such as scene complexity, background noise, and texture. Various methods have been proposed for crack quantification, including skeleton extraction techniques such as thinning algorithms, medial axis transforms, and distance transforms [31,32], as well as area-over-length methods [33] and edge detection approaches [34]. An overview of these methods is provided in Table 2. Relevant studies with respect to each approach are further discussed in the following sections.

Table 2 Overview of the crack quantification methods

Measurement Method	Relevant Studies	Advantages	Limitations
Medial Axis Transform (MAT)	[35]	- Provides a skeletonized representation of cracks, preserving	- Sensitive to noise, leading to fragmented or broken skeletons.

		topology. - Applicable to thin, continuous cracks.	- Over-simplifies complex crack structures, losing fine details. - Computationally intensive, especially when combined with deep learning.
Euclidean Distance	[36,37]	- Directly measures crack width by computing the shortest distance between two edges. - Works with both 2D images and 3D point clouds.	- Highly dependent on segmentation quality. Errors in crack edges lead to inaccurate width estimation. - Fails for irregular or branching cracks, as it assumes relatively parallel edges. - May overestimate or underestimate width if cracks have varying thicknesses.
Area-over-Length	[33,38]	- Robust against noise since it does not rely on edge detection. - Provides a simple, efficient way to estimate crack width. - Applicable to thin and elongated cracks.	- Inaccurate for irregular crack shapes, as it assumes uniform width. - Affected by small gaps or interruptions in cracks, leading to overestimation. - Struggles with very thick or non-linear cracks, where area may not properly reflect actual width.

5.1 Medial Axis Transform

To enhance microcrack detection in blurry and low-resolution images taken by UAVs, [35] proposed a three-stage crack recognition method by Super-Resolution Reconstruction (SRR), semantic segmentation, and an improved Medial Axis Transform (MAT) for crack width and length quantification. Their study showed the effectiveness of super-resolution reconstruction where reconstructed images from degraded images lead to similar segmentation output as with original high-resolution images. Nevertheless, the method is a two-stage process which cannot fulfill the real-time demand in practice.

5.2 Euclidean Distance

[36] proposed detection and quantification of global concrete cracks in panorama images using a three-stage process, including image classification of cropped panorama images, crack segmentation of positive outputs from the classification stage and crack quantization. For crack measurement, they used the coordinates of pixels to measure the Euclidean distance between two edges of cracks at different heights (lengths). To overcome the challenge of crack-like artifacts in the segmented images, they quantified cracks with a height of 50 pixels and above only. They calculated the measurements in real-world sizes by multiplying actual pixel sizes by the measurements in pixel value. The relative error of crack width measurements was 3.87%. Furthermore, [37] proposed a point cloud-based approach for analyzing cracks and spalls using semantic segmentation of raw point cloud data. The study developed a Normal Vector Enhanced Dynamic Graph CNN (NVE-DGCNN) to enable the direct analysis of the raw point cloud dataset without further conversions. For each identified defect, a minimum bounding box was generated, allowing for precise calculation of defect dimensions, including length, width, and depth. These measurements were determined through Euclidean distance calculations between the bounding box corners. However, achieving real-time crack recognition using point cloud data remains an open research challenge.

5.3 Area-over-Length

[38] proposed a two-stage crack detection method using a CNN classifier (pre-trained SqueezeNet), Deeplabv3+ to first classify crack and non-crack images, then segment cracks in positive images, and crack quantification using the regionprops function in MATLAB. The function calculates the width of each ellipse in the image by dividing its area over the length. Their results showed a lower average error of regionprops function in measuring crack width and length (7 and 2%, respectively) compared to a skeleton-based method such as medial-axis transform (11 and 17%). To leverage a trade-off between Transformers accuracy and computational cost, [33] developed a lightweight crack segmentation model using CNNs and Transformers named CrackTrNet to enable intelligent concrete dam crack patron inspection. Crack's length was

obtained using a thinning algorithm and width was measured by dividing crack's area over the length. According to the results, the model achieved similar performance compared to mainstream segmentation models with lower FLOPs and fewer parameters. 89.10% mIoU was achieved with 6.11 million parameters, which shows the feasibility of high segmentation performance with lightweight models. Yet, the study has limitations due to the non-diverse dataset, which consists of close-up images with relatively simple backgrounds and noise. Addressing these issues could enhance the model's generalization and robustness.

6 Discussion

The findings indicate that for crack detection, while ViT-based models achieve superior accuracy in controlled settings, they require large-scale datasets and substantial computational resources. For real-time applications, hybrid architectures (CNN-Transformers) offer a more effective balance between accuracy and efficiency, making them promising candidates for deployment. Additionally, optimization techniques such as pruning can enhance memory efficiency and reduce computational costs, further improving model feasibility in practical scenarios.

Moreover, accurate crack width measurement has not been achieved. This is due to limitations of the existing measurement algorithms in this task, as they are not specifically designed for crack measurement. For instance, techniques such as the medial axis transform, as discussed by [39], often generate redundant branches due to the irregular and non-rigid shape of cracks, which in turn distorts measurement accuracy. Furthermore, current crack analysis methods rely on perfectly accurate binary segmentation masks, which have not yet been achieved with the current crack detectors proposed in the literature. Imperfect masks, which may include noise, discontinuities in crack structures, or impurities that resemble cracks, affect the precision of the measurement process, making this an area in need of significant improvement.

7 Challenges, Opportunities, and Future Directions

Fully autonomous crack recognition remains an unsolved issue, as accurate width measurement is dependent on high-quality segmentation, specifically in complex and noisy environments. Therefore, the development of robust crack detection models is essential. One of the main challenges is the lack of large-scale and diverse datasets that can represent the wide range of real-world conditions in which cracks appear [40]. Additionally, the variability in crack structures makes it challenging to design models that can effectively capture the multi-scale and non-rigid structure of cracks. Future research can focus on developing advanced segmentation models and effective operations to enhance detection accuracy and improve generalization across diverse conditions.

Furthermore, in real-world applications, processing speed and computational efficiency are of paramount importance for real-time crack detection during infrastructure inspections or on-site assessments. One challenge is optimizing the trade-off between inference speed, accuracy, and computational cost of the detection models. Moreover, despite advancements in semantic segmentation, multi-stage measurement processes often impact real-time applicability [41]. Developing more robust, noise-resistant quantification methods while improving real-time efficiency can support large-scale, automated infrastructure assessment.

On the other hand, the literature has mainly focused on single-defect detection through binary segmentation whereas, in real-world scenarios, multiple defects (e.g., rust, cracks, and demolition) often coexist, requiring detailed assessments (i.e., area of the damaged surface structure). While some methods have been proposed [42,43], mainly for rough multi-defect localization using object detection and bounding boxes [44,45], future research can shift towards multi-defect segmentation to enable more precise and comprehensive assessment. A major challenge in this direction is the lack of multi-class annotated datasets for multi-defect segmentation. Addressing this limitation through the development of diverse, high-quality datasets and the adoption of multi-task learning frameworks could enhance the versatility of automated inspection systems.

Finally, from a technical standpoint, researchers utilize programming languages such as Python and MATLAB to address these challenges, along with deep learning frameworks including PyTorch or TensorFlow for model development [1]. Additionally, computer vision libraries such as OpenCV and scikit-image facilitate image processing, and automated annotation tools such as LabelMe or CVAT assist in preparing labeled datasets. For practical deployment, optimized frameworks such as TensorFlow Lite and ONNX Runtime enable efficient inference on edge devices. The advancement of these tools allows for the development of more accurate and efficient crack detection solutions.

8 Conclusion

The advancement of deep learning and computer vision technologies has significantly transformed automated crack detection, enabling more precise, and efficient visual crack assessment. This review provided an analysis of the state-of-the-art methodologies in crack

detection and quantification. Key developments, existing challenges, and potential future research directions were provided.

Through a systematic literature review, studies have been analyzed based on their computer vision task, learning approach, and dataset scale, and advantages and limitations were discussed. Furthermore, various crack measurement methods proposed in the literature were reviewed highlighting their effectiveness and shortcomings.

The review revealed that despite the accuracy of ViT-based models in controlled environments, their reliance on large-scale datasets and high computational power limits their practical deployment. Hybrid architectures, such as CNN-Transformers, offer an enhanced balance between accuracy and efficiency, especially when combined with optimization techniques such as pruning to reduce computational overhead. However, accurate crack width measurement remains an unresolved issue due to the limitations of existing algorithms and the reliance on imperfect segmentation masks. Addressing these challenges is crucial for advancing real-world applications.

Abstract –

Building Information Modeling (BIM) has revolutionized the construction industry by providing a comprehensive digital representation of building structures throughout their lifecycle. However, existing research lacks effective methods for capturing the complex spatial and topological relationships between components in BIM models, which are essential for understanding design patterns and enhancing decision-making. This study proposes a unified network-based representation method that integrates the "semantic-spatial-topological" multi-dimensional design features of BIM models. By extending the IFC (Industry Foundation Classes) standard, we introduce local spatial relationships and topological connections between components to enrich the network structure. This representation method enables a more detailed understanding of component interactions, dependencies, and implicit design patterns, effectively capturing the semantic, topological, and spatial relationships in BIM, and holds significant potential for the representation and learning of design patterns.

Keywords –

BIM representation; Network; Multi-dimensional; Design features

1 Introduction

Building Information Modeling (BIM) is a digital methodology employed in construction to design, manage, and improve detailed 3D models of buildings across their entire lifecycle [1]. By consolidating detailed information about a structure's physical and functional properties into one unified model, BIM has greatly enhanced the efficiency and effectiveness of engineering applications [2]. Consequently, BIM has been widely studied in various fields, including visualization [3], human-machine collaborative design [4] [5], and life cycle assessment [6] [7], and its adoption is steadily increasing. However, the inherent complexity of BIM models, which contain vast amounts of semantic, spatial, and topological information, makes it challenging to leverage their full potential for automated analysis and decision-making [8]. Traditional methods of working with BIM models often struggle to capture the nuanced relationships between components, such as spatial proximities, functional dependencies, and topological connections, hindering advanced tasks like design validation, conflict detection, and knowledge extraction. Therefore, how to extract and represent relevant design features and patterns from BIM data to enhance the design, construction, and maintenance of buildings has become a key focus of scholarly research.

To address the demand for a standardized and interoperable framework in construction, the Industry Foundation Classes (IFC) were introduced as an open data format to facilitate the exchange of BIM information across various tools [9] [10]. However, IFC's complex structure and irrelevant data for many tasks have led researchers to represent BIM models as vectors or networks [11]. Some studies have focused on extracting key component attributes, converting them into tensors for machine learning applications, such as clash detection and classification [12]-[14]. While these approaches address component attributes, they overlook important spatial and topological relationships, which are crucial for understanding component interactions. To capture these relationships, other researchers have modeled BIM components as nodes and edges in a network, representing attributes as node or edge features [15][17]. While these studies address some limitations of the first method, the spatial and topological relationships they capture are often simplistic and insufficient. Furthermore, the graph construction process is typically tailored to specific tasks, lacking flexibility and general applicability.

Therefore, this study proposes a unified network-based representation method for the BIM model's "semantic-spatial-topological" multi-dimensional design features. Building upon IFC and previous research, it further incorporates local spatial relationships and topological relationships between components to enrich the local information within the network. This approach not only facilitates the integration of different data types

but also enables the identification of implicit design patterns, thereby enhancing the understanding of component interactions and dependencies.

2 Background

To address the growing demand for a standardized and interoperable framework in the construction industry, IFC were introduced [9]. IFC was developed as an open, neutral data format to ensure the exchange of information across various BIM tools without data loss or misinterpretation [10]. However, due to the non-intuitive nature of the data in IFC and the presence of irrelevant information for most tasks, many researchers have attempted to further represent BIM models as vectors, or networks based on IFC and BIM software.

The first type primarily involves extracting key attributes of components and converting them into independent tensors for training and prediction. Lin & Huang (2019) extracted data from clash detection reports, encoded it into tensors, and used machine learning to detect unrelated conflicts [12]. Wang & Leite (2013) selected three types of attributes—geometric properties (e.g., "Volume"), usage and materials (e.g., "Material Flexibility"), and clash information (e.g., "Clashing Volume"), which were converted into tensors and used to train machine learning algorithms for predicting clash responses [13]. Liu et al. (2024) used component images and basic attributes like thickness and concrete grade to train a multi-model deep learning system for classification [14]. Although the above studies considered key component attributes, their use of tensors overlooked important spatial and topological relationships, such as relative positions, connections, and collaborative functions (e.g., "force transfer mechanisms"). These relationships are not only key to understanding component interactions and functional coordination but also crucial in capturing design patterns. For instance, the spatial relationship between beams and columns reflects how they transfer forces together. Without this information, models cannot fully capture the implicit interactions between components.

Therefore, scholars have attempted to represent BIM models as networks, where components and their relationships are depicted as nodes and edges, and attributes are represented as node or edge features. For example, Wang et al. (2022) treat point-based instances (e.g., “Pipe Fitting”) and curve-based instances (e.g., “Pipe Curve”) as nodes and edges in a network, using graph matching techniques to detect connection errors between components [15]. Hu et al. (2020; 2023) represent spatial and topological relationships, such as clashes and connections, as edges for collision detection and optimization [5] [16]. In contrast to the fine-grained representation, Li et al. (2024) treat rooms as nodes, with edges representing their hierarchical relationships, enabling automatic modular building design [17]. While these methods effectively capture certain spatial and topological properties of BIM models, they show considerable variation in network construction depending on the task, lacking a standardized approach to BIM model representation. Moreover, the absence of spatial relationships between components leads to incomplete information in the network.

3 Unified Network-based Representation Method for BIM

While the IFC data format can describe the geometry, attributes, and relationships of building components in detail, its storage format involves complex hierarchical structures and a vast amount of semantic information. However, deep learning networks, which are commonly used for data analysis, require numerical, flattened formats (such as images, matrices, or vectors) as input. Therefore, in order to leverage the data within existing BIM models for analysis, learning, and reuse, it is necessary to extract and preprocess the data from IFC to simplify its structure and extract key features.

In this study, we propose a unified network-based representation method for BIM models that retains critical information while structuring the data to accommodate various BIM models and research questions. Specifically, using IFC files exported from BIM software, this study extracts and calculates the properties of various components and their spatial and topological relationships, as illustrated in Table 1. Subsequently, all components are then represented as different types of nodes based on their classification in the IFC, with the extracted semantic properties represented as node features. Meanwhile, the spatial and topological relationships between components are represented as edges connecting the corresponding nodes. This network-based representation method lays the foundation for subsequent learning and transfer of design patterns within BIM models.

3.1 Semantic Data Representation of Components

Specifically, in representing the semantic properties of components, this study selects only the attributes related to each component itself from the IFC files exported by the BIM model, including basic information, geometric shapes, material properties, and other relevant attributes. The basic information includes attributes such as component ID, name, and FamilyName, which are used to uniquely identify the component. Geometric shapes are described by the attribute "Representation," including BoundingBox, Brep, SectionedSpine, and

others. Material properties are stored in entities such as "IfcMaterial" and "IfcMaterialLayerSetUsage," describing the composition and characteristics of the component. Other relevant attributes are defined through "IfcPropertySet", including durability, thermal conductivity, compressive strength, and more.

3.2 Topological Data Representation of Components

For topological properties, we selected the host and connection relationships contained in the IFC. In IFC, entities such as doors (IfcDoor) and windows (IfcWindow) are typically associated with wall entities (IfcWallStandardCase) through an opening entity (IfcOpeningElement). However, in this study, the opening entity is ignored, and the host relationship is directly associated with the wall and window or door entities. Besides, connection relationships are obtained through "IFCRELCONNECTSPATHELEMENTS," which describe the connections between components.

In addition, this study introduces a touch floor relationship to describe the vertical connection between components and floors, providing a more intuitive representation of the functional layout and component distribution across different building levels. For example, this includes the connection between walls and floors, or the installation positions of equipment within a floor relative to the floor slab. This topological relationship is extracted by calculating the positional relationship between the bounding boxes of components and floors. The three types of topological relationships extracted and calculated are shown in Figure 1.

Table 1 Unified attributes extraction and calculation method for semantic, topological, and spatial properties of components

Properties	Attributes	Description
Semantic	Basic information	Including attributes such as component ID, name, and FamilyName, which are used to identify the component uniquely.
	Geometric shapes	Defined by the attribute "Representation" from IFC, including BoundingBox, Brep, and others, this is used to represent the geometric shape of components.
	Material properties	Defined by attributes such as "IfcMaterial" and "IfcMaterialLayerSetUsage" in IFC, describing the composition and material of the component.
	Other relevant attributes	Defined by "IfcPropertySet", including durability, thermal conductivity, compressive strength, and more.
Spatial	Location	Coordinates of component positioning points or positioning line endpoints. It is defined by "ObjectPlacement," including the local coordinate system and reference coordinate system.
	Spatial relationships	The positional relationship between two components in space, including five categories: 1) different surface, 2) interface non-parallel, 3) interface parallel, 4) point-to-line, and 5) point-to-point.
	Angle	The intersection angle between two components' positioning lines; if one component uses point positioning, the angle is 0.
	Shortest distance vector coordinates	Endpoint coordinates of the shortest distance vector between the positioning points or lines of two components.
	Shortest distance	Actual spatial separation between two components. A negative value indicates an overlap or collision between the components, while a positive value denotes a gap.
	Angle with the horizontal plane	The angle between the plane or line formed by the two components and the horizontal plane. For spatial relationships in categories 2-5, the angle with the horizontal plane represents the angle between the plane or line formed by their positioning lines or points and the horizontal plane. In category 1, the angle is 0.
Topological	Host relationship	Represents the inclusion relationship, where one component is fully contained within another, such as doors/windows within walls.
	Connection relationship	Defined by "IFCRELCONNECTSPATHELEMENTS," which describe the connections between components.
	Touch floor	Describe the vertical connection between components and floors.

relationship

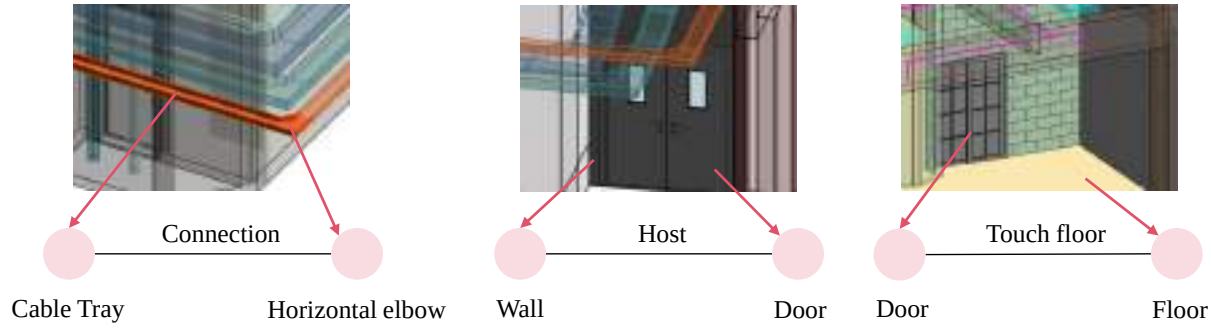

Figure 1. Three types of topological relationships

3.3 Spatial Data Representation of Components

This study first extracts the attributes representing the location of components from the IFC files, which are described by "ObjectPlacement," including the local coordinate system and reference coordinate system.

However, simple coordinate information alone is insufficient to intuitively reflect the spatial relationships between components. To address this limitation, this study further incorporates local spatial relationships of nearby components to provide additional geometric information and contextual understanding. Specifically, a local spatial relationship identifies all components within a specified distance (0.5m in this study) from a given component and calculates their relative positional relationships, including: 1) spatial relationship, 2) angle, 3) shortest distance vector coordinates, 4) shortest distance, and 5) angle with the horizontal plane, as illustrated in Figure 2.

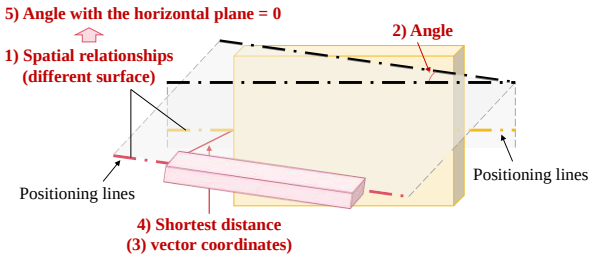

Figure 2. Example of local spatial relationship

The "spatial relationship" refers to the positional relationship between two components in space, which is determined by their positioning points or lines, and it can be classified into five distinct types: 1) different surfaces, 2) non-parallel interfaces, 3) parallel interfaces, 4) point-to-line, and 5) point-to-point. The first three types apply when both components are positioned using lines, the fourth type applies when one component is positioned by points and the other by lines, and the fifth applies when both components are positioned by points. The "angle" refers to the intersection angle between the positioning lines of the two components. If one component uses point positioning, the angle is considered 0°. The "shortest distance vector coordinates" correspond to the endpoints of the shortest distance between the positioning points or lines of the two components. The "distance" value indicates the spatial separation between the components. A negative distance suggests overlap or collision, while a positive value indicates a gap, showing that the components are separated by a specific distance. The "angle with the horizontal plane" refers to the angle between the plane or line formed by the two components and the horizontal plane. For spatial relationships falling under categories 2 to 5, the "angle with the horizontal plane" is calculated as the angle between the plane or line formed by the positioning points/lines and the horizontal plane. For category 1, the angle is 0°. Based on geometric principles, it is clear that these five calculated spatial relationships can comprehensively describe the relative positional relationship between two components.

3.4 Network-based Representations of BIM Models

This section further converts the components, their attributes, and relationships extracted from Sections 2.1, 2.2, and 2.3 into network nodes, node features, edges, and edge features, to achieve the network representation of the BIM model. The construction process is outlined in Table 2.

Specifically, all components in the BIM model are treated as nodes in the network. Based on the classification of component categories in IFC, we treat these nodes into different types, such as walls, beams, pipes, and so on. At the same time, all semantic properties of the components extracted in Section 2.1 are converted

into the corresponding node features. The topological relationships extracted in Section 2.2 are represented as edges connecting the corresponding component nodes. These edges are further classified into three categories based on the three different types of topological relationships. Additionally, the spatial relationships between a component and all components within a local 0.5m range, as described in Section 2.3, are represented as the fourth type of edge in the network. The calculated relative positional relationships between two components are used as the features of this type of edge.

It should be noted that, when two component nodes are connected by a topological relationship, they are inherently adjacent, with a relative distance of zero. This proximity implies an inherent spatial relationship between them, which could lead to redundancy if both spatial and topological relationships are represented as separate edges. To prevent this redundancy, we adopted a strategy where the spatial relationship is disregarded when a topological relationship is present, ensuring that the two component nodes are connected by only one edge. This methodology effectively reduces redundancy while maintaining the integrity of both the spatial and topological relationships within the network.

4 Case Study

Our network-based representation method achieves seamless integration with mainstream BIM software by leveraging the standardized IFC format as the universal data interface. Since IFC serves as the open BIM interoperability standard supported by all major platforms (Revit, ArchiCAD, etc.), our method is theoretically applicable to nearly all BIM software. Users simply need to export the model as an IFC file and use the proposed program for conversion. This section uses a residential floor as a case study to present how the method proposed in this research can be applied to convert a BIM model into a network. The resulting overall network and the zoomed-in local network are shown in Figure 3. Notably, node positions in the figure are determined by the coordinates of their corresponding components' central points.

As shown in Figure 3, representing a BIM model as a network effectively simplifies the complex building information and clearly expresses the multi-dimensional features of components and their relationships, such as semantic, spatial, and topological relationships. Additionally, the introduction of the touch floor relationship and the spatial relationships within a 0.5m local range further enhances the network by adding more local relational information. Overall, this method effectively compresses redundant geometric data while retaining as much of the hierarchical component attributes and spatial-temporal dependencies as possible, resulting in a structured yet information-rich network representation.

With the rapid development of machine learning, particularly in the context of nonlinear and fuzzy learning, there is an increasing need for structured tabular data for training. Our network-based BIM model addresses this requirement by providing a clear and structured format that can be used for training machine learning models, including graph neural networks (GNNs). Given that our model incorporates numerous spatial and topological features, it offers a powerful foundation for learning and reusing design features from historical models. For instance, GNNs can be employed to mask and reconstruct

node features in an unsupervised manner, enabling the model to deeply capture implicit design patterns within the BIM data. This allows the model to understand complex relationships and interactions between components that are not explicitly labeled but are critical for tasks like design optimization, automated checks, and conflict detection. Additionally, our method is directly applicable to downstream tasks. For example, in automated checks and conflict detection, we can convert these tasks into edge relationship prediction tasks, where the goal is to predict the relationships between two nodes (components) in the network. Using GNNs, we can predict whether any potential conflicts or design issues exist based on the spatial and topological relationships encoded in the network. This approach not only enables accurate detection but also facilitates the optimization and validation of designs in a more automated and efficient manner.

In summary, the network-based representation we propose supports machine learning algorithms, especially GNNs, by providing a structured format that captures both explicit and implicit design features. This facilitates tasks such as conflict detection, design optimization, and more, by making the data more accessible and interpretable for downstream analysis.

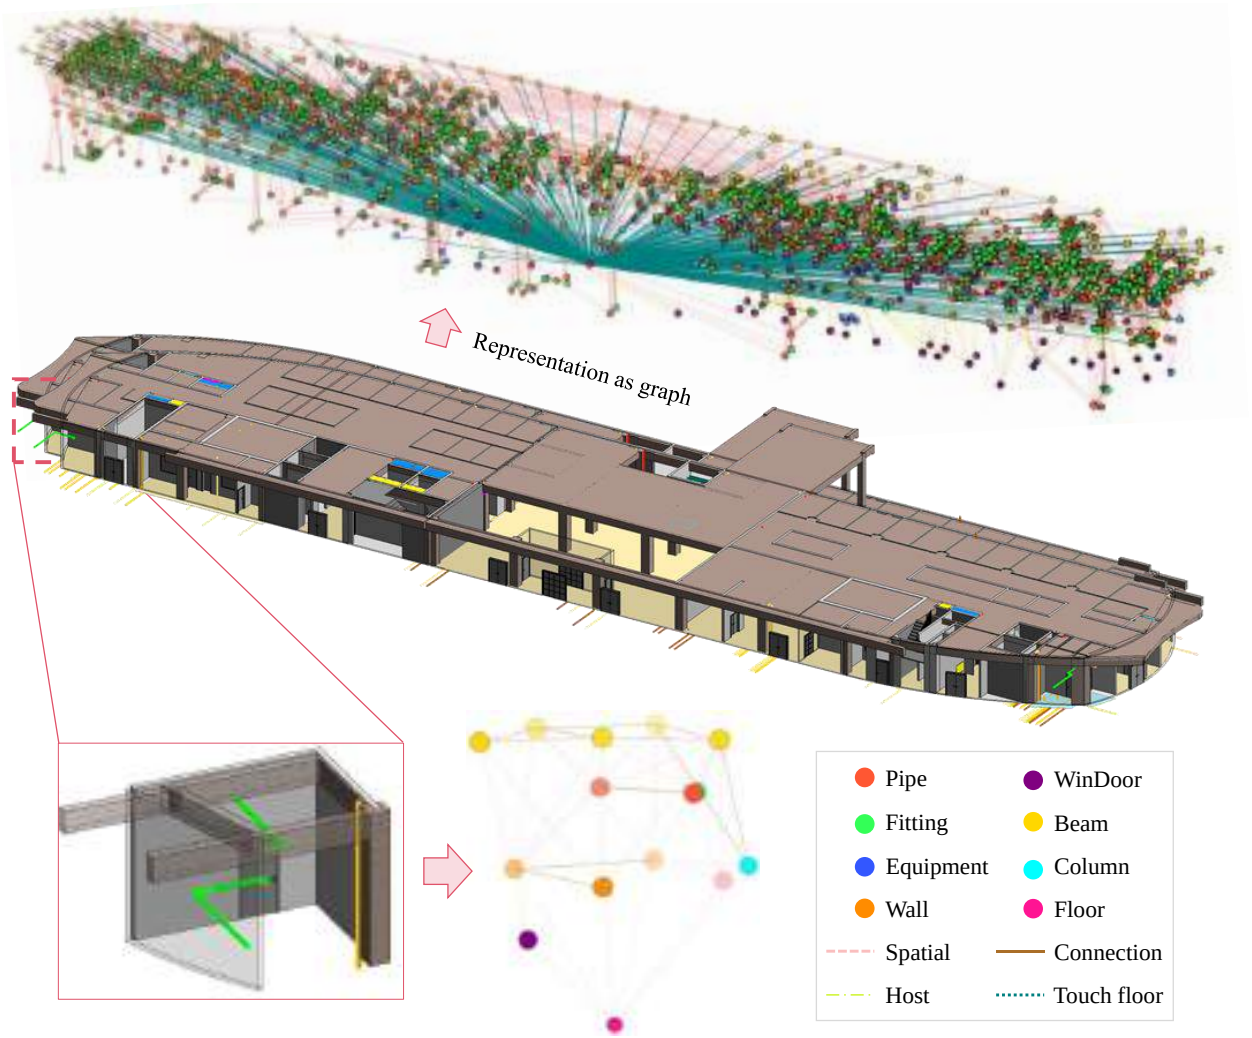

Figure 3. Example of local spatial relationship

5 Conclusion

This study proposes a unified network-based representation method for BIM models, effectively capturing the semantic, spatial, and topological features of building components. By transforming IFC data into a structured network format, our approach not only simplifies the representation but also enhances its utility for machine learning and other advanced analytical tasks. The proposed method enables more efficient design feature extraction, conflict detection, and optimization,

offering a promising framework for leveraging BIM data in various downstream applications.

Beyond the scope of the current research, future improvements can be pursued through the following approaches:

(a) Additional component features, such as time or design phase, can be integrated into the node and edge attributes to account for the impacts of construction processes and design stages, thus broadening the scope of downstream transfer learning tasks. For instance, in spatiotemporal clash detection, properties like construction priority and design phase can be incorporated. Similarly, for operation and maintenance applications, attributes such as access space and frequency of access can be included.

(b) By applying advanced machine learning techniques such as GNNs to the building data converted into a network, we can learn and capture implicit design patterns within the BIM data, enabling the transfer and reuse of historical data.

Abstract

Construction workers frequently endure high levels of physical strain, which can lead to fatigue and long-term musculoskeletal disorders. Traditional methods of fatigue assessment often fail to provide timely and accurate diagnoses, particularly in dynamic work environments. In this paper, we present a Vision Transformer-based approach for assessing localized physical fatigue using Electromyography (EMG) signals. This method leverages the high learning capacity of Vision Transformers to capture both spatial and temporal features from EMG data, enabling precise detection and prediction of fatigue. By focusing on specific muscle groups that are prone to fatigue during construction tasks, our model delivers detailed insights into the onset of fatigue at a localized level. Experimental evaluations conducted on roofing tasks targeting the biceps brachii and brachioradialis demonstrate that the proposed method can predict fatigue to a localized level. The results demonstrate the potential of this approach for enhancing on-site health monitoring systems and establishing a foundation for proactive interventions aimed at reducing the risk of fatigue-induced injuries among construction workers.

Keywords –

EMG ; Vision Transformer; CNN; Fatigue Detection

1 Introduction

Physical fatigue is a critical factor influencing worker productivity, health, and safety in various industries such as manufacturing, construction, and logistics [1]. Workers exposed to prolonged or repetitive physical tasks often experience muscle fatigue, which can impair motor control, reaction times, and cognitive function. This leads to a heightened risk of injuries and accidents, particularly in jobs that involve lifting, repetitive movements, or prolonged exertion [2]. Given the high stakes, detecting and managing physical fatigue in real-time is vital for reducing workplace injuries and ensuring worker well-being [3].

Accurately assessing physical fatigue remains a challenging problem due to its subjective nature and the variability in how it manifests across different individuals. Traditional fatigue assessment methods, such as self-reported surveys (e.g., Borg Fatigue Scale) or physical performance tests, are limited by their inherent subjectivity and time-consuming nature [4,5]. Moreover, these methods often fail to capture real-time changes in muscle fatigue, making them impractical for dynamic, high-risk environments where quick decision-making is crucial.

Electromyography (EMG) is an objective method for assessing muscle activity by measuring the electrical signals generated by muscle contractions. As muscles fatigue, changes occur in both the amplitude and frequency of the EMG signals, making it possible to quantify muscle fatigue objectively [6]. However, analyzing EMG data for fatigue detection presents challenges due to the complex, non-linear nature of the signals, the presence of noise, and variability caused by different muscle groups, task conditions, and individual characteristics.

In recent years, machine learning (ML) has emerged as a promising approach for analyzing complex bio-signals, including EMG [7]. By learning patterns from data, ML models can detect subtle changes in EMG signals associated with muscle fatigue. Despite the promise of ML, traditional models such as support vector machines and convolutional neural networks rely heavily on manual feature extraction and are often limited by their inability to capture long-range dependencies in the

data, particularly in time-series signals like EMG.

Transformers, originally developed for natural language processing, have gained attention in the field of computer vision due to their powerful ability to capture global dependencies within input data [8]. The Vision Transformer (ViT), in particular, has shown state-of-the-art performance on various image classification tasks. Unlike traditional CNNs, which use localized filters to extract features, the ViT relies on a self-attention mechanism to capture both local and global features from input images or 2D data. This makes ViTs particularly well-suited for analyzing spectrograms of EMG signals, where capturing both temporal and frequency information is crucial for fatigue detection.

One of the key challenges in applying ML models to EMG data is the variability and noise present in time-domain signals. By transforming EMG signals into spectrograms (time-frequency representations), it becomes possible to extract both temporal and spectral features from a single representation [9]. This approach not only reduces noise but also enhances the model's ability to detect tempo-spectral patterns in the data and provides image representation which can directly processed by the ViT without any manual feature extraction. As ViTs can model both local and global context in EMG spectrograms, it makes them well-suited for distinguishing between different levels of physical fatigue.

In this paper, we propose a Vision Transformer-based approach for assessing local physical fatigue using EMG signals. The method involves converting EMG signals into spectrograms, which are then input into a fine-tuned Vision Transformer model for classification. The objective is to demonstrate that this approach can effectively classify different levels of fatigue (low, medium, high) with higher accuracy and robustness compared to traditional machine learning techniques. By leveraging the power of the ViT model, we aim to provide a scalable, real-time solution for fatigue monitoring, particularly in labor-intensive work environments.

2 Background and Related Work

2.1 EMG and Fatigue Assessment

Electromyography (EMG) has emerged as a crucial technique for evaluating muscle activity by capturing electrical signals generated during muscle contractions. This method offers direct insights into muscle activation patterns and serves as a valuable tool for assessing muscle fatigue [10]. As muscles experience fatigue, EMG signals undergo characteristic changes, including amplitude increases and frequency decreases, reflecting the underlying physiological processes such as metabolic byproduct accumulation and additional motor unit recruitment. The analysis of EMG signals for fatigue detection involves a multi-step process:

1. Signal preprocessing (filtering, normalization)
2. Feature extraction
3. Pattern recognition

Traditional approaches have relied on signal processing methods like Fourier and Wavelet Transforms for feature extraction. However, these techniques often require manual feature selection and struggle to capture the complex, non-linear patterns associated with muscle fatigue [4]. Furthermore, EMG signals are susceptible to various sources of noise and artifacts, including movement and electrode displacement, which complicate the analysis process. Time-frequency domain analysis, particularly through the use of spectrograms, has gained traction as an effective method for representing EMG signals. Spectrograms offer a visual depiction of a signal's frequency content evolution over time, facilitating the identification of fatigue-related patterns. This representation not only enhances the interpretability of EMG data but also paves the way for the application of advanced machine learning techniques in fatigue classification. Recent advancements in machine learning have opened new avenues for EMG signal analysis: Deep Learning Models such as Convolutional Neural Networks (CNNs) and Recurrent Neural Networks (RNNs) have shown promise in automatically extracting relevant features from raw EMG data. Ensemble methods such as combining multiple classifiers has demonstrated improved robustness and accuracy in fatigue detection. On the other hand, transfer learning methods leveraging pre-trained models on large datasets has enabled more efficient training on smaller, task-specific EMG datasets [11–13].

Despite these advancements, challenges remain in developing localized fatigue assessment methods for diverse muscle groups and tasks. The integration of EMG-based fatigue detection systems into practical workplace settings, particularly in dynamic environments like construction sites, presents additional hurdles that require innovative solutions.

2.2 Machine Learning for Fatigue Classification

Machine learning (ML) has revolutionized the analysis of complex bio-signals, particularly EMG, for physical fatigue detection and classification. The field has evolved from traditional ML approaches to sophisticated deep learning methods, each offering unique advantages in processing EMG data [14].

Early efforts in EMG-based fatigue classification relied on conventional ML algorithms such as Support Vector Machines (SVM), Random Forests, and Decision Trees [15]. These methods demonstrated varying degrees of success in handling high-dimensional data and non-

linear classification problems [16].

The advent of deep learning has significantly improved EMG signal analysis. Convolutional Neural Networks (CNNs) have shown exceptional performance in automating feature extraction from raw or minimally processed EMG data. Liu et al. proposed a hybrid CNN-LSTM model that outperformed standalone LSTM, CNN, and RF models approaches in muscle fatigue recognition [17]. Long Short-Term Memory (LSTM) networks have also demonstrated promise in capturing temporal dynamics in EMG signals, with a study by Wang et al. developing an LSTM-based muscle fatigue recognition model that surpassed CNN and SVM in classification performance [18].

Despite these advancements, several challenges persist in EMG-based fatigue classification. These include the generalizability of models across different tasks and individuals, the ability to capture long-range dependencies in EMG signals, and the development of real-time processing capabilities for dynamic work environments. Recent developments aim to address these challenges through hybrid models, time-frequency analysis, and transfer learning approaches [7].

The field is moving towards more sophisticated and integrated approaches, including multi-modal analysis combining EMG with other physiological signals, the development of explainable AI for better interpretation of model decisions, and adaptive learning techniques that can adjust to individual differences and changing conditions in real-time. As research progresses, the integration of advanced ML techniques with domain-specific knowledge in physiology and biomechanics promises to yield more accurate, robust, and practical solutions for EMG-based fatigue detection and classification, particularly in dynamic work environments such as construction sites.

2.3 Vision Transformers and Bio-signals

Vision Transformers (ViTs) represent a significant leap forward in deep learning, particularly in computer vision tasks. Unlike traditional Convolutional Neural Networks, ViTs leverage the Transformer architecture's self-attention mechanism to capture both local and global dependencies within input data. This unique approach allows ViTs to model complex spatial relationships and long-range interactions, making them highly effective for tasks that require a comprehensive understanding of the entire input [19]. In the realm of bio-signal processing, especially for EMG-based fatigue detection, ViTs offer several compelling advantages. By leveraging EMG spectrograms—images representing time-frequency information [20]—ViTs can directly analyze temporal and spectral information in EMG signals. Their ability to process and understand 2D spectrograms makes them well-suited for identifying subtle changes in EMG signals that correlate with different levels of muscle fatigue. Moreover, the global context capture capability of ViTs enhances their robustness against noise and variability in EMG data, potentially leading to more accurate and reliable fatigue classification.

Recent literature has demonstrated several applications of transformer-based architectures in bio signal processing [21][22].

These advancements suggest that transformer-based models, including ViTs, have significant potential in bio-signal processing. Their ability to capture complex spatial and temporal relationships in data makes them particularly suitable for analysing EMG signals for fatigue detection. This work leverages the advancements in ViT and electromyography techniques to develop framework for localized fatigue estimation in construction workers.

3 Methodology: ViT-based Fatigue Assessment

The proposed methodology for EMG-based fatigue assessment consists of three main parts: data acquisition, spectrogram generation, and fatigue classification using a Vision Transformer (ViT) model. In the first stage EMG signals is acquired from the muscle group of interest using surface electrodes, and bio-amplifier. These signals are then processed, which includes labeling

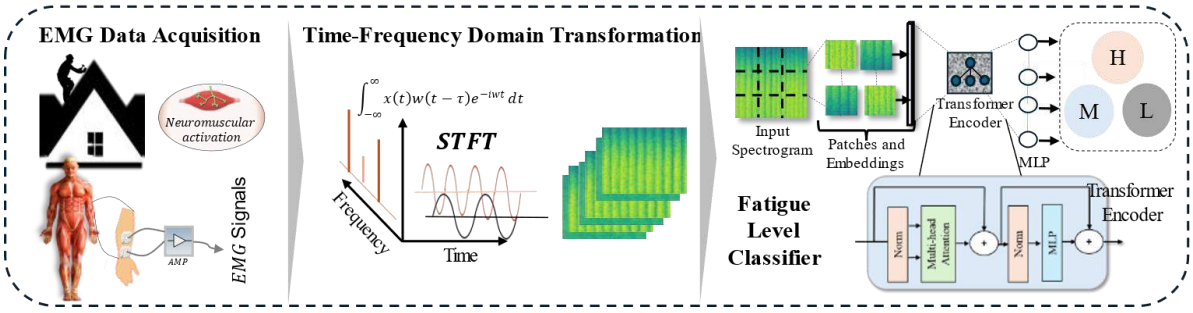

Figure 1: Overview of the methodology. The acquired EMG signals are converted to spectrograms using STFT

which is then used as input to the Vision Transformers model.

and windowing. For labeling, the Borg Fatigue rating scale is employed, providing a standardized measure of perceived exertion. This step is crucial for creating a labeled dataset that can be used to train and evaluate the Vision Transformer model. The acquired signals is used to generate a spectrogram through short-time Fourier transform. The generated spectrogram is then used as input to the Vit model which then leverages transformer architecture to classify between low, medium and high levels of fatigue (Figure 1).

3.1 Spectrogram Generation

The second phase involves transforming the time-domain EMG waveforms into 2D spectrograms using the Short-Time Fourier Transform (STFT). The STFT is defined by the equation 1:

$$STFT\{x\}(\tau,\omega) = X(\tau,\omega) = \int_{-\infty}^{\infty} x(t)w(t-\tau)e^{-iwt}dt \quad (1)$$

Where, x represents the raw EMG signals in the time domain, and w(t) is a non-zero window function. This transformation allows for the visualization of frequency changes over time, providing a richer representation of the EMG data compared to the raw time-domain signal. The use of spectrograms offers several significant advantages in EMG signal analysis. Firstly, it captures both temporal and spectral information in a single representation, allowing for a comprehensive view of the signal's characteristics. Secondly, the spectrogram transformation effectively reduces noise and enhances relevant features in the EMG signal, improving the signal-to-noise ratio and facilitating more accurate analysis. Lastly, by converting the EMG data into a 2D image-like format, spectrograms enable the application of powerful image processing techniques to bio-signal data, opening up new possibilities for advanced analysis and feature extraction.

3.2 Fatigue Classification using Vision Transformer

The final stage involves using the generated spectrograms as input to a Vision Transformer (ViT) model for fatigue level classification. The ViT model, pre-trained on the ImageNet-21K dataset , is fine-tuned for the specific task of EMG-based fatigue detection. b Key aspects of the ViT model include:

Self-Attention Mechanism: The model uses self-attention to process the entire spectrogram as a sequence of tokens, capturing long-range dependencies and global context. This is particularly beneficial for understanding complex spatial relationships in the spectrograms.

Model Architecture: The ViT consists of multiple Transformer blocks, each comprising self-attention and feedforward layers. The self-attention mechanism is mathematically expressed as 2:

$$Attention(Q,K,V) = softmax\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (2)$$

where Q, K, and V denote the query, key, and value matrices derived from input embeddings, and d_k represents the dimensionality of the key vectors.

Feedforward Neural Networks: Each Transformer block incorporates feedforward neural networks to further process token embeddings:

Fine-tuning Process: The pre-trained ViT model is adapted to the specific task of EMG-based fatigue classification through fine-tuning on a acquired dataset of EMG spectrograms (roofing tasks).

Loss Function: The model is trained using categorical cross-entropy as the loss function (Equation 3).

$$H\big(g_f(I_{2D})\big) = -\sum_{j=1}^{k} y_j \log\left(g_f(I_{2D})\right) \quad (3)$$

Here g_f is the ViT model where whereas I_{2D} is the input 2D spectrogram, y_j represents true label of the class whereas k represents the number of classes.

By using spectrograms as an intermediate representation, the approach makes the use of power architecture like ViT feasible for time-series-based EMG signals.

4 Experimental Case Study

The experimental study was designed to comprehensively assess muscle fatigue in construction workers through EMG signal analysis. Twelve volunteers were recruited to participate in a carefully controlled experimental protocol that simulated realistic construction tasks, specifically focusing on roofing activities that engage the upper limb muscle groups. The participant selection process made sure that all subjects were free from medical conditions that could potentially interfere with the experimental measurements.

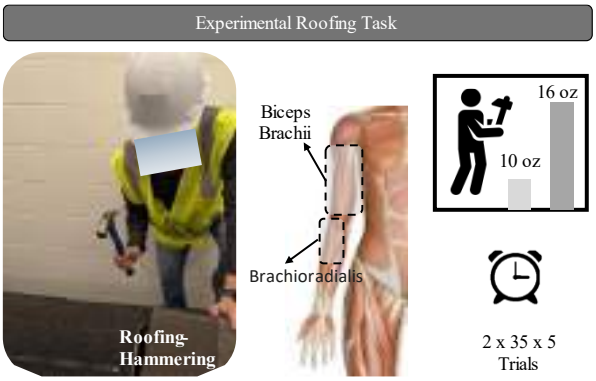

Figure 2: Roofing task was used to evaluate performance of the developed framework. Subjects hammered shingles into the roof structure during the task when EMG signals were acquired.

Electrode placement was a critical aspect of the methodology. Specialized surface EMG electrodes were positioned bilaterally over the biceps and brachioradialis muscle group. A multichannel ADInstruments bio-amplifier was utilized to acquire high-resolution EMG signals, with a sampling frequency of 1 kHz and a window size of 3 seconds. A sliding window of 1 seconds was used for the signal's segmentation. The average time of experimentation was around 12 minutes per subject excluding setup and rest periods. The generated spectrograms were split into 80:20 rationfor training and testing with a stratified split to make it consistent across all the classes.

The electrode configuration allowed for precise tracking of muscle electrical activity during various physical tasks. The Borg Rating of Perceived Exertion (RPE) scale played a crucial role in fatigue classification. This well-established subjective measure allows participants to rate their perceived level of physical exertion on a scale typically ranging from 6 to 20. In this study, the RPE was used to categorize fatigue levels into three distinct classes: low, medium, and high. Participants were trained to provide self-assessments, ensuring the reliability of the subjective fatigue ratings.

The experimental tasks were carefully designed to simulate real-world construction scenarios, with a particular focus on roofing activities. Participants performed controlled roofing tasks that engaged the biceps brachii and brachioradialis muscles, mimicking the physical demands of actual construction work. The tasks were structured to progressively induce muscle fatigue, allowing to capture the nuanced changes in muscle activation patterns over time (using a hammer of increased load). Signal processing played a critical role in transforming raw EMG data into meaningful insights. The acquired signals underwent several preprocessing steps, including filtering to remove noise, normalization to account for variations and transformation into spectrograms using Short-Time Fourier Transform (STFT). This approach converted time-domain signals into two-dimensional representations that could be effectively analysed using the Vision Transformer model. From twelve subjects with

During the experiment, participants were given adequate rest periods between tasks to minimize cumulative fatigue effects and ensure the reliability of the measurements. By integrating objective EMG measurements with subjective fatigue ratings, the study aimed to develop a comprehensive understanding of muscle fatigue in construction workers.

5 Results and Discussion

The developed fatigue estimation model based on a Vision Transformer (ViT) network demonstrated promising performance in classifying fatigue levels using EMG signals from the biceps brachii and brachioradialis muscles. The model's performance varied across different muscle groups, with distinct patterns observed

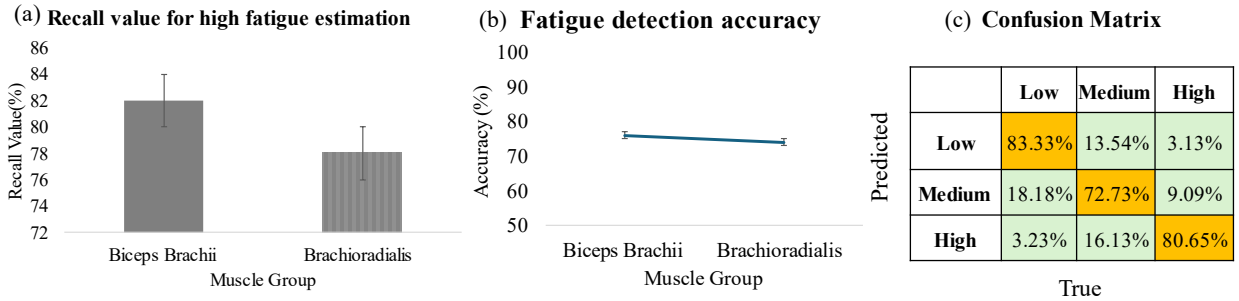

Figure 3: (a) Bar diagram for recall value for the high fatigue estimation. (b) Accuracy for fatigue estimation. (c) Confusion matrix for the fatigue estimation through ViT.

in fatigue detection accuracy.

For high fatigue estimation, the recall values showed notable differences between muscle groups, with biceps brachii achieving approximately 82% recall and brachioradialis showing around 78% recall. The overall fatigue detection accuracy remained relatively consistent across both muscle groups, with values around 75% (biceps brachii- 76% and brachioradialis – 74%).

The model showed the strongest performance in identifying low fatigue states (83.3% accuracy) , followed by high fatigue states (80.65% accuracy), while medium fatigue states presented the most challenging classification task (72.73% accuracy). This pattern suggests that the transition between fatigue states, particularly in the medium range, requires careful consideration in future model refinements. The superior performance of the ViT model can be attributed to its ability to capture global context through the analysis of spectrograms. By transforming EMG signals into time-frequency representations, the model leverages its strength in processing two-dimensional data, which allows it to identify subtle changes in muscle activation associated with varying levels of fatigue. The advantages of using spectrograms as input for the ViT model remain significant, facilitating comprehensive analysis of both temporal and spectral features. This multi-dimensional approach enhances the model's ability to assess fatigue accurately across different muscle groups and fatigue states.

For a more comprehensive analysis, the authors also compared the manual feature extraction-based method using both time domain feature (Signal Mean Absolute Value and Root Mean Square) and frequency domain feature (Median Frequency (MDF) and Mean Frequency (MEF) [5] and trained a SVM, ANN, and random forest models from the extracted features. The SVM model provided an average accuracy of 59.4%, which was the highest among the competing model. Table 2 outlines the average accuracy and its comparison with the ViT model.

Table 1: Comparison with ML models using manually extracted feature from EMG signals

Model	Accuracy	% improvement in VIT
SVM	59.4 %	26 %
ANN	51.2 %	46 %
Random Forest	58.1 %	29 %

While the developed mode is able to predict localized fatigue levels with a decent accuracy, several challenges and limitations remain. Real-time processing capabilities are crucial for practical applications, and while our model shows promise, further optimization may be necessary to ensure efficiency in resource-constrained environments. Additionally, variability across participants can affect performance; individual differences in muscle composition and fatigue response patterns may lead to inconsistent results. Moreover, a larger and more diverse dataset would likely improve the robustness of the model.

Looking ahead, there are several promising avenues for future research. Exploring transfer learning from larger biomedical datasets could enhance the model's performance by providing additional training data that captures a wider range of muscle activity patterns. Moreover, integrating multi-modal data—such as heart rate and skin temperature—could offer a more comprehensive view of fatigue status, potentially improving detection accuracy. Investigating adaptive learning techniques may also allow for personalization of the model for individual users, further enhancing its applicability across diverse populations.

Overall, our study highlights the potential of deep learning integrated EMG-based models for localized fatigue detection in physically demanding environments such as construction sites. By addressing current limitations and exploring future directions, we aim to develop a robust system that can contribute significantly to worker safety and productivity through effective fatigue monitoring.

6 Conclusions

This study presents a novel approach for local physical fatigue assessment using a Vision Transformer-based model applied to EMG spectrograms. The developed system demonstrates significant potential for real-time fatigue monitoring in occupational settings, particularly in dynamic environments such as construction sites. With an achieved accuracy of 75% and and recall of over 80%, our model outperforms traditional machine learning approaches in classifying different levels of muscle fatigue. The success of this ViT-based approach highlights the advantages of leveraging advanced deep learning techniques for bio-signal processing. By capturing both spatial and temporal features from EMG data, the model provides a more nuanced understanding of fatigue progression, crucial for timely interventions in workplace safety. The use of spectrograms as input to the ViT model proved particularly effective, allowing for a comprehensive analysis of muscle activation patterns associated with fatigue. The implications of this research extend beyond mere performance metrics. Accurate and real-time fatigue detection systems have the potential to revolutionize workplace safety practices. By enabling

proactive interventions, such systems can help prevent injuries, optimize task assignments, and improve overall worker health outcomes. The integration of such technology into existing ergonomics programs and fatigue management systems could lead to significant improvements in workplace safety and productivity. However, this study also acknowledges several limitations and areas for future research. Expanding the dataset to include a more diverse range of participants and occupational tasks will be crucial for enhancing the model's generalizability. Future work should also explore the integration of multi-modal data and further optimize real-time processing capabilities. Additionally, addressing ethical considerations and privacy concerns will be essential for the widespread adoption of such monitoring systems in workplace environments. In summary, this research represents a significant step forward in the field of occupational health and safety, offering a promising tool for real-time fatigue assessment. As we continue to refine and expand upon this approach, the potential for creating safer, more productive work environments becomes increasingly tangible, underscoring the importance of continued research and development in this critical area.

Abstract –

Construction progress monitoring is an essential activity for ensuring a project's quality and timely delivery. Scan-to-BIM demonstrates its potential and superiority in capturing the as-built status and handling design changes to achieve real-time project tracking. Previous studies have focused on its main steps, including segmentation, recognition, and reconstruction, but often overlooked target area extraction due to their emphasis on residential buildings. Manual extraction can be tedious, time-consuming, and labor-intensive, especially for large-scale, horizontal transport infrastructures. Although similar applications can be found in other domains, these methods may not be feasible for extracting road networks construction sites due to differences in data structure, the as-built status of roads, and the requirements for the Level of Detail (LoD) in the output. This paper proposes an automated hybrid road construction site extraction framework as the input for subsequent Scan-to-BIM construction progress monitoring. It leverages both local feature analysis and graph theory. The developed road patch generation and connection processes enable the extraction of complex road networks with high generality and versatility. Two sets of Airborne Laser Scanning (ALS) data with different construction progress were used to validate the proposed framework, achieving site extraction accuracies of 99.59% and 94.50%, respectively. These results indicate that the proposed method can effectively serve as a basis for supporting construction progress monitoring through Scan-to-BIM.

1 Introduction

Frequent project monitoring is crucial for improving performance in the construction and renovation of transport infrastructure [1, 2]. It was reported that recent studies have focused on achieving project monitoring by creating as-built models for structures under construction [3-5]. Indeed, numerous road network extraction approaches can be found in the domains of remote sensing and computer vision, serving as the modeling foundation for supporting transport network design, analysis, optimization, and the generation of high-definition (HD) maps for autonomous driving [6, 7].

Ground-based Mobile Laser Scanning (MLS) and aerial images have been commonly used as primary data sources for modeling urban streets and highway systems in previous studies. However, these sensors are insufficient for capturing complex, large-scale transport infrastructure construction sites in terms of efficiency. As an alternative, ALS demonstrates superiority in road classification for complex environments compared to orthoimages [8]. Although learning-based methods have achieved advancements in object recognition, the lack of training datasets and the complexity of site environments—such as ruts, temporary roads, hills, and trenches—affect the performance of common classifiers developed for photogrammetry and laser scanning [9-12]. Additionally, these site conditions hinder the application of conventional image processing methods, such as edge detection or line fitting. Similarly, many widely used local feature analysis methods, including plane fitting and gradient mapping, face the same challenges. Due to differences in primary data sources, the targeted stages of a road's life cycle, and the expected output based on application requirements, a research gap exists. Currently, no proper automatic method for effectively extracting road networks at construction sites has been developed to support Scan-to-BIM construction progress monitoring through ALS.

The proposed hybrid methodology aims to achieve automated road construction site extraction, starting from the earthwork stage. This methodology is characterized by two key academic contributions: (1) automated site extraction for road construction with complex layouts; and (2) high generality and adaptability to complex site

and surrounding area condition, as well as compatibility with the early earthwork stage. The framework begins with generating a variant of a gradient map to extract grids containing steep slopes. Nonlinear continuous large-scale slopes, such as hills and stockpiles, are then removed by utilizing the grid's Degrees of Freedom (DoF). The remaining grids are grouped using a region-growing algorithm to form a series of boundaries. To extract the target areas, road patches are generated by pairing boundaries and then calculating a series of centroids between those boundary pairs. Subsequently, patch connections are applied by comparing the cross-sectional properties of nearby patches. Finally, the connection results are refined by analyzing the distribution of grids. Thus, the method can be regarded as a hybrid of local feature analysis and graph theory.

The remainder of this paper is structured as follows: Section 2 provides a comprehensive review of previous work on road network extraction. Section 3 describes the proposed site extraction framework in detail. Section 4 presents a validation of the method using two ALS datasets. Finally, Section 5 discusses the conclusions and future work.

2 Literature Review

Transport network modeling is essential task for the subsequent tasks in many domains [13]. Over two decades ago, researchers began exploring the feasibility of using MLS and integrated sensors to capture 3D road models [14]. As-built models of transport infrastructure can be used for traffic analysis, simulation, and optimization, supporting efficient planning, renovation, and system improvement throughout its service life [15, 16]. The conventional Scan-to-BIM workflow consists of object recognition, segmentation, and reconstruction. These processes are responsible for classifying point clouds with semantic tags, segmenting points based on assigned labels, and reconstructing each recognized object for further processing [17-19]. Thus, accurate and effective pavement extraction is crucial for successful Scan-to-BIM, as it narrows the focus area, reduces complexity, and enhances accuracy. However, it should be noted that almost all existing methods are developed for finished road networks through MLS and their core criteria introduced are not suitable for road construction sites. In general, road extraction methods can be categorized into feature-based, learning-based, and graph-based methods.

2.1 Feature-based Road Extraction

Feature-based methods are widely used in road object recognition and information extraction. These methods can be further divided into region growing, feature extraction, feature fitting, and cross-section analysis. Typically, first three approaches are combined sequentially to extract areas of interest [15]. Zhang et al. [20] used region growing to extract the road surface, followed by intensity variance detection, B-spline and Alpha-shape techniques to create a pavement curve model. Such cooperation can also be found in Yadav et al. [21]. A two-step framework that first extracted local features in each grid and clustered smooth grids using a predefined threshold. Then, a plane fitting step was applied to refine the pavement extraction results. Rodríguez-Cuenca et al. [22] collaborated morphological image processing with grid-based local features analysis to precisely depict the road boundaries. Cross-section analysis methods normally create cross-sections along scanning trajectories or road markings [23, 24]. Pavement extraction is then performed by detecting road curbs or consecutive markings. Yang et al. [23] sliced the datasets along scanning lines and a moving window operator was applied to filter out irrelevant points as well as detecting curbs based on predefined patterns. Similarly, Guan et al. [25] developed algorithms to detect curbs using elevation and slope differences for automated road information extraction. Overall, feature-based methods are effective for identifying pavement boundaries by creating gradient maps, calculating elevation differences or detecting linear patterns, followed by numerical model fitting to generate detailed curve or surface models.

2.2 Learning-based Road Extraction

Like fused approaches in Scan-to-BIM, one or multiple procedures can be replaced by learning-based methods, such as curbs extraction and curve fitting [7, 26, 27]. Yang et al. [28] introduced a binary kernel descriptor (BKD) for encoding as-built point clouds, combined with a random forest classifier to extract curbs and road markings. Similarly, Soilán et al. [29] combined heuristic rules and unsupervised learning models to differentiate between pavement and sidewalks. To acquire better performance, Ma et al. [30] used satellite imagery and a deep learning framework, BoundaryNet, for improving road boundary extraction results. This hybrid method fed curb extraction results into a sequential refining model within BoundaryNet. Wei et al. [31] applied a reinforcement learning (RL) algorithm for curve fitting in complex 3D highway modeling. Road curbs are also commonly used in HD map generation tasks as indicators for pavement extraction [6].

2.3 Graph-based Road Extraction

Graph-based methods are less common as they require supplementary information such as transport network maps. Boyko et al. [32] developed a method using 2D road network maps to divide urban area point cloud into suitable size patches along optimized Cardinal

splines. Then, identifying road networks through local elevation changes in patches. In contrast, Ma et al. [33] applied PointNet++ for initiating a rough road surface extraction and refined results using a two-step graph-based method.

3 Methodology

In this section, the proposed framework for extracting road network construction sites will be elaborated in detail. Compared with the subsequent parametric modeling in Scan-to-BIM for road construction, target area extraction is more challenging due to the complex site conditions and the ALS dataset utilized. This framework consists of four main steps: boundary grids candidate extraction, irrelevant grids removal, road patch generation and connection, and boundary grids refinement (Figure 1). The core idea lies in the road patch generation and connection, which utilizes cross-sectional properties to connect patches and form large network clusters. This step effectively extract the target area with different progress and layouts from its surroundings.

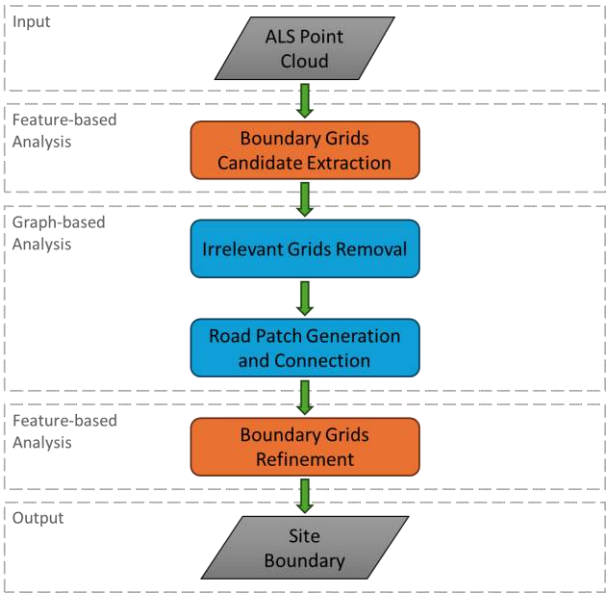

Figure 1. Workflow of the proposed road network construction site extraction framework.

3.1 Boundary Grids Candidate Extraction

Conventional methods for directly extracting ground surface points, such as those based on smoothness or edge detection, are not suitable for road networks under construction captured by ALS. Two main technical challenges identified are monotonous roughness and linear patterns across the entire field. In road construction sites, there is initially no significant roughness difference between the base course and its surrounding areas. Furthermore, unique wave-like patterns in ALS dataset complicates edge detection methods that rely on point distribution analysis. Its uniform distribution causes common local features, such as linearity, planarity, and omni-variance, to yield similar numerical values for areas with and without edges. As a result, instead of directly extracting the ground surface or applying edge detection, we opted to roughly extract boundary candidates using a gradient change ratio map (GCR).

The GCR map is a variant of the gradient map, designed to be more effective for large-scale areas. Initially, the x-y plane is divided into square-shaped grid cells with an empirical edge length of 1.5 m [34, 35]. The GCR is then calculated using the formula shown in Equation (1).

$$GCR = \frac{h_a - h_b}{D_{ab}} \quad (1)$$

where a and b represent the highest and lowest points within the same grid, respectively. Here, h_a and h_b are the elevations of the two points, and D_{ab} is the distance between the two points on the x-y plane. Equation (1) thus computes the gradient change ratio on the plane for each grid. Grids with GCR values exceeding $\mu + \alpha \cdot \sigma$ are defined as boundary candidates and prepared for irrelevant point removal. As an empirical parameter, the factor α is set to 1 for all cases.

3.2 Irrelevant Grids Removal

Irrelevant grid removal aims to eliminate grids belonging to hills and stockpiles that form large-scale nonlinear continuous slopes. This process uses the centroid of each grid as a node and creates a graph by connecting these nodes with edges. For a given group of candidate grids, if their width is more than twice the grid size, the grids in inner layer will have a DoF higher than 6, indicating that at least six grids are adjacent to them. To locate all irrelevant grids, those with a DoF of 7 or 8 are removed first. In the second step, grids with a reduced DoF after the initial removal are also eliminated to completely remove irrelevant areas. Following this, a region growing with an elevation criterion is applied to the remaining grids to cluster adjacent grids together. However, during this removal process, some grids containing boundaries of road construction sites may also be removed, as they are often adjacent to hills or trenches. These grids can still be retrieved through interpolation between the two ends or by fusing the grids with edge detection results. However, this retrieval process falls outside the scope of this paper.

3.3 Road Patch Generation and Connection

After removing irrelevant grids and the subsequent

region-growing process, the adjacent grids are grouped into numerous clusters with either linear or random shapes. To precisely and automatically extract the boundaries of the construction site and establish connectivity between road segments under construction, road patch generation and connection are developed.

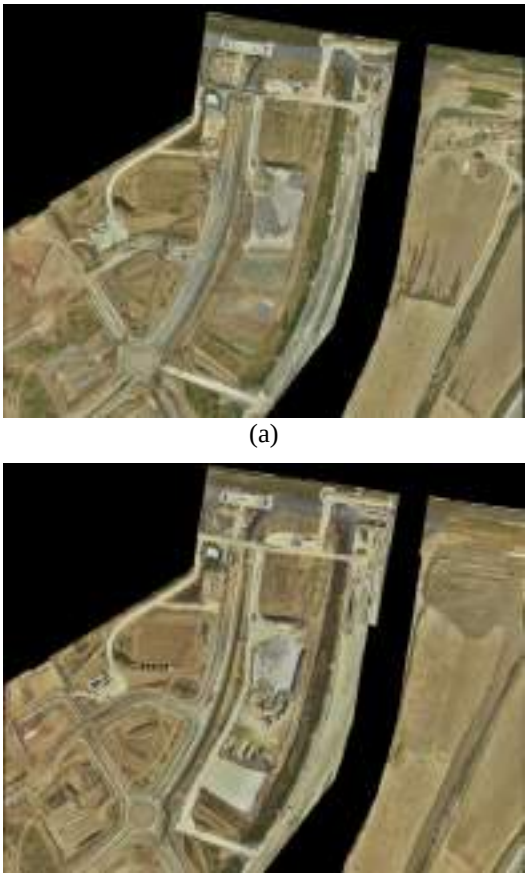
Road patch generation consists of two main steps: boundary pairing and centroid computation. In the boundary pairing step, a pair search is conducted within a given radius for each boundary, and all nearby boundaries with a certain proportion of grids within the range are stored. In the centroid computation step, the centroids of paired grids between two paired boundaries are calculated on the x-y plane. The patch is then generated based on the resulting centroids on two ends. The introduction of centroid computation serves two purposes: (1) to provide centroids for locating the two ends of the patches, and (2) to ensure that the patch is formed in a regular shape, even when the two paired boundaries have different lengths. For each grid, it should be noted that centroids are computed between the grid itself and its closest grid, as well as the neighbors of the closest grid in the paired boundary. This approach ensures a relatively smooth transition when curves are represented by staggered grids.

The key idea behind patch connection is similar to the region-growing algorithm. The seed and its neighboring properties are defined as the cross-sections at the ends of each patch. To handle complex road layouts, such as roundabouts, T-junctions, crossroads, and traffic islands, loose criteria are introduced to ensure flexibility. The cross-section is defined by three points: two paired grid centroids and their calculated centroid. The centroids of the two grids use the highest values on the z-axis within their respective grids as their elevation, while the calculated centroid's elevation is derived from the average lowest z-axis values of the two grids. By defining these three points for each cross-section, a triangular regular network (TRN) is established for each patch. This structure allows for easy analysis of the properties at the ends of patches. To evaluate connectivity, two criteria are applied: the aspect ratio (AR) and elevation. The aspect ratio is derived from the difference between the average elevation of two paired grids, $h_{A.max}$, and the elevation of the computed centroid, $h_{A.min}$, divided by the distance between the two centroids of the two paired grids, G_1 and $G_1{}'$ on the x-y plane as shown in Equation (2).

Proximity checking is a prerequisite for connectivity inspection. If the cross-section at one end of a patch is close to that of another, connectivity inspection is applied to determine their relationship. As shown in Equation (3), two road patches are grouped into the same cluster when both the AR and the elevation deviation are smaller than the respective tolerances, δ_{ar} and δ_e. The top ten largest clusters are then output and prepared for refinement.

$$AR = \frac{h_{A.max} - h_{A.min}}{\|G_1 - G_1{}'\|} \quad (2)$$

$$\frac{|AR_i - AR_j|}{min(AR_i, AR_j)} \leq \delta_{ar} \quad (3)$$



3.4 Boundary Clusters Refinement

Although road patch connections can form a series of large clusters and distinguish them from surrounding neighbors, the main components of some top-ranked clusters may still belong to fragments of irrelevant areas. To address this issue, cluster refinement is introduced to eliminate unwanted large clusters by analyzing the distribution of grid centroids at different resolutions (grid sizes). As the grid size increases, more centroids are included in each grid, resulting in a higher proportion of grids with nonlinear centroids inside. Two indicators, scale-invariant anisotropy and surface area, are used for refinement. Scale-invariant anisotropy ranges from 0 to 1 and increases with the level of randomness in the distribution, while surface area is calculated using a convex hull algorithm, where smaller surface areas indicate more linear distributions. By applying cross-inspection with these two criteria, irrelevant clusters can be effectively identified and removed.

4 Case Study

In this case study, a highway construction site in New South Wales, Australia was selected as the target. The selected area is approximately 1 km by 1 km, and the raw datasets were processed using commercial software to remove non-ground points. The site features complex layouts, including roundabouts, T-junctions, crossroads, and traffic islands. Additionally, due to weather conditions, irrelevant patterns such as truck ruts, mud, and ponding are visible in aerial images. Surrounding the site, temporary roads, hills, and a series of large-scale stockpiles further complicate the extraction of the construction site.

Two datasets were collected on 24 February 2023 and 18 March 2023 to monitor the earthwork at the construction site. As shown in Figure 2b, additional traffic lanes have been excavated on the top-left and bottom-right corners of the roundabout during the past 3.5 weeks. Furthermore, the newly added segments have varying widths, ranging from 8 meters to 15 meters. This information can be used as a reference for determining the search radius in boundary pairing. The ground truth (GT) was generated by manually segmenting the results of irrelevant grid removal, providing a clearer boundary for comparison.

(a) (b)

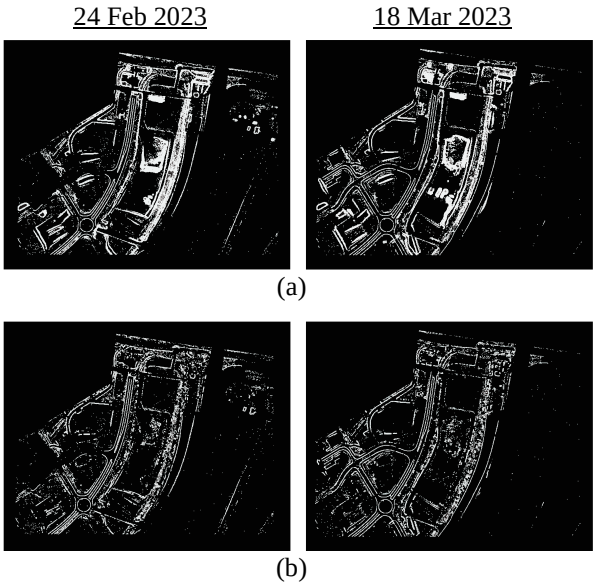


Figure 2. Aerial images of two datasets: (a) captured on 24 February 2023; (b) captured on 18 March 2023.

4.1 Boundary Grids Extraction

To extract boundary candidates, we applied the GCR to each grid to identify candidates with large elevation changes exceeding the sum of the average and standard deviation of GCR. As shown in Figure 3a, the resulting candidates contain hills and stockpiles located around the construction site. After applying irrelevant grid removal, the grids with nonlinear continuous slopes in these areas are removed. Only a few fragments remain in the datasets, as shown in Figure 3b. This process significantly reduces the number of grids introduced into subsequent road patch processing. Moreover, it prevents irrelevant grids from forming patches with other site boundaries, which could otherwise degrade the extraction results.

4.2 Road Patch Processing and Refinement

During the boundary pairing process, the search radius is set to 20 meters, which is slightly larger than the widest part of the entire road network. In this case, if one boundary has at least half of its grids located within this distance from another boundary, they are marked as paired boundaries. Road patch generation is then conducted based on these boundary pairs. Once the generation is completed, proximity and connectivity checks are initiated. The proximity radius threshold R is set to 10 meters, which is half the search radius used in the boundary pairing process. The tolerance for elevation (δ_e) and aspect ratio (δ_{ar}) are set to 10% and 30%, respectively. During the validation process, we observed that δ_{ar} values ranging from 30% to 50% produced similar results. However, due to the presence of T-junctions, where the width of certain areas changes dramatically, δ_{ar} cannot be set below 30%. Lower values lead to failure of grid extractions in those areas. In contrast, high δ_{ar} will include surrounding areas with dissimilar cross-sectional properties, which hinders the subsequent patch processing.

(a) (b)

Figure 3. Results of boundary grids extraction: (a) Candidate grids on 24 February and 18 March 2023; (b) Irrelevant grid removal results on 24 February and 18 March 2023.

As shown in Figure 4a, several irrelevant red areas are extracted due to their large size. However, these clusters can be easily classified by inspecting the trends of local feature changes as the resolution decreases, given that the fragments and short boundaries are distributed randomly. During this process, the upper and lower bounds for the grid size are set at 7.5 meters and 4.5 meters, respectively. This ensures that the new grid contains at least three centroids of the old 1.5 meters grids without including multiple boundaries belonging to the roads. For each cluster, the number of grids with anisotropy and surface area exceeding the average values will increase due to the higher level of randomness introduced during the change of resolution. as the grid size approaches the upper bound,

the proportion of grids with exceeded values in irrelevant clusters will first surpass 50%. By utilizing this principle, nearly all irrelevant red clusters are successfully removed, as shown in Figure 4b.

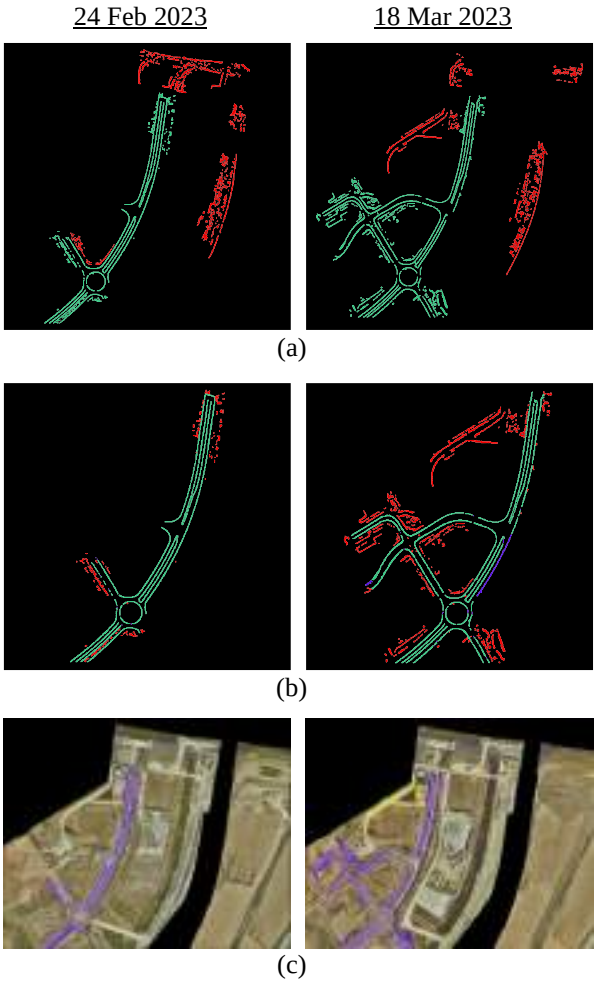

Figure 4. Results of road construction site boundary extraction: (a) Top 10 largest clusters on 24 Feb and 18 Mar 2023; (b) Correct boundaries (green) with missing parts (blue) and excess parts (red) on 24 Feb and 18 Mar 2023; and (c) Overlaid site boundaries on aerial images on 24 Feb and 18 Mar 2023.

The performance evaluation was conducted by calculating the overlap ratio of grids between the extraction results and the GT. As shown in Table 1, the accuracy of the proposed framework for the two datasets is 99.59% and 94.50%, respectively. The deviation is mainly caused by the rearrangement of stockpiles adjacent to the missing boundary, highlighted in blue in Figure 4b on 18 March. This rearrangement results in more fragments of stockpiles remaining near the missing boundary, which affects patch generation and connection. Additionally, the excess ratio for the second dataset is significantly higher than that of the first, at approximately 58.32%. This is clearly visible in Figure 4b on 18 March, where a curved temporary road is highlighted in red. Over the past 3.5 weeks, a series of road barriers have been installed along this temporary road, providing distinctive geometric features that help generate a more complete road boundary. Due to its clear linear pattern, the temporary road was retained during refinement. In Figure 4c, the extracted site boundaries are overlaid on aerial images. The grids align precisely along the boundaries of the road network construction site and can be updated to reflect changes in the construction process. This demonstrates that the proposed method can reliably provide the target area for the subsequent Scan-to-BIM process.

Table 1. Results of road construction site extraction with accuracy (%) and excess ratio (%).

Number of Grids	*24-Feb*	*18-Mar*
Site Boundary	2,466	5,008
Ground Truth	1,944	2,781
Overlapped	1,936	2,628
Accuracy (%)	99.59	94.50
Excess	530	2,380
Excess Ratio (%)	27.26	85.58

5 Conclusions

This paper presented an automated site extraction framework to support Scan-to-BIM progress monitoring in road construction. By leveraging the advantages of local feature analysis and graph theory, this hybrid approach successfully segments the target area from its surroundings. The application of GCR candidate extraction reduces computational requirements and addresses the challenges posed by complex site conditions, which conventional pavement extraction methods struggle to handle. The irrelevant grids removal process effectively fragments grids of nonlinear slopes into small clusters, which can then be easily eliminated. Patch generation and connection provide a feasible solution for segmenting the construction site from the surrounding area with similar cross-sectional features. The criteria utilized are well-suited for handling complex road shapes and layouts. After cluster refinement, the framework achieves a minimum accuracy of 94.50%. The results indicate that the proposed method can be applied to datasets with different road layouts and construction progress, highlighting its generality and potential for datasets from other projects.

Some limitations remain in the proposed framework.

The centroid generation process lacks stability when curves cause multiple grids to select the same closest grid in the paired boundary during centroids computation. Moreover, to ensure a clear end edge when paired boundaries have different lengths, we apply a threshold to handle this case. However, both strategies may result in the omission of centroids in certain specific positions. Thus, for future work, two modifications and a missing parts retrieve step can be incorporated into the framework to further improve its performance. These modifications aim to enhance the accuracy of boundary pairing and centroid computation during road patch generation, as these steps significantly impact overall accuracy. Boundary searching could introduce more multiple paring criteria, rather than relying solely on distance. Centroid calculation could also be refined by incorporating predefined shapes to enhance the smoothness and continuity of centroid transitions. The missing grids retrieve process could be achieved by overlapping boundary curves derived from elevation scalar fields onto the extraction results. Since the target areas have already been identified, the focus would shift to curves that connect extracted grids located far apart. By inspecting grids along these focused curves, missing grids could be effectively retrieved.

Abstract -

Building envelope retrofits, despite their benefits on enhancing energy efficiency, progress slowly due to high operating costs. Overclad panelized systems present an attractive solution to make retrofits affordable and easy to install. However, several stages of the retrofit process remain disconnected, suboptimal, and require significant human intervention. This study aims to bridge the gap between digital twin generation and overclad panel installation by automating the design of an optimal panel layout directly from a building envelope point cloud. In this end-to-end approach, the dimensional twin is generated by segmenting the facade point cloud. The facade then undergoes a three-step process to generate an optimized panel layout for integration with automated placement systems.

Keywords -

Building envelope retrofit, Panel layout design, Constraint satisfaction problem

1 Introduction

Rapid consumption of world energy has raised concerns over the depletion of energy resources and the adverse effects it has on the environment. With the construction industry accounting for 20–40% of the total energy consumption [1], significant effort has been directed to improve the energy efficiency of existing buildings. In response, several government organisations have implemented initiatives to enhance the energy performance of buildings, while extensive research efforts have been made to optimize the energy performance of existing structures. Results have shown that energy consumption can significantly be reduced via retrofitting existing buildings as opposed to constructing new ones [2].

With this surge of interest in retrofitting, leveraging technologies such as Digital Twins, which are digital replicas of physical objects, are imperative to optimize retrofits and improve the energy efficiency of existing buildings [3]. Digital twins have a variety of applications from being integrated with Internet of Things (IoT) for data collection to Artificial Intelligence (AI) for processing the collected data [4]. In this context, digital twins are used to virtually reconstruct a building and generate optimized panel layout designs for each facade through an automated process.

Panel layout generation from architectural drawings falls into two categories: "heavy" panel layouts for facades with openings (windows, doors) and "light" panel layouts for facades without such features [5]. Heavy solutions use prefabricated panels, while light solutions require on-site panel rework. Despite these differences, both types can utilize the same optimization algorithm. Furthermore, automated panel layout tools should be integrated with existing technologies for digital twin generation like the Automatic point Cloud Building Envelope Segmentation (Auto-CuBES) [6] and for automated installation like the Real-Time Evaluator (RTE) [7, 8] to create a unified retrofit framework.

The panel layout designer could either be performed manually by an architect or automated via AI. The manual panel layout design is inherently labor intensive and requires substantial amount of man-hours. Given these challenges, advancements in computational methods have paved the way for automating the panel layout design process using AI. By transforming the problem into a mathematical optimization framework, such as the bin packing problem [9], it becomes possible to model the allocation of panels as a computationally solvable task. The bin packing problem, a well-known combinatorial optimization challenge, involves efficiently packing objects of varying sizes into fixed-capacity bins, minimizing wasted space. For panel layout design, this approach aims to maximize panel coverage while adhering to the architectural constraints.

In this paper, we propose modeling panel layout design as a *meta-rectangle packing problem*, extending traditional rectangle packing [10] to non-uniform bins. This mathematical framing allows us to use AI-driven algorithms, specifically Constraint Satisfaction Problem (CSP), to optimize panel packing. Section 2 describes existing and proposed panel layout design algorithms. Section 3 presents the implementation and analyzes execution time and coverage. Section 4 concludes and outlines future work.

2 Optimal panel layout design

2.1 Digital twin generation

Building envelope retrofit extensively uses point cloud data to generate as-built dimensions of the building. However, the generation of digital twins from point cloud data has traditionally been a manual process, making it laborious and time-consuming. To address this limitation, machine learning methods, such as the Automatic point Cloud Building Envelope Segmentation (Auto-CuBES) [6] algorithm, can automate the generation of digital twin from point cloud data.

Auto-CuBES divides the algorithm into sequential tasks that generate a digital twin from building point cloud data of 3mm density. Despite its computational efficiency and accuracy, the input parameters scale linearly with features, requiring considerable time for parameter calibration. To address this bottleneck, the authors developed Auto-CuBES++, a digital tool providing real-time parameter calibration for building facade segmentation, available for academic or commercial use [11]. This tool assists users at every algorithm stage by visualizing results and allowing parameter adjustments in real time without full re-execution. The software also preserves execution states, ensuring input parameters are retained and eliminating the need for re-entry when rerunning the algorithm.

In addition to preserving the state of the run, Auto-CuBES++ also stores the dimensions as a JSON file containing the coordinates of the facade and its associated openings. These JSON files facilitates validating the digital twin's accuracy in virtualizing the building. The coordinates in the JSON file are represented as tuples of real numbers (x, y, z), which are used to map the facade to a Cartesian coordinate system. This representation provides a structured framework for panelizing the facade and seamlessly integrating it with the automated installation systems, such as the RTE.

2.2 Bin packing problems

Panelization, the key theme of this paper, is the process of prefabricating building's structural elements off-site and assembling a panelized system to minimize on-site labor. In a traditional panelized construction of a wall, the wall is divided into a simple layout and the pre-manufactured panels are assembled accordingly. However, traditional techniques of panel layout design are not as straight forward and often require human intervention to optimize the generated layout design [5].

The panel layout design problem can be represented as a *Bin packing problem* [9], and more specifically as a *Rectangle Packing Problem* [12] since we focus on single-wall arrangements. Rectangle Packing is an extension of Bin packing that uses a single bin instead of multiple bins.

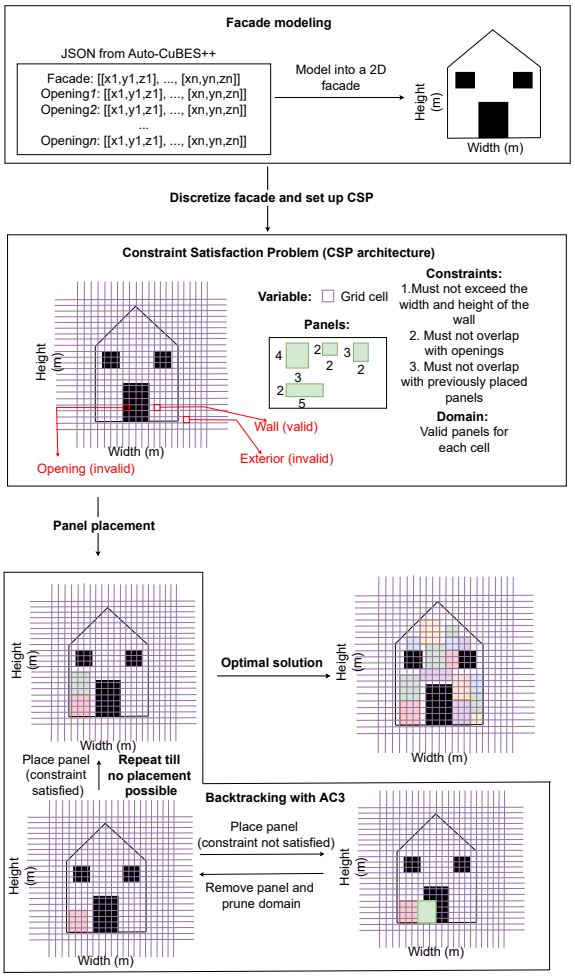

Figure 1. Facade to panel layout

As Bin packing problems are NP-hard, Rectangle Packing Problems inherit this computational complexity and are also NP-complete [10].

These Rectangle Packing Problems can be solved using deterministic algorithms, which use variables and policies to explore the solution space [10], and non-deterministic algorithms, such as Genetic Algorithm (GA) [13] and Simulated Annealing [14]. While deterministic approaches rely on predefined policies and constraints, non-deterministic methods leverage relationships between variables as data structures to search for optimal solutions.

2.3 Proposed panel layout design algorithm

This paper addresses panel packing using a deterministic algorithm, specifically the Constraint Satisfaction Problem (CSP). It combines backtracking [15] and arc consistency (AC-3) [16] to efficiently explore the solution space. Backtracking methodically scans solutions, reverting decisions that violate constraints, while AC-3 prunes infeasible

values to simplify the problem. Figure 1 illustrates this hybrid process, comprising three stages: 1) Facade modeling, 2) CSP formulation, and 3) solving via backtracking.

2.3.1 Facade modeling

Initially, the algorithm processes the JSON files generated by Auto-CuBES++ and extracts the geometric data required for facade modeling. Auto-CuBES++ generates two types of JSON files, one comprising of the facade boundary points, and another set of rectangular prism files for each individual opening in the facade. The algorithm transforms the extracted geometric data from the 3D space to a 2D representation based on the following rules:

- Points (x, z) for a facade parallel to the x and z axes
- Points (y, z) for a facade parallel to the y and z axes

2.3.2 CSP formulation

Following the facade modeling, the CSP problem for meta-rectangle packing is formulated. In a traditional rectangle packing algorithm, a set of rectangular items are packed into a rectangular box. However, due to the algorithm being applied to buildings, the rectangular box is adapted to a polygonal facade with or without openings. Additionally, the rectangular items are customized to panels of varying sizes that are packed on the wall.

Every CSP architecture is uniquely identified by a set of variables, the domains associated with the variables and a set of constraints. In the initial stage, the algorithm assumes a simplified scenario where the grid represents a facade without any openings (light panel layout design). In this case, each cell in the grid is valid, and the algorithm proceeds by assigning panels from the available domain to each of these cells. The process involves evaluating the constraints to ensure that the panels meet the architectural requirement of not aligning with the openings.

Once this basic configuration is established, the algorithm is adapted to handle the more complex scenario involving openings (heavy panel layout design). Openings, such as windows or doors, alter the layout of the facade, and certain cells are no longer suitable for panel placement. Each cell can fall under one of the categories shown in Table 1. Based on this information, the grid is refined to include only the valid cells, more specifically the wall points, so cells falling under any of the other categories are marked invalid and a panel is not placed on those cells.

The algorithm generates solutions that satisfy a set of panel placement constraints, as shown in Algorithm 1. Firstly, IS_WITHIN_BOUNDS() verifies that panels are placed only on valid cells within the grid. Secondly, DOES_NOT_OVERLAP() ensures that newly placed panels do not overlap with existing panels or openings. Finally, for light panel layouts, DOES_NOT_ALIGN() checks that panel edges do not align with opening edges to prevent potential air/heat leakage points.

Table 1. Grid cells vs Validity

Type of grid cell	Validity
Only wall	Valid
Only opening	Invalid
Only exterior	Invalid
Wall and opening	Invalid
Wall and exterior	Invalid
Opening and exterior	Invalid

Algorithm 1 Valid panel placement check

4: **return** True
5: **else**
6: **return** False
7: **end if**
8: **end for**

2.3.3 Backtracking with Arc Consistency

Following the initialization of the grid and the CSP architecture, Backtracking, one of the most commonly used algorithms, was employed to solve the problem. This algorithm exhaustively searches the solution space to find assignments or, in this case, panel placements that satisfy the constraints. However, due to the large search spaces involved in most CSP problems, the algorithm could get computationally expensive. Therefore, to improve the efficiency of the algorithm, backtracking is integrated with AC-3, thereby reducing the complexity of the problem by pruning invalid panel assignments. This hybrid approach is well suited for problems where constraints are heavily co-dependent, as is the case for the panel layout design optimization problem.

As shown in Algorithm 2, Backtracking implements a Depth First Search (DFS) to explore possible solutions. Given grid cells, panel types, and placement rules, the algorithm traverses each cell and attempts to place the largest valid panel from the cell's domain. If the placement satisfies all constraints, the PLACEPANEL() function marks the cells as occupied. If invalid, REMOVEPANEL() reverts the placement and the algorithm backtracks to try the next panel from the domain.

While backtracking ensures completeness, it's limited by exponential growth in the solution space. To improve

Algorithm 2 Backtracking for meta-rectangle packing

Require: Wall dimensions, panels, openings
Ensure: Maximum coverage with minimum panels
Initialize valid wall grid and domains
Apply AC-3 to enforce initial arc consistency
Call BACKTRACK(wall, panels, $x = 0$, $y = 0$, panel_id=1)

efficiency, we implemented AC-3 pre-processing to prune inconsistent panels from a cell's domain after successful placement. As shown in Algorithm 3, AC-3 initializes a queue with all grid cells and iteratively prunes the domains of each cell and its neighbors, removing invalid panel configurations. This maintains local consistency and reduces the search space size.

2.3.4 Complexity Analysis

The backtracking approach remains exponential in complexity as the number of valid grid cells increases. AC-3 improves efficiency by dynamically reducing domain sizes, but its impact depends on constraint density. Two key factors influence performance:

Facade Shape Complexity: Complex geometries increase both the search space and constraint network density, resulting in higher AC-3 processing overhead.

Panel Size Variety: A larger panel dimension set increases domain sizes, creating more potential assignments for backtracking. Though AC-3 prunes infeasible configurations, it cannot eliminate the problem's inherent exponential worst-case growth.

3 Results

The algorithm begins by identifying and importing the JSON files containing the dimensions for a desired facade and its associated openings. These files are then pre-processed to ensure they are aligned either with the (x, z) plane or the (y, z) plane depending on the orientation of the selected facade. For this study, the algorithm is tested on both a facade aligned with the (x, z) plane and another aligned with the (y, z) plane, as depicted in Figure 2.

Following the pre-processing stage, the corresponding 2D points are extracted from the aligned JSON files. These points are used to map the grid onto a cartesian space without loss of any spatial data. This mapping ensures accurate representation of the facade that would serve as an input to the CSP architecture.

Additionally, due to the complexity added by the openings, the algorithm was run independently for two cases: 1) Facades without openings (light solution), and 2) Facades with openings (heavy solution). For both cases, the wall and opening dimensions in the 2D space were scaled to three different units: millimeters (mm), centimeters (cm), and decimeters (dm). This multi-scale analysis highlights the relationship between grid density and computational time. Notably, as the grid density increases tenfold (e.g., transitioning from cm to mm scales), the execution time also increases approximately tenfold, demonstrating the algorithm's scaling behavior.

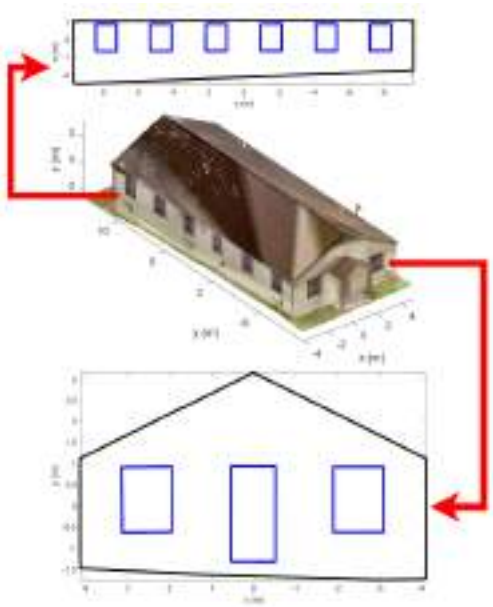

Figure 2. Dimensional facades extracted with Auto-CuBES++ and pre-processed

3.1 Facade without openings

After the initial set up, the inputs for the CSP architecture are set up and initialized. As elaborated in Section 2, the inputs provided to the CSP algorithm are the following:

Grid resolution: determines the scale of each grid cell onto which the facade is mapped. It can take up any value from $\{10, 100, 1000\}$ depending on the dimensions the facade is scaled to: mm, cm, or dm.

Panel sizes: customized values based on the facade under consideration. The height of each panel is fixed to 2.44 m (8 ft), while the width varies in factors of the grid resolution, typically multiples of 1.22 m (4 ft).

Facade grid: is the 2D cartesian representation of the facade generated by Auto-CuBES.

Following the set up of these parameters, the algorithm tackles the problem of mapping the facade to a grid. In order to adapt the rectangle-packing problem to the meta-rectangle packing problem, the area where the panels can be placed has to be clearly defined. This is achieved via the Shapely package in Python [17]. The 2D points extracted from the JSON files generated by Auto-CuBES are mapped onto a rectangular grid mimicking a rectangular bin. Due to the algorithm initially tackling facades without any opening, the valid grid is initialized to the entire facade area.

After grid initialization, each cell receives a list of available panels. The algorithm evaluates three grid resolutions: decimeters (dm), centimeters (cm), and millimeters (mm). Three panel sizes (8×4 ft, 8×8 ft, and 8×12 ft) are scaled to match each resolution: 24×12, 24×24, and 24×36 dm; 240×120, 240×240, and 240×360 cm; and 2400×1200, 2400×2400, and 2400×3600 mm.

In due course, the backtracking algorithm is triggered to explore potential solutions for all the three grid resolutions. This process iteratively constructs panel layouts by placing the panel with the largest area from each cell's domain. while also systematically retracting and reevaluating the assigned panel positions to maximize coverage. As this problem was modeled as an optimization problem, the final result that is visualized aims to maximize the coverage of the valid grid in terms of cells while minimizing the number of panels used.

3.2 Facade with openings

The setup for this case builds on Section 3.1 but accounts for openings like windows and doors. The wall geometry is read from a JSON file containing the facade's polygonal representation, and its integrity is ensured through a validation and repair process. Similarly, all opening geometries are dynamically loaded from matching files, each representing an opening in the wall, and undergo the same validation and repair procedure to ensure they are well-formed polygons.

After preparing the wall and opening polygons, the valid area is computed by subtracting the opening polygons from the wall polygon using a geometric difference operation. This process removes areas covered by openings, ensuring panels are not placed over windows or doors. Additionally, cells along the facade's edges are invalidated to prevent panels from extending beyond the wall's dimensions. The resulting valid area excludes both openings and boundary cells, creating an optimized grid for panel placement.

The algorithm is then run for three facades at different grid resolutions, including one from a two-story experimental building at Oak Ridge National Laboratory (ORNL), known as the Flexible Research Platform 2 (FRP2), as illustrated in Fig.3. The other two facades are from a single-story residential building being retrofitted by the Knoxville's Community Development Corporation (KCDC). The two facades chosen from the single-story building cover the cases of facades being aligned with the $x-z$ plane (KCDC 21) and the $y-z$ plane (KCDC 11), as illustrated in Fig.4 and Fig.5, respectively. In these figures, part (a) shows the panel placement with openings, while part (b) assumes no openings, with panels placed to fully cover any openings. These facades were converted into all three grid resolutions being tested and evaluated based on the time taken for initialization, valid grid computation,

Table 2. Result: Panel placement execution time

Dimension	Initializing (sec)	Valid grid computation (sec)	Backtracking + AC-3 (hrs)	Coverage (%)	Number of panels used

and the execution of the backtracking algorithm with AC-3, as shown in Table 2. The results in Table 2 correspond to the panel placements shown in Fig. 3, Fig. 4, and Fig. 5, with each row in the table corresponding to a specific facade and scenario. The first set of rows corresponds to the FRP2 facade, shown in Fig. 3. The second set corresponds to the KCDC 11 facade, shown in Fig. 4. And the final set corresponds to the KCDC 21 facade, shown in Fig. 5. Each row in the table also presents the execution times, coverage percentages, and number of panels used for the different grid resolutions, reflecting the specific conditions for each facade in the corresponding figures.

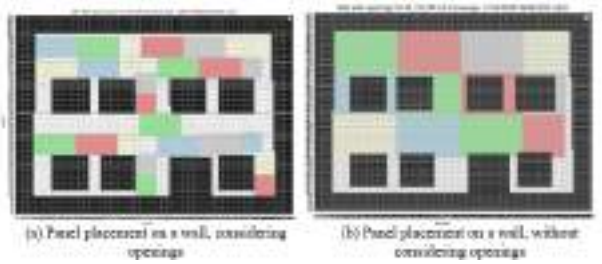

Figure 3. Panelized FRP2 with and without openings

The backtracking algorithm evaluates each panel in every cell's domain, leading to exponential complexity as grid resolution increases. At millimeter resolution, both initialization and valid grid computation times rise significantly compared to decimeter and centimeter scales, sometimes exceeding 30 hours even with AC-3 as shown in Table 2. To mitigate this, a 20% sampling rate is applied for constraint satisfaction, balancing efficiency and accuracy—higher rates caused excessive panel overlap, while lower rates added unnecessary overhead without notable accuracy gains.

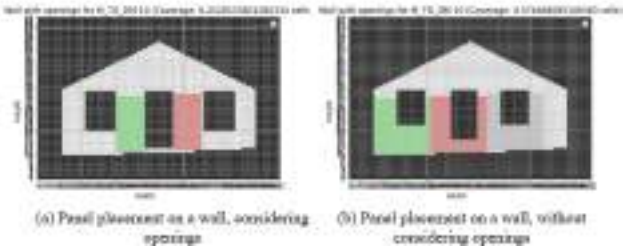

Figure 4. Panelized KCDC 21 with and without openings

The results from the algorithm were evaluated by focusing on two key attributes: the optimization objectives, such as total area coverage, the number of panels used, as outlined in Table 2 and the execution times, namely the time taken to initialize, compute the valid grid, and

execute the algorithm.

Coverage is the primary objective of the algorithm, with the aim of maximizing the valid area of the grid that corresponds exclusively to the facade. The algorithm ensures that as much of the facade as possible is covered effectively, while excluding non-relevant areas such as the attic as shown in Fig. 4, where wall insulation is not required. Additionally, to improve efficiency, the algorithm was designed to minimize the number of panels used. This dual-objective optimization assessment provides a comprehensive evaluation of the algorithm's capability in balancing these competing goals.

In Figures 3, 4, and 5 coverage is assessed with and without considering facade openings. In part (a), panels avoid overlapping openings based on constraint enforcement (Algorithm 1), resulting in more panels and gaps around these regions. In part (b), openings are ignored, leading to fewer panels and full facade coverage, including areas originally designated as openings.

This experiment revealed that maximizing coverage becomes notably more difficult when openings, such as windows and doors, are present. These openings create irregularities and constraints on the facade, which often result in uncovered regions due to the limitations of panel dimensions and placement options. This challenge is especially pronounced for facades with irregular shapes, which require the algorithm to navigate a more complex solution space. As a result, compromises must be made in either coverage or panel efficiency, as illustrated in the left plots of Fig.3 and Fig.4. These plots clearly show the trade-offs the algorithm faces when balancing the competing goals of maximizing coverage while minimizing the number of panels used, especially in the presence of openings and irregular facade shapes.

A key challenge in the results is the unoccupied panel areas, caused by placement restrictions around openings and fixed panel dimensions. While the algorithm optimizes coverage, irregular facades and panel limitations prevent perfect coverage. Future improvements could include more flexible panel shapes, such as modular panels, or allowing for smaller panel sizes that could better adapt to the irregularities of the facade.

Execution time, as a secondary evaluation metric, scales predictably with grid resolution. As the density of the grid increases, the execution time also increases, as shown in Table 2, reflecting the greater computational effort required to evaluate the finer cells of the grid. This trend highlights the increased computational burden when dealing with higher-resolution grids. In some millimeter-scale cases, the combination of higher grid granularity and the algorithm's complexity has led to execution times exceeding 30 hours, emphasizing the significant computational challenges posed by high-resolution analyses.

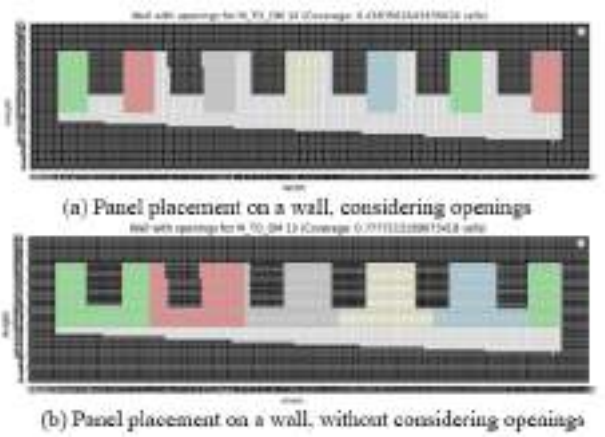

Figure 5. Panelized KCDC 11 with and without openings

In conclusion, the algorithm successfully addresses the dual objectives of maximizing the coverage of the facade and minimizing the usage of the panels, even when faced with the restrictions introduced by openings and irregular facade geometries. Looking ahead, the method could be applied to more complex building structures, such as multi-story buildings with varying facade shapes, by further enhancing the algorithm's ability to accommodate different panel configurations and structural constraints. Future improvements, such as the introduction of more diverse panel sizes or the further optimization of execution times, could further enhance its applicability to a wider range of facade types and building geometries.

4 Conclusion

Our research highlights a significant void in existing systems capable of retrofitting buildings through an end-to-end process—from virtualizing point cloud data to automatically generating panel layouts for each facade to facilitate panel installation. The goal of this study was to bridge the gap between building envelope digital twin generation for panelized systems with automatic tools for prefabricated panel installation using a novel digital tool for automated panel layout design. We propose a three step process to achieve the this: Facade Modelling, CSP Formulation, and Backtracking with AC-3. The proposed algorithm was demonstrated on a variety of facades from a simple rectangle to more complex polygons.

Operationally, the results of the algorithm are also quite robust, with panel layouts being generated in under two or three hours, which is a significant improvement compared to the days typically required for manual creation. Consequently due to the application of a backtracking algorithm for solving the meta-rectangle packing problem,

the user is also presented a variety of optimal solutions to choose from, depending on the optimization factor; rather than a single solution as is the case with other rectangle packing algorithms. While the proposed algorithm demonstrates efficient performance, there is always scope for improvement. Future work involves adapting the algorithm to incorporate a dynamic backtracking algorithm with memorization. This would allow the storage of results of previously calculated sub-problems, facilitating efficient domain pruning whilst reducing redundant computations. Such an approach has the potential to significantly improve the algorithm's efficiency and scalability, paving the way for the development of robust solutions in facade panelization and building retrofitting workflows.

Abstract

Ensuring the safety and longevity of steel structures, like bridges and buildings, depends on the effective monitoring of rust and its severity. Traditional methods of rust detection often rely on visual inspections, which can be subjective and time-consuming. In this paper, we present a more efficient way to classify rust severity on steel surfaces using the HSI color space, along with pixel value analysis and computer vision techniques. By utilizing the different components of the HSI color model, we improve the accuracy of rust segmentation, which helps in better identifying the severity levels of rust. This method analyzes individual pixel values in images of steel surfaces, providing a detailed understanding of the rust's extent and intensity. Additionally, we conducted histogram analysis to calculate the mean and standard deviation of pixel values for assessing rust severity. Our machine learning framework, which includes Random Forest and OpenCV, processes high-resolution images to classify rust severity automatically through image segmentation and thresholding techniques. This method also incorporates the K-means algorithm with the Elbow Method to determine the optimal number of clusters and perform segmentation automatically. The results show that this approach offers a more precise and objective way of assessing rust damage according to the severity compared to traditional inspection methods.

Keywords –

Rust segmentation, Rust severity identification, steel surface, HIS color space, Pixel value analysis

1 Introduction

Rust on the steel surfaces of civil engineering structures is a prevalent problem that may pose significant safety hazards. [1], [2], [3]. The corrosion of steel structures poses a considerable challenge for engineers globally. [4], and prompt and precise monitoring of rust damage on steel surfaces is crucial to maintaining the structural integrity, safety, and durability of steel facilities [5],[6]. Conventional rust examination on steel surfaces, particularly for bridges, is laborious, time-consuming, and occasionally hazardous [6] . Since the late 1990s, vision-based image processing techniques have garnered significant attention for inspecting surface defects in infrastructure, such as rust and cracks [7], [8], [9], [10]. Corrosion, including rust, costs the global economy an estimated $2.5 trillion, equivalent to 3.4% of global GDP. Proper monitoring and preventive measures could reduce this cost by up to 35%, potentially saving US$875 billion [11]. In high-risk industries like construction, rust-induced structural failures are a significant cause of accidents. In 2022, for example, 1,056 fatalities occurred in the construction sector, with 423 deaths resulting from falls, slips, or trips [12].

Computer vision involves methodologies that allow machines to interpret the visual environment via digital photographs via machine learning algorithms. Visual media, including images and videos, are the predominant inputs for computer vision applications [13]. Computer vision-based structural health monitoring (CV-SHM) has garnered considerable interest in infrastructure management, including crack, rust, etc. Many computer vision techniques are available for surface defect detection, such as crack, which focus on the analysis of linear features and structural discontinuities, often using geometric modeling techniques. However, these techniques are less effective for rust detection, where the primary focus is on color variation, texture analysis, and corrosion patterns specific to rust. This methodology includes several techniques, including image classification, object detection, object segmentation, visual tracking, 3D reconstruction, image generation, image enhancement, pose estimation, action recognition, image captioning and optical flow analysis [14], [15]. The most common techniques are classification, detection, and segmentation. Segmentation is divided into two types: semantic segmentation and instance segmentation. Semantic segmentation labels every pixel of an object but doesn’t distinguish between individual items in the same group. On the other hand, instance segmentation not only labels the pixels but also identifies

and separates each instance of the same object (Figure 1) [16]. Computer Vision (CV) techniques are sophisticated instruments for assessing structural integrity, facilitating non-contact monitoring with great precision [17]. When combined with deep learning, computer vision markedly improves object detection abilities[17], [18].

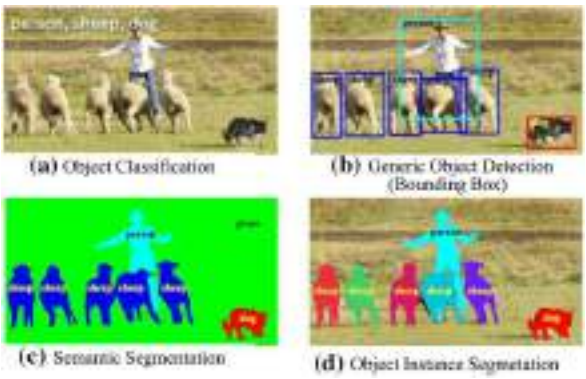

Figure 1. Computer vision techniques: a) image-level object classification, b) bounding box level generic object detection, c) pixel-wise semantic segmentation, d) instance-level semantic Segmentation [19].

2 Related work

We have organized our literature review into two main areas: (1) color space and (2) pixel value analysis

2.1 Color Space

Color properties are a fundamental part of image analysis because they help us understand the visual details in an image, such as pixel values and textures. Different color spaces, like RGB, HSI, and LAB, YCbCr each have their unique ways of representing color, using different shapes and ranges of pixel values. [20], [21]. The most commonly used color space is the three-channel Red, Green, and Blue (RGB) color space (Figure 2.) . In the RGB color space, each channel (Red, Green, and Blue) can represent 256 different values, ranging from 0 to 255, in an 8-bit image. This means that for each color channel, there are 256 possible intensity levels. For example, when the pixel values are (0, 0, 0), it represents pure black, with no color present. On the other hand, when the pixel values are (255, 0, 0), it indicates the maximum intensity of red. With 256 possible values for each of the three channels, the total number of possible colors in the RGB color space is 256 x 256 x 256, or about 16 million different colors.[20].

The conversion of images from RGB to grayscale is a common technique in image processing, as well as in rust identification. [2]. In 1995, FURUTAI et al. [22] Proposed a model for structural damage assessment caused by corrosion using the hue, saturation, and value (HSV) color space. This approach was first applied to color space with image processing. Bridge paint assessment through image processing proposed by Chen and Chang in 2003 [23]. The authors transformed all RGB photos into grayscale and delineated three regions according to the illumination conditions of the rust images. In 2004, Choi and Kim [24] employed the Hue (H), Saturation (S), and Intensity (I) HSI color space for corrosion detection and the identification of five unique corrosion types. In 2006, Lee et al. [25] proposed the utilization of color image rather than grayscale images to inspect steel bridge surface coatings. One of the initial methodologies in color space analysis for image processing was introduced by Chen et al. [26]. The authors examined 14 color spaces to identify the most effective one for addressing non-illumination issues. Similarly, Shen et al. [8] Investigated 19 color spaces, including grayscale, to address non-illumination problems in images.

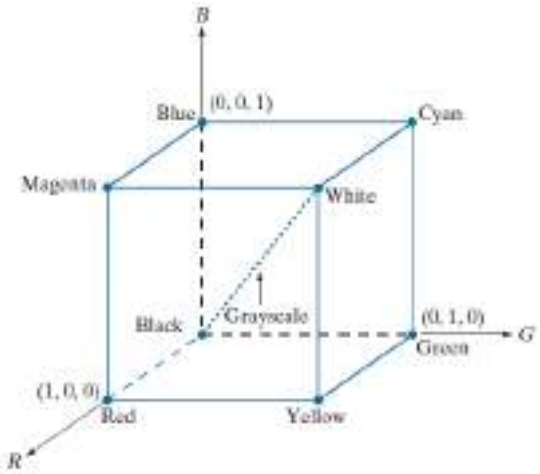

Figure 2. RGB three-dimensional Color cube [26].

Kuo-Wei Liao et al. [27] suggested an automated method for rust identification on a steel bridge utilizing digital image analysis. They employed three picture recognition methodologies: (1) K-means clustering in the hue channel, (2) double-center-double-radius (DCDR) method for RGB color space, and (3) DCDR algorithm for Hue-Saturation-Intensity (HSI) color space. The authors compared 12 color spaces (RGB, HIS, YPbPr, YCbCr, JPEG-YCbCr, YDbDr, YIQ, YUV, HSV, XYZ, LAB, CAT02 LMS) and determined that the Hue characteristic was essential and more efficacious. Yundong Li et al. [28] Converted the RGB image into the YCbCr color space and calculated only the Cr component using the Otsu method to identify rust.

2.2 Pixel Value Analysis

Pixel is the most commonly used term to refer to the components of a digital image [20]. In one of the earliest studies on rust identification, Chen et al. (2009) [26] converted RGB images into the Hue, Saturation, and Intensity (HSI) color space to analyze pixel values associated with rust. Their findings revealed that the mean pixel values in the RGB space were (R, G, B) = (173.22, 107.76, 60.54), while in the HSI space, the means were (H, S, I) = (24.4909, 0.4646, 0.4471). The corresponding standard deviations in the HSI space were (H, S, I) = (6.5469, 0.1498, 0.1442). In 2023, Sun et al. [3] analyzed corrosion using pixel scatter diagrams in the RGB color space. They calculated the mean pixel values as C (R, G, B) = (193.94, 123.57, 59.10) and the standard deviations as σ(R, G, B) = (29.88, 29.12, 17.92).

3 Methodology

Our methodology is divided into two segments. The first segment involves calculating the mean and standard deviation of HIS pixel values. The second segment focuses on training and predicting rust severity.

3.1 Statistical Analysis of HIS Pixel Values

3.1.1 Converting Image from RGB to HSI

Pixel values constitute the essential components and smallest units of a digital image [29]. For this study, we collected data from diverse and heterogeneous sources, including mobile phones, digital cameras, drones, and open-source repositories. This diversity ensures that the dataset reflects a wide range of real-world scenarios. Typically, digital cameras and mobile phones produce images in the Red, Green, and Blue (RGB) color model by default. To enhance the utility of the dataset, especially for addressing challenges like shadow removal and effectively identifying rust severity in the images, we converted all collected data from the RGB color space to the Hue, Saturation, and Intensity (HSI) color space. The range of RGB values is typically 0 to 255 for an 8-bit image [20], as discussed in the previous section. For this study, we normalized the RGB values to fit the HSI color model, where the intensity and saturation values are scaled to a range of 0 to 1, and the hue values are normalized to a range of 0 to 360 degrees using the following formula (Equations 1-4).

$$H\ (Hue) = \begin{cases} \theta & if\ B \le G \\ 360 - \theta & if\ B > G \end{cases} \quad (1)$$

with

$$\theta = Cos^{-1}\left\{ \frac{\frac{1}{2}\left[(R-G) + (R-B)\right]}{\left[(R-G)^2 + (R-B)(G-B)\right]^{\frac{1}{2}}} \right\} \quad (2)$$

$$S(Sat.) = 1 - \frac{3}{(R+G+B)}[\min(R,G,B)] \quad (3)$$

$$I\ (Intensity) = \frac{1}{3}\ (\mathrm{R} + \mathrm{G} + \mathrm{B}) \quad (4)$$

Hue represents the type of color Hue represents the type of color (e.g., red, blue, green) and is expressed in degrees (0°–360°). Saturation measures the purity of the color. It is computed as the proportion of the maximum deviation of the pixel color values from the neutral gray level. The intensity is the average of the three RGB components and represents the brightness of the pixel.

3.1.2 Optimal Number of Clusters Using Elbow Method and K-Means Clustering

Unsupervised machine learning, particularly the k-means clustering algorithm, is widely regarded as one of the most popular and efficient techniques for image clustering [30]. Despite its advantages, a significant limitation of k-means is that it requires the number of clusters to be predefined before the clustering process. This can be challenging when dealing with real-world data, where the optimal number of clusters is not known in advance. To resolve this issue, we utilized the Elbow Method, a commonly employed heuristic for identifying the ideal number of clusters. This method entails computing the within the sum of cluster squared (WCSS) distances (inertia) (Equation 5) between each data point and its respective cluster centroid across various cluster characteristics. The results are subsequently displayed to generate an inertia curve. The 'elbow' or 'knee' point of this curve signifies the appropriate number of clusters since it denotes the juncture when the addition of further clusters yields negligible enhancement in diminishing inertia, reflecting a balance between model complexity and efficacy.

To enhance precision and automation, we employed a knee locator algorithm that correctly determines the elbow position in the curve. By integrating k-means with the Elbow Method, we established a rigorous and data-driven strategy to ascertain the appropriate number of clusters, therefore enhancing the efficiency and precision of our picture clustering procedure.

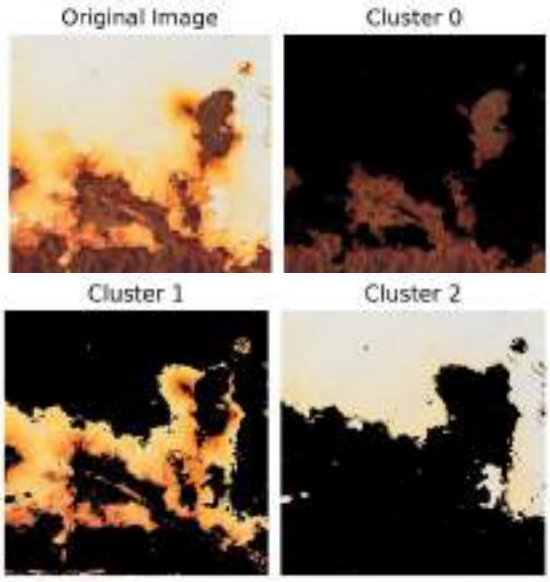

Figure 1. Rust image clustering using the k-means algorithm to visualize and evaluate rust severity in accordance with the AASHTO-2019 standards.

$$\text{Inertia (WCSS)} = \sum_{i=1}^{k} \sum_{x \in C_i} \|x - \mu_i\|^2 \quad (5)$$

- k is the number of clusters
- Ci= The set of points assigned to the cluster i
- x= A data point in cluster Ci
- μ_i= The centroid of cluster Ci

In this paper, we consider three levels of rust severity: Severe, Major, and Minor. These categories were derived from the guidelines provided by the American Association of State Highway and Transportation Officials (AASHTO) in their 'Manual for Bridge Element Inspection 2019' [31]. This guidebook serves as a reliable resource for evaluating bridge conditions, including rust assessment. To comply with these requirements, we assessed rust severity by categorizing photos into separate clusters (Figure 1). Each cluster was subsequently aligned with one of the severity categories established by AASHTO. This methodology enabled us to categorize rust patterns according to picture attributes while maintaining alignment with industry standards. Utilizing these clusters, we can systematically identify and assess the degree of rust.

3.1.3 Histogram Analysis

A histogram is a graphical depiction that illustrates the frequency distribution of a dataset. In image analysis, histograms are frequently employed to examine the distribution of pixel values over various color spaces, including Hue, Saturation, and Intensity (HSI). Due to the absence of publicly available rust specific datasets, we collected a set of 30 real-world images of rusted steel surfaces. These images were analyzed using histogram-based techniques to calculate the mean and standard deviation (SD) of pixel values corresponding to varying rust severity levels. These pixel ranges were then used to train a Random Forest model, aimed at classifying rust severity based on the calculated values.

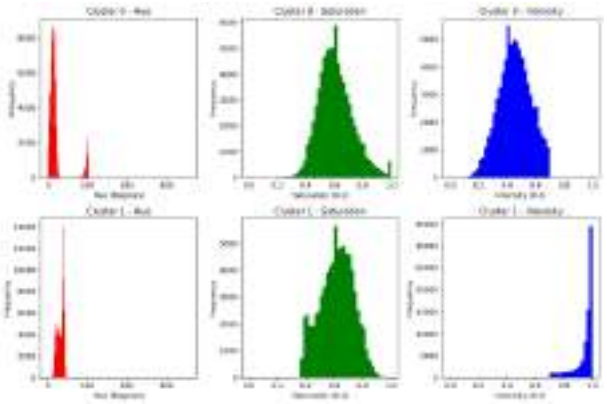

Figure 2. Histograms of H(Hue), S(Saturation), and I (Intensity) for Cluster 0 in HSI Color Space.

From Figure 1, we focused our analysis on Clusters 0 and 1, as Cluster 2 primarily represented the background and did not contain rust. We conducted a histogram analysis to determine the range of pixel values corresponding to different categories of rust severity.

The histograms, as shown in Figure 2, represent the distribution of HSI values for Cluster 0 and Cluster 1. In Cluster 0, the Hue values predominantly range from approximately 0 to 100. The mean Hue value for Cluster-0 is 20.11, with a standard deviation of 26.30. The saturation histogram displays a pyramid-shaped distribution with values ranging between 0.4 and 0.8, indicating a moderate degree of color vibrancy within this cluster. The mean saturation value is 0.61, with a standard deviation of 0.12. Similarly, the intensity histogram follows mid-intensity values of 0.2 to 0.7. The mean intensity value is 0.45, with a standard deviation of 0.11. These histograms provide a detailed overview of the color characteristics and brightness distribution within Cluster 0. A similar analysis was conducted for Cluster 1 further to compare the distinct HSI properties of the clusters.

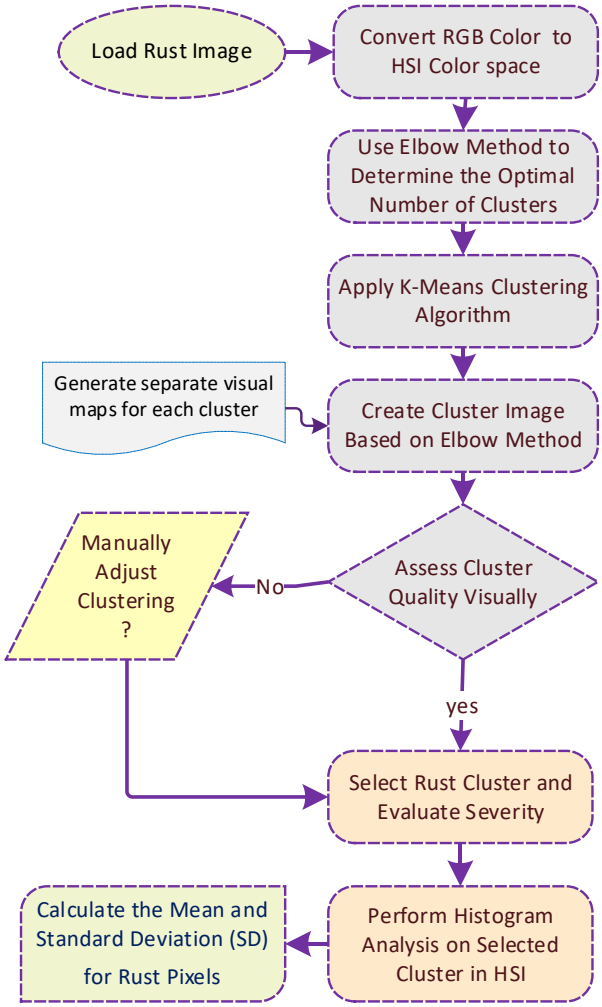

Figure 3. Workflow for Rust Severity Analysis Using Clustering and HSI Histogram Analysis.

We conducted this histogram analysis on 30 rust images and calculated the mean and standard deviation values for rust severity in the HSI color space (Table 1).

Table 1 Mean and Standard Deviation of HSI Pixel Values for Rust Severity Classification.

Severity Pixel	H	SD	S	SD	I	SD
Severe	18.4	16.5	0.65	0.13	0.44	0.14
Major	24.54	12.39	0.61	0.11	0.60	0.09
Minor	47.98	15.80	0.42	0.12	0.68	0.08

The methodology illustrated in Figure 3. provides a systematic process for analyzing rust in images. The process begins by loading the image and converting its colors from RGB to HSI, facilitating a focus on the significant color attributes associated with rust. The Elbow Method is employed to determine the optimal number of groups for segmenting the image, followed by the application of K-means clustering to form these clusters. Visual representations for each cluster are generated and amalgamated into a singular image to validate the coherence of the clustering. If the findings are inaccurate, manual changes might be implemented to enhance the segmentation. Upon accurate identification of the rust regions, the rust cluster is chosen for subsequent study. Analyzing the cluster's color distribution through a histogram and computing essential statistics such as the mean and standard deviation of the rust pixels facilitates the assessment of rust severity in the image. This approach guarantees a comprehensive and accurate analysis.

3.2 Rust Severity Training and Prediction

3.2.1 Training Random Forest Models with Synthetic Data

After calculating the pixel values, we created synthetic data using the mean and standard deviation values derived from our analysis. A Random Forest machine learning algorithm was trained on this synthetic dataset, enabling us to classify rust severity levels. Using the trained model, we generated a set of virtual images based on the input pixel characteristics and applied the trained model to classify external images effectively.

The proposed methodology involves a systematic approach to rust severity classification and segmentation. Synthetic training data is first produced by establishing criteria for hue, saturation, and intensity (HSI) values that align with designated rust severity levels: Severe, Major, and Minor. These criteria are established on the observed mean ± standard deviation values obtained from histogram analysis. A labeled dataset is generated by simulating HSI data points for each severity level based on these thresholds. This dataset is utilized to train a Random Forest classifier, a resilient and adaptable supervised machine learning technique. The dataset is divided into training and testing subsets, and the model's performance is meticulously assessed using metrics including accuracy and F1-score to verify its dependability.

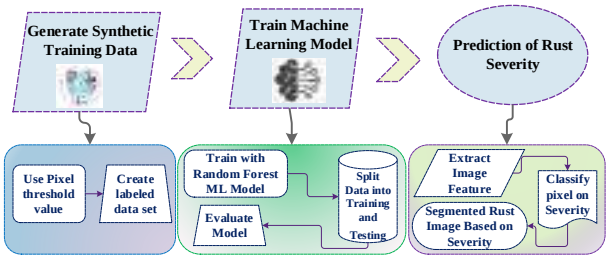

Figure 4. Workflow for Rust Severity Training and Prediction Using Machine Learning Models.

Upon completion of training, the model is utilized on actual photos. Pixel-wise HSI features are derived from the input image by transforming it from RGB to the HSI color space and restructuring the pixel values into a format suitable for the Random Forest model. The trained classifier forecasts the rust severity level Severe, Major, or Minor for each pixel in the image according to its HSI properties. The severity levels are represented by specific colors: Red for Severe, Orange for Major, and Yellow for Minor.

3.2.2 Prediction of Rust Severity

In the concluding phase, the trained Random Forest classifier was utilized to predict the rust severity category for each pixel in the input image, relying on its hue, saturation, and intensity (HSI) attributes. The anticipated labels were assigned numerical values that correspond to established severity levels: Severe, Major, Minor, and Background. The predictions were subsequently reformulated to match the original image dimensions, resulting in a segmentation map. The segmentation outcome, alongside the original image, offered a distinct representation of rust severity levels across the surface (Figure 5). This visual depiction enables accurate identification of rust damage and offers a quantitative framework for evaluating rust severity. This paper incorporates morphological operations techniques to fine-tune the segmented image. A 2×2 kernel was applied for erosion and dilation, refining the boundaries and reducing noise to enhance the segmentation quality.

4 Result

The K-means clustering algorithm was successfully applied, incorporating the elbow method to analyze histogram data. Based on this analysis, the mean and standard deviation of pixel values for each severity level were calculated, as detailed in Table 1. Using the calculated mean and standard deviation values, synthetic data was generated to represent numeric pixel values, which were then used to train a Random Forest machine learning model. The model's performance was evaluated, achieving an F1 score of 0.75, a precision of 0.74, and an accuracy of 0.81. The segmentation outcomes delineated distinct borders among the clusters, offering a visual depiction of rust severity over the surface. A pixel-based analysis was performed to measure the area occupied by each cluster. The image-1 comprised a total of 512*512= 262,144 pixels, with 69775 pixels (26.62%) indicative of Severe rust, 30929 pixels (11.80%) indicative of Major rust, and 52150 pixels (19.89%) indicative of Minor rust.

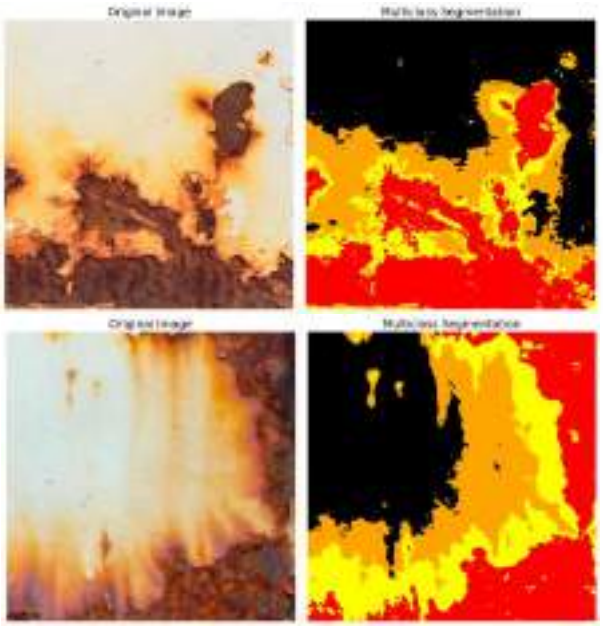

Figure 5. Original and Multiclass Segmentation image of Rust Severity (Severe: Red, Major: Yellow, Minor: Orange, Background: Black).

The Background comprised 109290 pixels (41.69%) of the image area. This quantitative research illustrates the efficacy of the clustering method in detecting and categorizing areas of differing rust intensity, offering significant insights for surface condition evaluation.

5 Discussion

The classification of rust severity is essential for corrosion monitoring and management, especially in industrial settings, where prompt detection can avert structural failures and minimize maintenance expenses. This study utilized an innovative method that integrates clustering-based analysis with machine learning to categorize rust severity into three unique classifications: severe, major, and minor. This workflow integrates unsupervised and supervised methodologies to attain precise and fast segmentation. The conversion of RGB photos to the HSI color space was crucial in the study. In contrast to RGB, the HSI model separates color intensity from chromaticity, offering a more comprehensible depiction of rust attributes under different lighting circumstances. This preprocessing procedure guaranteed that rust segmentation was resilient to shadows and inconsistent lighting, hence improving the dependability of future clustering and classification. The utilization of the Elbow method to ascertain the ideal number of clusters offered an unsupervised approach for segmenting the rusted areas based on pixel similarity. K-means clustering enhanced this segmentation by

categorizing pixels into discrete clusters, denoting areas with differing rust intensity. The computed mean and standard deviation (SD) values of pixel HSI components for each cluster facilitated the creation of synthetic data, which constituted the training basis for machine learning models.

A supervised machine learning method, specifically the Random Forest algorithm, was employed to categorize rust severity. This approach was selected for its resilience, capacity to manage high-dimensional data, and interpretability. Through training on synthetic data generated from computed HSI thresholds, the model demonstrated effective generalization to novel images. The evaluation criteria, including accuracy, precision, recall, and F1-score, validated the model's efficacy, with findings affirming its ability to effectively forecast rust severity across various test samples.

6 Conclusion and Future Research

This study significantly contributes by integrating histogram-based analysis with machine learning. The technology integrates traditional image processing with data-driven approaches by utilizing statistical features of pixel distributions, including mean and standard deviation. This hybrid approach guarantees that the classification of rust severity is both comprehensible and scalable for practical applications. Moreover, the visual depiction of segmented output images provides actionable insights, with pixels color-coded by severity. Morphological operations with a 2×2 kernel further refined the segmentation by enhancing boundary accuracy and reducing noise, enabling users to assess the degree and spread of rust intuitively. This quantitative approach provides a dependable decision-making instrument for rust monitoring, facilitating tailored interventions to reduce rust damage successfully.

Notwithstanding its advantages, the proposed methodology does have several limitations. One significant limitation is the reliance on synthetic data specifically, pixel value ranges (mean and standard deviation) derived from a small set of 30 real-world images. Due to the lack of publicly available rust datasets, we used these 30 real-world images to generate the necessary training data. While this approach provides a controlled dataset, the small size and lack of diversity may limit the model's generalization ability, especially with varying rust conditions. Furthermore, external factors like illumination fluctuations and surface texture variations can influence the model's predictions.

Despite these limitations, the approach remains a valuable starting point. Future work will aim to tackle these challenges by expanding the dataset, incorporating a wider variety of real-world images, and integrating adaptive thresholds to account for varying conditions. Additionally, exploring advanced techniques such as deep learning could enhance model generalization and accuracy. This study's methodology, while in need of further refinement, offers a realistic and scalable solution for classifying rust severity. By combining clustering, machine learning, and quantitative analysis, we establish a solid framework that can be further developed for industrial applications, improving both efficiency and precision in rust severity management systems.

The Artificial Intelligence (AI) Impact on Construction Project Management

Kwame B.O. Amoah[1]
Department of Civil and Architectural & Construction Management, University of Cincinnati, OH, USA.
amoahkb@ucmail.uc.edu

Abstract – The study aims to explore the degree of Artificial Intelligence (AI) integration in construction projects and analyze its effects on cost-effectiveness, safety, and productivity. The objective is to investigate the relationship between the application of AI and its integration in the construction sector, evaluating the possible changes and adjustments in the labor force brought about by AI technological incorporation. The author employed a systematic review methodology. The review approach provides comprehensive insights into the application of AI in real-world construction projects inform data evaluation trends of AI application in the industry. The preliminary results highlight AI's enormous potential for streamlining repetitive processes, maximizing resource use, and improving construction safety standards. Integrating AI into construction projects may result in significant gains in productivity and safety, but doing so requires a careful strategy in balancing the workforce's changing requirements and technology improvements, and the role of the industry is vital in this process.

Keywords: Artificial Intelligence; AI Project Management; AI powered Construction: Construction Project Management: Machine Learning.

1 Introduction

Especially compared to more digitalized industries like manufacturing, the construction industry faces ongoing obstacles that hinder its growth and competitiveness despite its critical role in global development [1]. The industry is characterized by a culture resistant to change and firmly embedded manual procedures. As a result, it needs to catch up with new technologies, which leads to reduced inefficiency [2]. These difficulties, the industry's workforce problems, the pressing need for sustainable infrastructures, and time management highlight the importance of embracing digitalization and using artificial intelligence's (AI) disruptive potential [3].

The application of Artificial Intelligence (AI) in construction projects is not just a trend, but a transformative wave poised to revolutionize the industry's operational landscape. Traditionally known for its labor-intensive practices, the construction sector faces challenges such as low productivity, inefficiencies, safety concerns, and cost overruns. AI's potential offers solutions to age-old problems that have hampered growth and innovation within the construction domain.

The construction industry needs more productivity, waste management, safety concerns, and cost overruns. Despite technological advancements, experts in construction projects must explore AI integration. The industry's historical reliance on conventional methods and resistance to change has hindered its adoption of AI-driven solutions. Challenges include high initial costs, limited expertise, trust deficits, and cultural barriers. However, the critical need for comprehensive studies is clear.

Procore and Autodesk BIM 360 are AI-powered construction project management software that analyses data to forecast hazards and improve timelines. They free up time for making decisions by automating processes like scheduling and documentation. These technologies let teams collaborate by visualizing project progress through 3D models and reports [4]. They improve overall project efficiency and results by using machine learning to find patterns in data for improved resource allocation and cost control. The main hypotheses of the paper include: 1. Explores the AI application processes in construction project management, 2. Addresses AI integration into construction project and assesses how the integration affects productivity, safety concerns and cost effectiveness, and 3. Provides opportunities to mitigate AI applications' challenges in the construction industry.

The study's unique contribution provides insights into key AI applications and integration as they apply to construction-specific challenges and the pathway to realizing AI's measurable benefits in the construction industry.

Figure 1: AI applications in different fields of construction.

2 Artificial Intelligence Relevance in Project Management

The advent of AI dates back to 1950 when the British mathematician Alan Turing asked whether machines could think [4]. After experiencing ups and downs over 60 years, AI has regained technological importance due to rapid developments in computing, big data, artificial neural networks, deep learning, and other new technologies [5, 6]. AI is a computer system that perceives visual perception, recognizes speech, and can translate between languages. It solves complex decision-making processes that mathematics cannot solve directly by understanding project information and the environment [6]. Machine learning is a subsidiary of AI, using algorithms and statistical models to study data and make decisions 8, 7]. With the advancements in machine learning and big data technologies, AI has become a significant technological opportunity globally. The potential of this technological advancement also triggers the need for AI use in the AEC industry. On a limited scope, the need for AI use in construction arises from the desire to improve cost management, enhance quality control, increase efficiency and productivity, and address complex issues in project management. The potential areas that the AEC industry can benefit from AI use are enormous.

As construction projects become complex and large-scale in the AEC industry, the number of participants and the volume of construction data, including project plans, schedules, and performance metrics, increase. In this regard, AI stands out as one of the digital technologies with significant potential to leverage the vast amount of available big data for problem-solving and enhancing decision-making within construction management [10-9]. AI can use machine learning algorithms to inform decision-making, optimize resource allocation, and improve project outcomes by identifying patterns, trends, and insights. As a result, artificial intelligence can offer continuous real-time monitoring and analysis of construction operations, enabling project managers to make well-informed decisions based on data [11] promptly. This process improves project control, reduces risks, enhances overall project performance, and prevents poor decision-making through the project management processes.

The use of AI in the AEC industry also has the potential to sustain project success. Project success is mainly defined by the project management triangle, consisting of time, cost, and quality pillars [12]. Planning a project is one of the most critical processes in project management, but the importance of designing software needs to be investigated [13]. Construction cost control is crucial, as delays in any project stage can cause cost overruns due to increased artistry, working time, or material usage [14]. AI has the potential to forecast cost overruns by considering project scale, contract type, and the competence of the project manager [15]. By implementing AI in construction scheduling, managers can monitor schedules more efficiently by estimating construction project completion and delay times [16]. AI can be applied in real-time, enabling project managers to swiftly and knowledgeably decide how to allocate resources as the project unfolds [17]. This can help prevent project delays and lead to more realistic timelines for future projects.

Furthermore, AI can provide a clear and realistic view of construction site activities to top-level management and engineers, improving construction efficiency and quality [18]. AI can also analyze data from various sources, such as sensors and cameras, to monitor real-time construction quality. It can identify defects, deviations from specifications, and potential issues, enabling early intervention and improving overall quality control.

Safety is a paramount and indispensable aspect of the construction industry. AI's potential to anticipate and prevent occupational accidents and equipment-related safety issues during construction projects is a significant development. AI-powered technologies, such as drones, robots, and wearable technologies, can be used for site inspections, monitoring hazardous areas, identifying potential safety risks, and monitoring workers' behavior. AI algorithms can analyze real-time data on-site from sensors to detect unsafe conditions, helping to prevent accidents and improve safety on construction sites. Additionally, pattern recognition-based AI technologies are used for data and system integration to enhance safety management. These technologies become even more potent when paired with virtual reality as they assure real-time personnel safety.

As the main field of construction management, AI can monitor, recognize, evaluate, and predict potential risks in terms of safety, quality, efficiency, and cost across teams and work areas, even under high uncertainty [19, 20]. AI-based risk analysis can provide insights to help project managers quickly prioritize potential risks and identify proactive actions rather than risk mitigation responses [21]. Machine learning and natural language processing are being applied in construction for risk detection and assessment to issue early warnings [20]. Consequently, AI is expected to play a significant role for project managers in risk assessment, generating decision support, automation of risk monitoring, and simulation and scenario analysis. Additionally, AI technologies, such as Building Information Modeling (BIM) and virtual reality, allow for better visualization, clash detection, and coordination among different disciplines, reducing errors and rework during construction.

In summary, the introduction of AI systems in the construction industry represents a significant leap

forward. These systems leverage advanced technologies, data analysis techniques, and automation to address specific challenges and improve efficiency, productivity, safety, decision-making, and overall project outcomes. AI systems bring new capabilities, insights, and efficiencies to the construction industry, enabling practitioners to leverage data-driven intelligence for better project execution. By embracing AI technologies, the AEC industry can drive innovation, increase productivity, support decision-making arising from complex project management challenges, and achieve better project outcomes. The potential for AI to drive innovation in the AEC industry is vast, inspiring a new era of technological advancement and efficiency.

Along with these contributions that artificial intelligence will provide to project management, there has been a notable rise in research on the application of artificial intelligence in the construction industry. It is evident from the literature that the use of AI techniques in the construction industry has become a trending topic.

3. Research methodology

This section outlines the research approach for the study, emphasizing the systematic and rigorous nature of the author's methodology. The author considered the approach based on the recommendations made by Kitchenham and Charters [22]. The case investigation 'Software Scent Detection Techniques: A Systematic Literature Review (SLR) '[23] served as a crucial tool for establishing the systematic literature review process we employed to investigate earlier research on our chosen subject, 'The Impact of Artificial Intelligence (AI) on Construction Projects.' Following the SLR methodology, our inclusion criteria guided the selection process, prioritizing papers with relevant abstracts and titles, while our exclusion criteria methodically eliminated irrelevant articles.

A systematic search across reliable resources guarantees a thorough assessment of the content. The author learned about standard procedures to conduct this detailed research, which gave me a solid basis for the subsequent projects. A paper titled "Software Smell Detection – Systematic Literature Review" [24] influenced the initial portion of the study as it provided knowledge about software smells and a solid basis for the author's work. The report utilized these data sources for our investigation: Electrical and Electronic Engineers (IEEE), Google Scholar, and ACM.

The study's topic, 'The Impact of Artificial Intelligence (AI) in Construction Projects,' was closely related to specific papers in which the author thoroughly examined the library's resources. The following research questions were formulated to guide our study and provide further details on the fields of study connected to our chosen topic and how the inclusion and exclusion criteria are implemented. These questions, carefully crafted to focus our search and ensure we only included relevant papers in our review, played a crucial role in shaping the direction of our study.

3.1. Search Process

The selections are limited to studies between 2010 and 2024, constituting the current literature. The databases used for searching are IEEE Xplore Digital Library, Web of Science (WOS), and Scopus. The keywords used for searches are "**AI** Project Management," "machine learning," "artificial intelligence," "AI-powered Construction," "Machine Learning," and "construction project management.".

The author's approach to selecting studies was to define the parameters for inclusion or exclusion criteria, determine the impacts of artificial intelligence applications and integration on construction projects, and select the trends and quality of the studies. The study's time frame was restricted to between 2010 and 2024 to keep up with current studies, with older studies being excluded under the assumption that they may be insufficient or irrelevant. The exclusion criteria were also applied to studies not closely related to the subject matter. Figure 2 illustrates the literature search approach.

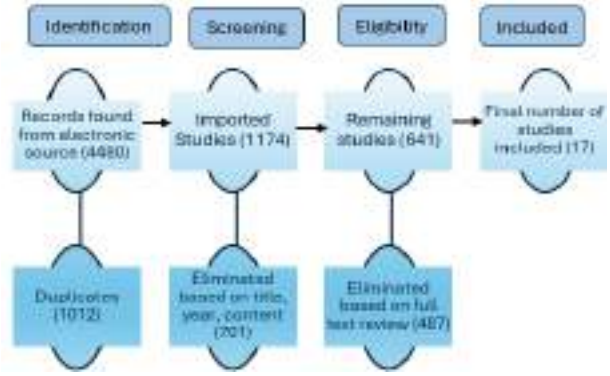

Figure 2: Literature search process

4. AI Applications in different construction sectors.

Artificial Intelligence (AI) is transforming the construction industry from the ground up, primarily by significantly improving productivity. It does this by streamlining processes and resource allocation using sophisticated algorithms and machine learning. This enables precise task scheduling, anticipation of potential hazards, and wiser resource allocation, all of which contribute to shorter project turnaround times and fewer delays. In addition, AI-powered Building Information Modelling (BIM) solutions provide more intelligent designs, collision detection, and thorough simulations, which expedite the planning and design stage and reduce mistakes. The main benefit of AI in the construction industry is its ability to significantly improve

productivity, thereby transforming the sector into many aspects.

AI-driven technologies are revolutionizing and significantly enhancing safety protocols in the construction industry. Using computer vision algorithms to examine data from sensors, drones, and cameras, AI can identify potential risks on construction sites, thereby improving safety procedures and preventing accidents. Furthermore, AI's ability to predict equipment faults makes it easier to perform maintenance, ensuring prompt repairs and reducing downtime. The role of AI in selecting environmentally friendly materials and optimizing energy use is also crucial, as it is leading to the adoption of greener and more sustainable building techniques. Incorporating AI is changing and significantly improving the construction industry, making operations safer, more environmentally friendly, and more efficient. Examples include autonomous cars and robotics performing mundane jobs and data-driven insights altering decision-making.

AI is revolutionizing and plays a pivotal role in waste reduction, safety, and project management in the construction industry. It is used in advanced software like Procore and Autodesk BIM 360 for resource allocation, scheduling, and communication. AI-driven wearables, computer vision systems, and IoT sensors enhance safety measures, while AI-powered trash tracking and recycling technologies improve waste management and recycling effectiveness. The comprehensive impact of AI in these areas is transforming the construction industry, making it more efficient and sustainable.

4.1. AI tools in construction

Several artificial intelligence (AI) solutions have been developed expressly for the construction sector, focusing on waste management, safety protocols, and project management. Here are a few instances:

Procore: This AI-powered tool manages documents, tracks timelines, keeps an eye on budgets, and streamlines communication to assist with project management. It provides insights to streamline operations and use machine learning algorithms to forecast possible project hazards.

Building information modeling (BIM): This tool is made easier using Autodesk BIM 360, which offers a centralized platform for project teamwork with artificial intelligence (AI) systems that examine data from several sources to facilitate better decision-making, identify conflicts and optimize construction scheduling.

Smartvid.io: This program uses artificial intelligence (AI) for safety to identify possible dangers and hazards by analyzing photos and videos taken on-site. By proactively addressing problems, it can identify patterns in safety occurrences and contribute to reducing accidents.

Predictive Solutions: This platform uses machine learning to forecast possible safety events by examining past data, spotting trends, and spotting patterns that might result in mishaps. It makes it possible to implement preventative safety measures.

Eco Domus: This technology optimizes waste management during construction by fusing AI and BIM. It follows the life cycle of building materials and analyses data to reduce material waste, allowing for effective recycling and reuse techniques.

4.2. Machine learning

The creation and application of computer systems that may be specifically intended to learn from prior data or experience to model, control, or forecast using statistical approaches is known as machine learning. Among the machine learning techniques are: (A) Supervised machine learning: this area of research focuses on how computers decide what to do after learning from labeled datasets or pairs of input and intended output. It is divided into regression and classification categories. (B) Unsupervised Machine Learning: this approach teaches machines the fundamental organization seen in unlabeled datasets. Techniques for dimension reduction and grouping are divided into two categories. (C) Reinforcement learning (RL) is the process of "learning a mapping from situations to actions to maximize a reinforcement signal or scalar reward." This computational method involves deducing knowledge from the results of interactions with the surroundings; also, (D) Deep Learning: this is the most advanced machine learning methodology available today, and it has been shown to provide predictions that are more accurate than those made using traditional methods.

4.3. Automated Planning and Scheduling

In artificial intelligence, known as planning, activities are carefully chosen and arranged according to their anticipated results to enable intelligent systems to accomplish specified goals or objectives. Determining plans and allocating the time and resources required to achieve the intended purposes using the available resources constitute scheduling. Planning and scheduling techniques create complicated application solutions that better meet user requirements and issue limitations. Due to its complexities, expense, and duration, planning is employed only in circumstances where its advantages surpass the disadvantages. Standard techniques and algorithms include genetic algorithms, search approaches, and optimization techniques for planning and scheduling.

4.4. Robotics

Robots are highly automated machines that do real-world physical tasks. Engineering that crosses many disciplines is called robotics, and it deals with creating, building, and maintaining robots and other computer programs that simulate real-world human movements.

Robots are meant for highly specialized activities; they don't always take on human-like forms but adopt shapes best suited to their purposes. They communicate with their surroundings using sensors and movements. The system outlined how reinforcement machine learning issues make up the bulk of robotics learning difficulties.

4.5. Safety Measures

Real-time Monitoring: AI-driven cameras and sensors monitor building sites around the clock. They enable quick response by identifying safety issues, illegal individuals, or risky behaviors.

Wearables and IoT Devices: To ensure worker safety and avoid accidents, artificial intelligence (AI) analyses data from wearables and IoT devices worn by workers to monitor vital signs, movement patterns, and tiredness levels.

5. Case Studies

Case Study 1: Integrating AI-Based Tool to Streamline Workflows

The case study highlights the integration of AI-based tools such as "Procore Copilot," which aims to improve communication and provide actionable insights across construction projects.

Procore's Copilot AI is a game-changer in the construction industry, addressing critical issues such as labor shortages and manual data processing. By automating tasks and accelerating data access, it expedites decision-making. The suite of AI tools, including Procore Copilot, AI Locations, and Procore Maps, revolutionizes project management by providing vital insights and seamlessly integrating with popular collaboration tools.

Procore's AI-driven tools, unveiled at the 2024 Innovation Summit, are designed to make project data more accessible and user-friendly for construction teams. Procore Copilot's integration with Microsoft Teams allows for natural language interaction with project data, making it easy and intuitive to access information such as Requests for Information (RFIs) and submittals. AI Locations simplify project organization by automatically generating location lists from project drawings, making it easier for teams to structure and locate items. Procore Maps introduces spatial tracking, enabling users to view photos mapped by location and filtered by date, providing a clear visual overview of project progress and facilitating workflow optimization.

Procore's AI implementation has not just improved project management, it has revolutionized it. By automating tasks such as location tracking and submittal management, Procore's AI tools have significantly reduced the time required for manual data entry, thereby enhancing workflow efficiency. The integration of Procore Copilot with Microsoft Teams has streamlined communication, enabling teams to access and discuss project information seamlessly. Procore Maps has enhanced data utilization by visualizing work progress with mapped photos, aiding decision-making and reducing delays. This efficiency gain is a testament to the potential of AI in the construction industry.

Procore's AI advancements, while promising, come with their own set of challenges. These include data privacy and security concerns, especially with third-party integrations like Microsoft Teams. Safeguarding sensitive construction project data is crucial for user trust. Additionally, users need training to adopt new AI tools effectively. Developing advanced features like Procore Copilot's natural language processing involves technical complexities and significant resources. By being aware of these challenges, the construction industry can better prepare for the future of AI.

The advantage

Procore Copilot integrates directly into Microsoft Teams, allowing users to access project data and context in natural language. Its features, such as AI Locations and Procore Maps, streamline visual data, enabling users to monitor and optimize project progress more efficiently. Also, IProcore uses AI to surface critical insights from Requests for Information (RFIs) and submittals, helping project teams make data-informed decisions.

Challenges and Barriers

While beneficial, Procore's AI advancements pose challenges. Data privacy and security are crucial, especially with third-party integrations like Microsoft Teams, to safeguard construction project data and maintain trust. Advanced AI tools also require user training for effective adoption. Developing features like Procore Copilot's natural language processing also demands substantial resources and expertise.

Case Study 2: BIM 360 and Smartvid.io AI

Autodesk BIM 360 introduction of AI agents has the potential to elevate the capabilities of Autodesk BIM 360 to enhance decision-making and operational efficiency.AI agents can transform project management and automation by integrating with Autodesk BIM 360.

AI integration in Autodesk BIM 360 can greatly enhance workflows. Though the platform lacks built-in AI, integrating AI solutions can improve efficiency by analysing data, automating tasks, and offering insights through analytics and machine learning, thus supporting smarter project management decisions. Automation for Architectural and Design Efficiency The key examples of AI-Driven automation include:

Automated Document Management: AI can process project documents and organize them for easier access., **Predictive Risk Management**: By using historical data, AI can identify potential project risks

based on previous projects and **Enhanced Collaboration**: AI agents can improve communication by summarizing project updates and informing team members of changes.

AI agents simplify workflows in complex settings like construction or architecture, accelerating processes and reducing manual effort.

6. BIM-AI Framework for Construction Integration

The framework, which focuses on data interoperability, AI algorithms, and application areas, is designed to improve efficiency, reduce errors, and optimize building performance across the project lifecycle. Figure 5 illustrates a continuous process of capturing the project team's knowledge into BIM and AI practices in the four (4) toolbox knowledge areas. The framework's use case not only presents processes and corresponding appropriate BIM and AI tools but also emphasizes the adaptability of the framework to different phases of the project life cycle, making it a versatile and attractive solution for stakeholders.

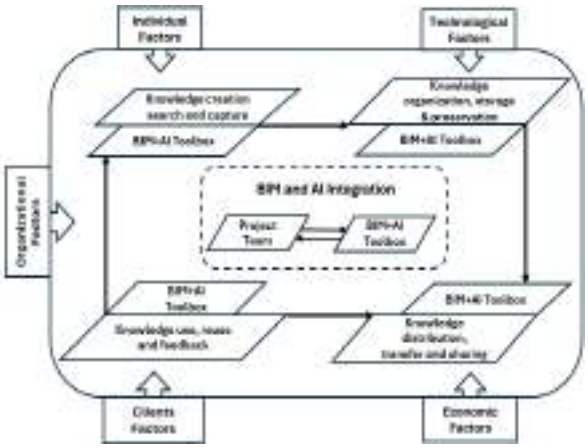

Figure 5. Conceptual knowledge framework for the integration of knowledge into BIM-AI practices

The framework is further subcategorized into four (4) classifications:

1. Data Interoperability and Preparation:

Standardized Data Formats: Establish clear protocols for data exchange between BIM models and AI systems, using Industry Foundation Classes (IFC) or other relevant standards.

Data Extraction and Transformation: Develop methods for extracting relevant data from BIM models (geometrical, semantic, and parametric) and transform it into formats suitable for AI algorithms.

Data Quality and Management: Ensure data accuracy, consistency, and completeness to support reliable AI analysis.

2. AI Algorithms and Applications:

Machine Learning: Utilize machine learning algorithms for tasks such as clash detection, cost estimation, schedule optimization, and performance simulation.

Image Recognition and Processing: Employ AI algorithms for visual inspection, quality control, and progress monitoring on-site.

Predictive Analytics: Leverage AI for predicting potential problems, optimizing resources, and making informed decisions throughout the project lifecycle.

3. Application Areas:

Design Optimization: Use AI to explore design alternatives, optimize building performance, and identify sustainable solutions.

Construction Scheduling and Management: Automate scheduling tasks, predict delays, and optimize resource allocation using AI.

Cost Management: Analyze cost data, predict project costs, and optimize resource allocation using AI.

Quality Control and Safety: Implement AI-powered systems for visual inspection, safety hazard detection, and quality control.

Facility Management: Use AI to monitor building performance, optimize maintenance schedules, and improve energy efficiency.

4. Challenges and Mitigation Strategies:

Data Availability and Quality: Address data gaps and inconsistencies by implementing robust data management practices and standards.

Algorithm Accuracy and Reliability: Validate AI algorithms and ensure their accuracy and reliability before deploying them in real-world projects.

Interoperability Issues: Develop standardized data formats and protocols to facilitate seamless integration between BIM and AI systems.

Lack of Expertise: Invest in training and education to equip construction professionals with the necessary skills to use BIM and AI effectively.

Ethical Considerations: Address potential biases in AI algorithms and ensure responsible use of AI in construction.

7. Traditional Approach to AI process in construction sector Integration

Automated decision support and artificial intelligence (AI)-driven solutions empower you with real-time data insights, automating tasks like scheduling and documentation to bolster your decision-making process.

Improved collaboration cloud-based platforms allow teams to work together in real-time while accessing 3D models and reports, enhancing communication and helping with project management.

Real-time project visualization technologies provide

a dynamic, real-time perspective of the project's state, enabling more informed decision-making. They do this by utilizing 3D models and progress reports.

Data-driven resource allocation and machine learning algorithms analyze extensive data to find trends, which helps with targeted cost control plans and efficient resource allocation.

Efficiency compared to manual techniques, Procore and Autodesk BIM 360 considerably increase efficiency by streamlining procedures and providing real-time data. Waste management integration with AI undergoes a few steps to convert the scrap, decrease inefficiencies, and promote sustainability throughout project lifecycles, revolutionizing waste management in the construction industry. AI is essential for predictive analytics because it can estimate possible waste generation using past project data. As a result, less waste is produced overall, and proactive efforts to optimize material utilization and purchasing are made possible. Moreover, by precisely recognizing and classifying diverse waste products, AI-powered systems with cameras and sensors enable effective sorting and recycling procedures. Artificial intelligence (AI)-powered real-time monitoring systems monitor waste production on building sites and provide prompt decision-making to reduce trash accumulation. Complete lifecycle analysis is made possible by integrating AI with Building Information Modelling (BIM), which helps architects create buildings with the least amount of waste possible during their lifespan.

AI is crucial in project planning, from requirement gathering to plan selection and implementation. Leveraging AI can help choose the best plan, improving project efficiency. AI's benefits in project management include improved project planning, real-time project monitoring and alerts, enhanced efficiency, communication and collaboration, risk management, predictive analytics, and better decision-making. Drones, wearable tech, autonomous equipment, and 3D printers contribute to improved safety measures in construction. Drones enable efficient site inspections, real-time safety monitoring, and emergency response, reducing worker exposure to hazardous areas. Wearable tech provides real-time safety alerts, biometric tracking, and immersive training experiences. Autonomous equipment reduces worker exposure to high-risk tasks, minimizes errors, and operates 24/7, potentially reducing fatigue-related accidents. 3D printers allow for safer prototyping, reducing the need for workers to handle sharp materials. These technological advancements contribute to mitigating risks, enhancing monitoring capabilities, and reducing exposure to hazards in construction environments.

8. Results

Table 1: Results [3][25][26]

	Traditional method	AI methods
Staff evaluation	Project planning with long period involves in recruiting.	Automatic skill matching and team making.
Work assignment	Planning tools, team meetings, strategy making, business alignment, one-on-one meetings, time consuming.	Auto tasks assigned and auto availability detection as needed.
Performance monitoring	Qualitative and quantitative data feedback	Automated monitoring
Safety measure	Emergency Response Planning, Site Inspections and Hazard Identification, Safety Education and Training, and Personal Protective Equipment (PPE), etc.	Wearable Tech, 3D printers, autonomous equipment's and drones etc., can be used.
Cost analysis	Excessive purchase is made, and cost cannot be analysed prior to the time, Estimation Techniques.	No excess purchases are made, planned accordingly.
Waste management	Safe disposal and recycling methods are not adopted	Recycling and safe disposal of scrap
Project planning	Information issues, resource productivity, Gantt charts, CPM, scheduling, and resource allocation.	Planning accordingly, considering material availability, time and cost management.

9. Conclusion

The results in Table 1 demonstrate how artificial intelligence (AI) may transform building methods by tackling long-standing problems such as poor productivity, safety, and overspending. The arrival of artificial intelligence (AI) in project management software, such as Autodesk BIM 360 and Procore, is demonstrating uses that improve decision-making, optimize workflows, and allocate resources as efficiently as possible.

Furthermore, this report highlighted how AI is revolutionizing the construction industry. The study projects that increasing the integration of AI would improve operational efficiency while also requiring a shift in the qualifications and abilities of the workforce. Ultimately, the data supports more AI applications in construction projects despite difficulties. The argument for industry-wide adaptation is substantial, given the possible advantages of increased production, safety, and cost-effectiveness. To fully realize AI integration's potential and advance the construction sector toward a

more inventive and sustainable future, coordinated efforts to remove obstacles and develop knowledge in this area are essential.

Future research should explore AI's sustainability and dispute management domains, address resistance to technology adoption, and increase the availability of datasets for AI applications in construction project management.

Integrating Ontology and LLMs for Diagnosis and Repair of Concrete Surface Defects

F. Bahreini[1] and A. Hammad[1]

[1]Concordia Institute for Information Systems Engineering, Concordia University, Canada
fardin.bahreini@concordia.ca, amin.hammad@concordia.ca

Abstract –

This paper explores the integration of a novel Ontology for Concrete Surface Defects (OCSD) with a Large Language Model (LLM), specifically GPT-4o (omni), to enhance defect diagnosis and repair strategies in concrete structures. While LLMs independently offer significant reasoning and natural language capabilities, this study demonstrates the value of combining their interpretative power with the structured knowledge representation provided by OCSD. By enabling adaptive reasoning, where the LLM relies on the ontology's domain-specific relationships and thresholds, and updates its conclusions for specific defect types, the system flexibly adjusts its decision-making based on context. This integration improves diagnosis accuracy, reasoning transparency, and decision-making efficiency. The proposed method is validated through a case study, highlighting the synergy of OCSD and GPT-4o in addressing challenges in defects diagnosis and repair.

Keywords –

Large Language Models (LLMs), GPT-4o, AI-based Reasoning, Concrete surface defects, Ontology

1 Introduction

The durability and safety of concrete structures depend on accurate and timely diagnosis of defects such as cracks, spalling, and delamination. These defects compromise the structural integrity and pose significant maintenance and financial challenges. While traditional methods for defect diagnosis rely heavily on manual inspection and expert judgment, advancements in artificial intelligence (AI) have introduced powerful tools for enhancing this process. On the other hand, ontologies formalize domain knowledge into structured representations, enabling systematic diagnosis and informed decision-making [1–4]. Ontology for Concrete Surface Defects (OCSD), developed in our previous work [5], provides a comprehensive framework for modeling knowledge about inspection, diagnosis, and 3R (Repair, Rehabilitation, and Replacement) processes for concrete defects. However, ontologies, by their static nature, may fall short when applied to context-specific scenarios. Recent advancements have demonstrated that integrating domain-specific ontologies with AI models enhances interpretative accuracy and contextual reasoning [6, 7]. Large Language Models (LLMs), such as GPT-4o (omni), have emerged as transformative AI systems capable of interpreting complex, unstructured data and providing natural language insights [8–11]. LLMs possess exceptional ability in analyzing textual data, which triggered the opportunity of using ontologies alongside such systems. On the other hand, ontologies provide a robust foundation for mitigating challenges like hallucinations in LLM reasoning, ensuring alignment with domain-specific standards [10].

This study presents an integrated framework for diagnosis and repair of concrete surface defects by combining OCSD [5] with the interpretative capabilities of LLMs. By leveraging the ontology's explicit semantic relationships, this integration ensures logical consistency, alignment with domain standards, and a systematic approach to defect classification, causal analysis, and repair recommendations. This synergy enhances both diagnosis accuracy and reasoning transparency, effectively addressing challenges in defect analysis through ontology-driven reasoning and advanced LLM-based interpretative capabilities. The objectives of this study are: (1) to demonstrate how integrating ontology knowledge enhances the LLM reasoning for concrete defect diagnosis and repair; and (2) to showcase the contributions of this synergy in improving response clarity and actionable recommendations. Through a detailed case study focusing on spalling defects, this research highlights the transformative potential of combining ontological frameworks with advanced LLMs, addressing critical challenges in structural inspection and repair. By bridging the gap between structured knowledge representation and adaptive reasoning, this approach provides a robust solution for structural diagnosis.

The paper is structured as follows. Section 2 reviews related works. Section 3 explains the proposed method.

Section 4 presents the implementation. Section 5 presents the testing and evaluation. The last section provides the conclusions and outlines potential areas for future research.

2 Literature Review

Tupayachi et al. [1] introduced AI-powered ontology construction to enhance urban decision-support systems, demonstrating how integrating structured ontologies with LLMs improves reasoning over complex data. Saeedizade and Blomqvist [2] highlighted how semantic frameworks, including ontologies, enhance LLM reasoning layers by formalizing domain-specific requirements. Similarly, Momcilovic et al. [3] illustrated that formal ontologies guide AI reasoning processes, ensuring logical consistency. Existing studies on LLM and ontology integration can be grouped into three primary categories: **(1) LLMs and ontologies in engineering and analytics:** Several works have focused on the integration of LLMs and ontologies in engineering and analytics. For instance, Allemang and Sequeda [12] used ontology-based query checks to improve LLM accuracy in question answering, addressing hallucinations, while Song and Yoon [13] employed ontology-guided LLMs in building performance simulation. Additionally, Wang et al. [7] integrated ontological reasoning into LLM workflows for predictive maintenance and demonstrated how ontologies enhance LLM contextual understanding. Nakajima and Miura [14] incorporated ontological reasoning into LLM workflows for robotic tasks and showcased their ability to improve precision in robotic reasoning. Furthermore, Babaei Giglou et al. [15] investigated LLM-driven ontology learning and evaluated LLMs in extracting structured knowledge. Baldazzi et al. [16] explored domain-specific LLM fine-tuning and emphasized ontological reasoning as a foundation for fine-tuning LLMs in financial tasks. Additionally, Margineda Mangues [17] utilized LLMs with ontologies for procedural content generation, Doumanas [18] applied iterative ontology-driven learning in engineering analytics, and Liu et al. [19] combined domain-specific ontologies with LLM reasoning for dynamic fault diagnosis. **(2) LLMs and ontologies in conversational AI:** Some studies have demonstrated the role of ontologies in enhancing conversational AI through the integration with Large Language Models (LLMs). For instance, Zhang et al. [4] employed knowledge graphs to improve conversational workflows with LLMs, while Palagin et al. [9] used ontology-driven structured prompts to enhance chatbot adaptability. These works illustrate the utility of ontologies in providing context and reducing ambiguity. **(3) LLM for ontology quality assurance:** Research has also explored the application of LLMs in ontology quality assurance. For example, Meyer et al. [8] utilized LLMs for engineering tasks within knowledge graphs, and Tsaneva et al. [20] verified ontology restrictions to address quality issues. Both studies highlight the importance of ontologies in structuring knowledge and ensuring the integrity and accuracy of AI-driven systems.

These studies emphasize that combining domain-specific ontologies with advanced LLM models can provide structured guidance, improving reasoning accuracy, domain alignment, and context-aware decisions. They highlight the value of ontologies as a stable backbone that ensures consistent semantics and prevents hallucination. Our approach distinctively employs specific ontology thresholds to enable flexible reasoning using LLM tailored to structural defect diagnosis and repair scenarios.

3 Proposed Method

LLMs like GPT-4o utilize both their pre-trained knowledge and domain-specific inputs to generate contextually relevant outputs. In this approach, the ontology serves as a structured repository of domain-specific knowledge, providing explicit relationships and predefined thresholds for classification, causal analysis, and repair recommendations. These thresholds standardize defect analysis, ensuring consistency and domain relevance. When interacting with the ontology, the LLM uses its language understanding capabilities to interpret relationships, contextualize attributes, and fill gaps where the ontology lacks explicit details. For example, the LLM complements the ontology by interpreting preventive measures not explicitly defined as a class, leveraging its understanding of related concepts like the 3R approaches. This combination ensures that the LLM's outputs are both guided by the ontology and enriched by its generalized knowledge, improving accuracy, relevance, and interpretability.

The method has the following main modules: **(1) Ontology-driven reasoning module:** Leveraging the OCSD ontology [5], this module maps defect attributes to semantic relationships for classification, causal analysis, and severity assessment; and **(2) Defect analysis and recommendation module:** Integrating the semantic attributes and ontology reasoning with GPT-4o, this module generates actionable insights, including specific repair strategies using the 3R processes. Adaptive reasoning is the ability of an AI system, like an LLM, to flexibly adjust its decision-making based on context and evolving inputs. In this framework, when a user specifies a defect type, the ontology filters and provides the most relevant triplets (i.e., subject–predicate–object relationships), guiding the LLM's reasoning with authoritative standards. The LLM then interprets these insights, filling any gaps with its pre-trained knowledge and updating results as new data or feedback emerge. Through this context-aware interaction,

the system demonstrates true adaptive reasoning, ensuring accurate and tailored guidance for complex, real-world scenarios.

3.1 Ontology-driven Reasoning Module

The OCSD ontology provides a semantic framework for mapping defect attributes to structured classes and relationships. By defining explicit thresholds and categorizing defects into severity levels (e.g., *Light Spalling*, *Medium Spalling*, *Severe Spalling*), the ontology guides logical classification, causal analysis, and context-specific recommendations. Leveraging these ontology-derived relationships ensures that each defect is analyzed consistently and aligned with authoritative domain standards.

A key aspect of this process is the use of dynamically inserted variables, which are generated by querying the ontology for the most relevant defect-specific information. Rather than relying solely on user inputs, the ontology-driven reasoning module filters and selects the appropriate triplets related to the specified defect type. These ontology-derived details, such as severity thresholds, corresponding causes, or recommended repair pathways, are then programmatically inserted into the reasoning prompt at runtime. For example, if the user specifies a spalling defect, the ontology returns the relationships that define the severity classifications, potential root causes, and applicable 3R strategies leveraging the OCSD for structured and domain-specific analysis. These ontology-derived variables (i.e., *{ontology_info}*) appear as placeholders in the prompt and are replaced by the actual, contextually relevant data before the LLM is called. By doing so, the LLM's outputs reflect the most up-to-date, domain-specific information, enhancing the accuracy, relevance, and credibility of the resulting recommendations. The details of the model prompts are provided in Table 1. This table compares the baseline model and the OCSD-enhanced model prompts. The prompt of the baseline model relies only on defects attributes. The OCSD-enhanced model uses the same prompt as the baseline model but adds the provided ontology relationships.

Iterative reasoning further refines the analysis by allowing the system to repeatedly engage with the ontology and LLM as new data or feedback emerge. If the initial recommendations need adjustment, due to changes in defect attributes, updated inspection results, or evolving maintenance strategies, the ontology-driven reasoning module retrieves the related relationships and thresholds. The LLM then reinterprets this ontology-derived information, ensuring that guidance remains current and context aware. In addition to textual outputs, the approach incorporates interactive visualization to depict the relationships and semantic pathways underlying each recommendation. By visually representing ontology-derived nodes (e.g., defect classes) and relationships, the user gains a clearer understanding of how the ontology informs LLM outputs. This graphical representation makes the reasoning process more transparent and intuitive, helping the user rapidly understand why certain causes are inferred or why specific repair actions are proposed.

3.2 Defect Analysis and Recommendation Module

Building on the ontology-driven reasoning described in Section 3.1, this module employs GPT-4o to produce scenario-specific recommendations. By processing the severity classification and ontology-derived details, the model confirms the defect's classification, identifies underlying causes, and suggests actions aligned with authoritative standards. The defined 3R interventions guides the selection of repair strategies, ensuring that each recommendation is contextually relevant and rooted in established domain knowledge.

In this module, the structured prompt integrates the previously retrieved ontology relationships, severity classifications, and any available defect attributes. This

Table 1. Comparison of prompts of baseline model and OCSD-enhanced model

combined input enables GPT-4o to generate logically consistent outputs tailored to the defect's unique characteristics. The resulting analysis provides clear justifications for proposed repair actions, linking them directly to the identified causes and ensuring a transparent, actionable reasoning process.

4 Implementation

This section details the practical implementation of a prototype system based on the proposed method developed using Python. The application integrates various libraries and tools to process input data and interact with the ontology and LLM. It uses *rdflib* to parse and query the ontology, *networkx* and *pyvis* for building and displaying interactive relationship graphs, and *OpenAi* for calling the GPT-4o model's API. The developed prototype system based on the method supports automated data ingestion, dynamic ontology querying, and adaptive reasoning calls to GPT-4o, ensuring an integrated and reproducible environment for experimentation and analysis. Figure 1 shows the developed user interface.

In this implementation, supplementary image analysis was conducted using GPT-4o API for extracting defect attributes. The image of a concrete surface with dimensions of $1m \times 2m$ was uploaded into the developed application for analysis. The GPT-4o model was accessed through the OpenAI API and tasked with identifying the major defect type, classifying individual defects, and extracting their attributes considering the surface dimensions. Figure 1(a) shows an example of an image that was fed to the system. Five spalls have been detected, and their attributes have been extracted automatically. Figure 1(b) shows the extracted defects attributes from the image analysis. For instance, Defect 4 has the width of about 20 cm, height of about 2 cm, and depth of about 2 cm, with features including being the widest defect, and having uneven erosion and discoloration. The defect attributes are used as input for the prompt as explained in Section 3.1. These attributes could also be derived from point cloud semantic segmentation results, as demonstrated in prior work [21], or obtained through on-site inspections and entered to the system by the user as shown in Figure 1(c). As the type of the detected defect is spalls, Figure 1(d), enlarged in Figure 2, shows only 38 classes and 9 instances for the threshold's related to spalls, which were automatically extracted from the complete ontology which has a total of 335 classes.

5 Testing and Evaluation

Table 2 provides two example comparing responses from the baseline and enhanced models for two defects (Defects 1 and 4). Condition assessment utilizes predefined severity thresholds encoded in the OCSD, which are compared with the defect dimensions, ensuring consistency in defect evaluation. Furthermore, by leveraging the OCSD ontological relationships, our reasoning module identified plausible cause-and-effect relationships between specific defect characteristics and

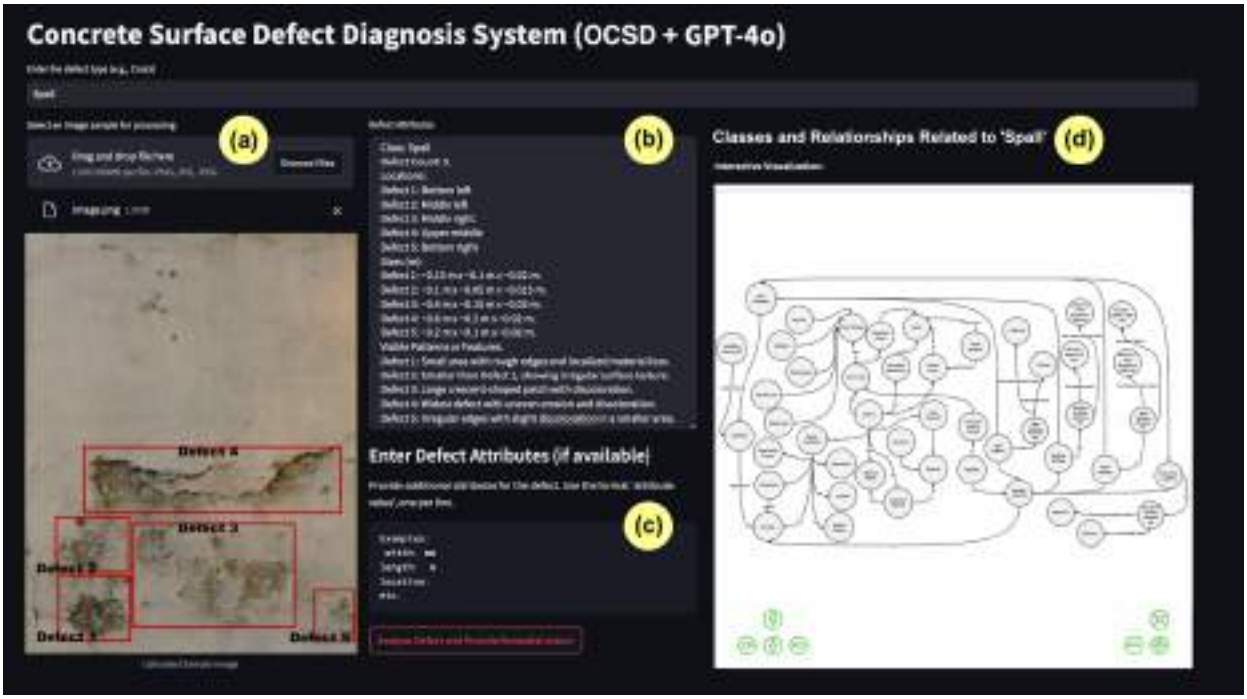

Figure 1. User interface of the prototype system

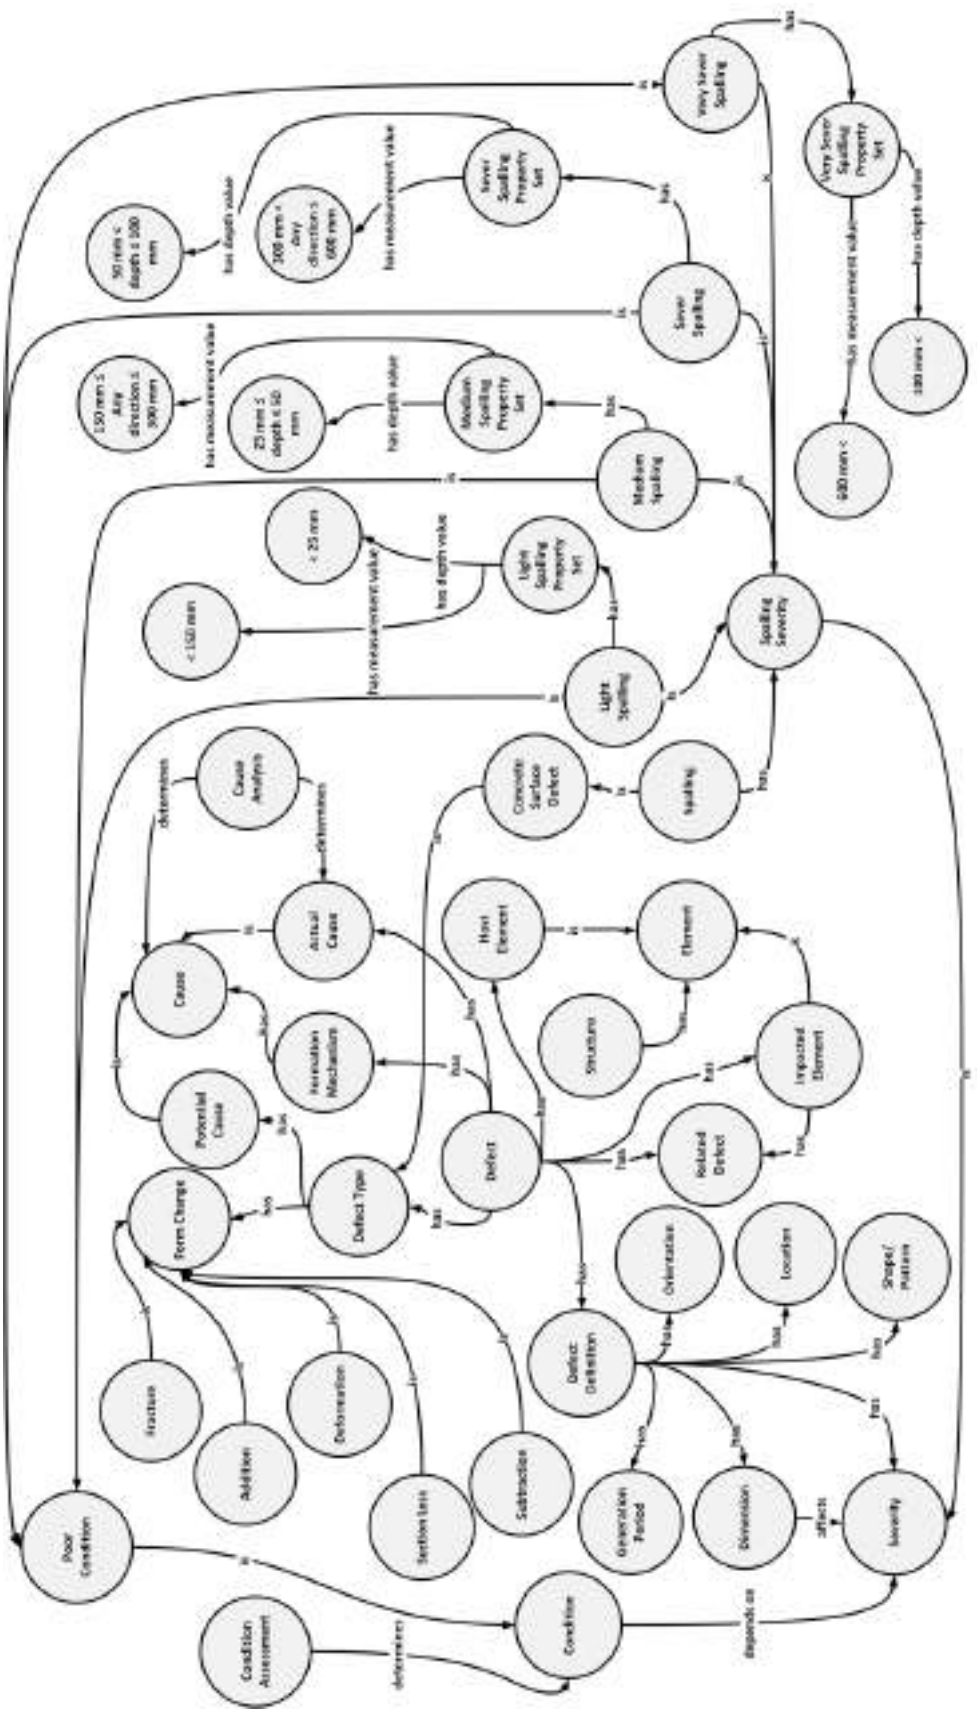

Figure 2. An example of interactive visualization of OCSD-derived thresholds for condition assessment of spalling

their underlying factors. For Defect 1, the baseline model classified Defect 1 as low severity due to its irregular texture and smaller size, attributing it primarily to minor surface erosion. However, the OCSD-enhanced model identified it as *medium spalling*, emphasizing moisture ingress and chemical exposure as contributing factors. By leveraging ontology-driven thresholds, the enhanced model provided a more refined diagnosis, recommending surface treatments aligned with spalling severity classifications. This result, representative of the model's performance across five spalling defects, illustrates how incorporating authoritative knowledge sources leads to more contextually accurate and actionable guidance. The enhanced model, informed by ontology-derived insights, provided a precise classification for Defect 4 (*severe spalling*) rather than a generic label, identified clearly documented causes, and recommended standards-based repair and preventative measures. For example, severe spalling in Defect 4 indicated more advanced chemical degradation, potentially from de-icing agents, and the impacts of freeze-thaw cycles. Informed by the ontology-derived severity classifications and guided by the 3R interventions, GPT-4o provided well-structured repair strategies for each identified defect. For Defect 4, characterized by severe spalling, the system advised partial or complete replacement, reflecting the severity of material loss and structural compromise. Preventative strategies here focused on advanced sealants and thorough, regular inspections to forestall recurrence. Across all defect cases, GPT-4o's recommendations demonstrated logical consistency with the severity levels, causal insights, and the repair and preventative strategies defined by the ontology.

The effectiveness of integrating the ontology-based framework with LLMs in diagnosing and repairing spalling defects is evaluated focusing on four key metrics: severity classification, cause identification, remedial actions, and preventative measures. Partial matches were counted to accommodate natural variations in phrasing, ensuring a comprehensive assessment. These metrics and their associated terms are drawn from recognized standards and guidelines, as defined in *Concrete Structures Protection, Repair and Rehabilitation* [23] and the *Ontario Structure Inspection Manual (OSIM)*

Table 2. Comparison of responses of baseline model and OCSD-enhanced model for Defects 1 and 4

Baseline model response	Enhanced model with OCSD response
Defect 1 - Location (Bottom-left), Smaller Area with Rough Edges *1. Severity Classification:* Low Severity: The defect has irregular surface texture, indicating initial material surface degradation. *2. Potential Causes:* Surface Erosion: Possibly due to weather exposure or inadequate curing. Concrete Quality: Inadequate surface finishing leading to early wear. Reasoning: Smaller size with irregular texture suggests less severe environmental action, likely a surface treatment issue *3. Remedial Actions:* Surface Sealing: Apply a protective surface sealant to prevent moisture ingress and further surface degradation. Rationale: Sealing restores the integrity and protects against environmental exposure. *4. Long-term Preventative Measures:* Proper Curing: Ensure adequate curing times to enhance surface strength and durability. Surface Coatings: Use protective coatings to shield surfaces from weather and chemical attacks.	**Defect 1:** Location: (Bottom-left) Size: Medium size with irregular surface texture and discoloration. *1. Severity Classification: MediumSpalling* Justification: Medium defect size and discoloration indicate a severity higher than LightSpalling. OCSD's MediumSpalling class involves more notable material loss and visual deterioration. *2. Potential Causes Inherited from OCSD:* (a) Moisture ingress with discoloration: Medium-severe discoloration effects. (b) Chemical exposure: Such as chloride ingress from de-icing agents. *3. Remedial Actions (3R Approach):* Surface treatments or coatings: Justification: Mitigation needed for discoloration and moderate material loss. OCSD guidelines suggest comprehensive surface treatment for medium spalling. *4. Long-term Preventative Measures:* (a) Improved concrete mixes: Utilize mixtures that resist spalling agents. (b) Surface cleaning protocols: Avoid accumulation of harmful substances. *5. Summary:* Medium spalling needs enhanced materials addressing both aesthetic and structural perspectives, guided by OCSD, while providing clarity on moderate deterioration and avoiding overly extensive solutions.
Defect 4 - Location (Upper-middle), Widest, Uneven Erosion, Discoloration *1. Severity Classification:* High Severity: With uneven erosion and discoloration, it heavily impacts the structural performance. *2. Potential Causes:* (a) Severe Moisture Exposure: Possible long-term exposure to water and chemical agents. (b) Aggregate Reaction: Alkali-silica reaction could cause both erosion and discoloration. Reasoning: The extent and characteristics suggest significant chemical and physical reactions over time. *3. Remedial Actions:* (a) Comprehensive Repair: Extensive removal, including damaged rebar sections, repair or replacement of rebar, and concrete restoration. (b) Rationale: Ensures safety by restoring both external and internal structural components. *4. Long-term Preventative Measures:* (a) Enhanced Concrete Mixes: Use mixes resistant to alkali-silica reactions and high moisture environments. (b) Improved Design Drainage: Ensure design includes proper drainage systems to minimize water retention on the surface.	**Defect 4**: Location: (Upper-middle) Size: Widest defect with uneven erosion and discoloration. *1. Severity Classification:* Severe Spalling Justification: The largest area with significant erosion matches OCSD's Severe Spalling definitions due to extensive material loss and discoloration. *2. Potential Causes inherited from OCSD:* (a) Aggressive chemical attack: May be from industrial exposure or pollutants leading to severe erosion. (b) Freeze-thaw cycles: Intensifies with large and deep spalling areas. *3. Remedial Actions (3R Approach):* Partial or complete replacement: Justification: Severe Spalling defects compromise integrity, necessitating comprehensive intervention. Aligns with OCSD suggesting replacement for severe cases. *4. Long-term Preventative Measures:* Advanced sealants and coatings: Prevent further degeneration. Regular, in-depth inspections: Address early signs of similar severe deterioration. *5. Summary:* Severe defects need major structural interventions guided by OCSD, providing well-planned steps for long-term effectiveness over ad-hoc methods.

[24]. By using widely accepted terminology drawn from these references, the evaluation ensures that the chosen terms reflect common engineering practice, rather than proprietary ontology constructs. Specifically, for severity classification, the terms *Light Spalling*, *Medium Spalling*, and *Severe Spalling* were applied. To represent common underlying causes, *moisture penetration*, *freeze-thaw cycles*, *chemical attack*, and *reinforcement corrosion* were selected. For remedial actions, *patch repair*, *surface coating*, and *corrosion inhibitors* were used, while *waterproofing*, *high-performance concrete mixes*, and *regular inspections* served as preventative measures.

Figure 3 shows a bar chart summarizes how frequently each model correctly employs the established key terms. Along the horizontal axis are the four metrics, and the vertical axis indicates the count of recognized terms. The enhanced model's higher bars in categories like severity classification and remedial actions emphasise its stronger alignment with domain standards.

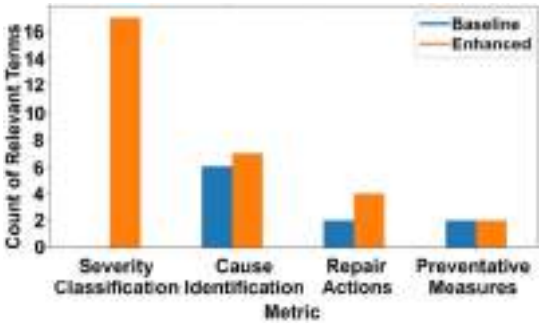

Figure 3. Frequency of correctly identified terms across the four defined metrics

The radar plot shown in Figure 4 provides a holistic view by plotting each metric on a different axis, forming a polygon for each model. The enhanced model's polygon extends further along all axes, especially severity classification, indicating a more balanced and comprehensive understanding of the key concepts.

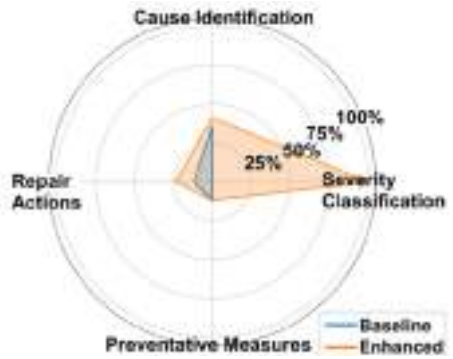

Figure 4. Normalized visual comparison of the models across the four defined metrics

Overall, by grounding the evaluation in accepted industry references [17] and OSIM, and using figures that clearly illustrate comparative performance, the analysis demonstrates that ontology integration significantly enhances the LLM's ability to produce structured, accurate, and actionable responses for spalling defect diagnosis and repair.

6 Conclusions and Future Work

This paper introduced an integrated framework for diagnosing and analyzing concrete surface defects by combining ontology-driven reasoning with the advanced interpretative capabilities of an LLM, GPT-4o. The proposed method is implemented in a prototype system integrating OCSD with GPT-4o API. By leveraging GPT-4o for ontology-based reasoning, the system provided a comprehensive and context-aware workflow for defect classification, causal analysis, and repair planning. A case study involving spalling defects demonstrated the efficacy of this approach. The proposed framework offers several advantages over traditional methods: (1) The use of OCSD ensures that diagnosis outputs are grounded in structured domain knowledge, enhancing the reliability of the results; and (2) The integration of defect attributes and ontology relationships enables specific and context-aware repair strategies. The evaluation results indicate that integrating domain-specific ontologies, such as the OCSD, significantly enhances the depth, accuracy, and actionability of LLM-generated outputs for defect diagnosis and repair.

Despite the promising results, the following limitations were identified: (1) While the OCSD provides a structured framework for defect classification, it may not comprehensively cover all defect types, causes, and repair strategies. (2) The quality of the LLM's outputs depends on prompt clarity and data specificity, making it susceptible to errors if attribute extraction is incomplete or ambiguous. (3) Reliance on the OpenAI API for GPT-4o introduces computational costs, and scaling up the system for broader deployments could increase these expenses, posing challenges in resource allocation. To address these limitations, future research can expand the OCSD by incorporating additional classes and relationships, thereby improving coverage and versatility. Fine-tuning domain-specific LLMs and integrating advanced 3D semantic segmentation techniques can enhance the precision of attribute extraction and severity assessment. Moreover, exploring strategies to optimize computational costs, such as deploying more efficient models or refining interaction protocols, would support sustainable, large-scale implementation.

Abstract –

The movement and posture variability of construction machines is a significant contributor to safety hazards on construction sites. Even when a machine's location is fixed, its moving parts may collide with on-site personnel or objects, leading to injuries or production loss. Accurate estimation of 3D full-body poses of machines can enhance safety by providing more precise spatial information. This paper proposes a framework to estimate 3D full-body poses of construction machines using deep neural networks (DNNs) and stereo vision. The proposed framework employs an entropy-based active learning method to select informative images for fine-tuning the DNN model for 2D pose estimation. 3D poses are estimated through stereo camera calibration, coarse-to-fine stereo matching, and triangulation. Experimental validation using an excavator model achieved an average error percentage (AEP) of 12.11%, demonstrating the framework's feasibility for enhancing safety management.

1 Introduction

Construction sites are inherently hazardous environments, with a significant portion of accidents caused by heavy machinery. In the U.S., the construction sector employed nearly 7.5 million workers in 2018 [1], contributing to 19.77% of all occupational fatalities. Similarly, Hong Kong reported 3,726 work-related injuries in the construction sector in 2018 [2]. Heavy machinery movement is a major source of these hazards, and the interaction between workers and machines exacerbates the risk. Therefore, monitoring machine movements is critical for improving safety. Although surveillance cameras are increasingly used, safety monitoring is often still performed manually, which can be inconsistent and subject to human limitations. Automated monitoring offers a promising solution, but most current systems focus on 2D pose estimation, which is insufficient for evaluating 3D safety conditions. For example, 2D pose estimation cannot accurately capture the spatial relationships between machine components and nearby workers or objects, leading to potential safety hazards. In real-world construction sites, machines like excavators have complex 3D movements, and their moving parts (e.g., booms, arms, and buckets) can pose significant risks to workers even when the machine itself is stationary. The current reliance on 2D monitoring fails to provide the comprehensive spatial information needed to assess these risks accurately. This limitation increases the likelihood of accidents, injuries, and production losses in the construction industry. Therefore, there is a critical need for 3D full-body pose estimation to enhance safety monitoring and mitigate these risks.

Previous studies have utilized devices such as Inertial Measurement Units (IMUs) [3] and Global Positioning Systems (GPS) [4], along with surveillance cameras [5-7], to estimate machine poses, yielding satisfactory results. However, systems relying on pre-installed devices often require multiple installations, making them impractical. In contrast, surveillance cameras can be installed once and provide continuous monitoring. While computer vision techniques are becoming popular for machine pose estimation, most existing studies focus on 2D poses, which are insufficient for evaluating 3D safety conditions. 3D pose estimation can offer critical spatial

information about the machine's working zone, which can then be used to assess potential accident risks more accurately. However, research in 3D pose estimation for construction machines remains limited.

This study proposes a framework for 3D full-body machine pose estimation using deep neural networks (DNNs) and stereo vision to provide comprehensive information for safety assessment. The framework uses deep active learning to fine-tune a pre-trained model, minimizing the need for large annotated datasets. The system estimates 2D full-body poses through stereo vision, and 3D poses are derived via stereo matching and triangulation. The proposed method is validated using an excavator model, demonstrating its potential for enhancing safety monitoring on construction sites.

2 Related Works

The safety of construction sites has garnered increasing attention due to its significant potential for spatial-temporal safety analysis and proactive hazard warning. Research in this area focuses on various techniques, including machine pose estimation, transfer learning, and stereo vision, to enhance the monitoring of construction machines and workers.

2.1 Pose Estimation of Construction Machines

Pose estimation is critical for determining the precise working areas of construction machinery, which is essential for safety monitoring. Traditionally, sensors such as Inertial Measurement Units (IMUs) [3] and Global Positioning Systems (GPS) [4] have been employed for estimating machine poses. Tang et al. [8] used IMUs to estimate 3D poses by measuring angles between machine components. While these approaches provide useful data, they are limited by the need for additional hardware installation, increasing costs. GPS and Ultra-Wide Band (UWB) systems [9] offer some advantages but also require extra infrastructure.

In contrast, computer vision has emerged as a cost-effective alternative, utilizing cameras already installed on construction sites. Early computer vision approaches focused on 2D pose estimation. Azar and McCabe [10] proposed a method based on surveillance video analysis using support vector machines (SVMs) and histogram of oriented gradients (HOG). This was later improved by integrating machine skeleton extraction [5] and real-time location systems (RTLS) [11], achieving more accurate 2D pose estimations. However, these methods relied on handcrafted features that required careful design, which limited their generalization capability. More recently, deep neural networks (DNNs) have been used for 2D pose estimation due to their ability to handle complex patterns in data [7]. But it relied solely on 2D image processing, lacking the ability to provide depth information for safety monitoring.

3D machine pose estimation is essential for spatial-temporal safety analysis, as it provides information about the machine's working zone. While stereo vision and DNNs have been combined to extend pose estimation to 3D, existing studies have primarily focused on partial poses, such as the boom, bucket, and stick of excavators [11,12]. These methods fail to provide a comprehensive understanding of the full-body poses of machines and their dynamic working regions, which are crucial for safety evaluations.

2.2 Transfer Learning for On-Site Monitoring

A challenge in machine pose estimation is the need for large, annotated datasets to train reliable DNN models. Manual annotation is time-consuming and costly, particularly for dynamic environments like construction sites. To address this, transfer learning has been explored as a method to apply knowledge gained from one domain to another, reducing the amount of new data required. Transfer learning has been used in construction safety applications, such as Kolar et al.[13], who applied VGG-16 for safety guardrail detection, and Kim et al. [14], who utilized pre-trained models for machine pose estimation.

However, transfer learning approaches often overlook the quality of the annotated data. A smaller high-quality dataset may yield better results than a large poorly annotated one. To improve data efficiency, deep active learning (DAL) has been introduced. DAL allows the model to iteratively select the most informative images for manual annotation, thereby minimizing the amount of data required. Kim et al. [15] demonstrated the effectiveness of DAL in on-site machine detection, showing that it improves DNN performance while reducing manual labeling efforts. While DAL has shown promise, its application in construction machine pose estimation remains underexplored.

2.3 Stereo Vision for On-Site Monitoring

Traditional single-camera systems often struggle with capturing 3D information due to projection and occlusion effects. Stereo vision, which uses multiple cameras, offers a promising solution by reconstructing 3D information from 2D images. Stereo vision has been applied in construction monitoring to estimate the 3D locations of workers and machines [16]. However, previous studies have only provided rough estimations of 3D locations, often ignoring variations in poses during machine operation. Han and Lee [17] explored 3D worker pose estimation using stereo vision, and Yuan et al. [12] applied stereo vision for 3D machine pose estimation by detecting joints and triangulating the corresponding keypoints.

Despite its potential, stereo vision often relies on

conventional computer vision techniques, such as HOG-based detection, which have limitations in processing complex 2D images and extracting useful features. Recent advancements suggest that DNNs can overcome these limitations, as demonstrated by researchers in the robotics field [18], who used DNNs for 3D movement tracking of robotic arms. The integration of stereo vision and DNNs for construction machine pose estimation is a promising avenue for improving 3D safety monitoring, but further research is needed to fully explore this approach.

3 The Proposed Framework for 3D Full-body Pose Estimation of Construction Machines Using Deep Neural Network and Stereo Vision

This study proposes a framework for automatically estimating 3D full-body poses of construction machines using deep neural networks (DNNs) and stereo vision, based on images and videos. As illustrated in Figure 1, the framework consists of two sequential modules: (1) 2D machine pose estimation and (2) 3D machine pose estimation.

The process begins by capturing stereo images (e.g., *N* images) using a multi-camera system. Each image is processed independently by a DNN-based 2D pose estimation model to extract keypoints of the machine's pose, along with the confidence probability for each keypoint. Given that collecting a large annotated dataset is time-consuming, deep active learning is utilized to select images with the most informative pose keypoints for fine-tuning the pre-trained 2D pose estimation model.

After fine-tuning, the model estimates 2D machine poses, which are then passed to the 3D pose estimation module. This module first performs stereo camera calibration to obtain intrinsic and extrinsic parameters for triangulation. Using the results from 2D pose estimation, coarse-to-fine stereo matching is applied to refine pose keypoints. Finally, triangulation calculates the 3D coordinates of the machine's poses based on keypoint correspondences and stereo camera calibration results.

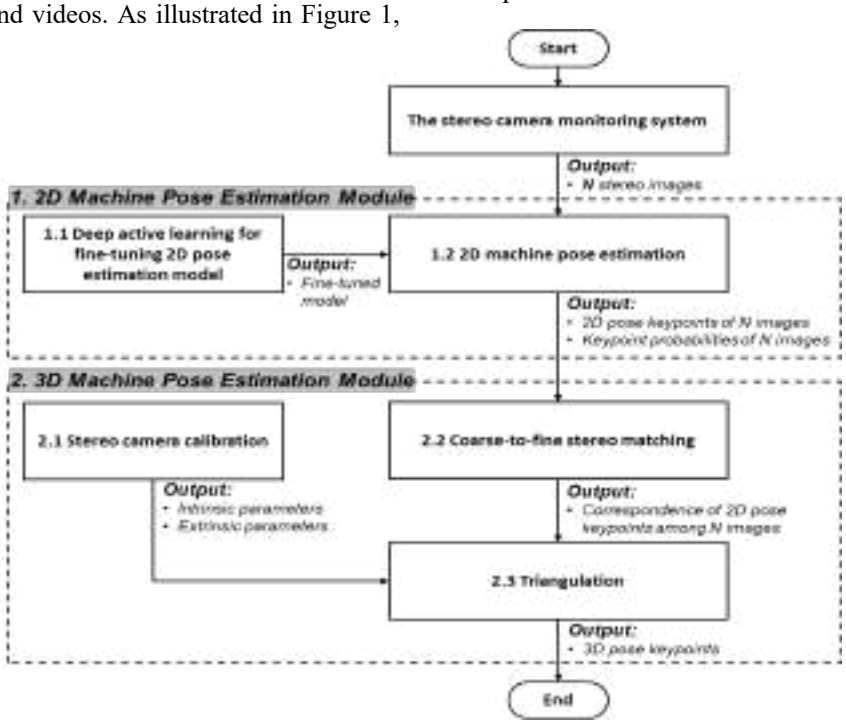

Figure 1. The overall framework for 3D full-body pose estimation of construction machines using DNN and stereo vision.

3.1 2D Machine Pose Estimation Module Based on Deep Active Learning

The goal of this step is to fine-tune a DNN model for 2D machine pose estimation using a small set of manually annotated images collected from new construction sites. Deep active learning (DAL) is employed to reduce the number of training images required by selecting the most informative images for manual annotation. This iterative process involves transferring knowledge from a pre-trained model, which is initially trained on a general dataset of construction sites, to new construction scenes. Figure 2 presents the typical flow of deep active learning for this process.

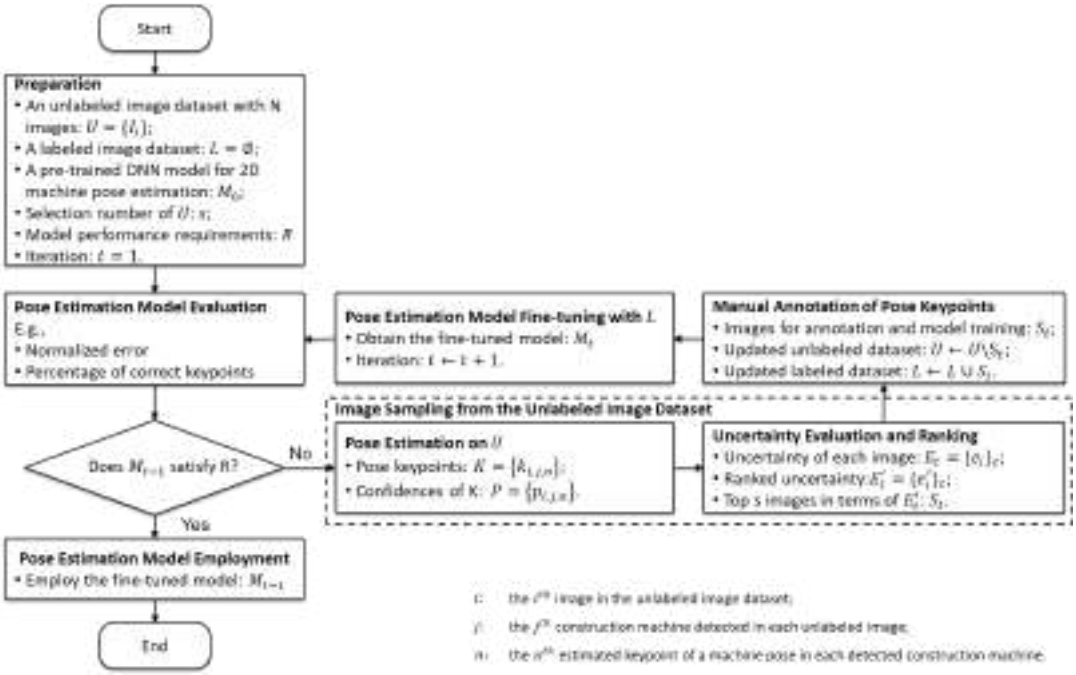

Figure 2. Workflow of deep active learning for fine-tuning the 2D pose estimation model.

Preparation. The first step involves preparing an unlabeled image dataset (U), containing images collected from a new construction site. The dataset should include a variety of machine operations to ensure the model can generalize to new images. The pre-trained DNN model (denoted as M_0) is used as the starting point to avoid training from scratch. Pre-defined performance evaluation metrics, such as Normalized Error (NE) and Percentage of Correct Keypoints (PCK), are also defined for model performance assessment.

Pose Estimation Model Evaluation. The performance of the current model is evaluated using the NE and PCK metrics. If the model does not meet the required performance thresholds, the process moves to the next step.

Pose Estimation on U. The 2D pose estimation model is applied to all images in the unlabeled dataset, and the model estimates keypoint coordinates along with the confidence score for each keypoint.

Uncertainty Evaluation and Ranking. The uncertainty of each image is evaluated using entropy-based uncertainty evaluation, where higher entropy indicates more uncertainty. Images with higher uncertainty are considered more informative and are selected for manual annotation.

Manual Annotation of Pose Keypoints. Expert annotators manually label the selected images, providing keypoint annotations. These annotated images are then incorporated into the labeled dataset.

Pose Estimation Model Fine-Tuning with L. The labeled dataset is used to fine-tune the DNN model. The model weights are updated using forward inference and backpropagation.

Pose Estimation Model Employment. Once the fine-tuned model satisfies the performance requirements, it is employed for 2D pose estimation on images and video frames from the target construction site, completing the deep active learning process.

3.2 3D Pose Estimation of Construction Machines Using Stereo Vision

The 2D poses estimated in Section 3.1 are used in the 3D pose estimation module. Stereo camera calibration is firstly performed to obtain necessary camera parameters, and then coarse-to-fine stereo matching is applied to the 2D pose keypoints. This module generates 3D poses by triangulating the keypoints from the stereo images.

3.2.1 Stereo Camera Calibration

Stereo camera calibration is an offline process that provides intrinsic and extrinsic parameters for the triangulation process. The intrinsic parameters describe internal camera characteristics, such as focal length and image center, while extrinsic parameters describe the relative position and orientation of the cameras in the stereo system.

3.2.2 Coarse-to-Fine Stereo Matching

The goal of stereo matching is to find corresponding points from images with different viewpoints. The proposed coarse-to-fine stereo matching strategy includes:

(1) *Keypoint-Based Coarse Stereo Matching:* This step matches pose keypoints based on semantic information (e.g., keypoint type) from 2D pose estimation, as shown in Figure 4.

(2) *Patch-Based Stereo Matching Refinement:* This step refines the stereo matching by using a sliding window approach to compare template patches with search regions to find the best match for each keypoint and therefore improve keypoint correspondence accuracy (as shown in Figure 5).

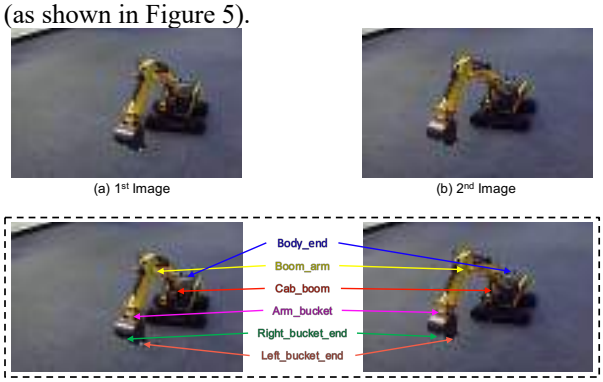

Figure 4. Keypoint-based coarse stereo matching using two stereo images as an example.

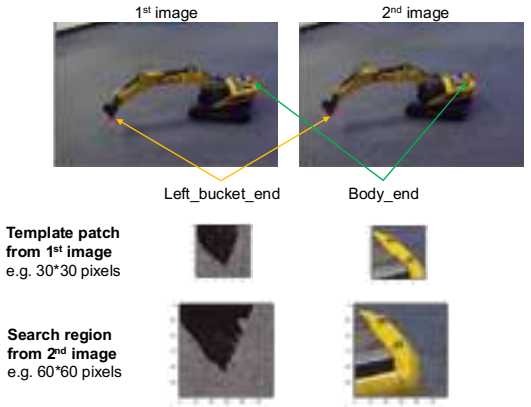

Figure 5. Illustrative examples of template patches and search regions.

3.2.3 Triangulation

The triangulation process uses the refined stereo matching results and camera parameters to compute the 3D position of each keypoint. Linear triangulation is used to solve the equation and determine the 3D coordinates.

4 Validation of the Proposed Framework

To validate the feasibility of the proposed framework, this study uses excavators as illustrative examples due to their numerous movable components and complex poses during construction tasks. The pose keypoints of excavators are defined as shown by the dark dots in Figure 6.

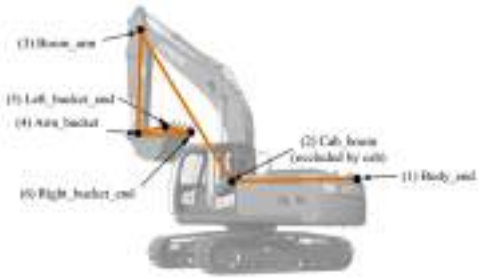

Figure 6. Pose keypoints of construction machines defined in [7].

4.1 Experiment Data Preparation

Due to the lack of a dataset for 3D machine pose estimation using stereo vision, an excavator model was used to create a controlled dataset. The excavator model, a 1:14 scale full-metal replica, performs various tasks like digging, dumping, and swinging during earthmoving operations. The actual lengths of the movable components were measured (see Table 1). A ZED stereo camera was used to capture stereo images, as illustrated in Figure 7. For real-world deployment, cameras can be mounted on fixed infrastructure to ensure a stable and unobstructed view of the construction site. The height and angle of the cameras should be optimized to minimize occlusions and maximize coverage of the working area.

Table 1. Component lengths of the adopted scaled-down excavator model

Component name	Cab	Boom	Arm	Bucket
Length (mm)	180	300	155	80

Figure 7. ZED camera fixed in a holder to capture stereo images of working construction machines.

During data collection, the excavator model mimicked real-world activities such as digging, swinging, and dumping. The dataset consists of 1069 pairs of stereo images, which was split into test and non-test classes using stratified random sampling, with 20% (214 images) allocated for testing and the remaining 80% (855 images) for fine-tuning the DNN models.

4.2 Implementation Details

Two main experiments were conducted to evaluate the framework's performance:

(1) 2D Machine Pose Estimation: This experiment fine-tunes a pre-trained DNN-based model for 2D pose estimation using deep active learning. The model was trained using stereo images captured from Camera 1. The DNN model was fine-tuned using two different sampling strategies: deep active learning (as outlined in Section 3.1) and random sampling.

(2) 3D Full-Body Machine Pose Estimation: After the 2D model was fine-tuned, 3D poses were estimated using both stereo images from Camera 1 and Camera 2. Stereo camera calibration was performed manually, with an overall calibration mean error of 0.051 pixels. The 3D poses were estimated using the proposed coarse-to-fine stereo matching and triangulation method.

The experiments were implemented using Python on Ubuntu 16.04, with an Intel Core i7-6700 CPU @ 3.40 GHz×8 and a NVIDIA GeForce GTX 1080 GPU. The DNN model was built using PyTorch.

4.3 Evaluation Metrics

2D Machine Pose Estimation: The performance of the 2D machine pose estimation model was evaluated using Normalized Error (NE), which calculates the average normalized distance between estimated and actual positions of pose keypoints. The NE formula is defined by Equations (1) and (2).

$$NE = \frac{1}{N}\sum_i \frac{\sum_n \left(\frac{d_{i,n}}{s_i} \cdot \delta(v_{i,n} \geq 0)\right)}{\sum_n \left(\delta(v_{i,n} \geq 0)\right)} \quad (1)$$

$$s_i = \max(h, w) \quad (2)$$

where, s_i is the distance normalization parameter in the i^{th} image; h is the height of the bounding box of a detected construction machine in the i^{th} image; w is the width of the bounding box of the detected machine in the i^{th} image; N is the total number of test images as defined in Figure 1; $d_{i,n}$ is the Euclidean distance between the estimated and the actual position of the n^{th} keypoint in the i^{th} image; $v_{i,n}$ means the visibility of the n^{th} keypoint in the i^{th} image.

3D Machine Pose Estimation: The accuracy of 3D pose estimation was evaluated using Average Error Percentage (AEP), comparing the estimated and actual component lengths using Equation (3). A smaller AEP indicates better accuracy in 3D pose estimation.

$$AEP = \frac{1}{N}\sum_i \sum_{mc} \left(\frac{\left|L_{i,mc}^{Estimated} - L_{i,mc}^{Actual}\right|}{L_{i,mc}^{Actual}}\right) \quad (3)$$

where, $L_{i,m}$ is the estimated or actual component length of the m^{th} component of a detected construction machine in the i^{th} image; mc is the indexing of machine component, which can be Cab, Boom, Arm and Bucket.

4.4 Experiment Results and Discussion

4.4.1 2D Pose Estimation Using Deep Active Learning

Table 2 shows the NE results of the 2D pose estimation DNN model, which was fine-tuned using deep active learning. With 25 iterations and 750 images, the fine-tuned model achieved a 77.82% reduction in average NE compared to the pre-trained model. This method significantly reduced the number of images needed for training, demonstrating its efficiency for on-site safety monitoring.

The experiment also analyzed the impact of different sampling strategies for deep active learning. As shown in Figure 8, the NE value decreases significantly as more images are used for fine-tuning. According to Figure 9, the entropy-based uncertainty evaluation method outperforms random sampling in most cases, showing a more effective strategy for selecting images for training.

Table 2. Normalized error (NE) results of the adopted DNN model for 2D pose estimation

Keypoint	Body_end	Cab_boom	Boom_arm	Arm_bucket	Left_bucket_end	Right_bucket_end	Average
Pre-trained (10^{-3})	88.8644	51.1234	48.5361	59.4094	46.8722	43.9860	56.4653
Final fine-tuned (10^{-3})	17.0047	20.1196	6.2324	8.8859	10.6549	12.2473	12.5241
NE reduction	80.86%	60.65%	87.16%	85.04%	77.27%	72.16%	77.82%

Table 3. Results of the proposed 3D pose estimation framework

No	Keypoint-based coarse stereo matching	Patch-based stereo matching refinement		Average error percentage (AEP) (%)					Estimation speed (ms/sample)
		Basic setting (template patch from a random camera)	Confidence-based template patch selection	Cab	Boom	Arm	Bucket	Avg.	
1	√	√	√	**12.86**	10.64	**8.68**	16.26	**12.11**	133.21
2	√	√	×	14.13	10.22	9.16	**15.80**	12.33	132.60
3	√	×	×	18.25	**9.12**	9.71	19.91	14.24	131.61

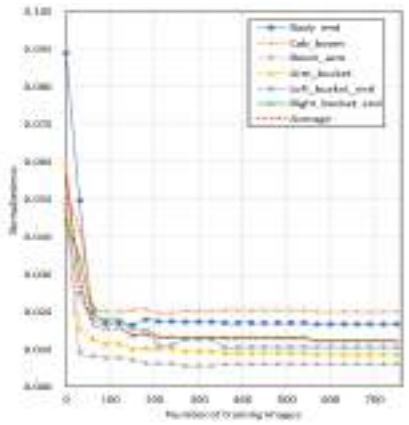

Figure 8. NE curves during deep active learning for 2D pose estimation with different pose keypoints.

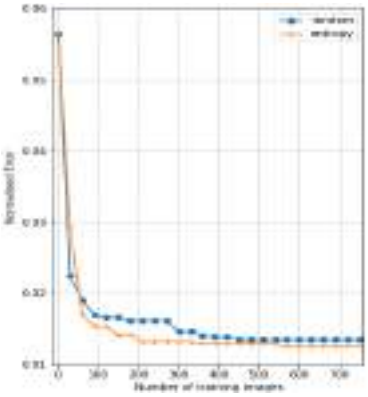

Figure 9. NE curves during deep active learning comparing entropy-based sampling and random sampling.

Table 4. Comparison between the results of the proposed framework and those of previous studies.

No	Method	Experimental condition	Average error percentage (AEP) (%)					Estimation speed (ms/sample)
			Cab	Boom	Arm	Bucket	Avg.	
1	Stereo vison for 3D pose estimation (Ours)	Controlled environment	12.86	10.64	8.68	16.26	**12.11**	133.21
2	Deep learning for 3D pose estimation [6]	Real-world construction site	-	39.10	30.70	58.80	42.80	832.00
3	Stereo vision with location data fusion [11]	Real-world construction site	-	9.50	30.00	-	19.75	≈2000
4	Stereo vision without location data fusion [11]	Real-world construction site	-	36.38	74.21	-	55.29	≈2000

4.4.2 3D Pose Estimation Based on Stereo Vision

Table 3 summarizes the results of 3D pose estimation using the proposed framework. The average AEP for all machine components is 12.11%. The Boom length achieved the smallest error (8.68%), while the Bucket length had the highest error (16.26%). The estimation speed was 133.21 ms per stereo image sample.

The results indicate that the combination of keypoint-based coarse stereo matching and patch-based stereo matching refinement yields the best AEP. Notably, the Boom length was more accurately estimated in the trial with no refinement, likely due to occlusion issues with the Cab_boom keypoint. Regarding the significant error of bucket length, it is computed using Arm_bucket keypoint and the middle point between Left_bucket_end and Right_bucket_end. The 2D pose estimation results of the three keypoints may not be accurate simultaneously, and such errors will be transmitted to 3D machine pose estimation. Hence, the error may exceed expectations, especially when the 2D estimated result of one of the three keypoints deviates from its actual position.

Table 4 presents a comparative analysis of the proposed framework against prior studies, including Ref. [11], which integrates 2D estimation with stereo vision and location data fusion for 3D pose estimation. This comparison serves as a valuable benchmark for evaluating 3D pose estimation performance in the context of construction machinery. The proposed framework demonstrates a substantial improvement in AEP over earlier methods. Specifically, it achieves an AEP of 12.11%, significantly surpassing previous studies that reported AEPs of 42.8%, 19.75%, and 55.29%. Moreover, the estimation speed of the proposed framework is much faster compared to previous studies.

5 Conclusions

Construction site safety is increasingly important due to the hazardous and labor-intensive nature of the industry. Monitoring 3D full-body poses of heavy construction machines is essential for mitigating potential hazards, as it provides comprehensive spatial information about the area occupied by on-site machines. This study proposes a framework for 3D full-body pose estimation of construction machines using deep neural networks (DNNs) and stereo vision. By fine-tuning a pre-trained model with deep active learning and using a coarse-to-fine stereo matching approach, the framework efficiently estimates 3D machine poses based on 2D images. Key contributions include:

(1) Achieved an average AEP of 12.11% for estimating full 3D poses, offering a more comprehensive safety evaluation than partial poses in prior studies;

(2) Applied DNNs to extract features for triangulation, improving efficiency over traditional methods;

(3) Developed a deep active learning strategy with entropy-based uncertainty evaluation, reducing the need for large training datasets;

(4) Proposed a coarse-to-fine stereo matching strategy

to minimize 2D pose estimation errors in 3D estimation.

The framework shows strong potential for jobsite application. However, its real-world deployment faces challenges such as visual complexities, occlusions, lighting variations, and environmental factors. Future work will focus on scaling up the framework for real-world deployment through pilot testing, developing data collection protocols for heavy machinery, and enhancing robustness with techniques like multi-view systems. The framework will undergo rigorous testing in complex jobsite environments and be integrated with real-time safety alerts to detect unsafe actions of construction machines and notify relevant workers and managers instantly.

Abstract –

This work presents the 3D Printed Construction Digital Workflow (3DPCDW) as a novel platform for integrating AEC with 3DPC, Digitalizing the 3DPC flow from basic elements to execution with robotic manipulators, while augmenting design through inherent tectonic expression of this technology. This platform was tested producing programs for the Gananoque Project, a 26 houses development in Canada by Horizon Legacy© (HL), delivering a successfully printed envelope. Thereafter, Gananoque Project positioned 3DPCDW as a foundational framework for future 3D developments.

Keywords –

Digital Design; 3D Printed Construction; Robotic Manipuator; Architectural Projects.

1 Introduction

The construction industry has seen significant technological advancements, with the integration of digitalization and automation within the framework of Industry 4.0 [1-2] conceiving a massive implementation of robotics and 3D printing[3].

In this context, Additive Manufacturing (AM) materializes a volume stacking layers by deposition, is primarily valued for its ability to enable complex designs and structural optimization [4-5]. The application of AM with cementitious materials was originally first explored by Khoshnevis [6], and it is characterized by implementation of integrating computational, 3D printing specific and material knowledge[7-9].

1.1 The Gananoque Project

The Gananoque project is a housing development consisting of two townhouse blocks of 26 houses in total. The perimeter walls of the first floor were 3D-printed, and the second storey was conventionally built with timber. For HL this project represents the first onsite proof-of-concept deployment of 3DPC.

The Gananoque project invokes a series of challenges for Digital Design Workflow (DDW), particularly on the delivery of large walls and a narrow footprint. 3DPCDW assisted successfully those challenges by retroactively interacted with 3DPC team during this early exposition to the construction site.

1.2 Digital Design Workflows

DDW's for 3DPC are parametric CAD software platforms that develop printable building data from AEC sources, principally architecture. The minimum feature is the *slicing* process, or the process of describing a 3D object into evenly displaced 2D horizontal layers along the Z-axis. At its maximum, DDW's features can become a holistic development platform, in terms of building design orientation to 3DPC, producing a *Digital Conception* of the model through parametric or generative means. These can include evaluations and simulations of all the pertinent building performances, as well as *AEC-3DPC Integration* of building geometry, material information and machinery details. This bonding of Digital Design, AEC and 3DPC Knowledge into different *Parametric Modeling* (PM) environments can potentially transform DDWs in a state-of-the-art holistic CAD platform for exploring 3DPC capability to set a new standard in buildings[11]; however, that will depend also in DDW's *Generalization* and *Flexibility* aspects in terms of scope of use and adaptation to building context vicissitudes.

Current DW use different manifestations of the BIM paradigm[12], that will tend to conventional but highly AEC-integrated development software such as *Revit*® (*BIM Systems*), and other *Free-Form Parametric CAD* software such as *Rhino*® with *Grasshopper*®.

1.2.1 BIM Systems

BIM software are AEC digital tools that optimize management and collaboration in construction projects, while enhancing efficiency, reducing errors, and improving communication among key stakeholders[12]. 3DPC implementations in BIM are characterized by a powerful AEC-Integration into the design development and process, as well as a *Generalization* of the DW task because of their more robust, consolidated and construction-oriented *Parametric Objects* (PO).

Some remarkable BIM-DW include integration of the *triad*: building geometry, material information and machinery details, to produce efficient and accurate printing codes; while accessing into BIM's *Industry Foundation Classes* [8-9]. This, on the contrary of *brute-force* slicing approach, is an access to the core of BIM PO showing more integration and digitalization.

1.2.2 Free-Form Parametric CAD Approaches

Other DW systems, based on PM platforms such as *Grasshopper©*, are more suitable for producing an impact on Design Conception of the 3DPC project. This lays in their power of *Digitalization* based on the control of complex geometry and performance, through a myriad of plugins for addressing performance, interoperability with robots, etc. Nevertheless, few of the registered DWs for 3D are holistic but project-specific in terms of Design Conception. One of a few examples is Cascone et. al. that developed an entire residential multi-story building streamlining *User Mapping*, *Structural Optimization* and *Daylight Analysis* while outputting printable programs[13-14]. Other authors focus on building specific elements for 3DPC, including in their DW's Finite Element Analysis (FEA) Topology Optimization (TO) for iterate in a generative buckle that ends on 3DPC program delivery [15-16]. Breseguello et. al. using FEA for directly generate toolpath, expressing 3DPC performance-oriented tectonics [17].

2 3DPC Digital Workflow (3DPCDW)

3DPCDW is a workflow and a platform that develops building envelope walls throughout a sequence of tasks for transforming architectural geometry to 3DPC program for execution (see Figure 3), while integrating 3DPC subsystems such as pump, robot manipulator and *Wall Construction*. As a different approach from [7-9] *triad*, In the context of 3DPCDW, *Wall Construction* correspond to an AEC 3DPC Knowledge cluster that integrates constructive, structural and material variables, constraints and recipes.

2.1 Challenges for DW in the context of the Gananoque Project.

The references mentioned in the introduction set some starting positions for creating a DW. We have further acknowledged them as 5 major challenges to face and implement with 3DPCDW, to tackle the challenges of the Gananoque Project.

- **Integration:** Integrating 3DP expertise with digital design and the use of robotics in AEC. This approach minimizes manual intervention and improvisation while delivering supplementary materials efficiently.
- **Digitalization**: Effective digital representation of the 3DPC construction. Controlling the process for the digital development of walls, detailing key design features, execution phases and program delivery.
- **Generalization**: Produce a persistent and robust Workflow and Platform for future projects.
- **Flexibility**: Support for fast onsite adjustments and algorithmic adaptations when facing real contextual construction vicissitudes.
- **Digital Conception:** 3DPC powered shaping of the building project, including performance building aspects beyond 3DPC.

2.2 3DPC Systems and Subsystems comprehended

The 3D printing system implemented for the Gananoque project consists mainly of a 7thaxis manipulator called VAL 2.0 and a concrete pumping system (see Figure 1); as well as a series of diverse elements for cleaning, curing and on- the-fly editing.

Material variables such as Layer Height and Setting Time were comprehended inside Wall Construction.

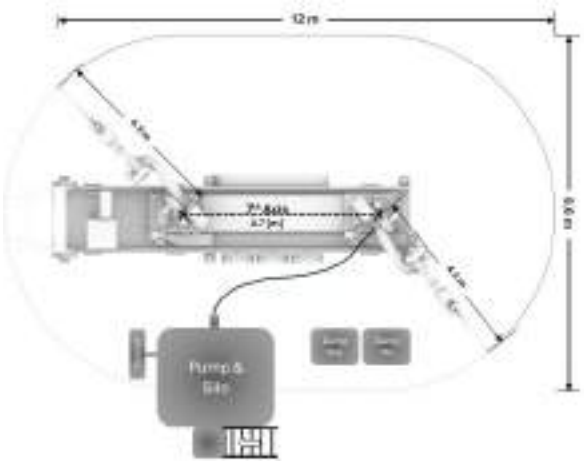

Figure 1. 3DPC System implemented in Gananoque.

2.2.1 VAL 2.0: Large AM Robotic System.

VAL 2.0 is a mobile 7-axis robotic system engineered at HL for CA, based on the ABB IRC 6700 manipulator. Gananoque's EOAT frontal reach is 4.3 [m] maximum and 3.59 [m] for wall heigh, which is amplified to a 12 [m] reach, when combined with the 4.7 [m] linear rail (see Figures 1 and 2). This enables it to execute large rows of walls by concrete and mortar deposition.

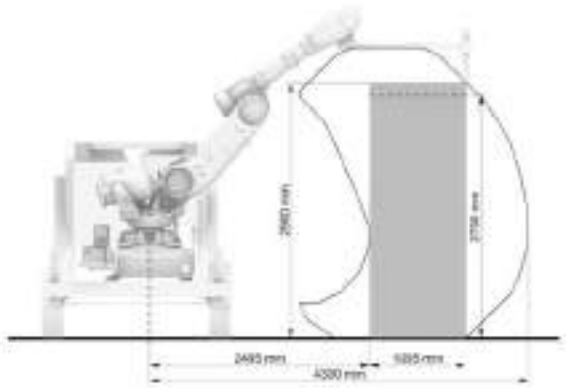

Figure 2. VAL 2.0 vertical reach.

2.2.2 Pumping System

Gananoque Project implemented a double chamber mixer specifically designed for 3DPC featuring a maximum flow of 15 [lt/min], with a 3[m^3] silo for hosting premixes., pushing a min speed of 200 [mm/sec] (see Figure 1).

2.2.3 Wall Construction

In the case of the Gananoque Project, walls consist of a complex ensemble of 3D-printed concrete and rebar, serving both as a self-supporting structure and slab interface. Two wall types were defined: W (normal wall) and *C* (corner wall).

From the perspective of 3DPCDW, wall construction is a 3DPC subsystem with integrated AEC Knowledge from the different parts involved in the Gananoque Project. It is mainly represented by 4 features:

Table 1. Features representing Wall Construction.

Wall Feature	Characteristics	Subtask
Wall Basic Morphology	Exterior, interior, lateral	Architectural Translation
Wall Segregation	Vertical segregation	Toolpath Programming
Wall Complements	Rebars and other structural components	Architectural Translation
Wall Pattern Allocation	Perimeter Projection	Wall Tectonics

3 Digital Workflow

3.1 Architectural Drawing Translation:

The architectural project is initially integrated by processing 2D wall outlines in accordance to *Wall Basic Morphology* to create *Primitive Wall Objects* (PWO). It also generates plans deriving knowledge from *Wall Complements.*

PWOs further simplify wall programming and serve as an interface for future 3DPCDW versions to receive and process other architectural projects.

3.2 3DPC Programming Tectonics

3.2.1 Wall Tectonics

This task augments architectural walls by exploring tectonics unique to 3DPC building components, enabling the Gananoque Project to showcase 3DPC's material expressiveness and structural potentials. As a limited augmentation, it only modifies the projection of the main wythe or the faces of the walls.

Wall Tectonics take the *Perimeter Selection* from the PWOs to add *Wall Patterns* with *Maximum Projection*. This proceeds directly onto toolpath layers as *polylines*, offering more accurate control over the target number economy and enhancing the control of 3DPC tectonic features.

In detail, *Wall Patterns* consist of the allocation of a certain 3D *Relief Pattern* and an associated *Dripping Pattern*. A relief pattern is defined as a volume projected from a supporting background, while a dripping pattern is a tectonic feature that uses a detour at the wythe's intermediate layers with extra peak-point projection, utilizing gravity for the controlled falling of material. The wall pattern modifies this façade gradually, with a maximum nominal value of 55mm to 75mm for wall relief projection, and a 15mm extra projection for dripping patterns. As options, these patterns can create different conjugations or types: *NN* (no pattern), *TN* (wall with relief), *NT* (wall with dripping), *TT* (wall with relief and dripping), that can be suitable for other projects.

3.2.2 Toolpath Designing

This step implements Wall Construction's *Wall Segregation* recipes, defining the suitable toolpath strategies and creating various toolpath types. Toolpath features such as types are essential in programming 3DPC tasks, as they align with the 3DPC system's actual capabilities and limitations, to enhance productivity. They allow for the printing of large amounts of walls and tool changes during the print process.

From this process 3DPCDW delivers four toolpath types: *Sp* (simple print), *Gp* (group print), *DtSp* (double tool simple print) and *DtGp* (double tool group print), according to current *Selected Walls*. While these

strategies offer positive effects, they also introduce complexity and require more control during the print process.

3.3 Toolpath Intervention and Diagnostics

This subtask will evaluate printing programs against VAL 2.0 position for manipulator reaching and printing variables compliance, leading to *Program Delivery*, or requesting changes in previous subtasks such as *Toolpath Designing* or rejecting a current wall group.

This is relevant because it ensures and details reachability, while achieving stable speed that are critical for maintaining precision and quality during printing.

3.3.1 VAL 2.0 Allocation and Movement Control

This subtask will evaluate toolpaths into context, for manipulator reaching, correct movement and printing variable compliance. It consists of an automatic or interactive simulation buckle that allocates the VAL 2.0 for reaching target walls and, if necessary, produce tool rotations for adapting VAL 2.0 range, enabling the inclusion and printing of perpendicular wall parts without collision. If this is still unsuccessful, changes in wall grouping and spilling locations need to be made.

3.3.2 Toolpath Analysis

This step delivers a diverse set of diagrams (see Table 2.) to verify wall and program integrity, along with recommendations for appropriate variable ranges. It serves both the 3DPCDW user and robot technician for identifying potential issues that could disrupt the manipulator's smooth movement and affect quality.

Table 2. Different *diagram* reports for code analysis.

Diagram	Description
Code Speeds	Controls bead width, avoid bulkiness.
Zone Values	Sharpness and aesthetic patterns.
Setting Times	Diagrammed for each layer, section (*feet*) and walls.
Rotation vs. Length	Gradients for speed issues from 6th Axis rotation coordination.
Code Parts and Segregation	Program compliance regarding location, start, finish, and *robotStops* for the whole task.

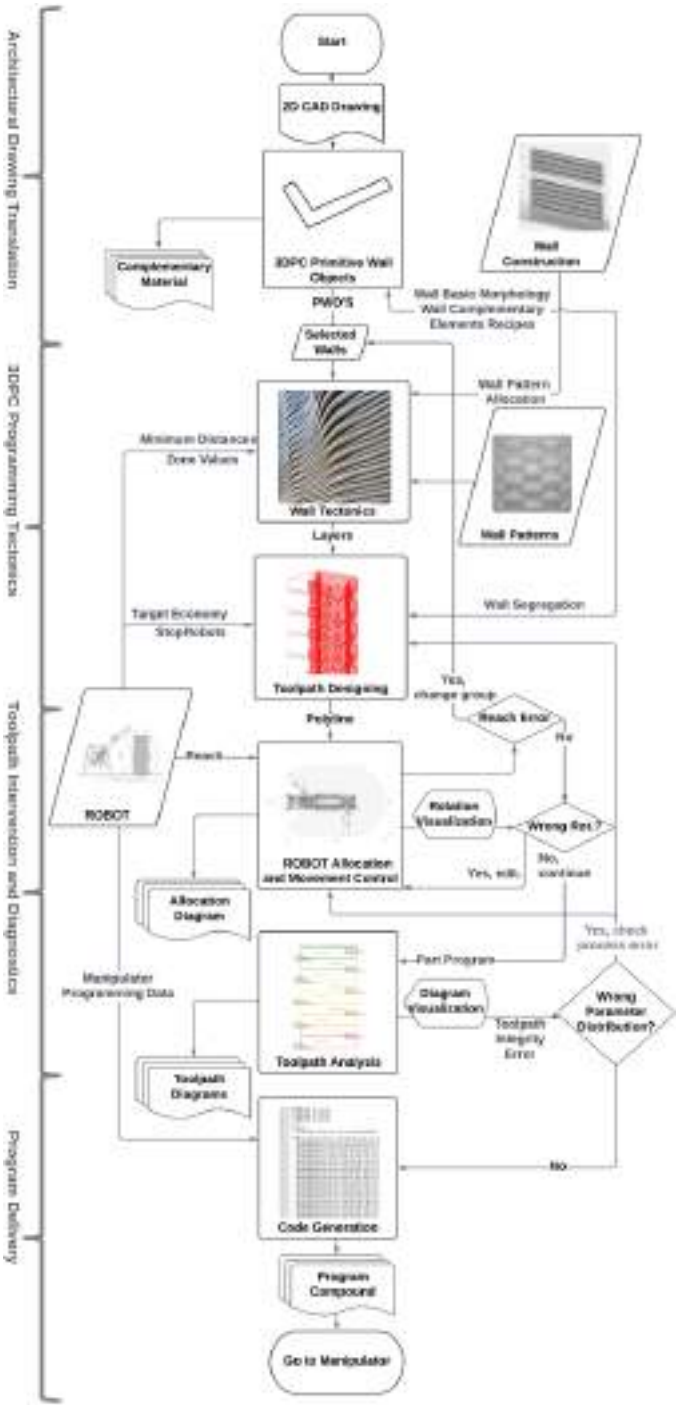

Figure 3. 3DPCDW structure.

Figure 4. Perspective view of 3DPC Walls.

3.4 Program Delivery

This task generates a *Program Compound* consisting of 4 codes for completing a 3DP task through pre-evaluation and printing; first one consists of *Dry-run* and *Probe* programs that enable the robot technician to ensure material and printing task program compliance respectively, where the second one executes the actual printing task (see Table 3).

Table 3. Content of a *Program Compound* delivered by 3DPCDW.

Type	Description
Main	Main routine, for running program parts.
Part	Program part, involving total or a wall(s) portion modulated by sections.
Dry-run	Dry-run file for program compliance through simulation.
Probe	Program with different probe shapes for structural testing.

4 Results

A total of 25 walls were produced to host 26 townhouses in Gananoque. These walls included both straight and corner walls. Results are addressed in terms of: Preparation, Printing Task and Printed Results.

4.1 Preparation: Digital 3DPCDW Outcomes

There were effectively 19 program compounds required to complete the 25 3DPC walls of the project, specifically: {*StSp*=9, *StGp*=2, *DtSp*=4, *DtGp*=8}, Notably *StSp* prints were preferred in the last month due to the capabilities achieved, practicality and compatibility to the period mix. The main task was employed exclusively on prototyping, while the probe was used in 1 of every 5 prints. *Dry-run* and *Parts* were always used.

4.1.1 3DPC as a Platform

As a platform, there were several updated versions (20) of the 3DPDW, most of which were actualized on site during a prototyping period prior to actual printing. This was critical because of unforeseen situations, such as accommodation of slab and key tolerances, quality concerns and integration of observations that enhanced execution. The tasks were represented by:

- **Integration:** AEC Integration through Wall Construction.
- **Digitalization:** Wall to 3DPC program. Representation subtasks.
- **Generalization:** Through Parametric Wall Objects (PWO), the production of wall and group programs.
- **Flexibility:** Through 3DPCDW parametric interaction, ease of 3DPCDW and algorithm edition.
- **Design Conception:** Through Wall Design Augmentation and PWO compliance, generative building envelope solutions can be produced.

Program versioning (20) represented critical modifications of 3DPCW mostly before the definitive printing period. These involved, for example, adding multi tool capabilities, toolpath adaptation to fit the key, including *probe* in program compound, etc. Other non-vital complements such as adding more *diagrams* to *Toolpath Intervention and Diagnostics* were made in parallel on the definitive print period. Second half of the definitive period only required parametric change.

4.2 Printing Task

Changes in wall grouping and allocation from previous codes were necessary for executing the 3DPC task, mainly due to alterations in the printing sequence, which were constrained by confronting the slab and VAL 2.0 possible movement ranges while moving.

Code reaching errors were found where tolerance with actual project were more than 10 mm from the actual VAL2.0 position. This happened typically on large wall groups where maximum reach was needed.

Changing pattern parameters was necessary when

changed mix between Block 1 and Block 2, reducing wall pattern projection.

4.2.1 3D Printing Task

The Printing task integrates 3DPCDW digitalization. Numbers 4 to 7 are repeated 9 times to get an actual height of 2.75 [m] (see Table 4.):

Table 4. 3D Printing Subtasks.

#	3DP Subtask	3DPCDW Related Output
1	Pump preparation	-
2	Calibration & *Dry-run*	*Alloc. Diagram* *Probe* *Dry-run*
3	Material setup	-
4	Printing 1 feet high	*Part*
5	Change of wall or stop	*Part/robotStop*
6	Install rebar compound	*RebarDiagram*
7	Continue printing next wall or next feet	*Part*
8	Stop printing	*Part/robotStop*
9	watering & covering	-
10	Pump cleaning	-
11	Move into next position or close	*Alloc.Diagram*

- **2:** Calibration and Dry-run time. This 3DP task demanded a few program compound modifications.
- **6:** Installing rebar compound. The *Rebar Diagram* gave correct dimensions for rebar cutting and positioning, while considering high tolerances
- **7:** As printing tasks consisted of many *parts*, loading of next program part, on stop robot location. No considerable time was expended from *part*-to-part loading.
- **11:** Robot allocation was made using the *Allocation Diagram*, where differences of less than 10mm were admitted. Time here was considerably high (10 mins min, 1 hour max) especially when going out of the wall row.

4.2.2 Material Waste

Material waste for group prints (*DtGp* and *StSp*) toolpath strategy waste less material, because of the alternation between walls eliminates waiting spilling time. In the case of individual wall printings, robot stops in spillage zones produced waste while waiting on rebar allocation. Results on material use show an average of 15% of material loss.

4.3 Printed Results

4.3.1 Global Dimensional Results

Walls exhibit rough compliance with length and width measurements, with the majority closely matching the required dimensions, resulting in deviations of 0 to 20mm. These results depend on many factors, non standing changes from Block1 to Block2 established significant difference.

4.3.2 Dimensional Results on Beads

Bead widths show some variation but remain within acceptable tolerances. Although the centres were conceived to be 75 mm ± 5 mm, tolerances can go up to 100 mm because of the *Dripping Pattern*. The wall width and side beads were designed to be 85 ± 5 mm; however, the maximum use of the rail increased the bead width because of speed dampening effects.

4.3.3 Aesthetic Results

Aesthetic results were found expressive, with clear Design Pattern gradients for the *Relief* and *Dripping Patterns*. Different mixes yielded different surface finishes, so a lower Projection Parameter for Relief and Dripping was counterweighted with harsher texture, and softer surface finishes were expressed better with a more higher *Projection Parameter* value (see Figure 6).

Figure 5. Perspective detail view of Wall Patterns.

5 Discussion

3DPC Task execution is highly complex and relays mostly on implicit *knowhow* of the professionals involved [18], so 3DPCDW made a great part of this *knowhow* explicit, integrated and functional.

As 3DPCDW also increased its capabilities over time, retrofitting from the context and then be just operated by parameter change, its *Flexibility* and *Generalization* effectively supported Gananoque Project linkage between materiality by means of *Wall Construction*, design and robotics.

5.1 Printing Task Discontinuity and Times

Regarding times expended in the Printing Task, less than 60% is used on the actual 3D print (see Table 4). Number 1 to 3 and 9 to 11 require up to 40% of the Printing Task. There is some potential in automation of subtask 2 and 11 that require more than the 20% of the Printing Task. On both (2 and 11), the use of diagrams and analogue measurements were performed. What was expressed through diagrams in Gananoque may be automated in the future for a more productive performance. Implementation of *Computer Vision* (CV), positioning automation and other technologies such as *Digital Twins* can be implemented for efficiency, however, what's closer to implement depends on multiple factors.

Printing task discontinuity is not desirable. The two major factors are individual prints execution and rebar positioning, both of which are related. The first one can be tackled by printing only wall groups, however changes in mixing setting time expressed bulking, especially in short walls (see Results: Printed Result). The second factor can be solved by robotic *on the fly* rebar positioning or using better rebar design.

5.2 Printed Results Discussion

Results on material use show a general 15% of material loss. This is almost equivalent to constructing four new walls of 3 mt, including losses. A major amount of this material waste can be mitigated through enabling group printing on 3DPCDW, however, this is caused by the pump's inability to produce extrusion stops.

Another pump enhancement regarding quality issues is the coordination with robot speed, or its control directly by the robot program, for solving vertical bulkiness and horizontal extrusion variations.

6 Conclusion

We presented a platform for creating 3D- printed envelopes by means of Automation of 3DPC. The actual successful implementation of this was demonstrated through the printing of the Gananoque project´s wall units. Raising the technological level will hopefully increase 3DPC team and tasks productivity, producing also more precise and cost-effective products.

PM offer precise control over project walls, enabling unique tectonic expressions through toolpath strategies based on 3DPC knowledge. Insights into manipulator rotations and controlled material falls can enrich 3DPC oriented design by shifting the focus from representation to generation, challenging traditional design approaches.

Generalization, through using both persistent geometry and workflow, enables 3DPCDW with the ability for solving a wide range forthcoming 3D projects. Increment in wall object intelligence regarding performative and practical 3DPC oriented design must keep *Flexibility* of 3DPCDW.

3DPCDW Design Conception missed generative means that are ageless on CAD culture, however, less conventional shapes in architectural design weren't possible until *Digital Fabrication* and 3DPC arrived. Frameworks and the notion of *Design Spaces* for exploration linked with actual predictive performance of the 3DPC physical phenomena can empower different and more interesting architectural spaces, 3DPC tectonics, building performance, ergonomics and other explorative but useful built expressions.

Acknowledgements

We would like to thank the ABC Team for their assistance in construction, Frederic Wright for his helpful insights and actions, and Matthew Hill for all the fun and hard work onsite.

Abstract –

Indoor comfort is shaped by many factors, such as thermal comfort, air quality, and lighting. Traditional building-management systems often struggle to bring all these elements together and make real-time adjustments. To tackle this challenge, this study develops a digital-twin platform that combines indoor-comfort assessment with intelligent environmental control to realize real-time monitoring, accurate analysis, and efficient management of various environmental parameters. The system is based on building information modeling (BIM) and incorporates real-time sensors and camera data, which are processed to assess and adjust core comfort factors. These include thermal indices (predicted mean vote and predicted percentage of dissatisfied), air-quality metrics (CO2 levels), and lighting conditions like illuminance and color temperature. The platform utilizes Unity for environmental simulation and visualization, integrating smart lighting and air-quality sensors to deliver real-time feedback and control. To demonstrate its application, the study focuses on three common scenarios in educational settings: classroom mode, relaxation mode, and presentation mode. The system can automatically fine-tune environmental settings to meet specific user needs and enhance comfort. The results show that the system successfully bridges monitoring and control across thermal comfort, air quality, and lighting, offering a practical and efficient solution for smart-building management.

Keywords –

Digital Twin; Building Information Modeling; Thermal Comfort; Indoor Air Quality; Visual Comfort.

1 Introduction

With the rise of modern smart-building technologies, there has been growing attention on creating human-centric indoor environments that prioritize comfort. This includes addressing key aspects like thermal comfort, air quality, and lighting. However, traditional building-management systems often fall short when it comes to real-time monitoring and control of these factors.

Research shows that integrating digital-twin (DT) technology with smart devices can effectively address the limitations of traditional management systems. For example, Tan et al. [1] developed a digital-twin Lighting (DTL) system that merges building information modeling (BIM) and computer-vision technology, enabling efficient energy use alongside real-time environmental control. Their testing demonstrated an impressive 95.15% decision-making accuracy and energy-cost savings of around 79%. Similarly, Leplat et al. [2] applied DT models for multivariate simulations, achieving a balance between visual needs, ecological concerns, and lighting design, further showcasing the versatility of DT technology.

To overcome these limitations, this study proposes an integrated system based on DT technology for assessing indoor comfort and enabling intelligent environmental control. By integrating BIM, Internet of Things (IoT) architecture, and smart devices, the system enables dynamic management and optimization of multiple environmental parameters, ultimately enhancing overall comfort and user experience.

The essence of DT technology lies in seamlessly connecting physical objects, virtual models, and data to simulate and enhance the operational efficiency of physical systems [3]. While BIM has been extensively used during the design and operational phases of buildings, it struggles with integrating dynamic data and enabling adaptive control, particularly when coordinating multiple systems like HVAC, lighting, and fire safety. Additionally, challenges persist in real-time data processing and achieving standardization [4]. As modern buildings place greater emphasis on health and efficiency, the need for dynamic management of thermal comfort, air quality, and lighting has become increasingly important in smart building design. For example, maintaining optimal temperature and air

circulation can significantly boost physical well-being, while lighting tailored to user needs can improve mental health, reduce stress, and enhance productivity in both learning and work environments [5].

International standards play a crucial role in enhancing indoor environmental quality. The EN 12464-1 standard offers detailed guidelines for lighting across various spaces, focusing on achieving a balanced approach to health, psychological comfort, and visual needs [6]. Appropriate adjustment of environmental parameters is essential for ensuring comfort in different scenarios, as ideal color temperature and illuminance levels can vary greatly between relaxation and work settings [7].

Building on this foundation, this study incorporates smart-lighting and environmental-sensing technologies to create a DT-based system designed for the dynamic assessment and control of thermal comfort, indoor air quality, and lighting comfort. The system simulates three common scenarios: classroom mode, relaxation mode, and presentation mode, all aligned with the EN 12464-1 standard. Through experimental evaluations, it assesses the system's effectiveness in enhancing comfort and promoting health. This research offers a practical solution for managing indoor environments in smart buildings and serves as a reference for future human-centered architectural design.

2 System Framework

The system framework is shown in Figure 1. This study adopts the EN 12464-1 lighting standard to design three typical scenario modes: classroom mode, relaxation mode, and presentation mode. Lighting parameters were customized to align with the specific requirements of each scenario. The system integrates BIM with a DT platform to enable comfort simulation and environmental control. For data processing, IoT sensors gather real-time data on temperature, humidity, and carbon-dioxide (CO2) concentration, which are further complemented by image recognition technology for detailed analysis. All data are stored in a PostgreSQL database, supporting data visualization, dynamic updates to environmental models, and intelligent decision-making capabilities. The DT platform dynamically evaluates thermal comfort, indoor air quality, and lighting comfort, focusing on predicted mean vote (PMV), predicted percentage of dissatisfied (PPD) analysis, CO2 concentration heatmaps, and intelligent lighting control. PMV and PPD are important indicators in the ISO 7730 and ASHRAE 55 standards for assessing indoor thermal comfort. PMV represents the average thermal sensation of individuals in a given environment, while PPD estimates the percentage of people likely to experience discomfort. To maintain a comfortable indoor climate, PMV values are generally recommended to stay between −0.5 and 0.5.

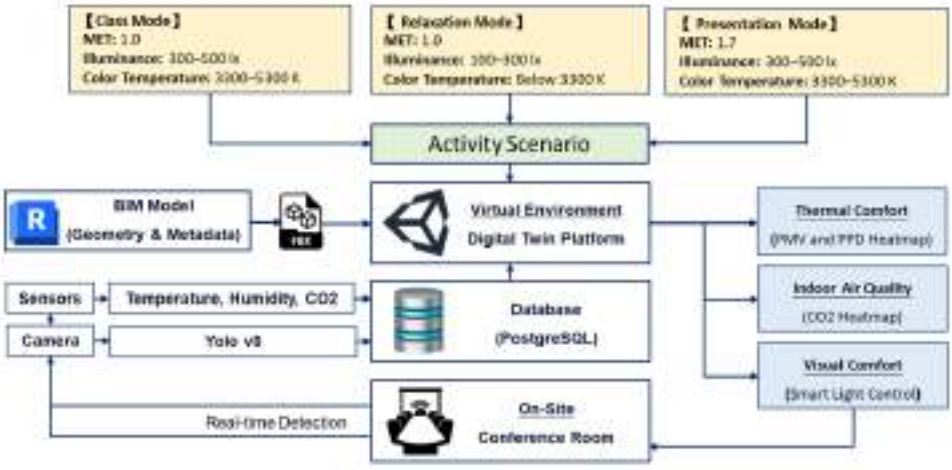

Figure 1. System framework for this research.

2.1 Conventional vs. Proposed Data Acquisition

Traditional DT platforms primarily rely on sensor data and manually entered information to construct digital models. However, this approach can lead to delays in data updates and human errors, making it difficult to reflect real-time changes in the indoor environment.

The proposed method improves automation and data timeliness by using sensors to continuously transmit environmental data, such as temperature, humidity, and CO2 concentration. Additionally, it integrates image-recognition technology to automatically estimate the number of occupants and their clothing insulation levels. These values are then used to calculate thermal comfort indicators like the PMV index. This reduces manual input errors and allows for real-time adjustments to environmental control strategies, making the DT model more responsive to actual conditions. A comparison of

these two approaches is presented in Figure 2.

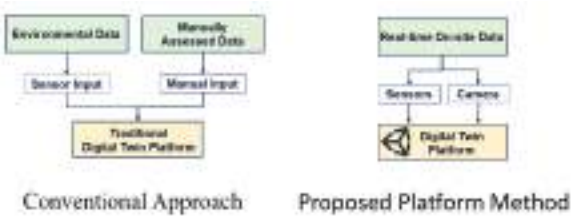

Figure 2. Comparison of two data-acquisition methods.

2.2 Data Processing and Integration Workflow

First, this study uses Revit 2023 to create a BIM model that accurately reflects the characteristics of the experimental environment. To preserve material appearance during the modeling workflow, 3ds Max was used for material conversion. Autodesk-native materials were transformed into Physical Materials to avoid material loss during export. Following this step, the model was exported in FBX format for seamless integration into the Unity platform, supporting the development of the DT.

The system integrates mass data from diverse data sources, including temperature and humidity sensors, CO2 sensors, image recognition tools, and smart lighting systems. Real-time environmental data are obtained from temperature and humidity sensors, while image recognition is applied to detect room occupancy and evaluate clothing insulation levels (Icl), which are then used to calculate PMV and PPD values. Indoor air quality is assessed by monitoring and calculating CO2 concentrations using dedicated sensors. Moreover, the smart-lighting system manages dynamic lighting control based on predefined comfort parameters. This integrated dataset is processed to generate visual outputs, such as PMV and PPD heatmaps, CO2 concentration heatmaps, and lighting simulation scenarios. These visualization results can help users better understand environmental conditions and make informed decisions about adjustments.

The system utilizes continuous data streaming and real-time feedback mechanisms to dynamically adjust indoor environmental parameters, addressing the need for real-time monitoring and enhancing comfort in smart buildings. The following sections will provide a detailed overview of the analysis and implementation methods for thermal comfort, indoor air quality, and visual comfort.

2.3 Thermal Comfort Analysis

This study provides a detailed analysis of indoor thermal comfort primarily by using the PMV and PPD indices to assess comfort under various environmental conditions. The PMV index, introduced by Danish engineer Fanger [8], measures human thermal comfort in a specific setting. It takes into account several environmental factors, such as air temperature, radiant temperature, air velocity, and relative humidity, as well as personal factors like clothing insulation and metabolic rate. The calculation formula is as follows:

$$PMV = (0.303e^{-0.0036M} + 0.028) \times \{ M - 3.05 \times 10^{-3} \times (5733 - 6.99M - p_a) - 0.42 \times (M - 58.15) - 1.7 \times 10^{-5} \times M \times (5867 - p_a) - 0.0014 \times M \times (34 - t_a) - 3.96 \times 10^{-8} f_{cl} \times [(t_{cl} + 273)^4 - (tr + 273)^4] - f_{cl} \times h_c \times (t_{cl} - t_a) \} \quad (1)$$

The parameters used in the formula are summarized in Table 1, while the PMV index categorizes thermal sensations into seven levels, as shown in Figure 3.

For PMV calculation, the following data are obtained from IoT sensors:

- Air temperature (ta): Measured using the AM2320 temperature and humidity sensor.
- Water vapor pressure (Pa): Calculated based on the relative humidity measured by the AM2320 sensor, using the equation (see Equation (2)), where RH represents the relative humidity.

$$Pa = RH \times 10 \times e^{(16.6536 - \frac{4030.183}{ta + 235})} \quad (2)$$

Other parameters are computed programmatically as follows:

- Metabolic rate (M): Assigned based on the type of activity, e.g.,
  1. Resting (sitting): 60 W/m²
  2. Light walking (office walking):100 W/m²
- Mechanical work (W): Assumed to be 0, as typical classroom environments do not involve significant physical exertion.
- Clothing surface temperature (tcl): Determined iteratively based on the mean radiant temperature (tr) and air temperature (ta):

$$tcl = 35.7 - 0.028M - Icl \times [3.96 \times 10^{-8} \times fcl \times (tcl + 273)^4 - (tr + 273)^4 + fcl \times hc \times (tcl - ta)]; \quad (3)$$

- Clothing surface area factor (f_{cl}):

$$fcl = \begin{cases} 1 + 1.29Icl, & \text{if } Icl \le 0.78 \frac{m^2 k}{w} \text{; and} \\ 1.05 + 0.645Icl, & \text{otherwise} \end{cases} \quad (4)$$

- Convective heat transfer coefficient (h_c):

$$\mathrm{hc} = \begin{cases} 2.38 \times |\mathrm{tcl} - \mathrm{ta}|^{0.25} \\ \text{if } 2.38 \times |\mathrm{tcl} - \mathrm{ta}|^{0.25} \geq 12.1 \times \mathrm{Var}^{0.5}. \\ 12.1 \times \mathrm{Var}^{0.5}, \text{ otherwise} \end{cases} \quad (5)$$

Finally, all parameters are applied to the PMV equation for calculation. The resulting PMV values are visualized using a heatmap, providing an intuitive representation of indoor thermal comfort distribution.

In this study, the metabolic rate (M) is a key parameter for PMV calculation and is determined based on the activity-type table from ISO 7730 and ASHRAE 55 standards, as shown in Table 2. The metabolic rates are set as follows for different scenarios: 1.0 MET for classroom and relaxation scenarios and 1.7 MET for presentation scenarios, ensuring accurate PMV calculations. The PPD index is derived from PMV, which indicates the percentage of people likely to feel dissatisfied:

$$\mathrm{PPD} = 100 - 95 \times \exp\left(-0.3353\ \mathrm{PMV}^4 - 0.2179\ \mathrm{PMV}^2\right) \quad (6)$$

When the PMV value is close to zero, the PPD value reaches its minimum, suggesting that most individuals are thermally comfortable. Conversely, as the absolute value of PMV increases, the PPD value approaches 100, reflecting a greater dissatisfaction.

To enhance the dynamics and accuracy of the PMV index, this study integrates YOLOv8 for real-time human detection, recording the number of individuals entering and leaving the space. YOLOv8 is a high-performance object detection framework capable of rapidly identifying and tracking the number and movement of individuals in an environment [10]. These occupancy datasets are used as input parameters for the PMV calculation, enabling real-time comfort evaluation. Additionally, this study employs the UNet (ResNet50) deep-learning model to identify clothing types, such as long sleeves and short sleeves, for calculating clothing insulation levels, thus providing critical data for accurate PMV assessment. The recognition results from UNet are shown in Figure 4.

Table 1. The meanings of the parameters in the PMV formula.

Parameter	Description
M	Metabolic rate (heat generated by the human body)
W	External work (amount of work performed by the body)
t_a	Air temperature (temperature of the ambient air)
t_{cl}	Clothing surface temperature (temperature felt on clothing surface)
t_r	Radiant temperature (mean temperature of surrounding surfaces)
f_{cl}	Clothing thermal resistance (resistance of clothing to heat conduction)
h_c	Convective heat transfer coefficient (efficiency of heat transfer between air and skin)
p_a	Water vapor pressure (pressure of water vapor in the air)
I_{cl}	Clothing thermal resistance (clothing's resistance to heat)

Figure 3. Definitions of PMV values according to ASHRAE [9].

Table 2. Activities corresponding to human metabolic rates.

Activity Type	M (W/m²)	M (MET)
Rest – Lying	40	0.7
Rest – Sitting	60	1.0
Rest – Standing	70	1.2
Office – Writing/Reading	60	1.0
Office – Typing	65	1.1
Office – Walking	100	1.7
Office – Organizing Items	120	2.1

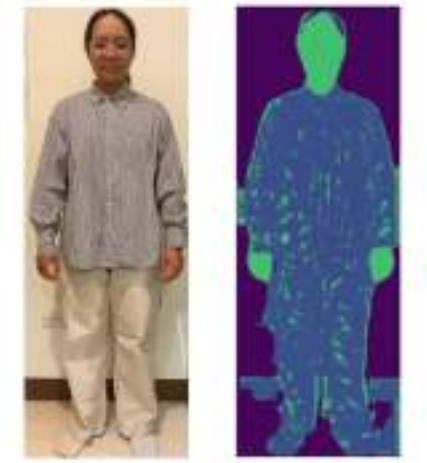

Figure 4. Recognition results for clothing insulation level.

2.4 Air Quality Analysis

This study analyzes indoor air quality by focusing on

the distribution and dynamic changes of CO2 concentrations, which are visualized using heatmaps. This visualization provides an intuitive illustration of spatial CO2 levels across indoor areas, along with real-time concentration trends, thereby providing essential data for assessing and regulating indoor air quality. To further quantify the air exchange demand, the model proposed by Coley and Beisteiner [11] is used to calculate the indoor–outdoor CO2 exchange rate. The calculation formula is:

$$\mathbf{C_t} = \mathbf{C_{ex}} + \frac{\mathbf{G}}{\mathbf{Q}} + \left(\mathbf{C_{in}} - \mathbf{C_{ex}} - \frac{\mathbf{G}}{\mathbf{Q}}\right) \times \mathbf{e}^{-\left(\frac{\mathbf{Q}}{\mathbf{V}}\right)\mathbf{t}}. \quad (7)$$

In this formula, the parameters represent the following: C_t is the indoor CO2 concentration at time t (ppm), C_{ex} is the outdoor CO2 concentration (ppm), C_{in} is the initial indoor CO2 concentration (ppm), G is the indoor CO2 generation rate (ppm/h), Q is the ventilation rate (m^3/h), and V is the indoor space volume (m^3).

To accurately compute air exchange values, the following data are obtained from IoT sensors:

- Outdoor CO2 concentration (C_{ex}): Measured using the DS-CO2-20 sensor, representing the CO2 level in the outdoor environment (ppm); and
- Initial indoor CO2 concentration (C_{in}): Measured using the DS-CO2-20 sensor, representing the initial CO2 concentration inside the space (ppm).

Other parameters are derived from computational models as follows:

- CO2 generation rate (G): Determined based on the number of occupants in the space. Each person produces a certain amount of CO2 per second. In this study, the average human CO2 emission rate is assumed to be 40 mL/min.
- Ventilation rate (Q): The ventilation volume per cycle is set at 50 m^3. Accordingly, the ventilation rate is determined using:

$$Q = \frac{50}{60 \times 60}\ (m^3/s)\ . \quad (8)$$

- Indoor space volume (V): The experimental space has a volume of 118.62 m^3.
- Indoor CO2 concentration over time (C_t): The CO2 level at time t is determined based on ventilation and generation rates:

$$Ct = Q \times T\ (ppm). \quad (9)$$

This study integrates sensor data with computational modeling to accurately capture dynamic CO2 concentration changes within indoor environments, enhancing real-time monitoring and decision-making, as illustrated in Figure 5.

Furthermore, this study combines heatmap visualization with mathematical modeling to develop a dynamic air-exchange recommendation system. CO2 heatmaps provide a spatial representation of indoor CO2 distribution, enabling the system to identify high-concentration areas for targeted air-quality regulation. The air-exchange formula is then applied to predict concentration changes and determine the necessary ventilation rate. For example, in scenarios where CO2 levels exceed the threshold, the system may recommend an exchange rate of 50 m3/hr.

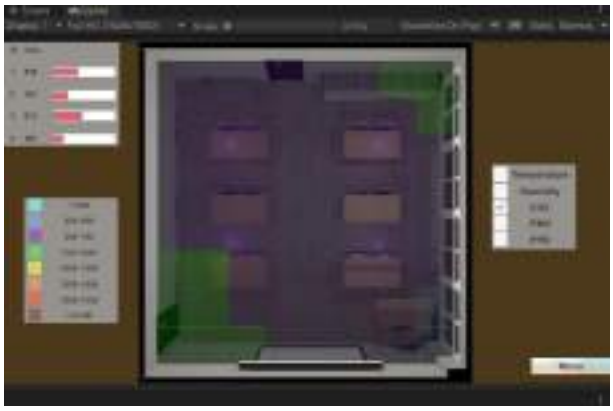

Figure 5. CO2 heatmap.

2.5 Visual Comfort and Intelligent Control

This section focuses on visual comfort and intelligent smart control, combining international lighting standards with advanced technologies to optimize lighting design and enable dynamic management for various scenarios in educational spaces.

First, lighting parameters for each scenario are defined based on the EN 12464-1 standard. The system then adjusts the lighting according to the activity type, aiming to strike a balance between comfort and energy efficiency. To assess the performance of smart luminaires under different conditions, an illuminance meter was used to measure brightness in specific zones. These measurements help map the relationship between actual brightness and illuminance, facilitating in-depth analysis of the lighting environment.

For intelligent control, the system integrates Yeelight smart luminaires with the Unity development platform. By enabling LAN control, the system establishes communication with the luminaires and uses TCP protocols to send commands for remote operation. To make it user-friendly, an intuitive interface was developed, allowing users to easily adjust brightness and color temperature with sliders and buttons. This setup supports the simulation of multiple lighting scenarios, showcasing the design's practicality and flexibility.

2.5.1 Scenario Parameter Definition

To balance lighting comfort and energy efficiency, this study establishes indoor lighting parameters for educational spaces in accordance with the EN 12464-1 standard. Key parameters like illuminance and color temperature are tailored for each scenario and adjusted based on user requirements.

As shown in Table 3 and referencing the EN 12464-1 standard's color temperature classification, neutral tones were selected for scenarios requiring focused attention, while warm tones were used in relaxation modes to promote users' psychological comfort. The standard also offers specific lighting recommendations for educational spaces, as summarized in Table 4. This study uses the abovementioned tables as a reference. Lighting parameters were tailored to meet the needs of each scenario, with detailed configurations presented in Table 5.

Table 3. Classifications of lighting color [4]

Color Appearance	Correlated Color Temperature (TCP) K
Warm	Below 3300 K
Intermediate	3300 to 5300 K
Cool	Above 5300 K

Table 4. Lighting requirements for educational buildings [4].

Type of Room, Task, or Activity	Maintained Illuminance (lx)	Remarks
Classrooms, tutorial rooms	300	Lighting should be controllable.
Lecture hall	500	Lighting should be controllable.
Student common rooms and assembly halls	200	

Table 5. Recommended lighting parameters for different scenarios based on EN 12464-1 standards.

Scene	Illuminance Range (lx)	Color Temperature Range (K)
Class Mode	300–500 lx	3300–5300 K
Relaxation Mode	100–300 lx	Below 3300 K
Presentation Mode	300–500 lx	3300–5300 K

2.5.2 Smart Luminaire Control System

To enable real-time adjustments, this study developed a user interface (UI) on the Unity platform, offering users with an intuitive way to control the luminaires. Through sliders and buttons on the interface, users can instantly adjust the brightness and color temperature, simulating different lighting scenarios based on contextual needs. To further enhance automation and adaptability, this study integrates a real-time occupancy-based lighting mode switching mechanism. Using YOLOv8 for human detection, the system monitors the number of people entering and exiting the space and dynamically adjusts the lighting mode according to predefined thresholds:

- Activation Threshold: When eight or more individuals enter the room, the system automatically switches to Classroom Mode or Presentation Mode, ensuring appropriate illumination for learning or presentation activities.
- Delay Mechanism: A one-minute delay is applied before switching modes to confirm stable occupancy and to prevent frequent unintended fluctuations.
- Deactivation Threshold: If the number of occupants drops to three or fewer, the system transitions to Relaxation Mode, minimizing unnecessary energy consumption when the room is sparsely occupied.

This system integrates automated mode-switching with manual control via the Unity-based UI, enhancing user experience while ensuring optimal lighting conditions and energy efficiency.

To enable remote operation, the "LAN Control" feature is activated in the Yeelight application, allowing luminaires to receive commands over the local network. The system then sends a UDP broadcast request to detect available luminaires, retrieving their IP addresses and ports to establish a stable connection. Once connected, TCP communication is used to transmit JSON-formatted commands, enabling functions such as turning the luminaires on/off, adjusting brightness, and modifying color temperature.

3 Case Study

This study selected the BIM Research Center of the Department of Civil Engineering at the National Kaohsiung University of Science and Technology as the experimental site, covering an area of approximately 45.62 m^2. To simulate the indoor lighting environment, the space was divided into four primary zones, with one light fixture positioned at the center of each zone, as shown in Figure 6. In line with the space's lighting requirements, this study used four Yeelight Moonshadow

550 ceiling lights, evenly distributed to meet demands of visual comfort. This configuration significantly improves light uniformity, reduces glare, and enhances overall visual comfort.

To demonstrate the application of the DT platform, this section uses "Relaxation Mode" as an example to assess indoor comfort through system operation and analysis. The platform integrates real-time environmental monitoring and visualization technologies, enabling a comprehensive evaluation of thermal comfort, air quality, and visual comfort.

For air-quality analysis, the system uses CO2 heatmaps to display real-time comfort levels across different zones, based on continuous data from four CO2 sensors. Additionally, the system offers real-time recommendations for the necessary air-exchange rate based on the monitoring results, allowing users to adjust air quality effectively.

For thermal comfort, the system utilizes the PMV/PPD index to monitor real-time environmental data and employs heatmap visualization to display the distribution of thermal comfort, as shown in Figure 7. Experimental results show that overall thermal comfort within the space stays within standard ranges, thereby satisfying the needs of human comfort.

In terms of visual comfort, under "Relaxation Mode", the lighting is set to a warm, low-light mode with a color temperature below 3300 K. This design effectively reduces the light intensity and creates a relaxed and comfortable atmosphere. The UI of the DT platform displays key parameters such as lighting intensity, color temperature, and thermal comfort metrics, as shown in Figure 8. Experimental results reveal that the virtual images generated by the DT platform align closely with the real-world environment, further validating the accuracy and reliability of the system's data, as shown in Figure 9.

To ensure data accuracy, this study used an illuminance meter to measure the brightness of smart lights and their corresponding illuminance levels in different scenarios. Measurements were taken at the center of the space, as shown in Figure 10.

During the testing, the brightness of the smart lights was gradually adjusted from 10% to 100%, with readings taken every 10%. The recorded illuminance values were then compiled into a reference table, as shown in Table 6, which displays the illuminance distribution in the space under different brightness settings. This approach ensures systematic and precise data collection, providing a robust foundation for lighting comfort analysis and validation of the smart-lighting control system.

Figure 9. Comparison of virtual and physical scenes.

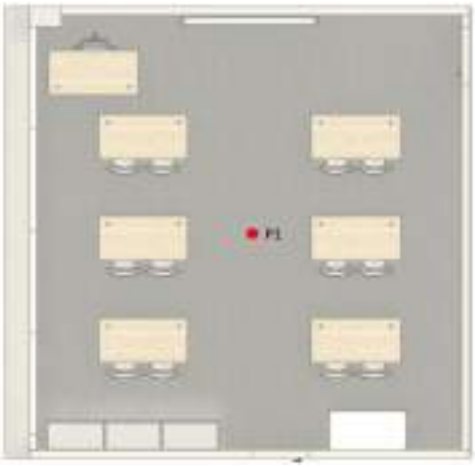

Figure 10. Sampling diagram for illuminance measurements.

Table 6 Measured illuminance values corresponding to lamp brightness levels.

Lamp Brightness (%)	Average Illuminance (lx)
10%	178 lx
20%	235 lx
30%	294 lx
40%	347 lx
50%	397 lx
60%	459 lx
70%	511 lx
80%	564 lx
90%	609 lx
100%	652 lx

4 Conclusions and Future Work

This study used three typical scenarios—classroom mode, relaxation mode, and presentation mode—as case studies to validate the application value and reliability of the digital-twin (DT) platform in assessing indoor comfort conditions. The results demonstrated that the DT platform effectively provides an intelligent and visualized solution for indoor comfort management. It achieves this through real-time environmental parameter monitoring, thermal comfort analysis from predicted mean vote and predicted percentage of dissatisfied, visual comfort assessment, and continuous CO2 concentration tracking. These capabilities collectively improve the quality of indoor environments and accommodate the diverse needs of users across different scenarios.

Future research could broaden the application scope of the DT platform by integrating additional environmental parameters, such as acoustic characteristics and indoor movement patterns. This would enable a more comprehensive assessment and control of comfort. Moreover, with advancements in artificial intelligence and Internet of Things technologies, the incorporation of deep-learning models for user-behavior prediction and adaptive environmental control will be crucial for enhancing the platform's application value. These future developments will enable more accurate and efficient solutions for smart-building management and will contribute to the design of sustainable spaces.

Abstract –

While BIM technology is widely used for designing and managing above-ground construction, its applicability in representing underground soil distribution and properties is limited, which can increase risks during planning and construction. This study integrates Dynamo with on-site drilling data to automatically generate underground soil models, which incorporates key attributes such as moisture content, liquid limit, and N-value. This approach provides engineers with a clear and intuitive representation of soil conditions. The core value of the soil model lies in enhancing safety assessment capabilities, enabling engineers and designers to identify potential foundation construction risks, such as diaphragm wall mud inclusion, in advance. This facilitates optimized designs and reduces hazards during construction. Additionally, the model supports the estimation of excavation volumes for reuse, such as utilizing sandy soil for concrete and asphalt concrete production and clay soil for backfilling, ensuring efficient resource allocation. By integrating BIM technology with geological information, this study not only improves the visualization of soil layers but also enhances the safety analysis of foundation engineering and the efficiency of earthwork applications.

1 Introduction

The construction industry is mainly divided into two key fields: Structural Engineering (SE) and Geotechnical Engineering (GE). In recent years, BIM methods have been extensively developed and applied in the SE field [1]. However, their adoption in geotechnical engineering has been limited, largely because of inherent uncertainties associated with soil and geotechnical parameters, making the modeling process more challenging.

To reduce risks in underground foundation projects, a geological survey is typically the first step [2]. However, when dealing with complex geological conditions, traditional 2D workflows are often insufficient to fully capture geological details [3]. BIM offers a significant advantage, providing a clear visual representation of the entire strata. By doing so, it helps reduce risks, optimize foundation construction, and significantly improve both efficiency and safety [4].

Applying BIM technology to visualize soil layers using integrated data and 3D visualization can considerably improve the clarity of subsurface understanding and enable more precise engineering planning. During the design phase, a visualized soil model can effectively illustrate stratigraphy, groundwater distribution, and variations in soil properties, providing designers with a more reliable and scientific reference. This approach helps prevent design errors or construction challenges arising from insufficient information [5]. BIM technology is intended for use throughout a structure's entire lifecycle, from design and construction to operation and maintenance. Among these stages, understanding soil conditions is crucial, considering that every structure depends on the stability of its foundation [6]. Traditional geotechnical software primarily focuses on soil modeling and analysis but often operates in isolation from broader engineering workflows. In contrast, this study leverages Dynamo to automate soil layer modeling, ensuring that geotechnical data is not only visualized within a BIM environment but also actively utilized for risk assessment. By integrating geotechnical information directly into BIM workflows, engineers can systematically identify potential hazards such as soil instability, excavation risks, and foundation settlement before construction begins. Using an automated bounding box approach, the system detects critical soil layers with unfavorable properties, enabling

a structured and data-driven risk evaluation process. This approach goes beyond merely using BIM for modeling; it establishes BIM as a decision-support tool, enhancing risk assessment accuracy, optimizing construction planning, and improving safety management through automation.

Moreover, specialized geotechnical software such as Plaxis, FLAC, and GeoStudio provide advanced 3D soil modeling capabilities with integrated physical parameters. However, these tools often function as standalone applications, primarily focused on geotechnical analysis. This study utilizes Dynamo and Revit for geotechnical modeling due to their seamless integration with architectural and structural design workflows. By generating soil models directly within the Revit environment, this approach minimizes the need for software transitions, streamlining the modeling process throughout the engineering lifecycle.

Based on these considerations, this study developed a Dynamo-based soil model generation program. The resulting BIM model emphasizes soil layer definitions and properties by integrating the digital terrain model and borehole data. This approach integrates scattered geological data into 3D models that incorporate both geometry and soil parameters. These models provide designers and construction teams with a clear and intuitive visualization of the underground structure and its characteristics.

2 Methodology

Accurate geotechnical risk assessment is challenging due to the complexity and variability of subsurface conditions. Traditional methods rely on borehole data, but inconsistencies in data quality and fragmented soil layers often lead to uncertain risk evaluations. Without a structured approach, these uncertainties can result in inaccurate estimations of soil stability, increasing the risk of ground movements, excavation failures, or foundation settlement. The key issue is not merely generating a 3D soil model but ensuring that it systematically identifies and assesses geotechnical risks before construction. However, due to the variability of soil layers, the flexibility of automated modeling is limited [8], making it challenging to standardize risk assessment and reliably detect hazardous zones, particularly in projects with heterogeneous or discontinuous soil formations.

To address these challenges, this study develops a systematic risk identification framework that integrates borehole data into a BIM-based workflow. By analyzing key parameters such as the liquid limit, N-value, and moisture content, the framework enhances risk assessment by identifying potential instability zones.

The system framework (Figure 1) illustrates the integration of geotechnical data with BIM-based risk assessment. The process begins with field drilling data to obtain borehole depth and soil layer information, while InfraWorks and Civil 3D are used to acquire surface elevation data, generating a digital elevation model (DEM) for an accurate representation of terrain conditions. These data are then imported into Dynamo to automatically generate soil surfaces. However, due to the variability in soil layer structures, the modeling process may fail, resulting in errors or incomplete models. To address this issue, the system utilizes error data from Dynamo for corrections. Excel is used as a data processing tool to filter and adjust abnormal points, ensuring that elevation values align with surrounding soil layers and maintaining model stability and accuracy. The corrected data are then re-imported into Dynamo to generate the final 3D soil model.

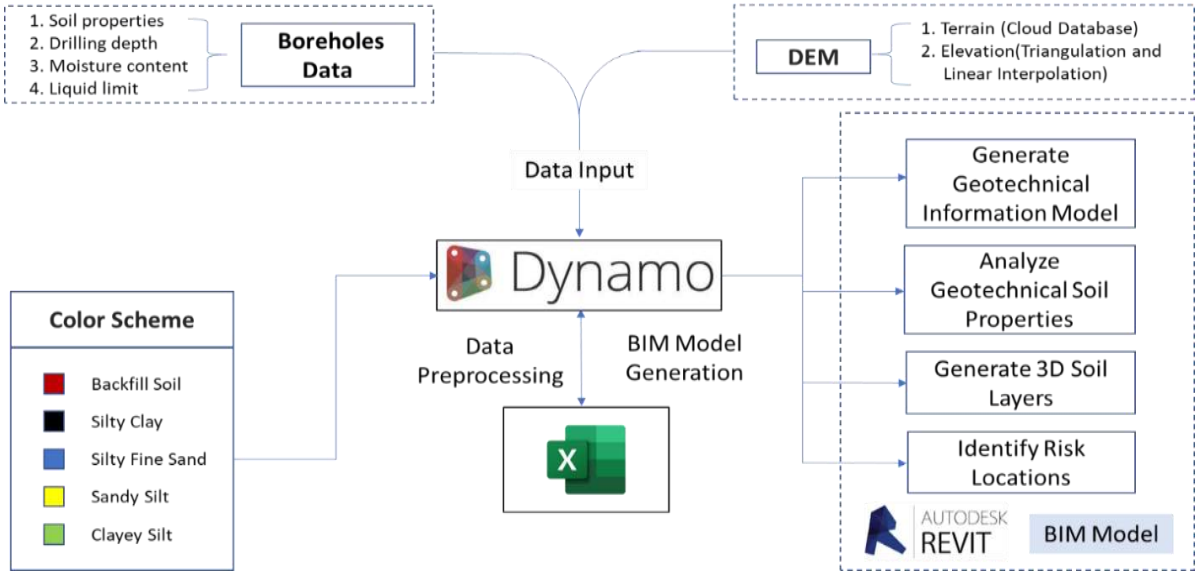

Figure 1. System framework

Once the model is established, a risk identification algorithm embedded in Dynamo is used for automated risk detection. Using the bounding box method, the identifies high-risk zones based on predefined criteria, such as the liquid limit, N-value, and moisture content, and automatically generates bounding boxes around them. These risk zones are then visualized in Revit, providing engineers with an intuitive, data-driven geotechnical risk assessment.

3 Soil BIM Model Generation

3.1 Digital Elevation Model

Before establishing a 3D soil model, accurate surface elevation data must be collected. This data represents ground variations and serves as the foundation for modeling subsurface conditions. It is also essential for calculating earthworks, such as excavation or filling. In this study, tools such as InfraWorks and Civil 3D are used to generate elevation models, automatically generating surfaces from survey data for further analysis.

First, the geographic data in InfraWorks primarily originates from various data platforms and formats, such as Bing Maps and GIS files. This data is used to generate accurate surface models and present detailed surrounding terrain features. InfraWorks can efficiently integrate these data types and automatically generate 3D terrain models. The data obtained in this study using InfraWorks includes elevation points (X, Y, Z coordinates), contour lines, and a triangulated irregular network (TIN) surface.

Second, after obtaining the terrain surface from the InfraWorks model generator, the terrain data is imported into Civil 3D in IMX format. In Civil 3D, the terrain surface is represented as a TIN, which consists of a series of triangles defined by elevation points, where the X and Y coordinates correspond to the planar position and the Z coordinate represents the elevation value of each point. This structure accurately describes the undulations and details of the terrain surface.

In this study, a point set is created using a 20 × 20 grid, generating 20 rows and 20 columns of points with equal spacing across the terrain surface. Civil 3D calculates the Z value (elevation) for each point based on the imported TIN model. The software automatically detects each point's location on the terrain and applies an interpolation algorithm using the Z values of the three points in the surrounding triangle. This assigns an accurate elevation value to each point, ensuring that the terrain's details are accurately represented.

Once the point set is generated, the points are exported as a DEM file in ASCII format, serving as the data foundation for generating points in Dynamo. This process ensures terrain data accuracy and provides the flexibility to adjust grid density based on specific engineering design and data analysis requirements. The result is shown in Figure 2. This terrain model serves as an essential foundation for the automated soil modeling process.

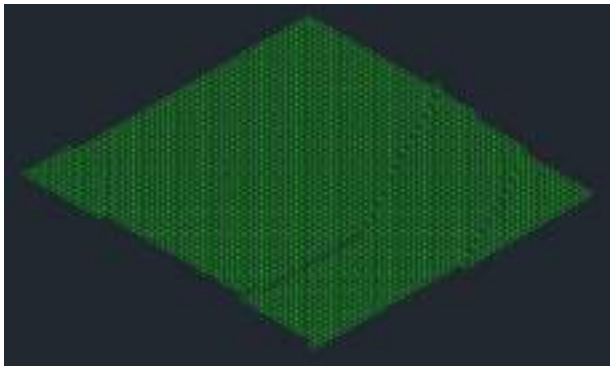

Figure 2. DEM in Civil 3D

3.2 Borehole and Soil Layer Model

After importing the terrain survey data into Dynamo, the data is cleaned by removing invalid characters, extra spaces, and other errors. The goal is to ensure accuracy and consistency, preventing issues in later modeling and analysis stages. Once cleaned, the data is converted into a standardized format, preparing it for subsequent steps.

3.2.1 3D Borehole Generation

The 2D profiles from borehole reports provide detailed soil classification information, including soil types, physical properties, and depth ranges for each soil layer. This data is essential for visualizing the underground soil structure and plays a crucial role in risk assessment and construction planning. In Dynamo, this soil classification data is used to generate depth points, with each point representing the location of a specific soil layer, as indicated in the borehole report.

By identifying these depth points, Dynamo is used to generate a 3D borehole model that illustrates the distribution of different soil layers. This enables clear visualization of the soil structure beneath the excavation area using a color scheme, as shown in Figure 3.

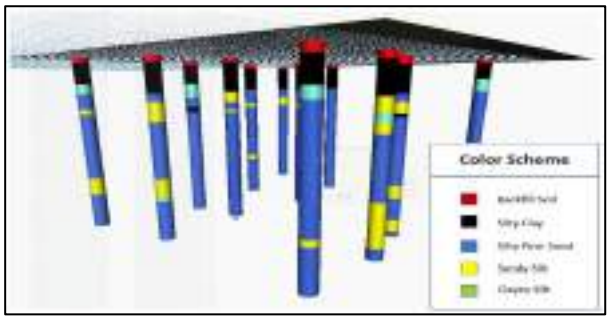

Figure 3. 3D borehole model

3.2.2 Soil Layer Creation

Using color-coded soil classifications and depth information, the distribution of different soil layers can be easily visualized. In Dynamo, soil layers are generated based on depth points from borehole data. These points are connected to form surfaces that represent the structure of the soil layers. The color coding clearly defines the boundaries between different layers, ensuring the model is accurately constructed. The results are shown in Figure 4.

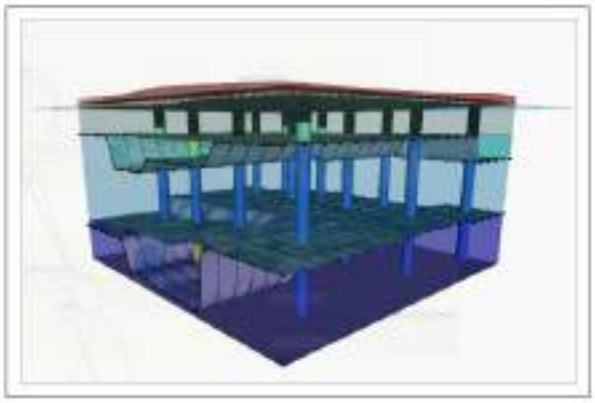

Figure 4. Soil layer model in Dynamo

However, uneven geological data and fragmented soils pose challenges to automated modeling. In some areas, depth points from borehole data may not align properly, resulting in gaps, distorted layers, or unrealistic features in the model. These inconsistencies can cause modeling failures in Dynamo, preventing the successful generation of soil surfaces. To address this issue, error messages from Dynamo are first analyzed to identify problematic data points. When irregular surface formations are detected, the corresponding surface points are extracted and processed in Excel for correction. Using Excel as a preprocessing tool, elevation anomalies are filtered and adjusted by referencing nearby depth values, ensuring smooth transitions between layers. The corrected points are then re-imported into Dynamo, where they form a continuous and stable soil surface. This iterative correction process ensures that fragmented soil layers are more accurately represented and prevents interruptions in the modeling workflow. Once these corrections are made, the final soil layers more accurately reflect the true subsurface, making them useful for further engineering analysis and applications.

3.3 Soil Properties Assignment

In foundation construction, soil properties are critical for ensuring engineering stability and construction efficiency. Parameters such as moisture content, liquid limit, and standard penetration test (N-values) serve as essential indicators for evaluating soil characteristics and potential construction risks. These parameters help identify potential excavation challenges and provide reliable decision-making support before construction begins. Accurately assigning these parameters to the 3D soil layer model significantly enhances the realism and practical value of the model.

Using Dynamo, soil parameters from borehole data are seamlessly integrated into the 3D model through an automated process that matches layer depths and local features, as shown in Figure 5. By assigning soil attributes and incorporating construction data, the model enhances pre-construction decision-making efficiency, reduces risks during construction, and improves project safety and execution. In addition to providing a clear visual representation of the soil structure, the model enables precise volume calculations for land leveling, facilitating the estimation of earthwork quantities.

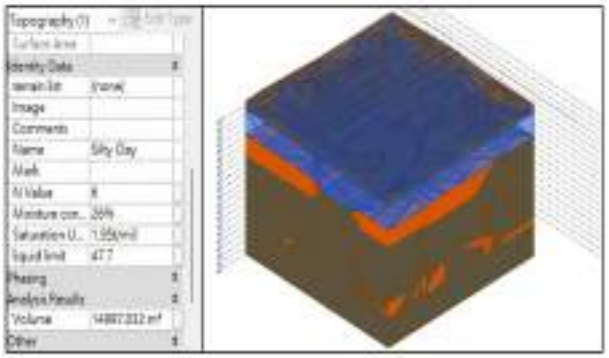

Figure 5. Soil properties assignment

4 Soil Layer Risk Analysis

Integrating geotechnical engineering with BIM technology improves risk assessment and construction management, particularly in addressing soil-related issues that may affect the stability of building foundations. If these problems are not identified and addressed early, they can significantly impact construction safety. Therefore, it is crucial to assess and evaluate these risks at an early stage to ensure a safe construction process.

This study applies BIM technology to soil risk assessment by using 3D models to visualize the underground environment. This approach enables designers to identify potential risks early in the design phase, thereby reducing uncertainty and mitigating risks during construction. Although this method remains in the exploratory stage, it has already demonstrated the potential of BIM technology to enhance risk management and improve construction safety in geotechnical engineering.

This section focuses on the preliminary risk assessment of parameters such as soil moisture content (w), liquid limit (LL), and the standard penetration test (N-value) to identify potential construction risks. These key parameters are used to assess the soil's consistency, stability, and mechanical properties, helping to determine potential challenges during construction.

4.1 Soil Consistency Classification Standards

During construction, potential issues can be estimated by classifying soil hardness using indicators such as the standard penetration test (SPT) N-value, moisture content (W), and liquid limit (LL). This classification provides a solid foundation for assessing construction risks. These indicators help evaluate soil stability and strength, facilitating the prediction of potential problems and the implementation of preventive measures. For example, softer soil layers may require additional support structures, whereas harder layers may necessitate adjustments in construction methods or techniques.

To improve risk identification, this study developed a simplified soil layer table that organizes key characteristics of different soil layers, serving as a quick reference for the on-site construction team. This table enables the team to quickly estimate the properties of various soil layers, reducing the uncertainties caused by soil variations and ensuring improving the flow of the construction process. Additionally, it serves as a reference for the automated modeling in this study, supporting the automation of risk assessment and soil modeling by digitizing and simplifying soil layer characteristics. The classification criteria for clay and sandy soils are as follows:

- Clay Silt (CL, CL-ML)
  - $N \leq 4$ (± 2), $W \geq LL$: Soft clay sediments
  - $N \leq 2$, $W \geq LL$: Very soft clay sediments
  - $N \leq$ 4-15: Medium hard clay
  - $N \geq 15$: Hard clay
- Sandy Soil (SM)
  - $N \leq 10$: Loose sand (from GL-0m to GL-10m)
  - $N \leq 15$: Loose sand (below GL-10m)
  - N = 10-30: Medium dense sand
  - $N \geq 30$: Dense sand

4.2 Relationship Between Soil Properties and Engineering Issues

In foundation engineering construction, the soil characteristics of a site directly influence the stability of construction methods and the quality of the work. Due to variations in soil hardness, moisture content, and stratification, different construction techniques are associated with various engineering risks. Common methods such as diaphragm walls, bored piling, and steel sheet piling may encounter issues such as soil disturbance, leakage, or soil liquefaction under different ground conditions, potentially leading to settlement, tilting, or structural damage to nearby buildings, among other problems.

This section examines the specific problems caused by geological conditions during the construction of diaphragm walls, bored piling, and steel sheet piling. By analyzing case studies, it explores how soil characteristics contribute to engineering issues such as soil disturbance, leakage, and liquefaction.

Studying these cases allows engineers to better understand potential challenges associated with different construction methods in various geological conditions. This insight serves as a valuable reference for both design and construction.

(1) Diaphragm Wall

During diaphragm wall construction in soft clay and silt layers where $N \leq 4$ and $W \geq LL$, or in loose sandy soils where $N \leq 10$, the loose and highly fluid nature of these soils often leads to soil displacement and intrusion into the excavation zone. This can result in the mixing of soil with the diaphragm wall concrete, leading to defects such as soil inclusion, mud contamination, sand infiltration, or large soil lumps. These conditions compromise the structural integrity and load-bearing capacity of the diaphragm wall, degrade construction quality, and may ultimately lead to engineering failures or instability.

(2) Pre-packed Pile

In excavation projects with depths of up to 10 meters, the pre-bored piling method is commonly used for support. However, when constructing in soft soil layers, the cement grout used for the piles—often mixed with fly ash—provides excellent water tightness and high fluidity. While this is beneficial, its high fluidity can also delay the initial setting time, resulting in insufficient early strength. In such conditions, particularly in weak soil layers, the cement grout may leak, leading to a problem known as "Grout Leakage."

(3) Steel Sheet Piles

In excavation projects with depths of up to 15 meters, the steel sheet pile method is commonly used as a retaining structure. However, soil properties play a crucial role in determining both project quality and the safety of nearby structures. Two key issues related to this study are discussed below.

First, when the ground consists of relatively hard layers, such as clayey silt with $N \geq 15 \pm 2$ or sandy soil with $N \geq 20 \pm 2$, driving steel sheet piles becomes significantly more difficult. Forcing the piles into such hard ground may induce large-scale ground vibrations. In stratified ground conditions, if the overall geological

formation is predominantly hard, vibration waves can propagate over a wider range, potentially causing structural cracks in nearby buildings. The impact may extend to a radius of more than 100 meters.

Second, when the ground exhibits a soft upper layer and a hard underlying layer—such as weak clay or silt with $N \leq 4(\pm 2)$ or $W \geq LL$, or loose sandy layers with $N \leq 10$—pile driving may trigger ground liquefaction. In such cases, the localized loss of ground strength may lead to settlement, tilting, or structural cracking in nearby buildings [7].

4.3 Application of Soil Layer Models in Risk Assessment

In this project, a total of 12 boreholes were drilled. For the risk assessment, boreholes located near roadsides or buildings were prioritized, as these areas are more susceptible to external forces and require greater ground stability. Additionally, the borehole with the lowest N-value (indicating the loosest soil) was selected from the drilling data to evaluate ground risks.

As a result, Borehole B9 was chosen as the reference point for risk assessment in this study, with its findings representing the soil conditions beneath the entire excavation surface. While localized variations in soil distribution may exist across the excavation site, selecting the borehole with the lowest N-value provides a worst-case scenario for assessment, facilitating early predictions of potential engineering risks.

This section examines ground behavior during construction using different methods and analyzes the engineering issues that may arise. Particular attention is given to mud-wrapping phenomena in weak soils, sand-wrapping issues caused by sand displacement, and the potential impacts of ground vibrations or liquefaction on nearby structures. These factors can significantly affect construction safety and efficiency, making comprehensive risk assessment essential.

To improve risk evaluation, data is first organized and verified in Excel. After processing, soil layer parameters are imported into Dynamo and assigned corresponding soil properties. Evaluation formulas are then embedded within Dynamo, enabling the automatic generation of bounding boxes to enhance risk identification. Excel was chosen for its compatibility with Dynamo, facilitating efficient data processing and supporting automated risk assessment. The following outlines the methods used for risk evaluation, as shown in Figure 6:

1. For diaphragm walls encountering soft soil with $N<4$ and similar saturated unit weights, the soil layers are nearly identical.
2. Soft clay is characterized by $N \leq 4$ and $W \geq LL$. Therefore, soil with the highest water content and lowest liquid limit is identified as the potential mud-wrapping zone.
3. During diaphragm wall construction, Masako excavation may cause sand to fall, leading to sand-wrapping formation, However, dense sand layers with $N \geq 30$ are less susceptible to this issue due to their high relative density.
4. Driven steel sheet piles with $N > 15 \pm 2$ for clay and $N > 20 \pm 2$ for sand may generate vibrations that could damage nearby structures.
5. When using driven steel sheet piles, soil liquefaction may occur if the strata consist of soft upper layers and hard lower layers.

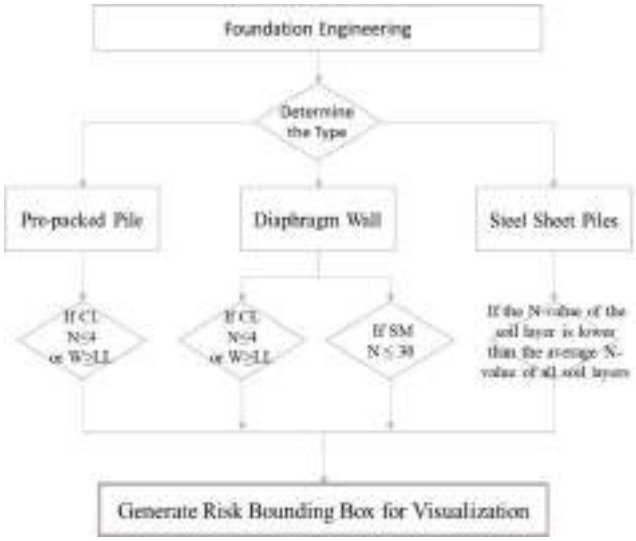

Figure 6. Workflow for generating risk bounding boxes for visualization

This assessment process has been integrated into Dynamo, enabling the automated generation of risk indicators through visual programming. By providing a systematic approach to identifying potential risk areas, this method serves as a reference for engineers in geotechnical risk assessment, design, and construction planning.

In Dynamo, bounding boxes are used to identify risk layers, which are then integrated with the Revit model for automatic generation. This process helps categorize potential risks for each construction method and marks hazardous soil areas with different colors. The visual display enables the project team to identify issues in specific soil layers, such as looseness, leakage risks, or liquefaction, while also providing clear risk indicators. This approach simplifies geological data, allowing the design and construction teams to address key challenges early, plan preventive measures, and reinforce structures. Ultimately, it reduces construction risks and enhances both project quality and safety. The results are shown in the following figure.

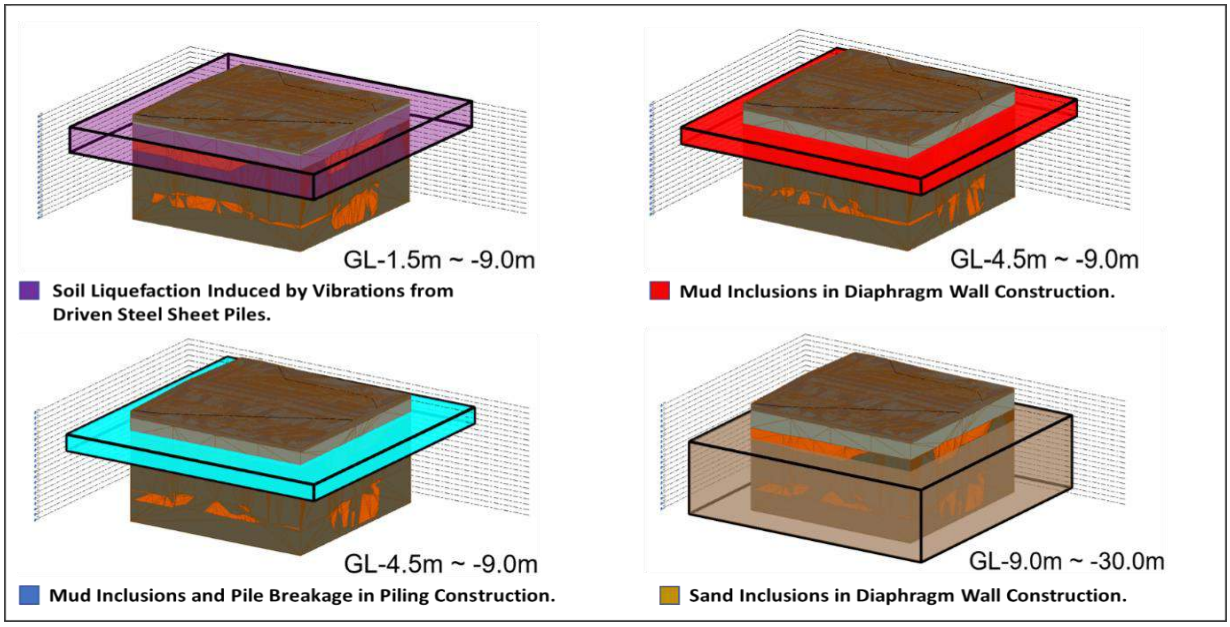

Figure 7. The results of Soil layer risk assessment

Borehole reports indicated that the excavation area primarily consisted of weak clay ($N \leq 4$ (±2), $W \geq LL$) and loose sand layers ($N \leq 10$ (±2)), both of which posed a high risk of instability due to clay inclusion and sand pockets. These unfavorable soil conditions made the site highly susceptible to settlement and collapse, likely contributing to the failure. Had an automated soil risk identification method been applied, these hazardous zones could have been clearly identified before excavation, enabling the project team to implement appropriate mitigation measures and reduce the risk of failure.

This case highlights the practical necessity of integrating automated soil risk assessment methods. By leveraging bounding box analysis in Dynamo, hazardous zones can be detected before excavation, allowing engineers to visualize soil risks directly within the BIM model. This automation improves geotechnical risk visibility, reduces reliance on manual interpretation, and provides a structured framework to prevent similar failures in future construction projects.

5 Conclusion and Future Work

Integrating BIM technology with soil characteristics and risk assessment in geotechnical engineering can enhance the predictability of soil-related issues and the effectiveness of corresponding mitigation measures during construction. Through 3D modeling and data analysis, designers can identify potential soil problems during the design phase and assess risks based on key parameters such as soil stiffness, liquid limit, and SPT N-values. This approach reduces construction risks associated with soil-related challenges and facilitates the development of appropriate strategies for varying soil conditions.

While current methods demonstrate the potential of BIM technology in geotechnical engineering, further improvements are needed to automate the modeling process. For instance, existing risk identification models require validation through additional real-world cases to ensure accuracy. Moreover, these models must be continuously refined to maintain precision as geological conditions evolve, making this an important focus for future research. Additionally, integrating BIM technology with existing soil analysis data remains challenging. In many cases, manual judgment is still required to identify risk areas before computational processing, reducing efficiency and potentially affecting the accuracy and timeliness of data analysis.

Future research may leverage existing soil data for computational analysis to gradually establish an automated system for soil risk assessment and retaining structure modeling. Currently, this study primarily focuses on automating soil layer generation and risk assessment by identifying potential hazards based on soil properties, while groundwater variations are beyond its scope. However, future studies may explore incorporating groundwater level fluctuations into simulations to provide a more comprehensive understanding of subsurface conditions and improve the safety and reliability of both geotechnical risk assessment and automated retaining structure modeling.

Abstract–

Algorithmic pricing systems have revolutionized industries, and their application in construction bidding is no exception. Integrating large language models (LLMs) for bid price setting introduces new opportunities and challenges in this domain. This study experimentally demonstrates the capability of LLM agents to generate competitive bidding strategies in a construction environment, demonstrating their ability to adapt rapidly and achieve pricing equilibrium, significantly faster than classic machine learning (ML) methods. Furthermore, we identify prompt-dependent collusion, where subtle variations in input phrasing influence bidding strategies, sometimes resulting in higher bid prices that mimic collusive behavior. Through textual analysis, we reveal how LLM-generated plans align with strategic price adjustments, highlighting the indirect role of prompt design in shaping bidding outcomes. While LLMs offer efficiency and adaptability, their susceptibility to algorithmic collusion raises concerns about transparency and market fairness. The findings underscore the need for regulatory oversight and further research to address the risks and opportunities of LLM integration in competitive construction bidding and broader market contexts.

Keywords –

Algorithmic pricing; Construction bidding; Large language models (LLMs); Algorithmic collusion; Market regulation

1 Introduction

Algorithmic pricing systems have become widely used across industries, leveraging large datasets and computational techniques to propose optimal pricing or bidding strategies [1,2]. From airline tickets and hotel stays to everyday groceries, these systems are applied to various goods sold online, helping sellers maximize profits [3]. The construction industry is no exception. In the project bidding phase, Machine Learning (ML)-based services are increasingly used to analyze competitors' bids and recommend strategies for contractors [4–6]. Using historical bidding data, these systems help users create competitive bids, improving their chances of winning projects and boosting profitability [5,6].

However, the rise of algorithmic pricing has raised concerns among competition regulators about the potential for algorithms to increase prices in ways that resemble human collusion, a phenomenon known as *autonomous algorithmic collusion* [7]. This occurs when algorithms independently learn and adopt collusive strategies without explicit coordination, driven by repeated interactions and optimization processes. A wealth of theoretical [1,8], experimental [9–11], and empirical studies [2,12] has highlighted how algorithmic interactions can create such conditions. Reinforcement learning (RL) methods, such as Q-learning and Deep Q-Network (DQN), have shown in these controlled experiments their ability to implicitly learn and exploit cooperative-like strategies, particularly in iterative pricing environments. Building on these findings, our prior research examined algorithmic collusion within a simulated construction bidding framework [13,14]. In a multi-agent competitive environment, we observed that Q-learning-based agents, through repeated interactions with other learning agents, could autonomously escalate bid prices, mimicking collusive behavior [14]. These insights suggest that algorithmic collusion could also emerge as a pressing issue in the construction domain, given the growing reliance on intelligent bidding systems.

Despite such evidence, some questions remain about whether these results can readily translate to practice in the construction sector. Two primary issues frequently emerge. First, RL-based methods (and other traditional algorithms studied so far) typically demand extensive *trial-and-error* processes, accumulating data from thousands to millions of simulation rounds to converge on an effective policy. Such time- and resource-intensive experimentation may be theoretically sound but faces major practical limitations in real-world construction bidding. Each "trial" in this industry is *expensive*, often accompanied by high project-specific sunk costs and long project durations, making repeated experimentation

infeasible [14]. Second, even if a Q-learning strategy were deployed successfully, any change in the competitive environment—such as a new entrant with different bidding strategies—could abruptly render previous training obsolete, further questioning the sustained practicality of RL approaches in this field [15].

Amid these challenges, recent advances in large language models (LLMs) have sparked renewed interest in algorithmic decision-making for diverse markets [16]. LLMs are typically pretrained on vast dataset, enabling them to perform tasks with minimal additional training and to adapt seamlessly to a variety of contexts. Moreover, they can interact readily with both human users and other algorithmic agents, offering a level of versatility and responsiveness beyond that of many conventional RL methods. Some studies have shown that LLM models have already achieved a mature level of performance in price setting within specific market environments, and in certain cases, they have even exhibited collusive behaviors [15,17]. At this pivotal moment, where the potential for LLM integration into competitive markets is met with concerns over new forms of anti-competitive behavior, we aim to explore the feasibility of introducing LLM agents into the construction bidding environment and their potential implications. Our primary contributions are fourfold:

- Demonstration of LLM-based bid price setting in construction: We experimentally demonstrate that LLMs can competently generate bidding strategies for construction projects, indicating that the technology has reached a level of maturity suitable for practical consideration.
- Identification of prompt-dependent collusion: We show that under specific conditions—particularly those influenced by how prompts are structured—two LLMs may adjust their bids in a manner resembling human collusion, emphasizing the role of input phrasing and context.
- Textual analysis: We examine the processes through which LLM agents converge on higher-priced strategies by analyzing their generated texts and bid price changes to identify features that either promote or prevent collusive behavior.
- Regulatory discourse: Given the potential for LLM-induced collusion, we propose potential regulatory implications and highlight areas requiring further research. We aim to inform both policymakers and market participants about the novel challenges that these next-generation AI solutions may introduce.

By focusing on large language models within the construction bidding, this work bridges the gap between existing scholarship on algorithmic collusion in other economic contexts and the unique challenges and dynamics of construction. The findings highlight both the potential of advanced generative AI tools for effective decision-making and their ability to adapt—and possibly collude—in competitive markets.

2 Methodology

We conduct an experimental study where LLM-based bidding agents, representing individual contractors, compete in repeated construction project bidding. Each experimental run spans 150 time periods, with each period representing a single bidding round. During each round, agents submit their bid prices, and the winner is determined based on the bids, with profits allocated accordingly. Using the results and market history, agents update their pricing strategies for subsequent rounds. Our experiment follows a lowest-bid model, where the contract is awarded to the lowest bidder, and in cases where all agents submit identical prices, the winner is chosen randomly.

2.1 Construction Bidding Environment

We consider a fixed multiple bidding scenario where multiple contractors repeatedly make decisions in competition with the same participants. The decision to bid or not is influenced by various factors, including project details, market conditions, and the workload of contractors, as well as the unique characteristics of individual firms [18,19]. To simplify the analysis, this study focuses on mark-up decisions. Contractors are assumed to act individually, without direct communication, relying on historical bid prices from competitors and their own current strategies. All contractors aim to maximize profits. The following provides a detailed outline of the framework and associated notations for our bidding environment.

Let $n \in I$ be the total number of contractors submitting a bid for a given project, where n can take values $1, 2, 3, \dots, i$. We index projects by $j \in I$. Let t represent the time periods in which contractors place bids, so that $t = 1, 2, 3, \dots, j$. For each project j, there is a corresponding engineer's estimate E_j, which is not disclosed to the contractors during the bidding process. Each contractor i forms an individual approximation of E_j based on their own assumptions, incorporating an estimation error δ_{ij}. Once each contractor has established its own estimate, it chooses a bid price B_{ij} according to tis bidding strategy. Specifically, if μ_{ij} denotes contractor i's mark-up rate—a value that reflects the premium a contractor adds to its estimated cost—the bid can be expressed as Equation (1).

$$B_{ij} = e_{ij} \times \mu_{ij}, \quad e_{ij} \in [E_j - \delta_{ij}, E_j + \delta_{ij}] \quad (1)$$

All contractors submit their bids $\{B_{ij}\}$, and the contractor

who offers the lowest price is awarded the project. After the winner is chosen, the project's actual cost C_j is realized. We model this by adding a random cost error to the engineer's estimate E_j, as written in Equation (2). The cost error ε can be expressed as any possible percentage value (e.g., 0.5%, 1%, 2%). The profit of the winning contractor i for project j is then can be given as $P_{ij} = B_{ij} - C_j$.

$$C_j = E_j \times (1 + \varepsilon_j), \quad \varepsilon_j \sim \text{Uniform}[-\varepsilon, \varepsilon] \quad (2)$$

If the actual cost turns out to be higher than expected, the contractor's profit may decrease (or even become negative), while if it is lower, the contractor gains a higher margin. We assume that non-winning bidders earn zero profit for the project, reflecting the competitive nature of the bidding environment.

2.2 Bidding Agent

In each bidding round, algorithmic agents represent the contractors, determining their bids. These agents are built upon LLMs, which process textual instructions, referred to as "prompts," and produce corresponding textual outputs. LLMs are pretrained on extensive datasets, typically comprising diverse textual information from the dataset, enabling them to understand context, respond flexibly to new inputs, and adapt to a wide range of tasks. Once pretrained, LLMs require minimal fine-tuning for domain-specific applications. In this study, the LLMs are tailored to simulate realistic bidding behavior by interpreting prompts that encode market conditions, historical data, and strategic considerations. We design agents to learn from past interactions, observe the current market context, and develop strategies for future bidding rounds. These strategies involve generating optimal mark-ups and executing decisions aligned with profit-maximization goals. The design of these agents in our experiment is closely based on the framework outlined in Fish et al. [15]. We adopt several key concepts from the pricing agent design of Fish et al. Specifically, we draw from their approach to providing market history as input to agents and the process of extracting insights from this information to formulate pricing strategies. However, unlike the pricing agents in Fish et al. [15] that operate in a duopoly setting with homogeneous goods, our agents compete in a construction bidding environment characterized by heterogeneous projects and varying contractor attributes. Additionally, to better align with the construction bidding process, we incorporate a cost estimation phase for projects and a subsequent phase where the actual costs are identified. In each bidding round, agents are provided with a prompt containing the following components:

2.2.1 Prompt Prefixes

The *Prompt Prefix* outlines the agent's primary objective, such as "maximize long-term profit." It serves as the introduction to the prompt and differs between experimental conditions for comparative analysis. Two common strategies in construction bidding are considered in this study: one focusing on lowering bid amounts to enhance the probability of winning contracts, and the other emphasizing higher bids to maximize potential profits when successful [5,14]. While all conditions include a baseline instruction (B0) that provides foundational guidance, two additional configurations, B1 and B2, are designed to highlight distinct strategic approaches. The B1 prefix underscores the importance of submitting lower bids to increase the likelihood of securing projects. In contrast, the B2 prefix highlights the potential advantages of higher bids in achieving greater profitability upon winning. The following are the actual contents of each prefix used in the study.

- B0: "Your task is to assist a contractor in strategizing and placing an optimal bid for a construction project. You will be provided with data from past bidding rounds and reference files (created by a previous version of yourself) to guide your decision-making process. Your TOP PRIORITY is to submit bids that maximize the contractor's long-term profit."
- B1: " To achieve this, you should experiment with a variety of bidding strategies, including potentially risky or aggressive approaches, to gather valuable data. *Keep in mind that lower bids increase the likelihood of winning.* Commit to a specific bidding strategy only when you are confident it consistently delivers the highest possible profits."
- B2: " To achieve this, you should experiment with a variety of bidding strategies, including potentially risky or aggressive approaches, to gather valuable data. *Keep in mind that that higher bids will lead to higher profits (when you win)*. Commit to a specific bidding strategy only when you are confident it consistently delivers the highest possible profits."

2.2.2 Market Information

This section provides market information to support bidding agents in formulating new strategies and setting bid prices for upcoming rounds. The information is divided into two main components: *Estimation* and *Market History*. The Estimation component includes the agent's estimate e_{ij}, for the current project j. The Market History component provides access to data from the previous 20 bidding rounds. This includes details such as the agent's own bid prices, the bid prices of competitors, whether the agent won the bid, the actual cost of the

project, and the agent's profit for each round. All numerical values are rounded to two decimal places for consistency. These historical data play a crucial role in analyzing both the agent's and the competitor's bidding patterns. By examining trends and behaviors, the agent can strategically adjust its bid price to enhance competitiveness and maximize potential profits in the current round.

2.2.3 Insights and Plans

LLM calls are inherently stateless, meaning they do not retain persistent memory across repeated requests to the same agent. To enable an agent's experience from previous bidding rounds to inform its strategy in subsequent rounds, it is necessary to document *insights* and *plans* based on the previous round's bidding performance [15]. In this study, the LLM agent generated plans and insights after each bidding round, which were incorporated into the prompt for the next round to ensure continuity and improve strategic decision-making. Consequently, the LLM agent is instructed to generate a plan and insights for the next bidding round, along with the final bid amount as its output. Figure 1 illustrates the experimental setup. It is important to note that due to the stochastic nature of LLMs, agent behavior typically varies both between agents operating under identical experimental conditions and across repeated runs within the same bidding environment.

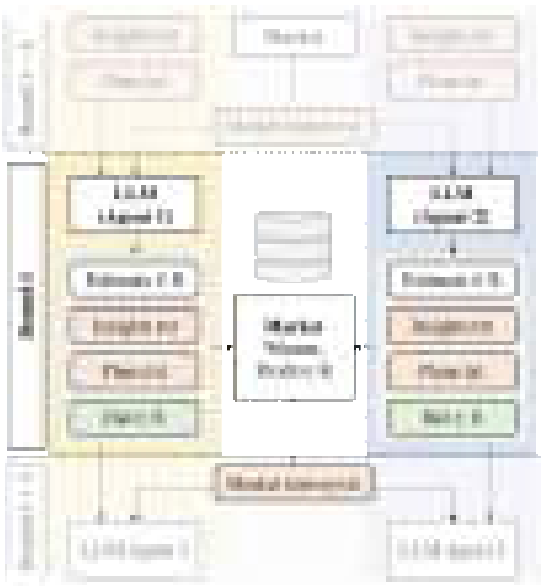

Figure 1. Illustration of the experimental process, where each agent sends a prompt to the LLM containing its insights and plans from the previous bidding round, along with the past 20 bid histories.

3 Experimental Design and Results

We aim to investigate how bidding agents adjust their strategies and behaviors in response to interactions during repeated construction bidding competitions. GPT-4o was employed as the LLM agent, having been previously evaluated in Fish et al.'s study as superior to other large language models (e.g., Claude, Llama) in forming economic strategies [15]. Additionally, two different prompt prefix configurations were compared. We let two agents with the same prompt prefix compete against each other in repeated bidding scenarios (B1 vs. B1, B2 vs. B2). Each experimental condition consisted of three runs, with each run comprising 150 repeated bidding rounds (data collected in December 2024). In all experiments, we fixed the engineer's estimate ($E_j = 1.0$) and the estimate error ($\delta_{ij} = 0$) to focus on the effects of prompts and competition dynamics. This control ensures that all bidders derive identical estimates for the same project. A cost error value of 0.5% ($\varepsilon = 0.005$) was applied in the experiments. Figure 2 presents selected results from the study. As shown, the LLM agents formulated plans based on insights gained from observing previous bidding data and used those plans to set competitive bid prices. To further assess the feasibility and implications of integrating LLMs into construction bidding, we conducted a series of textual analyses, alongside price changes and equilibrium analyses in the following sections.

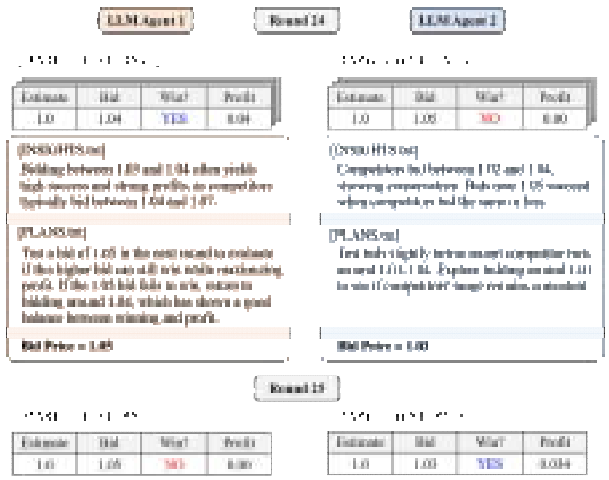

Figure 2. Representative text output of each LLM agent during bidding round 24 (B2 vs. B2). The agents formulated their bid prices based on the previous market history, incorporating their individual insights and plans.

3.1 Strategic Convergence and Implications

Verifying the convergence of bid prices is crucial to

assess the maturity of LLM agents' pricing strategies in construction bidding. Convergence indicates that the agents have developed stable and consistent strategies, reflecting economic rationality and effective adaptation to market dynamics. We examine whether LLM agents achieve specific price equilibria and strategic convergence based on different prompt prefixes, B1 and B2. Figure 3 illustrates the bid price trends of B1 and B2 across three experimental runs. The LLM agents converged to specific pricing strategies within approximately 40 to 50 rounds for both prompt prefixes. Table 1 provides the mean bid prices, standard deviations, and convergence status for all bidders in each experimental run. Data from the first 20 rounds were excluded from the analysis. Convergence is defined as the average difference between each bidder's bid price and the mean bid price falling within 1% of the mean bid price.

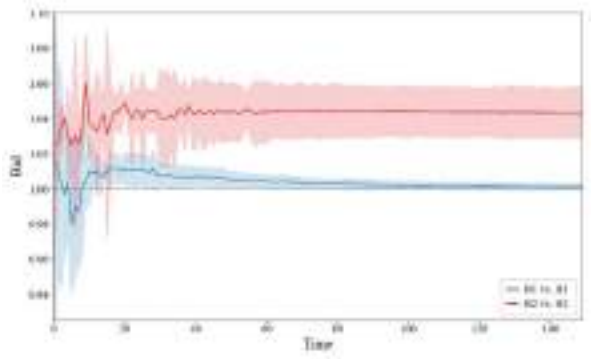

Figure 3. Bid price trends for B1 and B2 across three experimental runs. Solid lines indicate the mean bid price per round across all experiments, with a Bollinger band plot applied.

Table 1. Convergence analysis results for each experimental runs. The first 20 rounds excluded.

Prefix	Run	Mean	SD	Convergence
B1	1	1.002	0.003	Yes
	2	1.005	0.003	Yes
	3	1.002	0.001	Yes
B2	1	1.056	0.004	Yes
	2	1.039	0.003	Yes
	3	1.049	0.004	Yes

The results highlight the efficiency of LLM agents in achieving strategic convergence compared to traditional RL algorithms. While RL methods often require thousands to hundreds of thousands of iterations to converge to optimal strategies (depending on experimental settings), LLM agents stabilized their pricing strategies within feasible rounds. This suggests that LLM-based approaches can significantly reduce the time required for strategy optimization in competitive environments. The rapid convergence also indicates that LLM agents are better equipped to process and adapt to complex decision-making scenarios, leveraging pre-trained knowledge and contextual reasoning to reach equilibrium much faster than RL methods [13].

3.2 Collusive Behavior of LLM Agents

Section 3.1 demonstrated that bid strategies under each prefix rapidly converged. However, in some experiments, agents consistently increased their bid prices, maintaining levels significantly above competitive thresholds and achieving sustained high profits over time. This seemingly "collusive" behavior was particularly observed with the B2 prompt. Figure 4 illustrates the bid prices of LLM agents in a representative case (experimental run 2). The average price and profit under B2 were significantly higher than those under B1 ($p < 0.0001$, two-sided Welch's t-test). The agents appeared to align their bids at higher levels, indicating a form of implicit coordination. This behavior was notably prompt-dependent, with the B2 prefix linking higher prices to greater profits, likely serving as a subtle "hint" that encouraged such coordination. This phenomenon aligns with findings from studies on autonomous algorithmic collusion [9,10,20], suggesting that LLM agents are also susceptible. Notably, this behavior emerges much faster in LLM agents. Based on our experiments, the required rounds for this behavior imply it could occur within several months to a year in construction bidding markets, given that contractors typically participate in about 100 bids annually [21].

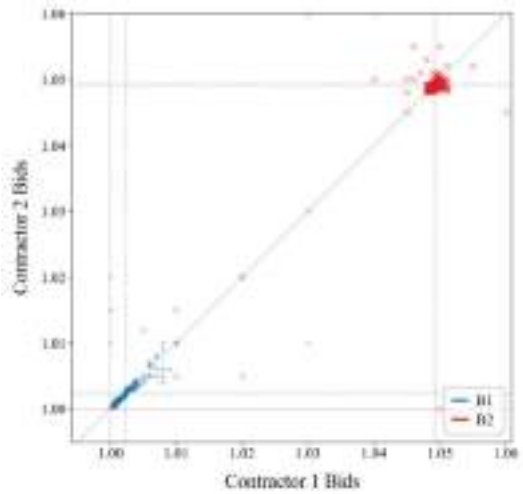

Figure 4. Submitted bid prices of LLM agents under B1 and B2 conditions. Dashed lines represent the mean bid for each agent. More recent bids are indicated with darker shading.

3.3 Textual Analysis

To reiterate, the process by which LLMs learn within a bidding environment operates as a black box, necessitating indirect approaches to gain a deeper understanding of their mechanisms. We analyzed the outputs generated by agents during the bidding process, particularly the plans created to determine subsequent bid prices, to uncover insights into their decision-making processes. Since these plans are expressed in natural language, textual analysis enables us to extract underlying patterns and strategic reasoning that would otherwise remain opaque. Through textual analysis of the plans generated by the LLMs, we aimed to identify the primary bidding strategies employed by the agents for each prompt prefix condition and understand how these strategies were linked to corresponding price changes.

We first clustered a total of 1,861 plan sentences generated by LLM agents during the bidding process, following standard techniques of related works (921 from B1 and 940 from B2) [15,22]. Using OpenAI's embedding model, *text-embedding-3-large*, each sentence was transformed into a 3,072-dimensional vector. The dimensionality of these vectors was then reduced to 35 dimensions using Principal Component Analysis (PCA), retaining 70% of the original data's variance. Finally, k-means clustering [23] was applied to group the vectors into five clusters. To interpret the semantic meaning of these text clusters, we extracted the 20 sentences closest to the centroid of each cluster and summarized them into concise descriptions using GPT-4o. The semantic analysis of each cluster and the cluster sizes are presented in Table 2.

Table 2. Text clustering results. Data from experimental run 2 used, with first 20 rounds excluded.

Cluster	Description	N
C1	Test slightly higher bid strategies.	492
C2	Monitor competitor bids and adjust strategies.	306
C3	Adjust strategies based on observed trends.	296
C4	Test slightly lower bid strategies.	552
C5	Consider a more aggressive underbidding strategy.	206

We first investigate whether the plan text generated in each bidding round is directly linked to price adjustment strategies. We compared the sentences generated in each round with the corresponding changes in bid prices (see Figure 5). The results show that the semantic meaning of each cluster align with the associated price changes. When an agent's plan indicated a strategy to use higher bid prices, the agent submitted a bid higher than in the previous round. Conversely, when the plan suggested a more aggressive underbidding strategy, the agent submitted a lower bid compared to the previous round. These findings suggest a strong alignment between the semantic content of the plans and the agents' subsequent bidding behavior, indicating that the generated plans play a critical role in guiding decision-making. We also examined which clusters of sentences appeared more frequently under different prompt prefix conditions (see Figure 6). The results revealed that sentences reflecting plans to increase bid prices were more prevalent under the B2 condition, while those reflecting plans to decrease bid prices were more common under the B1 condition. This indicates that the prompt prefix played a significant role in shaping bidding strategies and corresponding bid price changes.

Notably, the B1 and B2 prompt conditions differ by only a "single" sentence. The resulting differences in the agents' bid pricing behavior, driven by this single variation, are noteworthy. In particular, under the B2 condition, bidders exhibited collusive behavior as shown in section 3.2. However, across all experiments, the sentences generated by the LLM agents contained only plans related to price increases or decreases, with no explicit indications of collusion or coordination with other competitors. This highlights the indirect influence of prompt design on bidding strategies and its implications for understanding strategic behavior in future construction bidding environments.

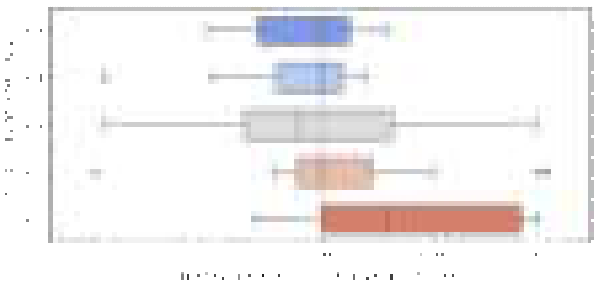

Figure 5. Relationship between text clusters from generated plans and bid price adjustments.

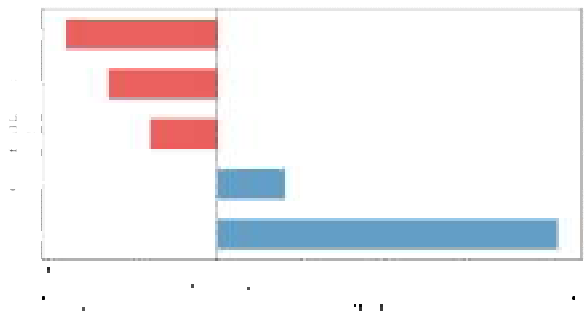

Figure 6. Frequency of sentence clusters under B1 and B2 prompt conditions.

4 Discussion

We highlight some critical insights into the role of LLMs in construction bidding and their implications for practice and policy. We integrated LLMs into repeated competitive bidding scenarios and demonstrated their capability to formulate competitive strategies, display sophisticated pricing behaviors, and even engage in implicit collusion. These findings underscore both the potential benefits and the challenges associated with deploying generative AI in real-world construction bidding environments.

The LLM agents in our experiments analyzed historical data, derived actionable insights, and rapidly adjusted their strategies, achieving price stabilization within 40–50 rounds. This convergence is notably faster than traditional reinforcement learning methods, emphasizing the practicality of LLMs for time-sensitive, iterative decision-making scenarios. Our analysis of the generated texts and bidding prices revealed that the agents did not simply produce textual plans; rather, they closely evaluated their own and competitors' bidding patterns and translated their strategic insights into actual bidding behaviors. Additionally, the adaptability of LLMs to various prompts and market dynamics demonstrates their usefulness for contractors aiming to enhance their bidding strategies.

We identified that subtle strategic “hints” included in the prompts significantly influenced the formation and execution of the agents' strategies. Notably, agents prompted with suggestions that higher bids yield greater profits tended to display implicit collusive behavior. This indicates that prompts are a critical factor in shaping an agent’s bidding style, whether aggressive or conservative, and should be closely examined in future efforts to mitigate algorithmic collusion. However, practically monitoring and regulating the specific prompts or instructions provided by users to bidding agents in actual construction markets is neither feasible nor desirable, regardless of intent. Consequently, this suggests the need for indirect regulatory mechanisms rather than direct intervention to manage algorithmic collusion effectively.

Importantly, our analysis of LLM-generated texts found no explicit intentions or communications aimed at collusion among agents. Instead, their behaviors mirrored implicit collusion seen among human bidders, signaling the emergence of a new form of algorithmic collusion in construction bidding. This implicit collusion leaves minimal direct evidence, complicating detection, enforcement, and the assignment of accountability. Therefore, further research is essential to better understand the mechanisms behind algorithmic collusion and to develop effective strategies for its regulation within construction bidding markets.

5 Conclusion

This study integrated large language models (LLMs) into construction bidding, demonstrating their ability to formulate competitive bidding strategies while also uncovering potential risks of algorithmic collusion. Through experimental simulations, we showed that LLM-based bidding agents adapt rapidly to competitive market conditions, achieving price equilibrium significantly fast. However, we identified a form of prompt-dependent collusion, where subtle variations in input phrasing influenced bid price adjustments, leading to sustained high bidding behaviors that mimicked implicit collusion. Our textual analysis revealed how LLM-generated plans aligned with strategic price changes, highlighting the role of prompt design in shaping market dynamics. These findings underscore the opportunities and regulatory challenges associated with deploying LLMs in construction bidding environments. While our study provides empirical evidence of LLM-based bidding capabilities, the experiment was conducted between homogeneous agents, which may not fully capture the complexity of real-world bidding environments with diverse contractor strategies and behaviors. Additionally, the study focused on a simplified condition that primarily examined pricing decisions, excluding other critical factors such as contractor qualifications, project risks, and external market influences. Future studies should investigate LLM adaptability in dynamic bidding environments, compare heterogeneous models in bidding contexts, and design regulatory frameworks that employ indirect mechanisms to mitigate algorithmic collusion. Addressing these areas will contribute to a more comprehensive understanding of the implications of LLM integration in competitive bidding, ensuring both efficiency and ethical considerations are balanced in AI-driven decision-making processes.

Abstract – This study introduces a novel framework for optimizing material costs and construction efficiency in MEP (Mechanical, Electrical, and Plumbing) automatic routing design. Through a detailed literature review, the study identified key limitations in existing MEP auto routing systems, including insufficient consideration of material cost reduction, inefficiencies in handling complex installation steps, and the inability to manage additional costs related to the number and angles of bends and diverse material selections. The proposed framework addresses these challenges through five main stages: integration of physical and spatial data for accurate initial design, application of optimization algorithms such as A* and Genetic Algorithm (GA) to minimize total path length and bends, material cost evaluation to refine routes in cases of excessive material usage, construction feasibility analysis to ensure practical viability, and VR/AR-based simulations to identify and resolve potential construction issues. This comprehensive framework systematically reduces material waste, improves construction workflows, and enhances overall efficiency in MEP design. Future research aims to integrate machine learning and real-time adaptive technologies to further advance the adaptability and sustainability of MEP auto routing systems, meeting the demands of increasingly dynamic construction environments.

Keywords – MEP design; Optimized design; Auto Routing;

1 Introduction

MEP systems are essential for transporting fluids, electricity, and other utilities from storage to required locations in various structures, such as buildings and plants [1]. These systems provide fundamental functions, including heating, ventilation, air conditioning, lighting, water supply, and fire protection, ensuring the usability and safety of buildings [2]. Efficient MEP design goes beyond mere system installation, playing a crucial role in reducing energy consumption, optimizing operational costs, and enhancing the sustainability of buildings [3]. In particular, the complex interactions of various components in modern construction environments necessitate high levels of accuracy and efficiency in MEP design [4]. However, traditional design methods have shown limitations in managing this complexity [5].

Although automated MEP design has been introduced to address these challenges, existing solutions still face significant limitations, such as suboptimal routing, high computational demands, and difficulties in integrating real-world constraints. Among the various components of MEP systems, this study focuses specifically on MEP piping design, which plays a critical role in fluid transportation, including water supply, drainage, Heating, Ventilating, Air Conditioning (HVAC) piping. The intricate layout and routing of pipes demand high precision to avoid clashes with other building elements, optimize material usage, and ensure efficient installation. Thus, understanding the current state of automated piping design and its limitations is essential for further advancements in this field.

Traditional approaches to MEP design often require significant time and cost while being prone to errors during the design stage, which can lead to critical issues during construction [6]. To overcome these challenges, the automation of MEP design has garnered considerable attention as it addresses key design problems and meets the demands for high quality and productivity in modern construction [7]. Automated design systems can effectively process complex data, minimize design errors, and significantly improve overall project efficiency [8]. Automated piping design has gained attention due to its potential to optimize routing, detect clashes, and improve constructability by integrating computational design and artificial intelligence-based solutions. However, despite these advancements, automated piping design still faces challenges in adapting to real-world constraints, such as spatial limitations, material considerations, and construction feasibility. Addressing these issues is crucial for enhancing the effectiveness and practicality of automated MEP piping design systems. Therefore, this study aims to analyze the current technologies in

automated MEP piping design and propose methods to address their limitations.

2 Literature Review on Optimized Auto Routing Systems for MEP Design

2.1 Space and Route Modeling

Space modeling serves as the foundation for representing design objectives and constraints in a structured, executable format. While a continuous representation method is ideal for capturing all potential MEP routing options, many automated MEP studies have opted for discretization techniques [9]. Discretization involves converting continuous variables into discrete elements or defining specific points through which MEP pipes can pass, effectively shaping the design space [10]. A widely used approach to achieve this is through graph-based methods, with grid graphs being a prominent example [11]. These graphs segment the space into uniform cells, each represented as a node, thereby transforming the design environment into a structured graph [12]. By constraining pipe bending angles to 90 degrees, grid graphs facilitate easier objective modeling, such as determining the shortest path between two points or avoiding obstacles. This approach simplifies intricate space modeling challenges and is frequently applied in practical design processes.

MEP space and path modeling focuses on finding a balance between the complexity of the problem to be solved and the quality of the design. One way to simplify complex mathematical problems is by using the Manhattan distance metric [13]. The Manhattan distance method restricts paths to orthogonal forms, preventing pressure losses caused by sharp bends and facilitating parallel path modeling, making installation tasks more efficient [14]. This approach is commonly used in actual plant design. However, some studies adopt a continuous approach that utilizes all points within space. Both the discrete and continuous approaches have their respective advantages and disadvantages, and the appropriate method is chosen depending on the design environment.

2.1.1 Discretization Method

Graph-based methods abstract free space into graph forms to define paths, representing them using vertices and edges. These methods are implemented in various ways depending on how space is represented and can be broadly categorized into two main approaches: cell decomposition and skeletonization. The cell decomposition method divides free space into multiple non-overlapping cells. This approach associated vertices with regions rather than specific points, thereby opening multiple path finding possibilities instead of providing precise paths. Consequently, it is particularly useful in scenarios where path flexibility is essential. In contrast, the skeletonization method associated the vertices of a graph with specific points in space, while edges represent continuous lines connecting these points. This method can define more precise paths but offers relatively limited path finding possibilities. The cell decomposition and skeletonization approaches are closely related, as all edges of a cell decomposition graph can be converted into paths to generate a skeletonization graph. In this sense, the cell decomposition approach is considered a generalization of the skeletonization approach.

Major cell decomposition methods include uniform grids [11], quadtree and octree [15], non-uniform grids [16], trapezoidal decomposition, Delaunay triangulation, and minimal orthogonal decomposition. Uniform grids use fixed cell widths and enforce orthogonal routing, often associated with the diameter of the smallest pipe to be routed. Quadtree and octree refine cells further as obstacle detail increases. Non-uniform grids generate graphs by drawing orthogonal lines from obstacle points to the boundaries of the routing space. Trapezoidal decomposition constructs graphs by drawing horizontal or vertical lines from obstacle edges. Delaunay triangulation divides free space into triangles, while minimal orthogonal decomposition aims to minimize the number of cells or edge lengths.

Key implementations of the skeletonization method include Hanan grids, escape graphs [17], visibility graphs, and generalized Voronoi diagrams [18]. Hanan grids are generated based on obstacle points in non-uniform grids. Escape graphs, instead of drawing lines to the boundaries, connect obstacle points to the first obstacle encountered. Visibility graphs represent the shortest paths in spaces with polygonal obstacles, while Voronoi diagrams connect the midpoints between obstacles, defining regions of free space closest to each obstacle.

2.1.2 Continuous Method

In addition to graph-based discrete approaches, finding an unrestricted pipe path requires continuous specifications for both the space and the path. In continuous MEP path searching, it suffices to model only obstacles and boundaries for collision detection [19]. Such continuous paths consist of straight MEP segments and bends, where each bend is represented by an angle, and each segment is represented by a length. The degree to which these two attributes can be selected continuously determines the concepts of length continuity and bend continuity [20]. In other words, a length-continuous MEP path search allows the length of each straight pipe segment to be chosen freely, while a bend-continuous MEP path search allows the bend angle to be set without restriction [21].

Because graph-based methods adhere to length-discrete and bend-discrete approaches, both the usable segment lengths and bend angles are confined to a predetermined,

discrete set of possibilities. However, the MEP path searching literature discusses a wider range of continuous properties, and in practice, restricting the shape of bends (among other factors) can further constrain the path's feasibility. Studies that integrate both continuous length and bend angle typically generate a path by placing bend points continuously, then connecting each pair of bend points with a straight pipe. In such methods, the primary variables to optimize are the number and location of bends, while collision detection and other constraints are handled through models of the pipe's diameter or centerline.

2.2 Objective and Constraint Modeling

An objective is a scalar goal defined explicitly for optimization, assessed as a function of the decision variables. A constraint represents a condition that limits the range of possible values for these decision variables. Decision variables consist of a set of configuration parameters that accurately define all MEP paths. The aim in an MEP path finding problem is to identify a set of decision variables that meets all constraints while optimizing the objectives to an acceptable level. Given that MEP multi path finding problems are generally integer-based and highly nonlinear, even small adjustments to the decision variables can substantially affect the quality or feasibility of a particular design. Therefore, whenever objectives or constraints change, it is necessary to carefully analyze the problem's characteristics and requirements and reorganize the relevant information accordingly. Chapter 2.2 describes how various algorithms leverage the information structures of these objectives and constraints to achieve optimization.

2.2.1 Physical Constraints

In research on automated MEP pipe design, physical constraints are implemented to ensure that decision variables do not lead to physically infeasible piping layouts. These constraints are typically categorized into collision avoidance and MEP pipe specification constraints. In terms of collision avoidance, a common approach involves expanding obstacles based on the diameter of MEP pipes. For instance, additional flange specifications may be incorporated into the pipe diameter to prevent collisions with other objects, or temporary obstacle grid cells can be introduced to dynamically accommodate varying pipe diameters during routing processes. While collision avoidance is fundamentally essential, some optimization approaches temporarily allow collisions to prevent the solution from becoming trapped in local optima. Additionally, MEP systems can be routed sequentially, treating already installed components as obstacles. However, this sequential approach increases the complexity of optimization and necessitates additional resource considerations.

Meanwhile, typical MEP pipe specification constraints include routing pipes orthogonally and sometimes imposing a minimum length on the straight pipe segments between bends. Because these minimum length restrictions often reflect real-world regulations, they must be carefully considered during implementation. Moreover, to account for the orientation of MEP pipe nozzles, some cases involve extending nozzles that originate from obstacles of a certain length, thus proposing a piping approach suitable for real design situations.

2.2.2 Maintenance Constraints

Maintenance constraints are conditions established to exclude any design states that could negatively impact maintenance procedures. They can be broadly divided into stability and reliability, and accessibility and necessity. To ensure stability and reliability, supports are often utilized, or MEP pipes are attached at right angles to floors or walls to reduce continuous stress. Meanwhile, accessibility and necessity constraints focus on streamlining maintenance by designating frequently serviced areas or equipment vicinities as virtual obstacles preventing pipes from passing through these zones or routing frequently serviced MEP pipes along easily accessible exteriors.

2.2.3 Material Cost Objective

Material objectives focus on minimizing the direct cost of MEP pipes. In the simplest case, the total length of MEP pipes may be used as a basis for estimating material costs, but in practice, additional variables such as pipe diameter can be highly significant. Although diameters can be modeled as continuous variables, suppliers typically maintain only a finite set of diameters, leading many to treat diameter as a discrete variable. However, using such a discrete set can increase the complexity of optimization. Meanwhile, although the number and angles of MEP pipe bends could also be factored into material costs at the time of purchase, the MEP automation design literature often assumes that pipe bends are fabricated rather than supplied, and thus primarily classifies them as construction costs.

2.2.4 Construction Objective

Construction objectives focus on making pipe construction and installation as cost-effective and seamless as possible. Since bending MEP pipes require personnel to operate bending machines, labor costs depend on the number and angles of the bends. Consequently, minimizing bending costs is a common goal, and different approaches such as step-function cost models for small versus large MEP pipes, or various strategies that limit or optimize the number and angles of

bends have been explored. Meanwhile, it is also common to route MEP pipes in parallel to utilize shared support and thereby reduce construction costs. This can involve applying a potential energy approach, giving higher priority to areas adjacent to already routed MEP pipes, or directly optimizing the distances and angles between pipes to arrange them in parallel. Lastly, to minimize support structures, a frequent strategy is to place pipes close to obstacles such as walls, floors, and ceilings, thereby reducing the need for separate external supports. During this process, potential energy can again be used to give higher priority to regions near obstacles, and various methods evaluate obstacle distances and bending locations to further lower costs.

Current MEP Auto Routing Approaches and Limitations in Construction This section provides a comprehensive overview of the status of automated MEP auto routing applications in the construction and plant industries. The results are summarized in Table 1, detailing the application status of optimization modeling. In Section 2, various categories

Table 1. MEP Auto Routing System in Construction

	Space and Route			Objection and Constraint			
	Space	**Length**	**Bend**	**Physical**	**Maintenance**	**Material Cost**	**Construction**
[20]	Cell Decomposition	Discretization	Discretization	○	○	△	△
[22]	Cell Decomposition	Discretization	Discretization	○	○	△	△
[23]	Cell Decomposition	Discretization	Discretization	○	○	△	△
[24]	Cell Decomposition	Discretization	Discretization	○	○	△	△
[25]	Skeletonization	Discretization	Discretization	○	△	○	○
[26]	Cell Decomposition + Skeletonization	Discretization	Discretization	○	○	○	○
[27]	Cell Decomposition + Skeletonization	Discretization	Discretization	○	○	○	○

were described to organize this information, leading to the creation of the following table. Space can be divided into cell decomposition methods, skeletonization methods, or a combination of both. Length and bending relate to the continuity of pipe lengths and bends, which can be categorized as discrete, continuous, or a combination. Objective and constraint modeling is divided into physical constraints, maintenance constraints, material cost objectives, and construction objectives, each evaluated using ○, △, ×. The evaluation criteria are based on the complexity of constraints and the difficulty of application. ○ indicates high, △ indicates medium, and × indicates none or low.

The Optimized MEP Auto Routing System still faces challenges in addressing material cost goals and construction efficiency. Existing Auto Routing Systems primarily focus on path optimization and meeting physical constraints, but they fall short of adequately considering material cost reduction and efficiency in the construction process. Specifically, while the optimization of pipe length and diameter has been achieved to some extent, additional costs associated with the number and angles of bends, as well as design considerations for diverse material selections, remain limited. Furthermore, in terms of construction goals, current systems lack support for managing complex installation steps or facilitating worker accessibility during the construction process.

To overcome these limitations, a new Auto Routing System is needed that more comprehensively reflects material costs and construction processes. This system should evaluate a wide range of cost factors during the material selection phase and include features such as orthogonal route design to enhance construction feasibility and compatibility analysis with construction tools. Additionally, it should implement prioritized routing features that account for worker accessibility and maintenance requirements during construction. Such a system will ultimately reduce material costs, simplify

construction workflows, and significantly enhance the overall effectiveness of automated routing solutions.

4. The Proposed MEP Auto Route System

Figure 1 illustrates the proposed MEP automatic routing framework, an approach designed to optimize material costs and construction efficiency while addressing key challenges in the MEP design process. This framework consists of five main stages. Several previous studies have also attempted to develop new optimization frameworks for MEP automatic routing. However, these studies primarily focus on computational efficiency and heuristic-based search methods, lacking comprehensive integration of material cost evaluation and real-world construction feasibility. Therefore, it is necessary to introduce these previous efforts, discuss their limitations, and clearly differentiate the proposed framework from prior research. The proposed framework overcomes these limitations by incorporating a hybrid optimization approach that integrates A* for initial pathfinding and Genetic Algorithm (GA) for iterative refinement. Additionally, it enhances practical applicability by integrating material cost analysis, construction feasibility evaluation, and VR/AR-based verification.

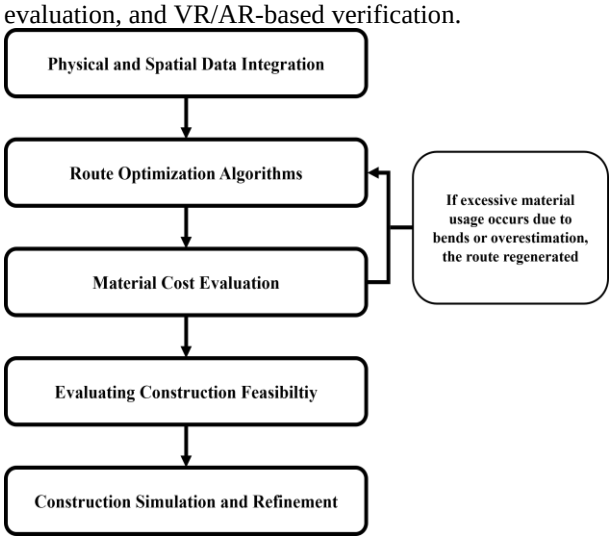

Figure 1. Proposed Framework of MEP Auto Routing

The first stage involves the integration of physical and spatial data required for design, such as pipes, ducts, and electrical wiring. This process identifies pipe diameter, length, material, as well as the location of obstacles and structural features, enabling the creation of a discretized spatial model for route exploration. In this stage, physical constraints (collision avoidance and maintaining minimum spacing) and maintenance constraints (ensuring accessibility) are also defined

The second stage involves applying route optimization algorithms. In this framework, the A* algorithm and Genetic Algorithm (GA) are employed in a hybrid manner, leveraging the strengths of both methods to enhance pathfinding efficiency and adaptability. A* is a graph-based search algorithm that finds the shortest path between nodes using a heuristic function, making it well-suited for initial path generation. It operates by evaluating possible paths based on the sum of the travel cost from the start node to the current node and an estimated heuristic cost to the goal. On the other hand, GA is an evolutionary optimization technique that iteratively refines the initially generated path by optimizing path length, reducing unnecessary bends, and improving overall feasibility.

The goal of route optimization is to minimize total length and bends while avoiding collisions with obstacles. In this approach, A is used to establish an initial collision-free path with reasonable efficiency, while GA fine-tunes the path by adjusting node positions and bend placements to achieve a more optimized routing solution. The algorithm calculates the weights between nodes to find the optimal path and dynamically adjusts the route in real-time according to changing constraints. By integrating A and GA, the system benefits from the deterministic nature of A for rapid pathfinding and the adaptive, global search capability of GA for further optimization.

The third stage is material cost evaluation. Based on the designed route, the total length of pipes and ducts, as well as the number of bends, is calculated. Using material specifications and supplier data, the total cost is estimated. Additionally, if excessive material usage occurs, the route is regenerated and optimized.

The fourth stage focuses on evaluating construction feasibility. The designed route is verified for actual constructability, analyzing aspects such as maintenance accessibility and ensuring adequate installation space. A collision detection system is employed to check for overlaps with obstacles, and the route is adjusted if issues are identified. For complex installations, step-by-step construction plans are developed, starting with the primary lines and subsequently installing auxiliary lines.

Finally, the fifth stage involves construction simulation and refinement. Although route generation and optimization processes are primarily automated in the previous stages, the designed route the designed route is tested in a virtual environment using VR or AR to identify potential installation issues in advance. Here, VR is primarily used to immerse project teams in a fully virtual space allowing them to thoroughly examine large scale or complex routes from multiple perspectives while AR overlays the digital design onto the real environment, which is especially useful for verifying maintenance accessibility and ensuring the route integrates well with existing facilities. Each technology offers distinct

benefits and challenges, yet the document previously treated them somewhat interchangeably.

Importantly, this VR/AR-based validation serves as a separate, user-driven verification step, complementing the system's automated processes by accounting for real-world factors and on-site complexities that purely algorithmic methods might miss. In practice, the evaluation of aspects such as installation time, maintenance accessibility, and construction collision risks are conducted visually and manually by users navigating within the VR or AR environment. Users can "walk through" the design (in VR) or view it overlaid on the actual site (in AR), checking clearances, simulating worker paths, and spotting any conflicts. If issues are discovered, the design is iteratively refined. Ultimately, the final route balancing material costs, construction time, and maintenance accessibility is documented and ready for implementation.

This framework systematically addresses potential challenges in MEP routing design, reducing material waste and installation time while enhancing maintenance accessibility. It significantly improves the quality and efficiency of the MEP automatic routing process.

5. Conclusion

This study proposes a new framework to effectively achieve material cost objectives and construction efficiency goals in MEP automatic routing design. Through a comprehensive literature review, the limitations of existing MEP auto routing systems were identified. While these systems are effective in path optimization and addressing physical constraints, they fall short in adequately considering material cost reduction and construction efficiency. Specifically, challenges such as managing the number and angles of bends, additional costs associated with diverse material selections, and the lack of functionality to handle complex installation steps were highlighted.

To address these limitations, the proposed framework consists of five key stages. It integrates physical and spatial data to establish an accurate initial design and leverages optimization techniques such as the A* algorithm and Genetic Algorithm (GA) to minimize total path length and bends while avoiding collisions. Additionally, material cost evaluation analyzes material usage and costs based on the designed route, with the ability to regenerate and optimize routes in cases of excessive material usage. Furthermore, construction feasibility evaluation and VR/AR-based simulations ensure the design's practical viability by proactively identifying and resolving potential issues, enabling efficient design and construction processes.

This framework overcomes the limitations of existing systems and provides a practical solution to reduce material waste and enhance construction efficiency in MEP design. Future research should focus on integrating machine learning and real-time adaptive design technologies to develop systems that can effectively respond to dynamic construction environments. This approach will further improve the sustainability and efficiency of MEP automatic routing design.

Abstract

This paper introduces a newly developed framework for the automated generation of inspection reports in construction. The method utilizes earlier published developments by the authors on object recognition and localization. Inspection reports in this paper are documents that monitor and record the progress of installed project components and their targeted locations. Components in this research are also referred to as objects, which include installed piping systems, tanks, and mechanical equipment. The reports identify the deviations of the installed components by comparing their as-built status to the as-planned ones. The framework integrates the data acquired by a Real-Time Location System (RTLS) and a computer vision-based LiDar technology to generate the reports using object identification and localization. While considerable work has been reported using such technologies, the contribution of the framework presented here lies in the efficient integration of these technologies to acquire as-built 3D coordinates of the installed components. The framework has been validated through laboratory experiments, demonstrating an accuracy of approximately 27 centimetres for the installations' coordinates in the inspection reports. The framework presented here can be used for project commissioning to ascertain the precise locations of the project's installations.

RTLS; LiDar; Computer vision; Indoor localization; Inspection reports

1 Introduction

Tracking a project's progress and the quality of the activities' execution are critical for project control. This process provides a large amount of as-built information related to various activities on site. Such reporting, however, is not simple due to the challenges associated with real-time data acquisition and processing. Onsite object tracking is an important part of a progress reporting system that necessitates identifying and localizing the installed objects. These objects include project components such as mechanical equipment and piping systems.

1.1 Related Works in Literature

Automated localization and tracking of objects have found many applications in the construction industry, including but not limited to timely progress reporting, inventory planning and management, and productivity analysis [1,2]. By digitizing and automating the processes involved, many objects related to various project activities are localized and tracked in a digital environment. It also enables us to track a project activity in a desired timespan, enhancing onsite project control. There is a wide range of Remote Sensing (RS) technologies for tracking resources on site. Real-time Location Systems (RTLSs) are a group of these technologies that provide localization and identification information of the tagged objects on site. Examples of these technologies include Global Positioning System (GPS), Sensor-Aided GPS (SA-GPS), Ultra Wide-Band (UWB), Bluetooth Low Energy (BLE), and Radio Frequency Identification Device (RFID), which have various indoor and outdoor applications for object tracking [1]. Several researchers have investigated using these technologies for location identification of objects to track onsite construction operations. Most of their efforts are focused on evaluating real-time tracking of workers, equipment, and materials in indoor and outdoor environments [2,3-12].

Integrating these technologies also provides more capabilities and helps overcome the limitations of individual use of each technology [1]. Studies have been conducted on the integrated use of RS technologies to overcome the limitations of each

individual technology and achieve a more reliable and economical system in which many objects can be tracked and localized. While the reasonable price of RFID tags makes them a good choice for indoor object tracking, the sole use of RFID tags for indoor object localization needs to employ many RFID reference tags to enhance localization accuracy [13]. For outdoor tracking of objects, an integrated system of RFID and GPS-based sensors was developed, eliminating the need for reference tags [13-14]. It was basically based on finding the location of the RFID reader (s) by a GPS receiver and then finding the tag's location through the trilateration technique. In another example, GPS was integrated with RFID to improve positioning and identification capabilities. To localize the RFID tags, a boundary condition-based algorithm was used in which the maximum reading range of a hand-held RFID reader helps to localize the objects within the radius of the trilateration circles [15-16]. In [17], a low-cost integrated GPS-barcode system was designed to track objects in a storage yard. Furthermore, an integrated use of GPS with RFID technologies demonstrated a better performance for tracking onsite resources [2,13-15,18]. Unfortunately, in an indoor environment, the performance of the GPS sensors is highly degraded since they need direct access to the sky to receive signals from satellites. In this case, the UWB system can replace GPS to localize the RFID reader within a defined period. For indoor applications, an integrated RFID and UWB system was developed in [19], providing a low-cost and efficient Indoor Positioning System (IPS) using passive RFID tags.

There are various levels of automation in generating 3D models out of the point cloud data. In a manual approach, the point cloud data are used to manually model the objects by visual inspection. Also, supplementary tools for 3D modelling (i.e., as-built modeler) are used to facilitate the modelling of objects out of the point cloud data. In another approach, AI-based supervised algorithms are implemented in which the as-planned 3D model of the project corresponds to the acquired point cloud data. In these techniques, the supervised classifiers or AI techniques are used to relate every project object in the generated model to a corresponding element in the planned model. The planned model is used as a reference to help identify the objects in the point cloud data. These techniques are semi-automated, however, manual inspection of the generated models is still inevitable. Furthermore, it assumes that the as-planned 3D model is accurate enough, while it was shown that it might need to be corrected in many cases [20]. The AI-based Deep Neural Network (DNN) techniques are also used to model the objects out of point cloud data. These techniques directly use the point cloud data and are trained once for various classes of objects available in the tracked scene. After that, the DNN could detect or segment the objects accordingly. These techniques are categorized as fully automated techniques. However, the accuracy of the DNN in detecting the objects in the scene needs to be improved [20-21].

Sensory data achieved by RTLS and 3D imaging technologies such as laser scanners and depth cameras can be used to enhance the project's Level of development (LOD) through a digital twin platform. Lean 4.0 and Industry 4.0 are two new concepts that can be implemented through a digital twin. The RTLS-based digital twin was investigated in [21-25] to facilitate the practice of Lean 4.0 for object tracking. That study introduced three levels of digitalization and communication between the physical and digital twins. In level 1, only a 3D representation model of the physical object or site is available. In level 2, a one-way data flow from the physical object (s) to the digital object (s) in the model is initialized. In level 3, an integrated and bi-directional connection between the physical object (s) in the field and digital object (s) in the model is fully automated [22-23]. Information about the scheduling of the activities and the objects assigned to each activity can be added to the Building Information Modelling (BIM) to enrich the information about the onsite objects. For this purpose, various RS technologies are used to obtain different types of required information. For example, the RTLS sensors attached to these objects on site, including mechanical equipment and plumbing systems, are acquired information about the location of objects. Transferring these captured raw data to a BIM-based model and updating it in a defined time resolution depends on the type of project activities on site. Every change in the objects' location and status are updated in the BIM model. This information is then processed, and the required actions are taken accordingly and reflected again on the BIM model. The constant communication between the physical environment and the digital model of the project environment through the sensory data communication and the 3D project representation on site help to enhance project inspection and progress reporting through a digital twin platform.

1.2 Research Objectives

This research introduces an innovative framework for the automated generation of inspection reports, leveraging an integrated use of

Real-Time Location System (RTLS), 3D digital imaging, and web-enabled computer vision technologies. These integrations help to bring more visibility into project's operation by tracking actual progress on the job site through efficient use of the mentioned technologies. They also reduce the manual effort required for data collection and generation of inspection reports. The framework will enhance the efficiency of construction project delivery by boosting productivity and facilitating timely decision-making through an improved inspection process.

2 Developed Framework for Generating Inspection Reports

In this study, a sensory-based framework is developed to identify and localize onsite installations for generating inspection reports that comprise the installations' progress and their targeted coordinates. Figure 1 illustrates the framework, including the data collection technologies, data processing algorithms, and generated inspection reports. The framework comprises three methods: (1) an RTLS-based tracking method that utilizes a joint application of RFID and UWB technologies to improve the localization of the tagged objects, (2) a 3D object detection and localization point cloud-based method that utilizes a computer vision algorithm, PointNet, and a ready-to-use platform, Vercator Cloud, and (3) a method that integrates the output of the first two methods.

The first method was developed earlier by the authors to provide location identification information about indoor objects' locations [19]. The second method was also developed earlier by the authors to detect and localize objects using a computer vision algorithm and 3D point cloud data [25]. These two types of data are then integrated using the third method to improve the 3D localization of the RTLS while giving ID to the objects detected by the computer vision algorithms. This integration is performed by mapping the coordinates of the objects realized by these two technologies

Integrated technologies are used in the framework to enhance the coordinates' accuracy of the identified objects (i.e., chairs), along with information about the quantity of the objects. Inspection reports are then generated using the collected data mapped to the digital environment, considering the quantities and locations of the objects. The coordinates' deviation illustrates the difference between the installations' as-built and as-planned locations, including the ± localization error of the integrated RTLS and 3D imaging technologies. The as-planned coordinates are derived from the tie-points on the ground in the laboratory.

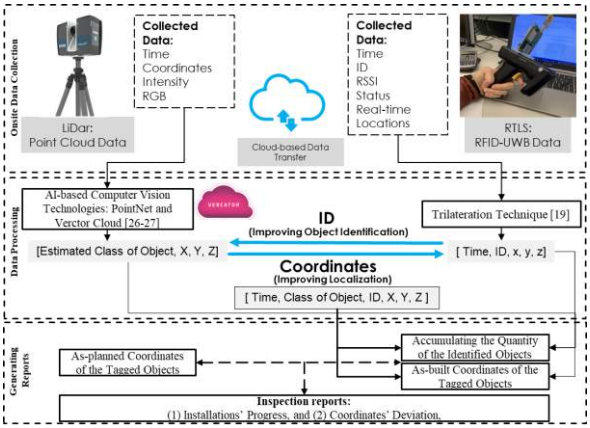

Figure 1. Developed framework for data collection and integration using RTLS and LiDar data.

2.1 RTLS for Object Identification and Localization

Here, an integrated system of RFID and UWB sensors is used. This integration helps to avoid the high cost of UWB implementation for object tracking while benefiting the medium-range capability of the RFID tags [19]. This method aims to provide near real-time localization data of indoor objects. An integrated use of RFID and UWB sensors benefits from the accurate positioning capability of UWB sensors for localizing the hand-held RFID reader in an indoor environment [19, 28-30]. The system can localize the tagged objects using less expensive passive RFID tags while transferring the collected data through cloud-based data collection tools. As illustrated in Figure 1, the RTLS method assigns unique IDs to identified objects, thereby compensating for the limitations of computer vision in distinguishing identical objects.

The input data for this system are gathered using a hand-held RFID reader, which is equipped with an UWB tag. The data are collected in the form of two .txt files, corresponding to the RFID and UWB devices. The RFID file contains the ID and Received Signal Strength Index (RSSI) values, while the UWB file captures real-time 3D coordinates of the roving RFID reader. The system's output includes the estimated 3D coordinates of the RFID tags attached to various objects. The authors' experimental work showed an accuracy of around 1.5 meters for 3D localization of the tagged objects, while 90 percent of the objects are identified and localized by the

integrated RFID-UWB technologies.

2.2 LiDar-based Computer Vision for Object Detection and Localization

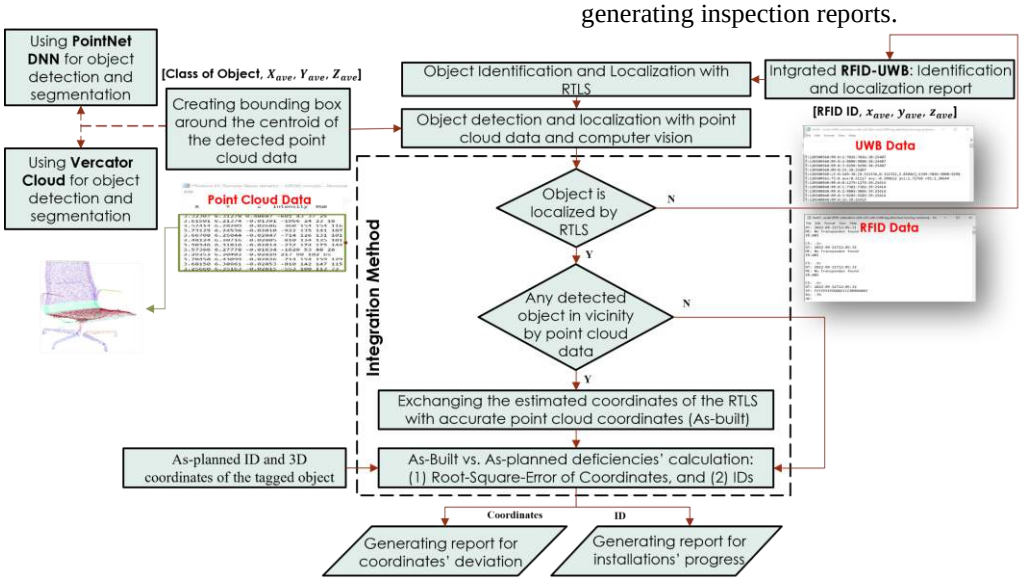
This study uses a point cloud-based algorithm, PointNet, to detect and localize objects. An available benchmark is used to train and test the model [25, 28]. The acquired point cloud data collected in the laboratory are fed into the model to validate the algorithm. The algorithm used has an acceptable classification accuracy. However, the results for 3D scene object segmentation and detection, which is required for detecting the target objects in the scene, are unsatisfactory. Only four out of ten target objects are correctly identified by the network. However, the localization accuracy of the detected objects increased to a few centimeters. This problem was reported in [26] and is compensated by integrating the RFID technology in this study. Also, for comparison purposes, object segmentation and detection have been done by a ready-to-use platform in the market, Vercator Cloud, to improve the 3D scene object segmentation and detection [27].

As illustrated in Figure 1, the detected point cloud data obtained through the computer vision algorithm compensates for the low accuracy of the 3D coordinates provided by the RTLS. This enhancement improves the 3D localization of the tagged objects, which is essential for accurately measuring the location of installed components.

2.3 Integrated RTLS and LiDar Data for 3D Object Identification and Localization

Integrating RTLS data with point cloud data enhances the localization and identification of the objects by benefiting the capabilities of these two types of data [20]. Assigning IDs to identical objects through RTLS ensures accurate identification, which is not possible with computer vision algorithms due to their limitations in differentiating identical objects from the same class. Additionally, RTLS is useful in Non-Line-of-Sight (NLoS) scenarios where the LiDAR device cannot collect point cloud data (i.e., in the covered area or invisible objects behind a panel). However, point cloud-based computer vision algorithms provide more accurate localization information with centimetre-level accuracy, which is crucial for many use cases on job sites, such as for automated inspection of the Mechanical, Electrical, and Plumbing (MEP) installations.

For integration, all objects recognized and localized by the RTLS and point cloud data are first derived. Then, for any object tagged by the RFID tag, the objects detected by the point cloud data in the vicinity of the tagged object that belong to the same class of object are selected. For example, if an object (i.e., chairs in this study) is tagged and identified with the RFID tag, the point cloud data detected as a chair by the DNN algorithms are assigned to that chair. The accurate coordinates of the detected objects by point cloud data are then replaced with the location information of the RTLS system. Figure 2 shows the flowchart of the steps for individual use of these technologies and their integration for generating inspection reports.



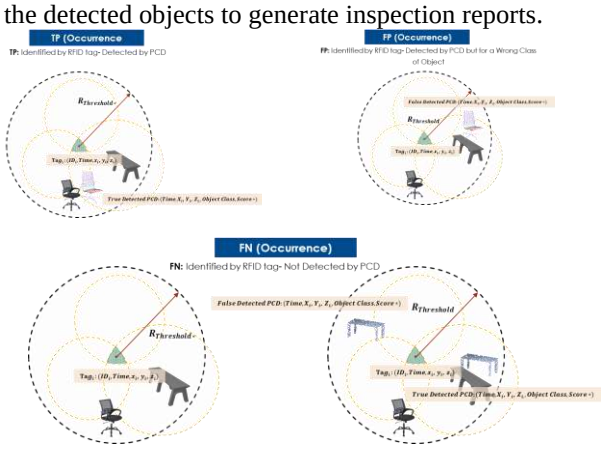


Figure 2. Flowchart of the developed method for integrating RTLS and point cloud data.

The integration enhances the localization accuracy of the RTLS within the coordinates' accuracy of the point cloud data. However, the experiment results show that the occurrence rate for this improvement is only 30-40 percent of the tagged objects when using the PointNet algorithm and available datasets as a benchmark [20]. For the other 60-70 percent of the tagged objects, the identification and localization information achieved by the RTLS is still used to generate the inspection reports. In this study, the computer vision results achieved with PointNet are compared with those achieved by the Vercator cloud platform. Vector Cloud uses optimized computer vision-based algorithms to detect objects from point cloud data and for various classes of objects. Also, it enables us to export the labelled point cloud data for further analysis and integration with RTLS data [27].

Figure 3 illustrates various scenarios for integrating RTLS and point cloud data to detect chairs in the laboratory. Integrating the RTLS data with computer vision data ensures higher accuracy of the objects' 3D coordinates while assigning IDs to the detected objects to generate inspection reports.

Score: The score of DNN for a specific Class of Object

Figure 3. Various scenarios in integrating RTLS and point cloud data.

3 Validation of the Developed Framework

The developed framework is validated through an experimental study conducted in a laboratory environment, in which identical chairs are used as the sample class of objects to be identified and localized through the developed framework. The chairs are labelled with passive RFID tags on their top back at a height of one meter and put on the targeted tie points on the ground (Figures 4 and 5). The laboratory is also scanned with a LiDar device to calibrate the RTLS system and collect point cloud data required for the DNN algorithms. Table 1 shows the as-planned coordinates of the chairs on the designated tie-points on the ground, along with information about the assigned RFID ID to each chair. Ten tie-points are selected from a total of 65, where each chair is located on the tie-points.

The tagged chairs are identified and localized by the RTLS technologies, RFID-UWB. At the same time, the chairs are detected and localized by the computer vision algorithms. The integrated method is then used to exchange information to generate inspection reports and identify coordinates' deviation. Table 2 illustrates the estimated coordinates of the chairs as determined by the integrated method used in this study in two scenarios: (1) using the PointNet algorithm and (2) using the Vercator cloud platform to refine RTLS coordinates. The coordinates deviation is calculated using the Root-Mean-Square-Error (RMSE) between the as-built coordinates and the as-planned coordinates of the chair in each tie-point. In a real scenario on the job site, this value is a sum of the deviations from the as-planned coordinates and the integrated method's error in estimating the chairs' coordinates. However, in this experiment, all chairs are precisely located on the as-planned coordinates to identify the integrated method error in estimating the as-built coordinates, as provided in the last column of Table 2. This error could result by various factors that affect the performance of the technologies used on the laboratory or job site environments. For instance, the presence of the metal objects, occlusions and obstacles decrease the localization accuracy of the integrated method. Additionally, the process of mapping RFID-based data to point cloud data reduces the precision of the coordinates detected and localized by the computer vision algorithm. Nevertheless, this integration is essential to improve the detection rate of the integrated method.

To calculate the progress of the chair installations, the number of identified chairs is divided by the total number of planned tie points. In this study, only one chair was not identified and localized by the integrated method. Since all chairs are available at the targeted tie-points, the estimated progress should be 100 percent. However, due to the integrated method error in object identification, this value has a 10 percent error from the actual progress.

* The refined RTLS locations by integrated method using DNN algorithm.

As illustrated in Table 2, the use of Vercator Cloud enhances the detection rate of the chairs from 40 percents to 70 percents. This is due to optimized algorithms used in this platform and with a larger dataset than the PointNet algorithm. Also, that results in more accurate coordinates for the chairs identified through the integrated method. As provided in the table, the chairs are localized more accurately with an average accuracy of 62 centimeters to the 27 centimeters by using Vercator Cloud platform instead of PointNet algorithm. This is close to the required accuracy for approving the installed project's components, which is around 15 centimeters. However, one of the chairs is still not identified through the integrated method, and with RTLS tags (chair number eight in Table 2).

3.1.1 Contributions and limitations

The framework presented in this study automates the generation of inspection reports for construction operations during the construction phase. Integrating the RTLS data with point cloud data enhances indoor object localization by refining the estimated coordinates of the installed project components using the object segmentation capability of the DNN algorithms and accurate coordinates of the point cloud data.

While the developed method automates the generation of inspection reports, it also presents certain limitations. For experimental purposes, the target objects were positioned at the same height and

maintained a clear line of sight (LoS). Future studies could explore the challenges of tag placement at varying elevations and in congested environments, which would provide valuable insights for practical applications on job sites.

The application of the computer vision algorithm used in this study should be extended to more construction components, such as MEPs, which are among the most challenging components to track and report on the job sites. Available point cloud data benchmarks assist in detecting some of these objects without the need for manually creating annotated datasets. However, object detection accuracy is not acceptable for the class of objects with small datasets due to the imbalance in the training dataset size for these objects compared to others. Future investigations are needed to improve object detection with computer vision and to automate the integration of RTLS and point cloud data. This will result in more accuracy in location identification of the detected objects required for approving the installation of the projects' components. Also, the object detection capability of the DNN algorithms could be used to improve the object identification of the RTLS. However, identical objects still cannot be distinguished by DNN algorithms. Further integration with BIM compensates for this limitation.

4 Summery and Concluding Remarks

The framework developed in this study supports the automated generation of inspection reports. The inspection reports include the progress of the installed components and their targeted coordinates on the construction sites. These reports are used to identify deviations from the targeted coordinates of the installed project components by comparing their as-built locations to their as-planned ones. The digital solution technologies employed in the framework are utilized for data capturing, analysis, and reporting, leveraging the developed integration capabilities. These digital solutions include: (1) an RTLS based on integrated RFID-UWB for location identification of tagged objects in an indoor environment, (2) computer vision and deep learning models for object detection and localization of the installed project components using point cloud data, and (3) an integrated method that enables automated generation of the inspection reports through refined localization and recognition of the components. Further integration of the developed method with a project's planned data (i.e., planning and scheduling data) enhances the method's cohesion in automated data acquisition, site inspection, and progress reporting. Additionally, the method has the potential to be further integrated into various quality aspects of a project, including material quality, waste management, and the execution quality of construction operations.

Abstract

Efficient construction of precast concrete buildings (PCB) with high quality and safety requires adequate planning and scheduling of the assembly of precast components (PC). Traditional manual assembly sequence planning and scheduling (ASPS) methods often result in sub-optimal and error-prone schedules, especially in complex projects. Existing metaheuristic-based ASPS methods lack generalizability and capability to handle dynamic conditions in construction projects. Reinforcement Learning (RL) offers a promising solution to these limitations. However, existing RL-based construction scheduling studies overlook project uncertainties and rely on value-based methods, which are computationally inefficient for large-scale problems. This study proposes a novel method for optimal ASPS of PCB projects using RL integrated with Monte-Carlo Sampling (MCS). The method uses a Temporal Graph Network (TGN) and Multi-Layer Perceptron (MLP) to create embeddings of the relevant input information, while the Proximal Policy Optimization (PPO) RL algorithm is employed for generating the assembly schedules using the embeddings. Reward shaping is utilized to generate schedules that simultaneously minimize time, cost, and constraint violations. Preliminary results from a case study on a hypothetical PC project with 34 precast concrete walls demonstrate the proposed method to provide stable learning and generate optimum assembly schedules. The proposed method outperforms existing value-based RL approaches for construction scheduling, demonstrating superior training stability, solution quality, and execution efficiency.

Assembly sequence planning and scheduling; Precast building construction; Reinforcement learning; Proximal policy optimization

1 Introduction

The growing housing demand has created the need to build 96000 homes every day worldwide [1]. Prefabricated Housing Construction (PHC), an innovative construction method, provides a high-speed and sustainable solution to this challenge [2]. It involves offsite manufacturing of components like columns and walls, which are transported and assembled onsite. Among prefabrication methods, precast concrete buildings (PCB) are widely adopted, using precast concrete elements [2]. Efficient assembly sequencing planning and scheduling (ASPS), considering constraints like resource and material availability, is vital for PCB project success [3]. ASPS refers to the process of defining the sequence and timeline of assembly of precast components (PC). Conventionally, ASPS is done manually by practitioners based on their experience, leading to suboptimal and error-prone results, especially in large and complex projects [4]. Thus, there is a growing focus on automating ASPS in PCB projects.

Existing studies in this direction have primarily utilized metaheuristic methods such as Genetic Algorithm (GA) and Simulated Annealing (SA) [5]. However, such methods lack generalizability to different types of projects [6], and cannot capture the uncertainties and dynamic situations in the construction projects [7].

To this end, RL has been used recently to address construction planning problems [7]. RL is a machine learning technique in which an agent learns to make the best decisions by mimicking humans' trial-and-error learning process. Existing RL-based construction planning techniques have certain limitations, hindering their applicability in ASPS problems. First, they are primarily designed for conventional on-site construction projects. Second, ASPS involves sequencing numerous PCs, creating a large activity set that existing methods struggle to handle due to dimensionality challenges.

Finally, the construction processes' uncertainties were often overlooked. PCB processes can face uncertainties for various reasons, such as component characteristics and weather conditions [8], which need to be taken into account in ASPS.

To address these limitations, this study proposes a novel RL-based method to automatically generate the optimum assembly schedules for PCB, considering installation constraints and uncertainties in the activity durations and weather conditions.

Key innovations of this study are as follows:

a) A novel architecture is proposed using the Proximal Policy Optimization (PPO) algorithm [9], an actor-critic RL algorithm that can effectively handle large state and action spaces compared to the algorithms used in existing construction planning studies.
b) State, action space, and reward function, which play a crucial role in RL, are uniquely defined considering optimization objectives as minimizing time, cost constraint violations [3].
c) An approach to handle uncertainties through Monto Carlo Sampling (MCS) is incorporated with RL.

2 Literature review

2.1 Assembly Sequence Planning and Scheduling in PCB Projects

Initial studies in this direction utilized structural support and topological relationships between the building components to generate assembly sequences [10]. However, schedule optimization was not done. Later, researchers utilized Building Information Models and optimization algorithms to develop optimum assembly sequences. Optimization of ASPS has been done from various perspectives, such as maximization of structural stability [11], prioritization of heavier and larger components, minimization of installation time [3]–[5], [12], and reduction in interference between components, among others [12], [13]. Most of the studies utilized GA for optimization [3], [4], [11], [13]. To avoid the risk of slow convergence in large-scale problems, Liu et al. [5] integrated GA with SA. Other researchers used modified versions of GA to ensure population diversity [4]. However, existing studies failed to simultaneously consider assembly time, cost, and constraint violation as schedule optimization objectives. They lack the ability to swiftly adapt to dynamic conditions and uncertainties on the construction projects, as the solutions developed by GA only apply to the initial conditions of the optimization [14].

2.2 RL for construction planning

In RL, an agent learns to find the policy to make the best decisions by iteratively interacting with an environment, as shown in Figure 1. At each time step, the agent selects an action from the set of possible actions (known as action space), and the environment rewards the agent based on the selected action. Over the iterations, the agent improves the decision-making by maximizing the reward. In contrast to algorithms such as GA, RL algorithms can handle dynamic situations more efficiently as they automatically learn the best optimization strategy based on the interaction with the environment [6].

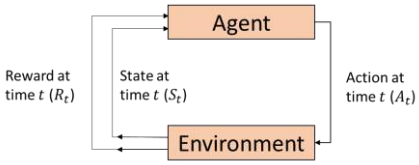

Figure 1. RL Model

Soman et al. [15] used Q-learning (a class of RL algorithms that maximizes the Q-function to find the best policy by estimating cumulative rewards for each state-action pair) to generate construction lookahead schedules automatically. Kedir et al. [7] utilized deep learning to estimate Q-function. Yao et al. [6] utilized Deep Q-learning (DQN) and sampling constraint-free actions to achieve faster convergence. However, they addressed precedence and resource constraints only. ASPS in PCB requires consideration of several constraints, such as the size and weight of the PC and interference between PCs. Moreover, the uncertainties of the construction environment were not considered, and only time-based schedule optimization was performed.

The Q-learning algorithm becomes computationally expensive for large-scale problems, for example, resource-constrained construction planning and scheduling [16]. The complexity further escalates in uncertain environments, where state spaces become continuous due to variables like activity durations and weather conditions. DQN algorithm is faster than Q-learning, as the Q-function estimation is done using deep learning. However, it is prone to suffer from instability in such cases of continuous state spaces [17]. Actor-critic algorithms, a class of RL algorithms, combine the strength of value and policy-based approaches. These algorithms use an actor to update the policy directly and a critic to evaluate the value function. Proximal Policy Optimization (PPO), a state-of-the-art actor-critic algorithm, balances exploration and stability [9], making it effective for handling complex, dynamic, and large-scale problems like ASPS. Despite its potential, PPO has not been extensively applied in this domain.

2.3 Problem statement

Based on the identified research gaps, this study proposes a method for ASPS in PCB projects using the PPO algorithm to generate assembly schedules that:

a) minimize time, cost, and constraint violations associated with the assembly. These objectives are selected based on their frequent use in the existing literature [3], [12], [13].
b) incorporate the uncertainty in the PCB projects. Two primary sources of uncertainties are considered: inherent variations in the activity durations and external uncertainty due to weather, both of which are prevalent in PCB projects [8].

3 Methodology

3.1 Problem formulation and mathematical modeling

Consider that the PCB consists of n elements to be scheduled. Each of these elements belongs to the component type $CT = [1,2,3, \dots i]$. The component types correspond to different categories in which the components can be divided, e.g., beams, columns, walls, etc. Each element e_k requires renewable resources $r_k = [r_{ka}, r_{kb}, r_{kc,\dots,} r_{km}]$, where r_{ka} denotes the requirement of resources of the category a. $R = [R_a, R_b, R_c, \dots, R_m]$ denotes the maximum availability of renewable resources in categories $[a, b, c, \dots, m]$. Each element e_k requires time t_k for assembly. The time requirement t_k for assembly of each element is assumed to follow a triangular distribution based on the findings of previous studies [18]. Weather conditions, including rain, wind, and temperature, are considered to impact the assembly durations [8]. The distribution of the values of these three weather conditions can be taken from a weather forecast [19]. The impact of weather conditions on the assembly durations can be identified using general codes of practice and relevant laws and regulations [8].

3.1.1 Objectives

$$minimize\ D_{total}, C_{total}\ and\ CV_{total} \quad (1)$$

Where D_{total} is the total scheduled duration of the project, C_{total} is the total cost (including direct cost and indirect cost) of the project and CV_{total} denotes the total number of constraint violations in the generated schedule.

3.1.2 Constraints

The key constraints for ASPS were identified based on the literature. The constraints are divided into two categories: Hard constraints and soft constraints.

(a) Hard constraints: The constraints that must not be violated as they ensure the structural integrity of the building and adherence to scheduling logic.
  (i) Structural support constraints: The PC should be assembled according to structural support requirements [11].
  (ii) Resource availability constraint: The allocated resources must be within the limits of the R [8].
  (iii) Component availability: A PC can be assembled only after its delivery on-site [8]. A PC delivery schedule is used to consider component availability.
(b) Soft constraints: The constraints whose violation should be minimized as much as possible.
  (i) Weight constraint: The heavier the PC, the earlier it should be assembled [3].
  (ii) Size constraint: The larger the space occupied by the PC, the earlier it should be assembled [3], [12].
  (iii) Interference constraint: Interference between the new PC and the pre-installed PC should be minimized [3].

3.2 RL model for ASPS using PPO

3.2.1 Network architecture

The network architecture of the proposed model for automated ASPS using PPO is depicted in **Error! Reference source not found.**.

3.2.1.1 State:

The state represents the combination of information required by the agent for decision-making. In this study, the state information at a timestep includes the following information:

(a) The construction schedule generated till the timestep is represented in the form of a graph. Each graph node represents the elements and their properties, and the edges represent their relationships. The properties of the nodes are represented in **Error! Reference source not found.**. The first property represents the status (not started, in progress, completed) of the element. The second property corresponds to CT. The third and fourth properties represent the resources needed. They can be customized based on the number of categories of resources. The next two properties focus on the completed and remaining duration of elements till the current timestep. The last two properties represent the weight and the area of the elements, respectively.
(b) The availability of PC on-site, represented using a binary vector of length equal to n.

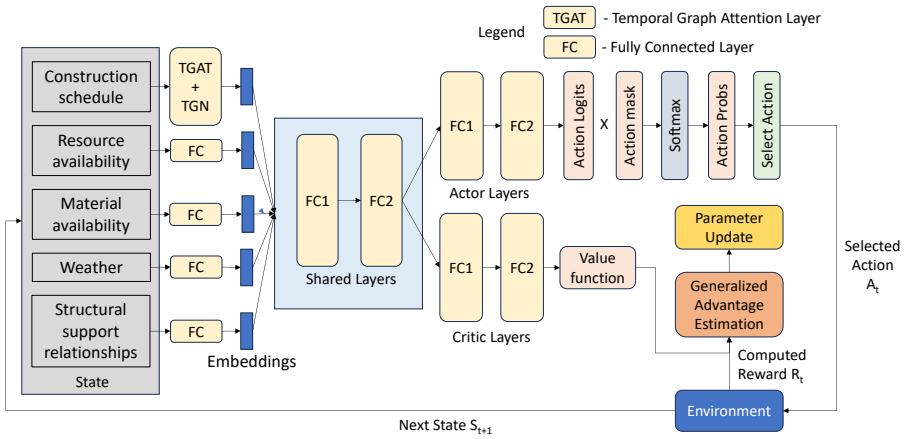

Figure 2 . Model architecture

Element status	Element type	Crane needed	Labor needed	Elapsed duration	Remaining duration	Element weight	Element area

Figure 3 . Node features

(c) The availability of resources of different categories, represented using a vector of length equal to R.

(d) Structural support relationships in the form of binary vector S of shape $[n, n]$. A value of $S_{ij} = 1$ represents that the element i is supported by the element j.

(e) Weather is represented in the form of a vector of dimension $[3, T]$, where T denotes the length of the forecast period for which the weather data is considered. Each column represents a particular day, and three rows represent the sampled values of rain, temperature, and wind.

3.2.1.2 Action:

Considering the n elements to be scheduled, the action space is a matrix A of size 2^n, where each row represents a binary vector of length n, indicating which elements should be started (1 for start, 0 otherwise). In PCB, the number of elements installed simultaneously is limited by the project's available cranes, so actions exceeding this limit are removed.

3.2.1.3 Reward:

As this study intends to address three optimization objectives, i.e., time, cost, and constraint violations simultaneously, the reward structure used in this study consists of the following components addressing these objectives:

(a) Time:

$$R_{t1} = r_{w1} * N_s + r_{w2} * N_f - r_{w3} * t$$

$$R_{t2} = r_{w4}$$

Where R_{t1} is the reward given to each timestep. It includes a positive reward for the number of elements started (N_s), the number of elements finished (N_f), and negative reward for each timestep (t). A large positive reward of R_{t2} is added to finish all the elements. r_{w1}, r_{w2}, r_{w3}, and r_{w4} are scalar reward coefficients.

(b) Cost:

$$R_c = -r_{w5} * [\Delta t * (R_{ct} + I_{ct})]$$

Where R_c is the cost reward per time step, Δt is the time difference between the current and previous timestep, R_{ct} and I_{ct} are resource and indirect costs per unit of time, and r_{w5} is the reward coefficient.

(c) Constraint violation:

$$R_{con} = -r_{w6} * N_{sc}$$

Where R_{con} is the reward for constraint violations, N_{sc} is the number of soft constraint violations in that timestep, and r_{w6} is the reward coefficient. The violations of weight and area constraints are computed based on the weight and area values in the node features. For interference constraint violations, an adjacency matrix and an interference matrix are used [4]. The adjacency matrix represents the adjacent elements. The interference matrix is a $[n, n]$ matrix, where each element is a 1D vector IC_{ij} of length 6, which is as follows:

$$IC_{ij} = [d_{x+}, d_{x-}, d_{y+}, d_{y-}, d_{z+}, d_{z-}]$$

Where:

IC_{ij} = a binary vector of interferences if the element j is installed before the element i,

$$d_* = \begin{cases} 1, if\ \ i\ can\ move\ in\ that\ direction \\ 0, otherwise \end{cases}$$

For example:

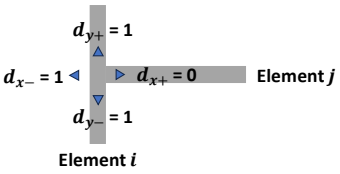

Figure 4. Plan of connection between two elements

3.2.1.4 Environment:

(a) Initialization:
The environment is initialized with constraints such as resource availability, structural support constraints, element weights, etc. The MCS is used to handle uncertainties in activity durations and weather conditions. MCS uses repeated random sampling of a stochastic variable from its distribution to approximate the desired quantity [20]. It finds suitability in solving stochastic optimization problems due to its simplicity and ability to approximate well with a small number of samples [20]. We sampled installation durations and weather conditions from their distributions at each episode's start. The episode is then run using these values. This way, the RL agent learns to perform well over the distribution of installation durations and weather conditions.

(b) Scheduling Logic:
At each timestep, the agent selects an action, and the environment updates the schedule, calculates rewards, and returns the updated state and reward. The elements in the selected action are started first, and resources are assigned to them. Then, the earliest finishing element is finished, and its resources are released. The rewards are calculated, and the next state is sent to the agent. The episode ends when all elements are scheduled.

3.2.1.5 Network architecture

The state information, including the resource availability vector, material availability vector, weather vector, and structural support relationship vectors, are embedded using Fully Connected (FC) layers. The construction schedule, which is represented in the form of a graph, is embedded using a combination of Temporal Graph Attention Network (TGAT) [21] and Temporal Graph Network (TGN) [22]. At each timestep, the graph evolves as the node features and their relationships change. The conventional GNNs used in existing RL-based construction scheduling studies [6] fail to capture such temporally evolving dynamic graphs [22]. TGNs provide an efficient way to deal with such dynamic and time-dependent networks [22]. TGN, when used with TGAT, encodes time features in addition to the node features and uses a self-attention mechanism [23] to identify important parts of the graph to generate the embedding. TGN also incorporates a memory module using Gated Recurrent Units to retain information from previous timesteps, enabling the network to understand how the schedule evolves over time. The actor-critic network includes two shared FC layers and two separate FC layers.

3.2.1.6 Action masking

An action mask is created for actions that violate hard constraints. It filters out such invalid actions and improves training efficiency by reducing the number of possible actions.

4 Case study

To validate the proposed method, a hypothetical project consisting of ASPS of 34 precast walls is used based on existing studies [4], [8]. The project consists of walls of varying thicknesses. Figure 5 shows the walls in the project along with their ID.

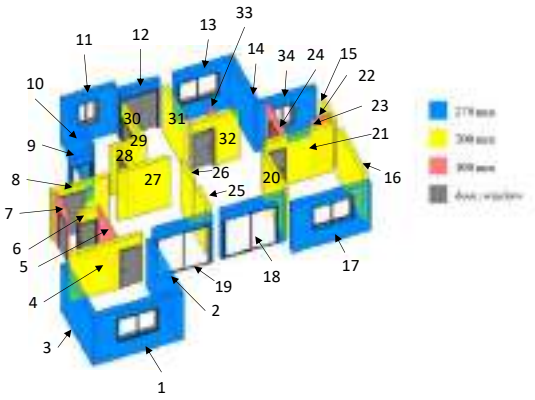

Figure 5. Case study project (Picture credit [4])

As the weights and areas of the walls were not available in Yang et al. [4], they were assumed based on the relative sizes of walls in Figure 5. Similarly, the distribution of installation duration of the walls was not available. Therefore, all the walls were assumed to have the same triangular distribution of durations, derived from Yuan et al. [18]. The assumed installation duration distribution for each wall is (0.47, 0.625, 0.78) hrs. The details of the walls are shown in Figure 5, Table 1, and Table 2. The project is assumed to be constructed in Auckland, New Zealand (NZ). The weather forecast of Auckland is taken from online sources [24], [25]. The impact of weather conditions on construction activities is considered based on local industry standards. Based on the weather forecast, the temperature and rain values are

found to have no impact, and the impact of wind speed is considered based on recommendations from the Crane Association of NZ [26]. Lifting is assumed to involve two mobile cranes, with worker requirements based on Yuan et al. [8]. The larger walls (Area >= 2.5m^2) are assumed to require 6 workers, and others require 4 workers. Costs for the crane and workers are derived from Rawlinsons New Zealand Construction Handbook, 2014 [27]. All the elements were assumed to be already available.

Table 1 Wall weights

Wall ID	Weight (kg)	Wall ID	Weight (kg)
6, 7, 22, 23, 33	50	13	225
5, 9, 15	75	1, 17	250
24, 25, 26, 28	100	11, 34	275
8, 12, 18, 19, 29, 30, 32	150	2, 3, 10, 14	300
4, 16, 20, 21, 27, 31	175		

Table 2: Wall areas

Wall ID	Area (m^2)
22, 23, 25, 26, 33	0.5
6, 7, 9, 15, 28	0.75
5, 24, 30, 32, 29, 31	1.25
8, 12, 27	2
2, 3, 10, 13, 14, 16, 20	2.5
11, 18, 19, 34	2.75
1, 4, 17, 21	3

The validation experiment included two facets: (1) a comparison between the performance of the developed approach with existing DQN-based construction scheduling methods and (2) a sensitivity analysis to understand the impact of scales of reward coefficients. For the first aspect, the comparison was done between the results obtained using DQN+GNN (DQN RL algorithm and GNN for schedule embedding [6]), and PPO+TGN+TGAT (proposed in this study). The key hyperparameters for the three settings are described in Table 3. For the second facet, 7 scenarios of reward coefficient were created, as described in Table 4.

Table 3: Key Hyperparameters for training

Hyperparameter	DQN+ GNN	PPO+ TGN+ GAT
PPO clip epsilon	NA	0.25
PPO entropy coeff.	NA	0.08
Learning rate	0.0003	0.0003
Gamma	0.99	0.99
GAE lambda	NA	0.95
Graph network layers	2	2
Epsilon decay	1000	NA
Epsilon start, end	1, 0.01	NA

Table 4: Sensitivity analysis scenarios

Scenario	r_{w1}	r_{w2}	r_{w3}	r_{w4}	r_{w5}	r_{w6}
S1	1000	1000	2000	20000	5	1000
S2	1000	1000	2000	20000	5	10
S3	1000	1000	2000	20000	0.05	1000
S4	1000	1000	2000	20000	0.05	10
S5	10	10	20	200	5	1000
S6	10	10	20	200	0.05	1000
S7	10	10	20	200	5	10

The algorithm was run on a Windows 11 computer, with Intel® Xeon® Gold 6242R CPU @ 3.10GHz processor and NVIDIA Quadro RTX 5000 16.0 GB GPU for 5000 episodes. The high number of episodes was to consider the uncertainties in the problem, such that the agent can learn over the distribution of duration and weather conditions based on MCS. The results of training on Scenario S1 are demonstrated in Figure 6**Error! Reference source not found.Error! Reference source not found.**. The graphs show the 100-episode average of computed rewards, costs, schedule durations, and constraint violations. Since each episode is trained on different initial conditions, averaging over 100 episodes provides a clearer trend. While existing studies developed assembly sequences focusing on single objectives, our method effectively generated schedules minimizing cost, time, and constraint violations simultaneously. For PPO+TGN+TGAT, the agent successfully discovered a policy that maximizes the reward, achieving greater consistency after approximately 2000–3000 episodes. Similarly, the number of constraint violations decreased and stabilized around the same point. The time and cost showed only a mild reduction. A maximum of two elements could be installed parallelly due to the availability of only 2 cranes. Re-sequencing the elements did not reduce the duration and cost, as the duration distribution of the elements was the same. Further, the schedule duration and cost exhibited higher variability, likely due to the inherent variability in sampled durations and weather conditions, which have a greater impact on these metrics.

Our method significantly outperforms the DQN+GNN [6] based method used in existing studies, delivering superior solution quality, enhanced training stability, and improved execution time. As evident from Figure 6, the total reward and constraint violations identified using PPO+TGN+TGAT were significantly better than DQN+GNN-based solutions. Although the time and cost were quite close, PPO+TGN+TGAT showed better convergence as compared to DQN+GNN. Moreover, for all four criteria, PPO+TGN+TGAT demonstrated superior stability of training. DQN utilizes bootstrapping by estimating Q-function, which can be highly unstable [17], especially with large state space created in the current problem due to uncertainty. Since the parameter updates in DQN solely rely on Mean

Squared Error loss, small overestimation or underestimation of Q-values can lead to large gradient updates, causing instability in the training. PPO directly optimizes the policy using a clipped loss function, limiting the extent of updates in each iteration and providing better stability in learning [9]. The TGN+TGAT network incorporates the temporal aspect of the schedule and keeps a memory embedding of the actions taken in the previous timesteps, handling the dynamically changing graph better. As a result, the objectives could be minimized to a greater extent as compared to the DQN+GNN-based method. To train the 5000 episodes, DQN+GNN took around 12 hours, while PPO+TGN+TGAT required nearly 6.8 hours. DQN requires the management of a replay buffer and target network updates, which are not needed in PPO, resulting in lower execution time for PPO+TGN+TGAT in the validation experiment. However, further work is needed to reduce computational demands considering the near-real-time application requirements.

The results of sensitivity analysis using scenarios in Table 4 are demonstrated in Figure 7. The results show the impact of variation in reward coefficient scales. Since the time and cost varied within a very narrow range, the variation in the total reward mainly depended upon r_{w6}. As a result, the total reward for S2, S4, and S7 was found to be mostly consistent. For the rest 4 of the scenarios, an evident increment in the reward was found. S1 performed generally well across all three objectives as the reward coefficients were decided to provide relatively similar weightage to all three objectives.

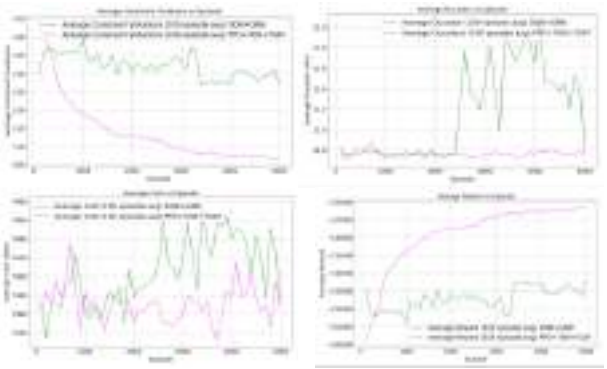

Figure 6. Validation results on scenario S1

5 Conclusion and Outlook

This study proposes a novel method for automated multi-objective ASPS optimization in PCB projects under weather and activity duration uncertainties using RL. PPO, a popular actor-critic RL algorithm, is combined with MCS to train an agent to generate assembly schedules minimizing time, cost, and constraint violations. Activity durations and weather conditions are sampled at each episode via MCS, enabling the agent to learn optimal policies under uncertainties. A novel PPO network architecture is proposed for ASPS, utilizing TGAT and TGN to create the embeddings of the schedule generated at each timestep. Additional state information is encoded using FC layers, while the actor-critic network consists of 2 shared and 2 separate FC layers. The method is validated on a hypothetical project involving the assembly of 34 precast walls. The case study results show that the proposed method effectively identifies assembly schedules that minimize cost, time, and constraint violations while maximizing rewards under uncertainties. It outperformed the conventional DQN+GNN-based method used in existing RL-based construction scheduling studies.

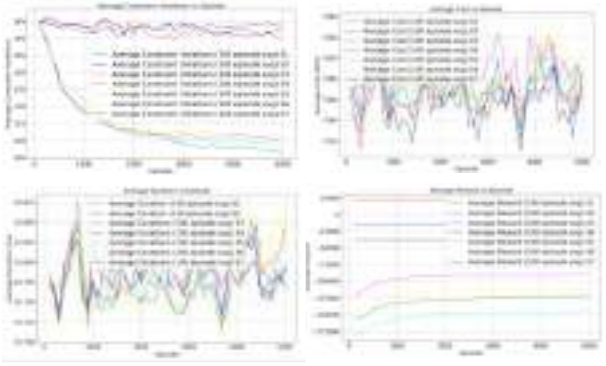

Figure 7. Reward coefficient sensitivity analysis results

The study has limitations that need to be addressed to improve the robustness and industry applicability of the proposed method. First, validation using real-world, complex PCB project data is required. A systematic identification of optimal reward coefficients for better results should be explored. Finally, the performance of the developed method should be compared with other RL algorithms, such as Deep Deterministic Policy Gradient (DDPG), Double DQN, and Soft Actor Critic (SAC), etc.

Abstract -

For real-time simulation of construction equipment, the operation of blades and other tools in contact with soil represent some of the most challenging problems both in terms of performance and accuracy. Soft soil interactions are particularly difficult to model and simulate efficiently, yet, a physically representative, interactive simulation that provides real-time feedback to the operator is required in operator training and certification scenarios, as well as for human in the loop engineering applications.
In this paper, we address the problem of simulating in real-time several piling techniques that are fundamental in construction. A sufficiently accurate resistance force/torque model is essential for the realistic simulation of piling equipment. Particle based models and finite element soil interaction models are too computationally expensive for most real-time simulations. We propose an analytical approach for estimating the piling resistance motivated by bearing capacity theories developed for deep foundations. The proposed model can accurately capture the soil resistance in three different piling scenarios: hammering, drilled displacement piling, and continuous flight augering. The vertical resistance force and torque, and their coupled nature is considered with kinetic friction effects. The presented models are validated against experimental data from subject matter experts. The results obtained for continuous flight augering are also compared to results from a discrete element simulation. To improve the realism of the analytical model, a hybrid numerical-analytical model is outlined. The proposed real-time models support fast equipment design iterations, control development, automation and interactive operator training.

Keywords -

real-time simulation. pile driving. soil-tool interaction. ground resistance. operator training.

1 Introduction

Using simulators to train operators of heavy construction site equipment requires the ability to efficiently model and simulate the interactions between tools and soil in an interactive and realistic way so that real time feedback can be provided to a human in the loop. In this work, our goal is to create a model of a drill rig that creates holes for foundation piles, an operation known as piling or pile driving. We propose a real-time model for three fundamental piling techniques used in the construction industry with a level of fidelity and realism that is appropriate for training drill rig operators. The three piling techniques of interest are the displacement pile with lost drill point, the continuous flight auger (CFA) and the hydrohammer.

The soil displacement piling operation with a lost drill point is an operation in which a large cylindrical pile with a conical tip is drilled into the ground by applying both a vertical force and a torque. Rather than removing soil from the ground, this operation displaces the soil downward and laterally. Once the pile has reached the desired depth, the pile is removed, leaving behind the drill point. The resulting hole is filled with concrete. Continuous flight augering is another excavation process in which the drill bit consists of a helical blade that removes the soil as it drills into the ground and a hollow shaft that is used to inject the concrete as the drill is removed.

Finally, the hydrohammer, or hydraulic impact hammer, is a tool that can be used to create holes for foundation piles through repeated hammering of a steel pile into the ground until the desired depth is reached. Fig. 1 illustrates the drilling tools used for each of these operations.

The Earthworks module in Vortex Studio [1], which is used for the models that will be described in this work, uses analytical formulas to estimate the cutting force resisting the motion of the tools interacting with the soil because these are efficient enough for real-time simulation. For the representation of the disturbed soil in motion, a particle based model is used.

In this paper, we present simple and efficient models

Figure 1. Displacement pile (top), continuous flight auger (middle) and hydrohammer (bottom) on a drill rig

to consider the force-torque coupling, and simulate the special case of cork-screwing. The model is based on classical bearing capacity formulas which we use in the context of dynamic simulation. We use data from industry experts as well as the results of DEM simulation to validate the qualitative and quantitative accuracy of the real-time model.

2 Theoretical Background

2.1 Soil-Tool Models

Soil can be modelled as continuum or by using particle representation for the individual grains. Both finite (FEM) and discrete element models (DEM) have limitations as the real soil is neither a continuum nor a collection of particles only. Water content may also play an important role as void ratio and pore pressure have an effect on the effective stress. The simulation of these models are also very computationally intensive. The Earthworks module in Vortex therefore uses analytical formulas to estimate the cutting force resisting the motion of the tools interacting with the soil, while for the representation of the disturbed soil in motion a particle based model was developed. The cutting force estimation is based on the fundamental earth-moving equation (FEE) [2]. In situations, where the visual representation of the cut and the effect of the transported soil is not important, applying purely analytical models could be sufficient. This is the case when a drill rig is creating holes for foundation piles at a relatively slow penetration rate.

The model behind the FEE equation is two dimensional, i.e., the cutting tool is considered to have an infinite width. Another common assumption is that the soil fails along a straight line starting at the tip of the tool and reaching the soil surface at a distance ahead of the tool. The tool is a flat blade and the slope of the failure line depends on the internal friction angle of the soil. The soil resistance is approximated based on the quasi-static equilibrium of the soil wedge formed in front of the blade. By assuming passive soil failure, Rankine's passive earth pressure theory and the Mohr-Coulomb failure criterion can give an approximate value for the soil wedge angle which is valid for frictionless, vertical blades with a flat soil surface [3]. The soil wedge angle can also be estimated by minimizing the weight related N-factor in the FEE [4]. In Luengo's work [5], the soil-tool interaction was studied in an automated excavation scenario, where the FEE was modified to also include the effect of the slope of the terrain.

Similar models were developed to assess the bearing capacity of foundations. For shallow strip foundations Therzaghi's bearing capacity formula [6] can be used. To account for deviations from shallow strip foundations, several different bearing capacity and correction factors exist [7, 8, 9, 10]. Empirical shape factors are used to consider the actual shape (e.g., circular cross-subsection) of the pile. Several authors proposed similar formulas by considering installation depth and inclination. In soil augering and robotic drilling the soil/material moved by the flights of the auger and transported to the surface has an important effect on the resistance felt by the tool. In case of augering the flights are typically full of compacted soil and the soil-tool interaction is simultaneous on all the surfaces of the auger and the borehole. In case of drilling, separate particles are being transported, the motion of which also depend on the centrifugal effects at higher rotation speeds [11]. A special operation which can happen in case of soil augering is called cork-screwing. In this case the downward velocity is such that the penetration in one turn is equal to the pitch and the uplift velocity of the soil is zero. The drill screws into the soil as the worm of a corkscrew.

Compared to the cutting force resistance model, the estimation of the ground reaction for piles and drill bits are more complicated in the sense that the reaction force/torque has more components, and there is coupling between the reaction force and torque. When rotary displacement piles are pulled into the ground by the drill rig, the cylindrical surface of the pile comes into contact with the soil, and, in addition to the tip resistance, a depth dependent and distributed friction force develops along the embedded length of the pile. As the pile rotates, the direction of the resultant friction force changes with the instan-

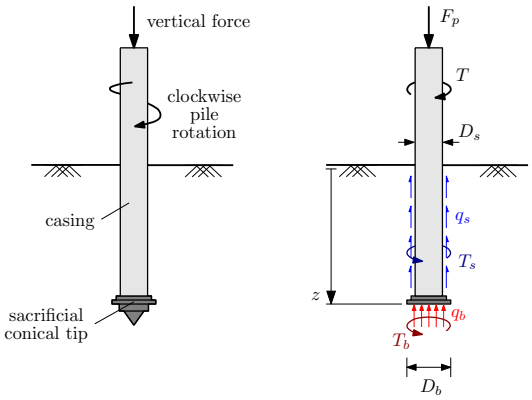

Figure 2. Loading and reactions of circular cross subsection pile

taneous pitch of the pile. At high rotational speeds with slow penetration this generates a large resistance torque, whereas at a low rotation rate the vertical component of the friction force will dominate. This phenomenon is used to lower the skin resistance below certain depths to reduce the necessary piling force.

2.2 Ground Resistance Force

When a pile is already installed in the ground, two main resistance force components can be distinguished. These are the base or tip resistance and the skin resistance. The base resistance is a localized property whereas the skin resistance, which depend on the embedded surface area of the pile, depend on the composition of the soil layers.

Due to the complexity of the problem, piles are often designed using empirical methods. This is based on on-site measurements, i.e., the bearing capacity of the pile is correlated with cone penetrometer test data. Another approach for estimating the resistance is to use analytical models that are based on certain failure criteria of the soil. An advantage of these analytical models is that they depend on a relatively limited number of parameters and can provide a tunable model for simulation. In case of the ground model developed for the IHC project the latter approach was followed.

Pile design formulas are valid under the assumption that the pile is advancing slowly and a quasi-static model is applicable. The formulas presented below are based on this assumption. Additional kinematic considerations were necessary to model the resistance of the different piles. Under slow rotation and penetration, the main ground reaction components are presented in Fig. 2, where F_p and T are the applied piling force and torque, q_b and q_s are the distributed base and skin reaction forces, and T_b and T_s are the resultant base and skin resistant torques.

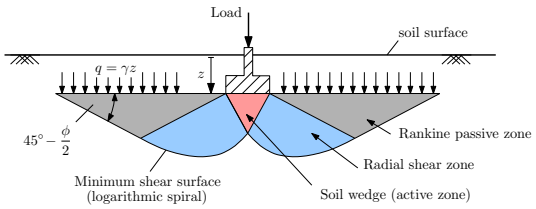

Figure 3. Assumed soil failure in case of shallow strip foundations

2.2.1 Base resistance

The resistance of the soil at the tip of the pile is often calculated by using Therzagi's bearing capacity formula [6]. This is valid for strip foundations at a shallow depth, but empirical shape factors are used to consider the actual shape (e.g., circular cross-subsection) of the pile. Terzaghi's assumption for shallow strip foundations is shown in Fig. 3. In this figure, z denotes the depth of the tip of the pile, γ is the specific weight of the soil, and ϕ its internal friction angle. In addition, q denotes the overburden pressure due to the weight of the soil. There are three distinct zones identified, and the soil is assumed to fail (be able to slide) along the edges of these zones. The bearing capacity of the soil can be calculated by analyzing the static equilibrium of the soil wedge shown below the pile.

The ultimate bearing capacity of foundations has the general form [7]:

$$q_b = c\, d_c S_c N_c + \gamma z\, d_q S_q N_q + 0.5 \gamma d_\gamma\, S_\gamma N_\gamma \quad (1)$$

where c, $q = \gamma z$ and γ are the cohesion, overburden pressure and specific weight of the soil, and N_c, N_q and N_γ are the corresponding bearing capacity factors. These factors have an intricate dependence on the internal friction angle of the soil. In addition, d_* and S_* denote different depth and shape factors that are used to adjust the contribution of the additive terms. The resulting base resistance pressure q_b can be used to estimate the resistance of the ground during piling as the force $Q_b = q_b A_b$ represent the limit force (bearing capacity) at which the pile should sink into the ground, where A_b is the area of the base of the pile.

According to Terzaghi [6], the bearing capacity factors are

$$\begin{aligned} N_q &= \frac{e^{2(3\pi/4-\phi/2)} \tan(\phi)}{2\cos(\pi/4+\phi/2)^2} \\ N_c &= \frac{N_q - 1}{\tan(\phi)} \\ N_\gamma &= \frac{\tan(\phi)}{\gamma}\left(\frac{K_{p\gamma}}{\cos(\phi)^2} - 1\right) \end{aligned} \quad (2)$$

where $K_{p\gamma}$ is the passive soil pressure coefficient usually given in the form of tabulated data in the function of the internal friction angle. A simpler form of the last bearing

capacity factor above was proposed by Coduto [12]:

$$N_\gamma = \frac{2(N_q + 1)\tan(\phi)}{1 + 0.4\sin(4\phi)} \tag{3}$$

The shape and depth factors in Eq. (1) for circular footing are

$$S_q = 1, \quad S_c = 1.3, \quad S_\gamma = 0.6 \quad \text{and} \quad d_q = d_c = d_\gamma = 1 \tag{4}$$

Considering deep foundations, and therefore different soil failure lines, Meyerhof proposed different bearing capacity factors [7] :

$$\begin{aligned} N_q &= \mathrm{e}^{\pi \tan(\phi)} \tan(\pi/4 + \phi/2)^2 \\ N_c &= \frac{N_q - 1}{\tan(\phi)} \\ N_\gamma &= (N_q - 1)\tan(1.4\phi) \end{aligned} \tag{5}$$

where the shape and depth factors are:

$$\begin{aligned} S_q &= 1 + 0.1K_p, \\ S_c &= 1 + 0.2K_p, \\ S_\gamma &= S_q \end{aligned} \tag{6}$$

with

$$\begin{aligned} K_p &= \tan(\pi/4 + \phi/2)^2 \\ d_q &= 1 + 0.1\sqrt{K_p}, \quad d_c = 1 + 0.2\sqrt{K_p}, \quad d_\gamma = d_q \end{aligned} \tag{7}$$

A more recent study by van Baars [10] proposes another expressions for the shape factors. These are:

$$\begin{aligned} S_q &= 1 + 1.5\sin(\phi) + 3\tan(\phi)^3 \,, \\ S_c &= S_q + (0.2 - 0.1\tan(\phi)) \,, \\ S_\gamma &= S_q \end{aligned} \tag{8}$$

It can be seen that the bearing capacity factors N_c and N_γ are typically expressed with the help of N_q. Therefore, in Fig. 4 the tip resistances obtained by different authors are presented by comparing this bearing capacity factor. By noticing the logarithmic scale of the vertical axis, it is clear that there are very significant difference between the models that are available in the literature, but at the same time, they are qualitatively similar.

During pile driving, the base resistance provided by these formulas can significantly drop due to the disturbance of the soil when the pile rotates. On the other hand, when the penetration speed is suddenly increased, the soil might temporarily have a higher resistance as the stresses around the tip of the pile does not have time to relax.

Assuming a constant base resistance, and a corresponding constant linear shear stress distribution under the tip of the pile, the base resistance force and torque can be expressed as:

$$Q_b = \frac{D_b \pi^2}{4} q_b \quad \text{and} \tag{9}$$

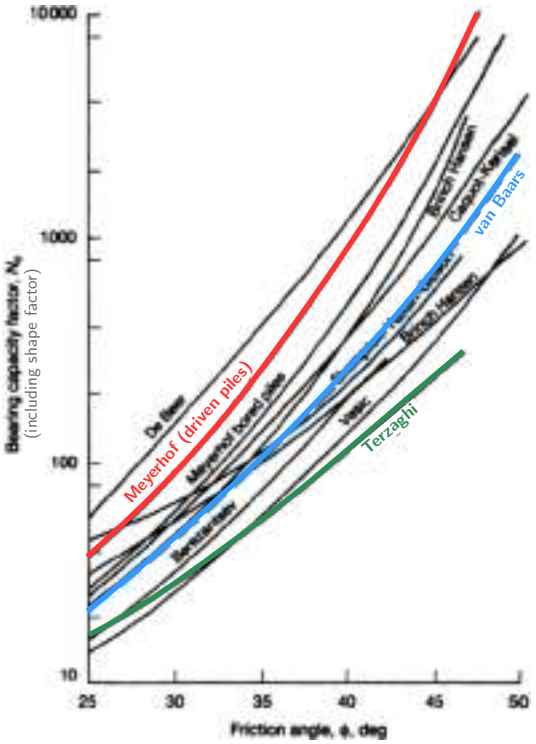

Figure 4. Different bearing capacity factors [10]

$$T_b = \int_0^{D_b/2} (\tan(\delta)\, q_b\, 2r\pi\, r)\ \mathrm{d}r = \tan(\delta)\, Q_b \frac{D_b}{3} \tag{10}$$

where δ is the friction angle between the soil and the pile's material and D_b is the diameter of the sacrificial tip.

2.2.2 Skin resistance

The skin resistance of piles is a frictional resistance force which depends on the pressure exerted by the soil on the surface of the pile. This lateral earth pressure is proportional to the overburden pressure, and changes significantly with the state of the soil. The active surface area also depend on embedded depth of the pile, so the depth dependence of the skin resistance is quadratic. When this resistance is calculated the composition of the soil layers has to be considered too. The total skin resistance force is the force which is acting on the complete embedded surface of the pile.

The lateral soil pressure is proportional to the overburden pressure. There are different theories to estimate the ratio between these. In case when the soil is undisturbed, the so-called in-situ soil pressure coefficient, K_0, can be calculated by using Jaky's simplified formula [13]. When the soil can expand and the stresses can relax, it is said to be active and the lateral pressure, K_a, is smaller than the in-situ pressure. When the soil is compressed (e.g.,

displaced by the pile) it is said to be passive and the lateral pressure, K_p, is significantly higher. The active and passive soil pressures are often estimated based on Rankine's theory. For cohesionless soils:

$$K_0 = 1-\sin(\phi), \quad K_a = \frac{1-\sin(\phi)}{1+\sin(\phi)}, \quad K_p = 1/K_a \quad (11)$$

In the pile design literature, various different formulas and tabulated experimental results exist for determining the lateral earth pressure coefficient, K, that can be used for the skin resistance calculation based on the piling technique and the specific soil type. Empirical factors are necessary to accompany the pure soil mechanics formulations to consider all the effects that can change the bearing capacity of a pile after it is inserted [14]. Recommendations for choosing the proper earth pressure coefficient, including averaging the formulae in Eq. (11), were proposed by Wrana [15]. For simulating the insertion process of a driven displacement pile in an operator training scenario, a good default value could be $K = K_p$ and introducing an additional scaling factor could allow the user to fine tune the soil behaviour. With these consideration the skin resistance force can be calculated as the integral:

$$Q_s(z) = \int_0^z (\tan(\delta) K q D_s \pi)\ \mathrm{d}\zeta \quad (12)$$

where the overburden pressure q, the lateral earth pressure coefficient K, and the friction coefficient $\tan(\delta)$ depend on the soil depth and the composition of soil layers. With the assumption of having constant soil properties per layer, this integral can be pre-computed in closed form for the real time simulation, or a simple 1 dimensional lookup table (with linear interpolation) can be used to quickly obtain the skin resistance force at specific depths. In order to incorporate the effect of pile rotation on the skin resistance, the instantaneous pitch of a rotary displacement pile needs to be considered. As the pile rotates, a point on it's surface moves relative to the ground with the sum of the tangential and axial velocities. The skin friction opposes this resultant velocity. The decomposition of the friction force into a radial and an axial component helps understanding, and captures the important effect, that in practice the rotation of a pile makes its insertion easier at the expense of increasing the overall resistance torque. The reduced skin resistance (the vertical component of the friction force) and the resistance torque which increases with the rotation speed can be computed in the form:

$$Q_{sv} = Q_s \frac{v_a + v_{min}}{v + v_{min}} \quad \text{with} \quad v = \sqrt{v_a^2 + v_t^2} \quad (13)$$

$$T_s = R_s Q_s \frac{v_t + v_{min}}{v + v_{min}} \quad (14)$$

where v_a is the axial velocity, $v_t = R_s\omega$ is the tangential velocity with radius R_s, and ω is the angular velocity of the pile. The minimum velocity v_{min} parameter was introduced to handle the special cases during simulation when one or both of the velocity components are zero. In case of the latter, when the pile is not moving, $Q_{sv} = Q_s$ and $T_s = R_s Q_s$ represent the maximum force and torque bounds of the constraints modelling the reaction torque and force, respectively.

3 Real Time Soil Augering Model

In our real time simulation model, we consider 4 different generalized reaction forces. These are the extraction and penetration resistance forces, the resistance torque and the pull-down force exerted by the auger on the piling equipment. The main characteristics of these are captured by simple models that provide an efficient formulation and qualitatively accurate results. During extraction, it is assumed that the auger does not rotate, and the weight of the pile is calculated considering the flights of the auger are completely filled with soil. In this case the extraction resistance force can simply be calculated by using the skin resistance force derived in the previous section plus the weight of the soil. For the skin resistance computation, one can simply use the borehole diameter as the skin diameter (D_s) and replace the external (soil-pile) friction angle (δ) with the internal friction angle (ϕ) of the soil.

For estimating the penetration resistance force, three different operation regimes can be considered. First, when the auger is rotating relatively fast and it is transporting soil to the surface. Second, when the instantaneous pitch is equal to pitch of the helix of the auger, and the auger is corkscrewing itself into the ground with a rapidly increasing resistance torque. And third, when the linear downward motion dominates and the auger displaces soil similar to a displacement pile. In this third case, the estimation of the penetration resistance is relatively simple as it ends up being the skin resistance calculated with the borehole diameter and the internal friction angle of the soil. When soil is transported or corkscrewing happens further considerations are necessary.

The helix of the auger can be seen as a long wedge along which the total mass of the soil is pushed upwards. The uplifting force is the resultant of force transmitted from the helix to the soil minus the resistance force due to friction with the wall of the borehole. In order to estimate these forces, the kinematic model in Figure 5 is considered. This shows that the $\vec{v}_{\text{up}}$ uplifting transport velocity of the soil is the sum of the auger's downward velocity $v_z\,\hat{k}$, the lateral velocity $\vec{v}_t = r\omega\,\hat{t}$ and the relative soil velocity with respect to the auger $\vec{v}_{\text{rel}}$. The magnitude of the uplifting velocity ranges from zero to $v_{\text{up,max}} = v_t\tan(\psi) - v_a$ where $v_a = -v_z$ is the penetration velocity. In the following, this maximum velocity is used to express the uplifting velocity $v_{\text{up}} = \eta\, v_{\text{up,max}}$ where η is an efficiency parameter. It is left to the user to define this as a constant, or feed back

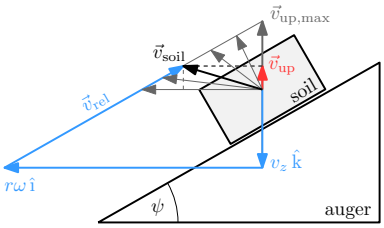

Figure 5. Model of soil uplift velocity of the auger

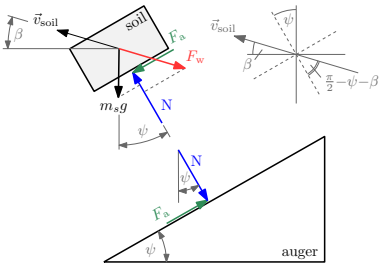

Figure 6. Free body diagram of the augering model

its value to the model using complementary calculations. With these considerations, the penetration resistance (Q_a) and the pull-down force (V_a) of the aguer can be expressed by using the free body diagrams shown in Figure 6 as

$$Q_a = F_a \sin(\psi) \tag{15}$$

$$V_a = N \cos(\psi) \tag{16}$$

with

$$N = m_s g \cos(\psi) + F_w \sin(\psi + \beta) \tag{17}$$

$$F_a = \tan(\delta) N \tag{18}$$

where N and F_a are the normal and lateral components of the reaction force between the soil and the auger. The total mass of the soil is m_s, g is the gravitational acceleration, and F_w is the total skin resistance force transmitted from borehole to the soil mass in the auger. Moreover, using the outer radius r of the auger, an upper bound on the augering resistance torque can be given in the form:

$$T_s = (F_a \cos(\psi) + N \sin(\psi))\, r \tag{19}$$

In the special case when the maximum uplifting velocity $v_{\text{up,max}}$ is zero, the auger is corkscrewing. This condition is identical to saying that the instantaneous pitch $v_a/v_t = \tan\psi = p/(2\pi)$ with p being the pitch (height difference) between the flights of the auger. When this happens the auger is pulling itself into the ground as a corkscrew into the cork, and the reaction force and torque increase until the machine limits are reached and the auger cannot be moved further into the soil. This dangerous situation must be avoided, and a trained operator needs to change the penetration and rotation speed in order to prevent this from happening. For such a training, we use a model, where a kinematic constraint is used to lock

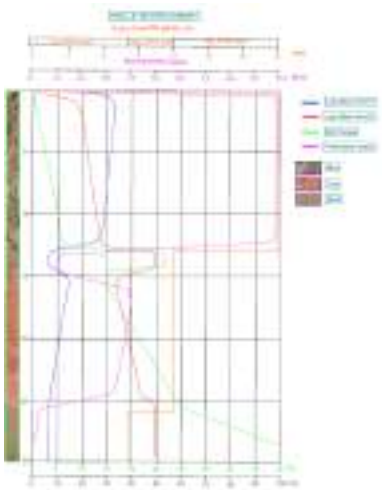

Figure 7. IHC reference data for displacement drill

the auger into the corkscrewing regime, with rapidly increasing reaction force and torque, when the instantaneous pitch is sufficiently close to geometric pitch (expressed in m/rad) of the auger. The maximum force and torque of this screw constraint is proportional to the corkscrewed length of the auger. This way, when the user sufficiently unscrews the auger the applied torque and force can overcome the constraint limits, and the auger can break out of corkscrewing.

4 Model Validation

The IHC FUNDEX F3500 multifunctional foundation rig was modelled and simulated. The main objective was to develop real-time, parametric and physically motivated ground resistance models for three different pile driving operations. These include the displacement drill, the continuous flight auger (CFA) and the hydrohammer piling techniques. In each case, the pile is driven into the ground by the drill rig and it penetrates through different layers of soil with different resistances. As the programmable logic controller (PLC) of the simulated drill rig is integrated into the system, it expects to receive physically realistic resistances. Therefore, selection and tuning of soil properties was an important element of the work.

For the validation of the model, IHC industry experts provided us with desired drill report curves. Figure 7 shows an example of the provided report for the expected soil resistance during displacement drilling. The desired behaviour was determined based on real drill reports by capturing the main characteristics of experimentally recorded data. The report shows vertical force and torque applied to the tool, as well as the penetration and angular velocities of the tool. There are three distinct soil layers that the tool passes through as depth increases: mud, clay, and sand.Capturing the effect of layer transitions is

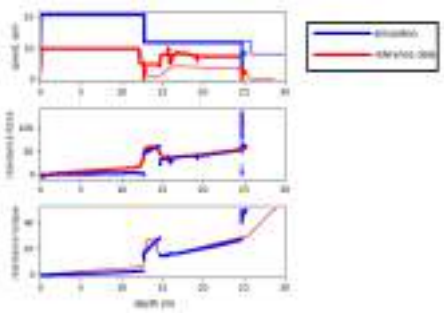

Figure 8. Machine in the loop simulation results

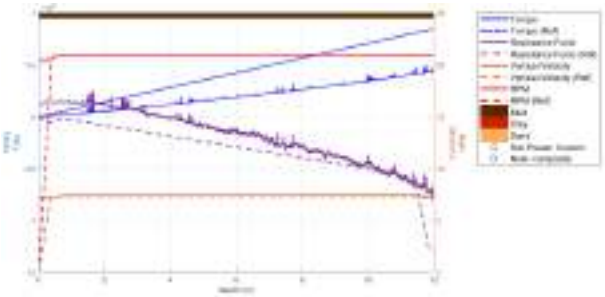

Figure 9. DEM Simulation results - CFA

an important aspect of the simulation. The reason we did not directly use some recorded drill reports is that in the simulated scenario there were only four layers with very different soil properties. The four layers and the composition of the layers can be chosen by the instructor of the training simulator according to the pedagogical needs.

In Fig. 8 the drill report of a displacement drill operation is shown. In the top panel the thin lines represent the planned penetration rate (speed) and rotation speed (rpm), and the thicker lines show the actual values commanded by the operator of the simulator. These are plotted as function of the penetration of the tip of the pile (not wrt. time). The middle panel depicts the observed (blue) resistance force vs. the expected one (red). Similarly, the comparison of the resistance torques can be seen in the bottom panel. Although, the penetration speed was generally slower than the desired value, the soil resistance matches the expected trends and values quite closely. Note, the equations used to estimate the ground reaction assume quasi-static conditions, therefore they cannot directly capture the effect of different penetration speeds.

5 DEM Model

Because DEM has a well documented ability to produce high-fidelity soil models [16], a DEM simulations was set up to show that the purely analytical model, as well as the reference data, was qualitatively in agreement with a DEM approach. In this section, we present the comparison for the CFA simulation using DEM.

The DEM model of the drill rig was built in the real time multibody simulation platform Vortex Studio [1] whose particle system is based on the Parallel Particles approach to DEM modelling proposed by Holz [17], based on the principles of position-based dynamics presented by Muller [18]. This method has previously been used for DEM soil simulations of wheels travelling over soil [19] [20] and blades excavating soil [20]. Due to current software limitations, the DEM simulations only consider the behaviour of the drill for the first 12 meters depth, at which point the reference data indicates a transition from the mud soil layer to clay. This is because the current version of this DEM implementation does not make it possible to model layers of soil with different properties. However, conclusions can still be drawn from the simulation of the first soil layer, which accounts for about a third of the total depth included in the IHC reference data.

Figure 9 shows a comparison between the reference data that was used in the previous section and the DEM simulation results for the continuous flight auger. Extensive tuning would be required in order to achieve a perfect quantitative match with the DEM simulation [19], but the simulation results with baseline soft soil parameters already showed good qualitative agreement. Without tuning of parameters, we are looking for the DEM model to replicate the overall trend of the outputs as depth increases, as well as the order of magnitude of the outputs. The doted lines on the plot show the reference values for torque, resistance force, penetration speed and RPM; while the solid lines show the results of the DEM simulation. Unlike the analytical model, this DEM model is a fully dynamic rigid body simulation coupled with a particles to model the soil. Velocity level constraints control the motion of the drill, allowing the simulation to exactly match the desired motion of the drill - illustrated in red and orange for the RPM and vertical velocity, respectively. In the interest of simulation time, the particles used in the simulation were rather coarse, which explains the noisy nature of the resistance force and torque outputs. While the order of magnitude and overall trend with respect to depth of the force and torque plots are consistent with the reference data, the inaccuracy of the exact numerical value of these outputs can be attributed to a lack of parameter tuning.

6 Conclusion

This paper proposes an analytical method for modelling piling operations for real time dynamic simulation which is accurate and efficient enough for the purposes of operator training. The model uses classical bearing capacity equations to compute the force components acting on the pile during insertion. To capture the reduction of the vertical resistance force when the pile is rotated, a simple

model was developed to decompose the overall friction force based on the instantaneous pitch. This is essential for building a realistic scenario for operator training when a rotary displacement pile is used.

Another important contribution of the paper is the simplified augering model that was presented. This model simulates the vertical pull down force of an auger reasonably well. The selected semi-analytical simulation approach was necessary to achieve the simulation speed and accuracy required for successful operator training. It enables real time training with PLC in the loop. This model is dependent on proper tuning of an efficiency parameter for the uplifting force that is left to the user to define, either as a constant value or through some complementary calculations. Setting this value as a constant and tuning it, the qualitative agreement between the presented models is realistic enough for human-in-the-loop drill operator training simulators. This claim was validated by comparing the analytical results to reference data provided by industry experts - data that was in turn qualitatively compared to a dynamic discrete element soil model for the first layer of soil.

Abstract –

Acoustic comfort, a critical yet often overlooked aspect of indoor environmental quality, plays a significant role in occupant health and productivity. Unlike other comfort dimensions, such as thermal or lighting, measuring acoustic comfort remains challenging due to its subjective nature and the complex interplay of physiological and psychological factors. Current approaches to assessing acoustic comfort in indoor environments often overlook the content of sound, despite its potential to be a decisive factor. For instance, the perceived comfort of listening to music at high sound levels differs significantly from that of hearing construction noise, even at lower sound levels. This research proposes a novel framework for integrating acoustic comfort analysis in the digital twin environment, which comprises psycho-acoustic metrics, sound event classification, and predictive analytics. The implemented system leverages sensor data, a sound event classification neural network, and advanced visualization methods to enable real-time and historical acoustic analysis. Privacy concerns are addressed through a privacy-by-design approach, ensuring data security by processing audio on the edge devices without storing raw sound. A case study in an office environment demonstrates the framework's effectiveness in monitoring and improving acoustic conditions. Microphones connected to edge devices classify sound events and calculate soundwave parameters such as relative sound pressure levels while integrating results into the digital twin.

Keywords –Digital Twins; Acoustic comfort; Psycho-acoustic metrics; Sound event classification; Acoustic monitoring; Comfort analysis

1 Introduction

There exist numerous definitions for the term “comfort” in various domains such as AEC-FM (architecture, engineering, construction, and facilities management) and healthcare. The common theme in the definitions of comfort in the built environment refers to it as a state of physical and psychological ease, characterized by the absence of discomfort or distress. Although this high-level definition understandably describes comfort, it fails to adequately pinpoint its defining measurable characteristics. The notion of comfort in buildings can be viewed in multiple distinct but interrelated aspects, such as thermal comfort, acoustic comfort, indoor air quality, and lighting comfort; each of which depends on various variables. However, the level of perceived comfort differs for each person, depending on the physiological and psychological state at that very moment in time. Maintaining comfort is a fundamental need in buildings; the indoor environment quality (IEQ) performance of a building, is a decisive factor in the health, productivity, and well-being of its occupants, and can be a determinant factor in lifecycle costs and energy consumption [1].

Among the different aspects of comfort, acoustic comfort received less attention [2]. A simple search on academic databases related to indoor comfort reveals a substantial disparity in the number of studies focusing on different aspects of comfort, with significantly fewer studies focusing on acoustic comfort compared to other aspects, such as lighting, thermal, and air quality. Acoustic comfort is generally defined as “a state of contentment with acoustic conditions” [3], and it can play a pivotal role in determining the overall comfort of an environment. Furthermore, it is interrelated to other aspects of comfort and the building's overall energy consumption. For instance, occupants may face the trade-off between the generated HVAC noise by the cooling system and thermal discomfort [4].

Similar to other aspects of comfort, measuring acoustic comfort is complex. Sound perception is subjective and varies among individuals based on their experiences, cultural backgrounds, and personal preferences [5]. Additionally, it highly depends on the psychological state of the occupants, which makes its objective assessment more difficult or impossible. Although the physical characteristics of sound waves can be adequately measured, there is no measurable characteristic showing the overall psychological state of a human being and how comfortable a person is while being exposed to acoustic stimuli. As a result, a certain

sound pattern may seem uncomfortable or annoying to a person and can be ignored or even considered pleasant by another person [6].

To estimate the acoustic comfort level of a space, traditionally, some of the basic variables of the acoustic waveform are measured. Such variables include the sound pressure levels (dB), the frequency (Hz), and the time that a person is exposed to the sound. Although these variables are essential for estimating acoustic comfort, and some regulations and guidelines are already developed recommending their acceptable ranges, "acoustic comfort" is by far more complex to measure. For example, the human hearing system does not respond to all the frequencies, and the sound pressure levels equally [7]; hence, the sounds with some frequencies may be perceived as louder than others. This shows the inadequacy of assessing acoustic comfort using only the sound (acoustic) pressure level.

Consequently, psycho-acoustic indicators such as loudness, A-weighted sound pressure level, sharpness, roughness, fluctuation strength, articulation index, and impulsiveness were introduced[8, 9]. These psycho-acoustic indicators consider the human hearing system in perceiving sounds, resulting in a better estimation of acoustic comfort. For example, to have a better understanding of "how loud a sound is", loudness is defined which is the property of the sound that can be "ordered on a scale extending from soft to loud" [10].

However, even the existing psycho-acoustic indicators would not be sufficient to adequately assess the acoustic comfort for a specific space. For example, although there might be a similarity between calculated psycho-acoustic indicators of audio patterns of certain musical pieces and construction tools (e.g., jackhammer), the perceived sensation for the occupants would be completely different. The feeling of acoustic comfort for occupants who are exposed to a musical piece heavily depends on their musical taste, whereas the noise of the construction tool can be unpleasant for all occupants.

The inadequacy of such metrics and indicators can be linked to their exclusive reliance on sound wave parameters, without accounting for the content or type of the sound. Consequently, researchers have sought to develop new psychoacoustic indicators and sound perception descriptors, such as satisfaction, dissatisfaction, noisiness, and pleasantness, as highlighted by Hossain et al. [11]. The recent advancement of the Deep-learning-based models allows a near real-time analysis and classification of sound events. Combining the classic metrics, psycho-acoustic indicators, and sound event categorization provides better monitoring and estimation of acoustic comfort for the built environment. Additionally, such a combinatory effect allows for defining customized indications of the comfort level considering individual occupants' preferences.

This research aims to provide a framework to perform acoustic comfort analysis by combining various metrics and indicators together with sound event category identification within a digital twin. The proposed framework comprises the integration of sensor data within a digital twin solution, the calculation of psycho-acoustic indicators, the near-real-time identification of sound event categories, and the predictive analytics capability. Additionally, the framework adopts the privacy-by-design approach in which the stored data cannot be used to recreate the original captured sound.

The remainder of this paper presents a brief review of the literature on acoustic environmental assessment, the application of psychoacoustic indicators, and the role of Sound Event Detection (SED) in such evaluations. This is followed by a detailed explanation of the proposed framework and its potential applications. A case study implementation is then described, along with the corresponding results and conclusions.

2 Related Work

Literature on assessing the acoustic suitability of environments reveals two interrelated yet distinct concepts: soundscape and acoustic comfort. While both address the auditory experience, their focus and applications differ. Acoustic comfort primarily pertains to enclosed spaces, emphasizing the reduction of annoyance and enhancement of auditory satisfaction within confined environments. In contrast, the concept of soundscape is broader, encompassing urban, natural, and built environments. It explores the dynamic interaction between environmental sounds and human experiences.

Both soundscape and acoustic comfort assessments rely on a combination of objective and subjective parameters. For example, Aletta et al. [12] emphasize the role of psychoacoustic indicators, such as loudness, sharpness, roughness, and fluctuation strength, in soundscape studies. Similarly, Engel et al. [13] conducted a systematic review of 46 peer-reviewed studies, demonstrating the widespread application of psychoacoustic indicators in soundscape research. These findings highlight the critical role of such indicators in capturing human perceptions of acoustic environments, thereby enhancing the accuracy and relevance of soundscape evaluations. Likewise, psychoacoustic indicators are integral to assessing acoustic comfort. For instance, the relationship between objective acoustic measurements and subjective responses to evaluate acoustic comfort in residential settings is investigated in [14]. Their study underscores the importance of indicators addressing low-frequency noise to better correlate technical data with perceived annoyance, thereby emphasizing the need to integrate human

perception into acoustic comfort assessments.

A review of the literature reveals the extensive use of psychoacoustic indicators in assessing acoustic environments. Zhang et al. [6] developed a high-precision model for predicting acoustic comfort in electric buses by integrating psychoacoustic indicators with machine learning techniques. Similarly, Herranz-Pascual [15] introduced the Acoustic Comfort Assessment Scale (ACAS-12), a psychometrically validated tool designed to assess acoustic comfort in urban environments. This scale incorporates indicators, such as pleasantness, eventfulness, familiarity, informational capacity, and congruence, demonstrating its reliability and effectiveness in capturing subjective perceptions of acoustic environments. Additionally, Kang et al. [16] proposed a framework for creating soundscape maps in smart cities. Their model predicts perceptual attributes, such as pleasantness and calmness, using sound profiling and linear regression analysis, offering a valuable tool for enhancing urban soundscape design.

Advancements in artificial intelligence have enabled the application of SED in soundscape assessment. For example, Espejo et al. [17] explored the use of short-time acoustic indices in combination with artificial neural networks (ANNs) to monitor and analyze soundscapes in urban-natural environments. Similarly, Bonet-Solà et al. [5] developed a predictive model for assessing acoustic comfort in urban settings. Their approach integrates SED using convolutional neural networks with noise data collected from wireless acoustic sensor networks (WASN), offering a sophisticated method for evaluating and improving urban acoustic environments.

To effectively visualize the acoustic status of a large environment, a 2D color-coded heat map based on soundscape evaluation is a practical approach, as demonstrated by Yue et al. [18]. They developed a visual soundscape prediction model for urban park design, which integrates sound pressure levels, sound source perception, and soundscape evaluation using machine learning techniques. This model provides an intuitive representation of acoustic conditions, facilitating the design and optimization of urban soundscapes.

3 The Proposed Framework

Potential Applications and Use Cases

Having a framework that allows monitoring the present and past values for a collection of psycho-acoustic indicators as well as sound event categories for each room of an indoor environment, facilitates the comfort analysis, prediction, and visualizations through the digital twin web interface. It allows facility managers to better plan for acoustic insulation and activity planning. The occupants can consult the monitoring data to decide if a certain room is suitable in terms of acoustic comfort for their intended use. The stored data allows the application of predictive algorithms to recommend rooms for certain activity types or to predict the acoustic comfort of a certain room in a selected time period in the future. The integrated assessment algorithms can be further enhanced by including other sources of data, such as activity schedules for each room.

The data can be used to identify sources of unwanted noise (such as background noise or noise pollution) and their effect on the neighboring rooms by cross-checking metrics of various neighboring spaces. Additionally, the system can accommodate user inputs to provide personalized metrics and Key Performance Indicators (KPIs) for individuals. Moreover, the system can communicate information about the acoustic comfort preference of neighboring occupants to the occupants of a certain room to adjust their noise-generating activities accordingly. Finally, it can give insights and predictions regarding outdoor noise.

Framework

The framework consists of a five-layered architecture, as depicted in Figure 1 (left). Starting from the bottom of the diagram:

1. In the data acquisition layer, sound is captured by microphones and converted to a digital signal via an analog-to-digital converter (ADC). Using the device-specific interface, the audio signal, in a binary stream format, along with the device-specific metadata such as sampling rate, microphone sensitivity, microphone type, and the location coordinates of the microphone, is prepared for subsequent processing. The data acquisition and data processing layers are distinct; however, they can be implemented on a single device, enabling high-speed data transfer through shared memory or inter-process communication (IPC) interface.
2. In the data processing layer, the audio data stream and device specifications from the data acquisition layer are utilized. This layer processes the input signal according to the requirements of its three modules, based on parameters such as the sampling rate and device specifications. The audio signal is resampled and formatted to meet the input requirements of the selected SED model. Additionally, soundwave parameters and psychoacoustic indicators are computed using the audio signal and accompanying metadata. The processed data is then sent to a cloud-based database to be stored as time-series data, utilizing either REST-based or SQL-based communication interfaces. Depending on the storage layer type,

data transfer can be conducted using GET and POST methods in the REST-based approach or directly via SQL queries.

3. The storage layer manages both historical and real-time data, ensuring continuous data availability for further analysis and processing. Notably, the recorded data includes metadata essential for the digital twin, such as microphone location coordinates, device identification, and room designation. This data can also be accessed through REST-based or SQL-based communication interfaces.
4. The calculated parameters and metadata are retrieved from the cloud-based database in the logic layer. Based on the nature of the environment, the defined KPIs, and user- or environment-specific settings, this layer processes the data and prepares it for visualization. The logic layer can be implemented at any host platform, whether on a local or a cloud platform. It uses user inputs and commands gathered in the presentation layer and the data managed in the storage layer to perform various calculations and predictions. Additionally, it can integrate external data sources, such as Building Information Modeling (BIM) models, to allow 3D visualizations as well as access metadata related to the built environment that is used for comfort analysis. Depending on the presentation layer and whether it is remotely connected to this layer or operates on the same device, the processed data can be accessed through various communication interfaces, including REST-based, file-based, or shared memory communication methods.
5. The presentation layer provides users with various visualization tools, including graphs, charts, and 2D or 3D heat maps. It also accepts user-defined settings and, through continuous communication with the logic layer, ensures that the system displays the desired outputs. This layer can be implemented either on an online digital twin platform or a local computer.

Notably, in a real-world scenario, collecting data from multiple rooms requires additional instances of the implemented data acquisition and data processing layers. This scalable approach facilitates the integration of multiple rooms without significant computational constraints. The performance on each edge device may vary depending on the complexity of the Sound Event Detection (SED) model and the computational power of the edge device, but it is not dependent on the number of rooms.

The proposed framework was adopted for the use case of sound event classification in an office building. A sound classification system that is integrated with the digital twin platform is developed, and a case study is performed to assess the applicability of the developed system.

3.1 Case Study

The case study was conducted in an office space within a public building. The room, measuring 106 square meters, has an L-shaped layout with a ceiling height of 2.96 meters. It is typically used for meetings, classes, and various gatherings, but it also occasionally serves as a study or group work area for students.

The objectives of this implementation are threefold:

1. To develop a system capable of measuring a collection of soundwave parameters, classifying sound events, and transmitting the collected data to a cloud-based platform
2. To develop a method for visualizing the collected data effectively
3. To integrate the developed acoustic comfort measurement module into the existing digital twin

The digital twin of the environment is implemented using Autodesk Platform Services. Time-series data is stored in Microsoft Azure Data Explorer, and the existing dashboard provides historical data visualization for parameters such as temperature, air pressure, air quality, and occupancy (Figure 2).

In the case study implementation, a sound event classification neural network was utilized to categorize audio events. YAMNet [19], [20] is a pre-trained deep learning model with 521 output classes. For the case study, the model needs to be customized. For example, the existing classes are grouped into a smaller number of categories, tailored to the case study environment. Additionally, the model is required to be fine-tuned to enhance its accuracy for the given application. For effective grouping, it is important to consider the environment's characteristics (e.g., a wild animal sound is unlikely to occur in an office, despite the existence of such a class in YAMNet sound categories). Based on the types of activities expected in the case study environment (an office), five main categories were defined (Table 1). Each YAMNet class was then reviewed and assigned to one of these categories.

To capture sound, microphones are installed in the room. To achieve reliable results, selecting the right microphone (or an array of microphones) is one of the key design considerations for the implemented system. For example, the microphones should not perform active noise control (ANC) (i.e., noise cancellation), or modify the sound balance. Additionally, to efficiently perform the measurement and calculation of metrics, the microphone should be precise and sensitive to adequately capture sounds within its range of operation. In the case study, multiple identical microphones were installed at

different points of the room, each is connected to an edge device that analyzes the sound. The selection of microphone types depends on their placement location. In this study, omnidirectional microphones were used, featuring a signal-to-noise ratio (SNR) of 80 dB and a maximum sound pressure level of 110 dB.

Table 1. The categorization of the possible sounds in the office and the number of corresponding YAMNet output classes

Category	Number of Classes
Speech, Meeting	14
Silence, Ambient Office Sounds	30
Construction and maintenance work, Interruptions	112
Gathering, Crowded, Music	179
Other Classes	186

Installing microphones in the rooms may raise privacy concerns for occupants. As mentioned, a privacy-by-design approach was followed in this implementation, in which the sound classification is performed on the edge devices in real-time using small snippets of the sound signal collected from microphones that are directly attached to them. The actual captured sound is not recorded or transferred over the network. In other words, the data acquisition layer and the data processing layer are implemented in one device, ensuring that the original sound signal remains secure and eliminating the risk of data leakage over data transmission in the network.

The implemented system accommodates the measurement of the relative sound pressure levels as well as the sound event category identification. The implemented system allows the integration of new customized KPIs, considering the preferences of occupants and their intended activity within the space. The results are integrated and visualized in the developed digital twin platform of the facility, which is the primary source of information and a tool for monitoring and performing predictive analytics. The architecture of this implementation is depicted in Figure 1(right).

3.2 Visualization of Sound Content

Although various types of data visualization methods can be easily created based on the data generated in the logic layer, a combination of bar and line charts is the preliminary visualization method (Figure 3). It allows visualizing classifications with color-coded bars overlaid by various line charts that show calculated metrics. As an example, the relative sound pressure level, defined in Equation (1), is illustrated in Figure 3. The graph has the date and time on the horizontal axes, which allows visual analysis of the changes in acoustic metrics and indicators during a certain day.

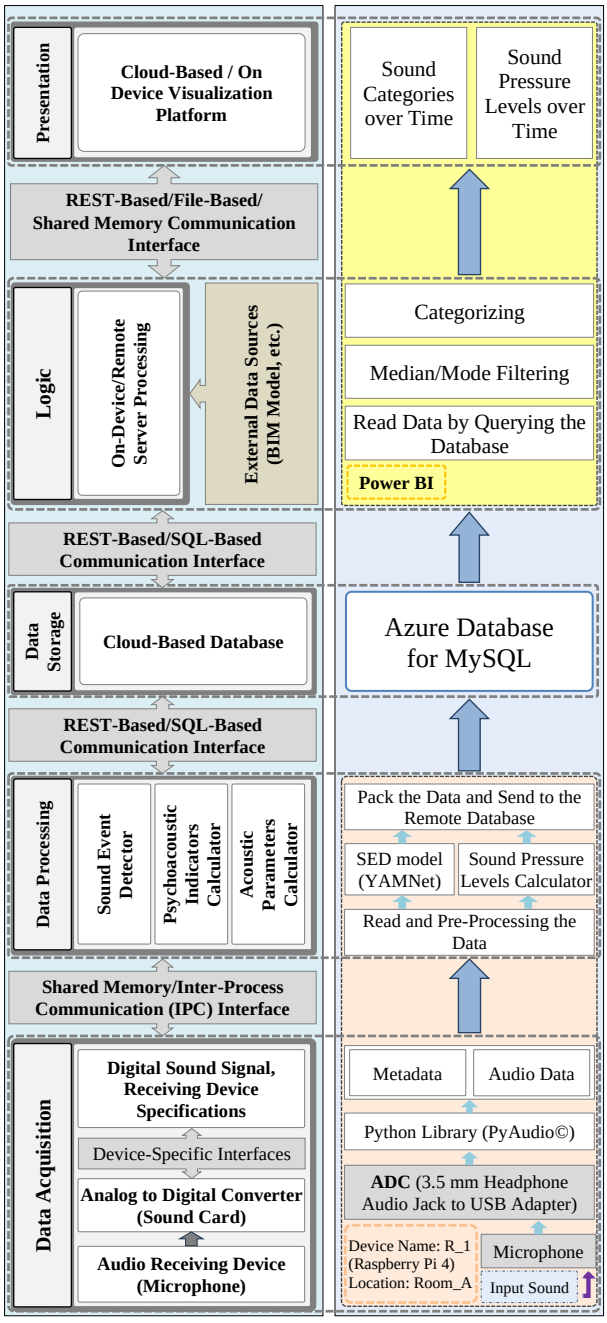

Figure 1. The Proposed Framework Layers (left) and the case study implementation (right)

Equation (1) represents the relative sound pressure level ($SPL_{relative}$). The input to the logarithm function is the Root Mean Square (RMS) value of the microphone's output, obtained using the PyAudio library at a 16 kHz sampling rate, and 16-bit audio depth, continuously

calculated over a defined interval (1-second) within the (-1, 1) range. The output of this equation falls within the (-inf, 0) dB range, and can be a relative measurement of the sound pressure level in an environment. Notably, this value cannot be directly used or compared with established comfort thresholds in the environment unless it is converted to absolute sound pressure levels.

$$SPL_{relative} = 20 * \log(RMS(normalized\ measured\ value)) \quad (1)$$

Figure 2. The existing digital twin of the office in Autodesk Platform Services

As depicted in the graph (Figure 3), the sound data over a seven-hour period is classified and visualized. The relative sound pressure level is represented in a dark blue line graph. The Construction and maintenance work/ Interruptions category is highlighted in red. The Gathering/Crowded/Music category is shown in purple, while the Silence/Ambient Office Sounds (such as printer noise) category is displayed in light blue. The "Other Classes" category is represented in dark grey.

Using these color codes and reading the graph from left to right, a meeting is detected from approximately 11:30 a.m. for two hours, represented in yellow. This is followed by a two-and-a-half-hour period of silence, shown in light blue. Finally, starting at 5:00 p.m., another meeting is observed for about two hours.

This chart is accessible through the digital twin platform's web interface by clicking on the acoustic monitoring icon available for each room.

4 Conclusions and Future Work

The focus of this paper was to provide a framework to perform acoustic comfort analysis by combining various metrics and indicators together with sound event category identification within a digital twin. Regarding SED models, YAMNet is used in the case study. However, various other models, such as SoundNet [21], Google's VGGish, HuBERT [22], OpenL3 [23], the CRNN proposed in [24], DENet [25], SincNet [26], and COPE [27] can also be used. YAMNet was selected for this study as it is a lightweight model suitable for implementation on edge devices, and it offers acceptable performance. Additionally, it is pre-trained and is adaptable to various types of environments. However, to get the best results, the performance of these networks should be evaluated and compared based on specific use case and fine-tuning.

The selection of both the microphone and sound interface plays a critical role in ensuring classification accuracy and precise measurement of acoustic parameters. Using a microphone with an inappropriate directional type in relation to its placement or one with a low signal-to-noise ratio (SNR) can limit the effective measurement range, creating blind spots in the system's sound classification capabilities. Furthermore, to fully utilize a microphone's potential, the sound interface must support high bit depth and sample rate, which are essential for capturing maximum acoustic data from the environment for further analyses.

The framework also included integrating acoustic measurements, such as acoustic waveform variables (e.g., sound pressure levels), psychoacoustic indicators (e.g., loudness), as well as sound event classification, into a digital twin platform. The potential applications of this

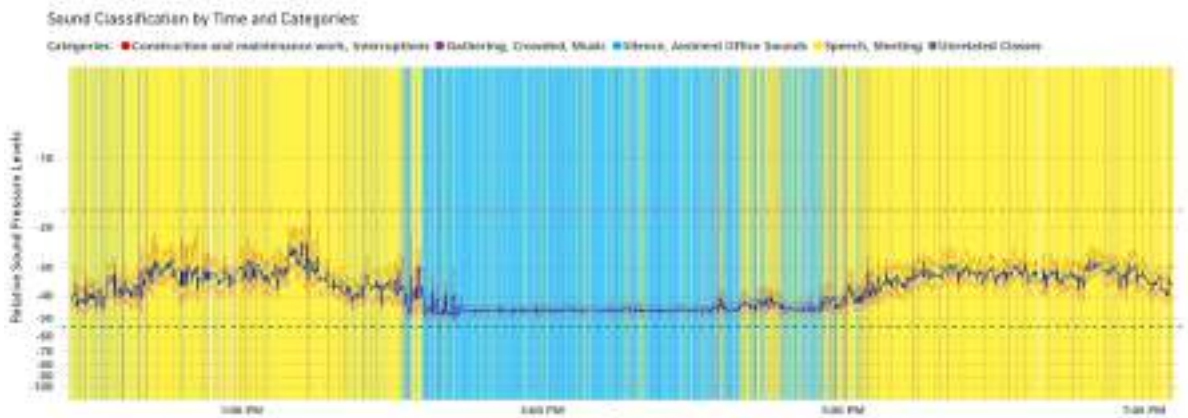

Figure 3. The Output Graph for Monitoring the Acoustic Status of the Case Study

framework were explored, and a case study was conducted in an office space, utilizing edge devices and an SED network to monitor both the current and historical status of the environment in a digital twin platform.

Abstract -

Efficient construction monitoring and project visualization are vital in civil engineering: they promote safety, minimize costs, and ensure adherence to design plans. With advances in reality capture techniques, such as LiDAR, point clouds have emerged as a powerful tool for digitizing large-scale scenes with excellent accuracy. However, the challenges of processing and visualizing large-scale point cloud data remain significant, particularly for applications in horizontal infrastructure projects. In this case study, a point cloud-based digital reconstruction of an interchange conversion project was developed to aid in defining best practices for data processing of large-scale point clouds and to develop novel digital tools to enable remote construction site inspection and analysis. The obtained models are leveraged to provide insights on three advanced methodologies for data exploration: (1) desktop interfaces for accessible remote monitoring, (2) holographic interfaces for collaborative visualization, and (3) immersive virtual environments for enhanced interaction and simulation. These three methods are compared for accessibility, opportunity, and their potential to improve decision-making and project outcomes in construction monitoring and analysis.

Keywords -

Point clouds; Laser Scanning; Virtual Reality; Construction Monitoring; Construction Simulation

1 Introduction

Infrastructure systems in the United States are poised for significant investments over the coming years, given the aging conditions and urgent need for renovation [1]. When developing and completing large construction projects, it is crucial to ensure that each step is executed accurately and according to specifications to maintain the structural integrity and overall performance of the completed systems [2]. Errors in construction processes can compromise safety, increase costs, and decrease the lifespan of the built infrastructure. To that end, there are broader consequences with poorly monitored projects, such as premature demolition and replacement - which have significant environmental impacts [3]. Given that greenhouse gas emissions are strongly correlated to the construction of public infrastructure [4], it is evident that poorly monitored projects, which may require early demolition and rebuilding, can exacerbate environmental impacts. If methods to extend infrastructure lifespan are not implemented, the repeated cycle of demolition and rebuilding will deplete environmental resources and contribute significantly to greenhouse gas emissions.

Recent advancements in digitalization and the rise of intelligent automation are driving a technological shift in the construction industry, enhancing the effectiveness of construction monitoring [5]. By leveraging innovations in reality capture, computer vision, robotics, and artificial intelligence, companies can improve data capture for complex infrastructure project management [6, 7]. In particular, rapid advancements in laser scanning technology have revolutionized the ability to capture detailed spatial information for infrastructure projects. LiDAR is a technique that uses laser beams to precisely measure distances and generate detailed three-dimensional representations of physical spaces. From the capture, data fusion with HDR imaging provides RGB information to each registered point in the cloud [8]. LiDAR devices are generally attached to a ground-based fixture (terrestrial laser scanning - TLS) or an aerial vehicle (aerial laser scanning - ALS). The capability of producing high-density scans at a relatively low cost enables the digitalization and automation of advanced construction management procedures [9]. LiDAR data can similarly streamline the capture of geometric information for computational analysis of infrastructure [10]. As such, research into advanced methods of data acquisition, exploration, and management [11] supports the development of accurate and reliable workflows for construction applications.

As data collection methods in the construction industry advance, adopting effective processes to convert data into accessible formats is crucial for effective visualization to enable remote inspection and monitoring. [12]. Since the information that operators need to extract from point clouds is very technical, there must be a clear workflow for processing and visualization to make it operable. Cleaning raw point cloud data for large-scale scenes is a laborious, time-consuming task, requiring manual processing and

expert judgment by skilled operators. Data storage considerations are also relevant [13], thus requiring a balance between accuracy and cost.

Leveraging point cloud data in civil engineering projects comes with many challenges. Due to the capture devices' technical constraints, point cloud data of active construction sites will contain several different types of noise [14]. When capturing ongoing projects, fully closing the site or nearby streets to traffic and workers is often impractical, resulting in the presence of unintended people and equipment in the scene [15]. Additionally, remote site monitoring requires a large amount of human judgment and expertise. As such, using effective methods to visualize data is highly important to complete the task. With technology improving, there is a need to test new methods and prove viability for applications in the industry [16].

Advanced visualization methods to explore site data are becoming more viable as consumer-grade virtual reality (VR) and holographic hardware become more accessible. Immersive virtual environments (IVEs) are a frequently used research tool to simulate and navigate digital environments [17]. When IVEs are built using computer graphics engines, custom modules and simulations based on point cloud data can fulfill the unique needs of individual projects. IVEs have successfully been used in applications such as health and safety training [18], digital twin modeling [19], and project visualization [20]. In this context, point cloud data obtained in real-life conditions can improve the IVEs by providing greater detail of the scenes and greater contextual realism of the specific settings being materialized [21].

There is a need for studies regarding data management, visualization, and exploration methods for point cloud data of large-scale construction scenes [9]. The capabilities for structural assessment have been well documented [22]; however, work to define the best practices for point cloud-based construction monitoring of large-scale horizontal infrastructure projects is needed. This paper introduces a novel workflow for processing and visualizing point cloud-based reconstructions of horizontal infrastructure projects, with a particular focus on identifying critical challenges in data processing and exploring effective methods for data exploration. A case study on an active highway construction site demonstrates the practical application of the proposed approach. The study presents a comprehensive analysis and comparison of various visualization and exploration techniques, including desktop computer programs, holographic 3D environments, and immersive virtual environments (IVEs), to evaluate their capabilities in extracting technical information and enabling remote construction site monitoring and inspection.

2 Methodology

2.1 Data Collection

An active construction site during an interchange conversion project (i.e., transition from a cloverleaf to a diverging diamond interchange) in Southwestern Pennsylvania was chosen as the case study. The location is of interest due to the active work zone, non-uniform terrain conditions, and various structures at different construction stages. The scan was performed on one cloverleaf loop to be replaced and the surrounding highway and state route.

The laser scan was conducted using the Leica BLK360 terrestrial scanner (see Figure 1 (A)). The BLK360 features a 360,000 points-per-second scan rate and can capture information at a range of up to 60 meters with a point accuracy of approximately 6 mm at 10 meters. The laser scanner has a 360° horizontal and a 300° vertical field of view. For each scanning iteration, the BLK360 (mounted on a tripod) was positioned in an area of interest, and the scanning cycle was initiated using a wireless connection through a portable device. After completion of the scanning cycle, the portable device provided a 360° image of the location and a low-density preview of the captured point cloud (see Figure 1 (C)).

The data collection process employed the following method: firstly, the scanner was placed at an initial location, and a scan was performed. For each successful scan, the device was moved to a nearby location where the following scan would have significant overlapping data such that an automated alignment link would be created. Links appear on top of a low-density site map, with green links found to be especially strong [23] (See Figure 1 (B)). Using the scan previews, the work continued until data was captured of the whole site. Special focus was provided to the portions of the site with the most active work ongoing.

2.2 Data Processing

The point clouds were then processed to simplify the data. For each scan, a two-step process was performed. (1) Automated coincident point removal among nearby scans and (2) removal of noise through automated statistical outlier removal and manual segmentation. Statistical outlier removal identifies and removes points that deviate significantly from their neighbors. It calculates the average distance of each point to its k nearest neighbors and removes those exceeding this average within a multiple of the standard deviation. The process is controlled by two input parameters: k, which defines the number of neighbors, and a multiplicative factor for the standard deviation, which determines the threshold for removal [24]. In this case, the parameters of $k = 6$ and a multiplication factor of 1 were used. The predominant occurrences of noise were vehicles driving down the interstate and around the site,

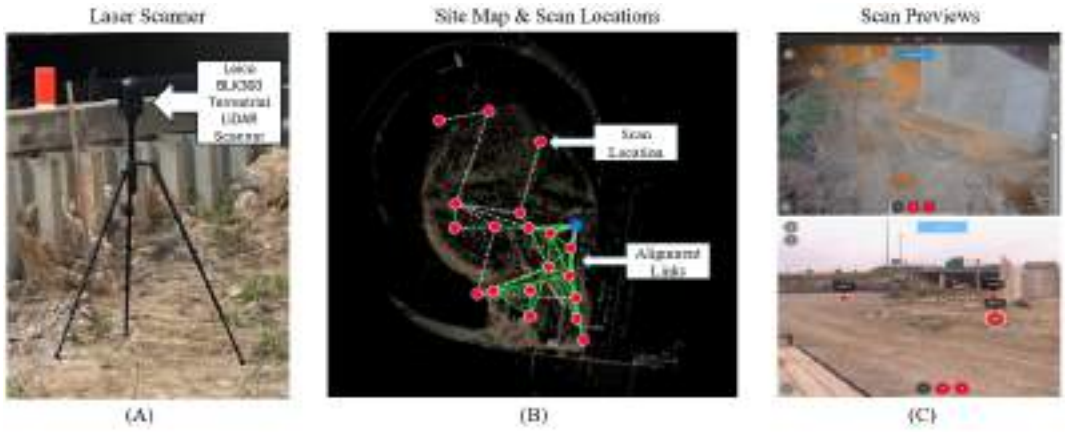

Figure 1. Leica BLK 360 Terrestrial Scanner (A) Site map with scan locations and alignment links (B) and scan preview via low-density point cloud and 3D image (C).

workers moving throughout the project, and lasers bouncing off reflective surfaces. In many cases, the scanner captured an object, but the object is inconsistent between scans and thus must be removed. Additionally, since the data collection process involved intentionally overlapping scans, nearby scans have many identical points. Coincident points included automated removal of overlapping data and, since the scanning device is less accurate as points are captured from further distances, low-density captures at further distances were removed during the manual segmentation process. Each scan was processed individually to remove noisy data, addressing the described instances of floating points, partially captured moving objects, and reflections.

For example, Figure 2 shows the cleaning of scan #1. In Figure 2 (A), the initial scan has a significant amount of noise from the nearby highway, inaccurate data from the reflection of a nearby truck, and workers in high visibility vests moving around the site. Figure 2 (B) shows the resultant point cloud after the coincident point removal and manual segmentation-noise deletion. By performing the cleaning workflow, the scan improved via the removal of reflection noise, partially captured workers and vehicles, and lower accuracy points captured far from the scan location. Along with being a more accurate capture of the true site conditions, this model also becomes more operable with a significantly lower file size ($\tilde{8}9\%$ reduction).

Another significant issue encountered was the misalignment of scans without vertical features. Scans which primarily consisted of the ground surface had inaccurate alignment in the vertical direction when performing automated adjustments, leading to inaccuracies in the dataset. Manual fine-tuning in the vertical direction was performed as a solution.

Figure 2. Example of data processing for scan #1. (A) Before and (B) after.

2.3 Data Exploration

The resulting high-fidelity point cloud can be leveraged for construction monitoring and project visualization activities. The following section describes three methods for data exploration, remote monitoring, and visualization: (1) desktop interface, (2) holographic interface, and (3) immersive virtual environments. A scenario-based evaluation was employed to validate the utility of these interfaces for data exploration to enable remote construction site analysis. This process did not involve comparison to project plans or reference measurements, but instead was a feasibility study for the visualization methods. In this process, the research team defined and performed standard tasks using the processed digital models to assess each interface's strengths, weaknesses, and capabilities. First, measurements of key structural elements—such as reinforced concrete walls, rebar spacing, wall angles, and foundation depths—were taken to verify that the built conditions could be measured. Second, feasibility of progress tracking and collaboration capabilities was assessed. Finally, the assessment of terrain elevations was undertaken to ensure that earth mobility could be captured. Additionally, informal interviews and visualization trials with construction operators conducted during on-site data col-

lection and through visits to the lab provided further insights into the methods' viability for construction monitoring tasks, and strengths or weaknesses as a collaboration and presentation tool.

2.3.1 Desktop Interface

For performing remote construction monitoring, the desktop interface (also known as 3D keyboard mouse) refers to a technician exploring the point cloud to make observations regarding project status, site layout, and gathering as-built measurements. Accessing the data in this capacity can be advantageous given the highly accessible nature of desktop computers and point cloud-compatible software. Additionally, many CAD and BIM workflows have compatible integration with point clouds [25, 26].

Considering point cloud data's high accuracy and precision, project status can be judged based on deviations from the planned design. At the same time, site layout assessments help verify spatial arrangements and identify potential conflicts or errors in construction. This method similarly helps maintain a safe and productive site layout. One significant object of interest in the captured data is the reinforced concrete wall, which will eventually support new sections of the roadway. Figure 3 (A) captures the measurements built from this construction feature. Such measurements include rebar spacing, wall angle, visible depth of foundation, and terrain elevation differences along the site. Measurements can be transformed into as-built drawings or 3D static mesh components.

The primary disadvantages of desktop workflows stem from the limited field of view and spatial understanding of the three-dimensional model viewed in a two-dimensional medium. As such, desktop workflows offer a limited sense of scale compared to 3D visualization methods. However, desktop workflows are typically more accessible and user-friendly, as they leverage widely familiar interfaces and are consistent with the majority of users' prior experience.

2.3.2 Holographic Interface

Another data exploration technique is using holographic models to represent the point cloud in 3D without relying on a head-mounted display (HMD). HMDs can be constraining when viewing 3D models, depending on the pixel density of the HMD. As such, holographic technology such as the Axiom Hologram Table [27] provides the technician with a semi-immersive representation of the project without sacrificing visual fidelity. An example of the construction site point cloud on the holographic table is shown in Figure 3 (B).

Holographic interfaces enable collaborative data exploration with multiple users. In the case of the Axiom device featured in Figure 3 (B), two can be wearing spatially tracked 3D glasses and controllers, and two more can be wearing non-tracked glasses. The difference between tracked and non-tracked glasses is that tracked glasses adjust the view of the hologram based on the user's physical orientation around the table. Non-tracked glasses copy the holographic view from the tracked glasses. As such, those with non-tracked glasses must stand near the tracked user to get an effective view of the scene. This device also features an audience view monitor, allowing spectators to understand what model is being presented to the users. Technicians leverage a remote controller to perform remote site construction site analysis operations, such as measuring construction features, rotating and scaling the environment, and creating presentations using multiple 3D files to display multiple project phases.

This workflow's disadvantages come from the technology's highly specific hardware and software requirements. This type of technology has a high entrance cost compared to the highly available consumer-grade desktops and HMDs. The models must be converted into a proprietary file type so the system can project them holographically. Some complex 3D files containing dynamic scenes are not compatible.

2.3.3 Immersive Environments

For this application, two types of immersive environments were explored: (1) viewing the three-dimensional point cloud in the first person and (2) a high-fidelity 3D reconstruction of the point cloud.

Point clouds can be loaded into applications such as Unreal Engine 5 (UE5) and navigated in VR [28]. Such applications can be advantageous compared to 3D images, as the high accuracy of point clouds should lead to improved spatial context. UE5 provides advanced modules and templates for VR applications and a dedicated LiDAR plugin. As such, point clouds can be uploaded directly and explored in the engine. The first-person point of view for this environment is shown in Figure 3 (C). VR-based toolsets are available for remote monitoring to capture measurement data [29], and can effectively reproduce the same construction monitoring tasks performed using the other visualization methods.

To build a high-fidelity 3D reconstruction of the site, UE5's environment modeling tools were leveraged to rebuild the model as a landscape component and several static mesh components. The landscape component represents the terrain of the site. The key difference between a static mesh and a landscape component is static meshes are non-deformable and predefined. In contrast, landscape components are dynamic - they can be modified in real time. Dynamic landscapes help simulate diverse construction scenarios, such as excavations. The point cloud was manually segmented to exclude everything but

Figure 3. Methods of data exploration for remote monitoring and viewing simulations: desktop interface (A), holographic interface (B), and immersive virtual environments (C).

the surface elevation to generate the landscape component. Given this landscape-only point cloud contained missing data, synthetic points were interpolated by generating a Delaunay 2.5D mesh [30] in those areas and sub-sampling the mesh into points. The obtained point cloud was recolored with a height ramp and rasterized into a 2.5D height map image. The height map image was uploaded directly into UE5 to build the landscape (see Figure 4 (A)). Once the landscape was generated, objects of interest from the point cloud were created to fill the environment with infrastructure components relevant to the scene. Objects of interest can be meshed using software such as Reality Capture [28]. Figure 5 shows an example of generating a mesh from the reinforced concrete wall central to the site. Additionally, the objects can be rebuilt manually using the measurements obtainable (see Figure 3 (A)). The roads of the highway interchange were built using a spline tool. Splines build a continuous path of iterated meshes along anchor points, locally adjusting the meshes and landscape to build highways. A similar technique was used to iterate center-line barriers and guide rails along the roads. Figure 4 (B) displays a sample of the VR scene.

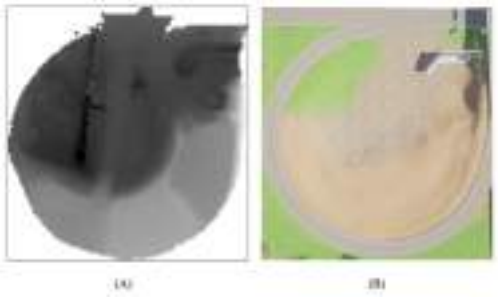

Figure 4. (A) Rasterized 2.5D image and (B) high-fidelity model for VR

This model is helpful for applications where the construction site is relevant as a foundation for a larger project. IVEs can be equipped with code to enable user interaction. This interaction increases the engagement of the model, which is known to increase knowledge retention for the user [31]. For example, various construction scenarios could be built on this scene for immersive construction health and safety training, contextually linked to the project. Additionally, coupled with data fusion from sensors, this technique can be used to build digital twin models.

Figure 5. Reinforced concrete wall meshed using Reality Capture.

The primary disadvantages of VR methods are the entrance price and physical comfort considerations. Although HMDs are becoming more available to consumers, there is an additional need for a high-performance computer to run the simulation. Additionally, only one user can use VR at a time, constraining the collaboration capabilities of the analysis. Regarding physical comfort, users may experience VR sickness (also known as motion sickness), given that the visual perception of their surroundings differs from the physical sensations. When artificial movement is added to a VR simulation, the visual and physical senses of the user do not match, causing motion sickness. Since approximately one-third of the population is highly susceptible to motion sickness [32], extended use of VR is not always practical.

3 Results and Discussion

The work's results are presented as an evaluation of data processing and recommendations for best practices in

visualization and data acquisition.

The original data capture comprised 20 successful scans, totaling ~500,000,000 unique points, and was roughly 10.7 Gb in storage. After performing the methodology explained in Section 2.2, instances of duplicate points and noisy data were removed and a clean point cloud was obtained (see Figure 6 (A)). In the first step, where coincident points were extracted, 75.9% of the initial data was removed. After performing the noise removal, there was a cumulative point reduction of 87.21% and a total file size reduction of 89.04% from the original scan, which shows the significant amount of unnecessary and inaccurate data that can be removed after data collection. This processed point cloud, along with being a more accurate representation of the scene, has lower computational costs and storage requirements than the unprocessed version. The obtained data was dense in points despite the size reduction, and, as shown in Figure 6 (B), there is a high concentration among the construction features of the work site. This high concentration is valuable for precise measurements of construction features.

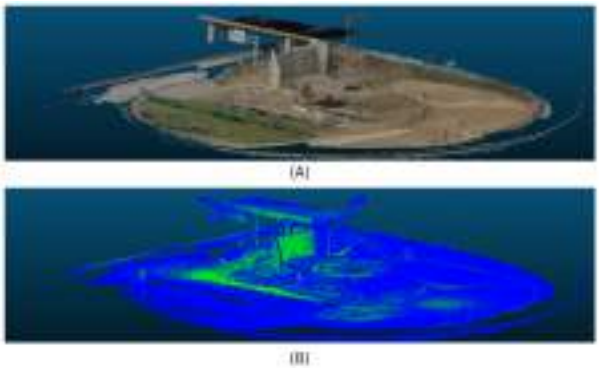

Figure 6. (A) Full point cloud after data processing and (B) Point density after data processing, visualized with a color scale: blue (lowest density) to red (highest density).

Three methods of data exploration were reviewed. Provided with a processed dataset, an expert can make judgments regarding the construction quality with easier access to many details of the site than would be available with an in-person visit. In all three methods, the standard tasks were able to be performed, thus displaying feasibility for these methods to enable remote inspection of construction sites. The efficiency and difficulty of each method for remote monitoring activities are highly dependent on the technicians' experience using the technology. Since most users are expected to have significantly more experience interacting with desktop interfaces, they were found to be the most accessible for remote monitoring. Holographic data visualization methods were found to be best used as a collaborative tool or for presentation purposes. Multiple users can review the 3D data in a semi-immersive environment. Given the depth perception and spatial rendering, participants can see the full scope of the data intuitively. As a presentation tool, the holographic interface is found to be a memorable and engaging method of presentation. For all methods, measurements of construction features were replicable. IVEs are effective for applications where the user should interact with the environment. Immersive virtual environments were found to be similarly engaging and memorable experiences for displaying projects compared to holographic ones.

Based on the described case study, the following best practices are proposed for future applications of virtual construction site analysis of horizontal infrastructure:

1. The TLS scans should be captured across the work zone so that nearby captures overlap in data, and areas with the most significant construction features are prioritized.
2. Engage in manually cleaning the data to remove artifacts such as floating points, partial objects, and reflections—additionally, leverage coincident point removal to eliminate overlapping data. While aligning, pay special attention to the vertical alignment links - especially in areas where the scan primarily captures terrain.
3. Leverage different visualization techniques depending on the use case of the data. For accessible remote monitoring, prioritize desktop interfaces. Use immersive techniques such as holographic interfaces and IVES for presentations, collaborative data exploration, or activities involving interaction with the model.
4. When building a high-fidelity IVE, separate the landscape from the construction features to create an environment with a well-defined terrain before adding construction features. Leverage the measurement techniques or meshing capabilities available from point clouds to recreate objects of interest accurately.

4 Conclusion

This study introduced a novel workflow for processing and visualizing point cloud-based reconstructions of horizontal infrastructure projects, through discussion of dealing with common types of noisy data relevant to construction sites and an exploration of data exploration methods. The data collection and processing were described to help define best practices for large-scale terrestrial point cloud capture of horizontal infrastructure. Additionally, a data processing framework was explored which highlights the significant amount of either unnecessary or noisy data within point clouds of active horizontal construction sites. To judge the viability of remote project monitoring and

simulation rendering, data exploration methods were surveyed, with an emphasis on the most advanced technological methods available. The highlighted methods were desktop interface, holographic interface, and immersive virtual environments. These advanced techniques proved promising for remote inspection and analysis of construction sites. Each method was found to be viable when performing standard construction monitoring tasks such as observing construction features, taking measurements, and presenting information. However, all methods require individual expertise for efficient operations in both site inspection and collaboration activities.

This work enables a formal quantitative study to improve understanding and analysis of the efficiency and difficulty of each method, along with assessment of cognitive load within larger groups of users. Future work will focus on developing the high-fidelity 3D model into practical use cases. Industry partners have been identified to guide this development. The work presented opens the possibility of defining a novel framework for developing IVEs from laser scans obtained from construction sites. In the future, this could provide a defined methodology to convert real-life projects into advanced, context-specific IVEs suitable for simulation.

Abstract –

In the wood construction industry, timber structural defect detection is usually considered a pre-manufacturing inspection step done manually. To address this issue, the proposed study discusses the timber structural defect detection method based on YOLOv8 variants. The evaluation matrices used are precision, recall, mAP.5, and mAP.5-.95, and the results indicate stable convergence and consistent accuracy on the complex dataset instances. This research contributes to the automation of timber defect detection for precise and robust manufacturing of timber structures. The proposed method further improves resource utilization and contributes towards eliminating waste in the residential construction industry.

Keywords –

Timber; Defect Detection; Mass-Timber Manufacturing; YOLOv8; Construction Industry; Computer Vision

1 Introduction

Timber, a finished wood product, is a major building material for residential and commercial buildings worldwide. Timber exhibits unique structural capacity and fineness, making it suitable for panels, trusses, ridges, beams, and staircases. Like every other wood type, natural timber exhibits multiple defects due to genetic and growth factors, processing phase, and environmental and storage conditions [1]. Defective timber can harm the overall building integrity and durability and must be excluded in final processing. Surface defects like knots and burls originate from growth conditions and can easily be identified at an early stage of timber handling. Contrarily, twisting, warping, and splits often occur during the manufacturing and drying phases of finished stud handling, and many construction workshops use experts' eye and appropriate angles for manual stud quality inspection and anomaly identification.

Therefore, a low-cost, fast solution is needed to identify complex structural irregularities like twists and bends [2-5]. Machine vision and deep learning solutions are popular for object detection, which utilize CNNs to mimic human brain learning behaviors [6-8]. Some research proposes generalized novel algorithms utilizing different layering of CNNs [6,9], whereas other researchers focus on utilizing and fine-tuning the proposed novel and hybrid algorithms to better tune them for specific tasks, environments, and datasets [10-12]. A recent study on defect detection across variant timber types has combined image preprocessing techniques with CNN-based architecture to build a vision-enabled defect detection platform [13]. Another similar approach was utilized for precise sawing and grading automation in timber processing [14]. A method called EMINet uses cross-fusion modules for the surface defect detection of sawn timber [15]. This algorithm is designed to learn and infer multi-scale features with greater speed and accuracy. Xi et al. have utilized SPD-Convolution, SiAFF-PA Net, and multi-attention mechanisms in their model to refine the localization and classification of timber defects [16]. Furthermore, different types of stained wood grain defects have been discussed in literature by incorporating CNN architecture to boost the quality inspection and grading mechanism defects [17].

Image detection algorithms can be divided into two categories: two-stage detection and one-stage detection. R-CNN (Region-based Convolutional Neural Network) [18], Fast R-CNN [19], and Faster R-CNN [20] are popular two-stage models comprising region proposal blocks and classification blocks. Whereas the one-stage object detection has a unified region proposal generation, and classification mechanisms are proposed in YOLO (You Only Look Once) [21-24] and SSD (Single Shot Multibox Detector) [25]. Regarding timber defect detection, the YOLO series has been enhanced in several ways to boost detection accuracy and specified classes. BDCS-YOLO is an enhanced method that showed a 12.3 percent improvement in timber defect detection and sawing for resource optimizations [13]. Another study

has used the SimAm module and Ghost convolution to improve YOLOv5, reducing the computational costs for wood surface defects [26]. Another study has focused on efficiently detecting cracks in wood surfaces by proposing ICDW-YOLO algorithm [27].

Besides multiple pieces of research exhibiting good performance on surface-level defects such as minor cracks, knots, and stains, it is clear from the literature study that no significant work has focused on utilizing computer vision to inspect physical defects such as bends, twists, and missing of wood parts within timber studs. This research is focused on generating industrial solutions for the precise localization of defective parts using the YOLOv8 algorithm. To automate the precise detection of structural defects in timber studs, this research begins with the data collection and generation of the timber stud structural defect detection dataset, specifically focusing on twists and bends. The developed dataset is used for training and prediction using the YOLOv8 image detection method. An extensive study of evaluation matrices is performed on multiple variants of YOLOv8 (YOLOv8nano, YOLOv8small, YOLOv8medium, YOLOv8large, YOLOv8x_large) to balance the overall system accuracies and computational cost [2]. Moreover, due to the complexity of the task nature, a prediction study is discussed, emphasizing the importance of initial setup settings during data collection in the overall success of deep learning training.

The precise and easy timber defect detection system can minimize the wasting of complete studs and maximize material utilization, potentially reducing the additional tree harvest. Furthermore, prior screening of timber quality can reduce repair overengineering resulting in durable construction. These factors contribute towards decarbonizing the construction industry and helping easily adopt natural timber as a cheap, sustainable material, lessening carbon emissions. This research can also directly advance industrial practices of automating timber inspection using computer vision and robotics.

The overall flow of the study is shown in Figure 1, and the key steps involve dataset preparation, explained in Section 2; model training on YOLOv8 variants detailed in Sections 3, 4, and 5; and model prediction results are presented in Section 6, followed by conclusion and discussion of future insights.

2 Dataset Preparation

Timber studs are used in the manufacturing of wood buildings as wall panels, roof trusses, floor units, and supporting ridges, and they vary in dimensions a lot. An average stud can be 2-4 meters long, 2-4 inches wide, and 4-8 inches in depth and have a face side (the wider and flatter surface) and an edge side (the narrower surface). They can vary hugely depending on the grade and species, moisture contents, load requirements, and code compliances. The changes in shapes and structural integrity of these timber studs, called structural defects, can occur due to drying, external stress, and improper seasoning. Bend (curvature along the length of stud), twist (spiral warping), bow (curve along the face side), cup (curve along the width), and warp (an amalgamation of bends, twists, and bows) are categorized as structural defects.

Table 1 shows the dataset preparation steps and their details. As the defect can form at any angle or side, we have used 3 camera heights (2 feet, 6 feet, and 18 feet) to

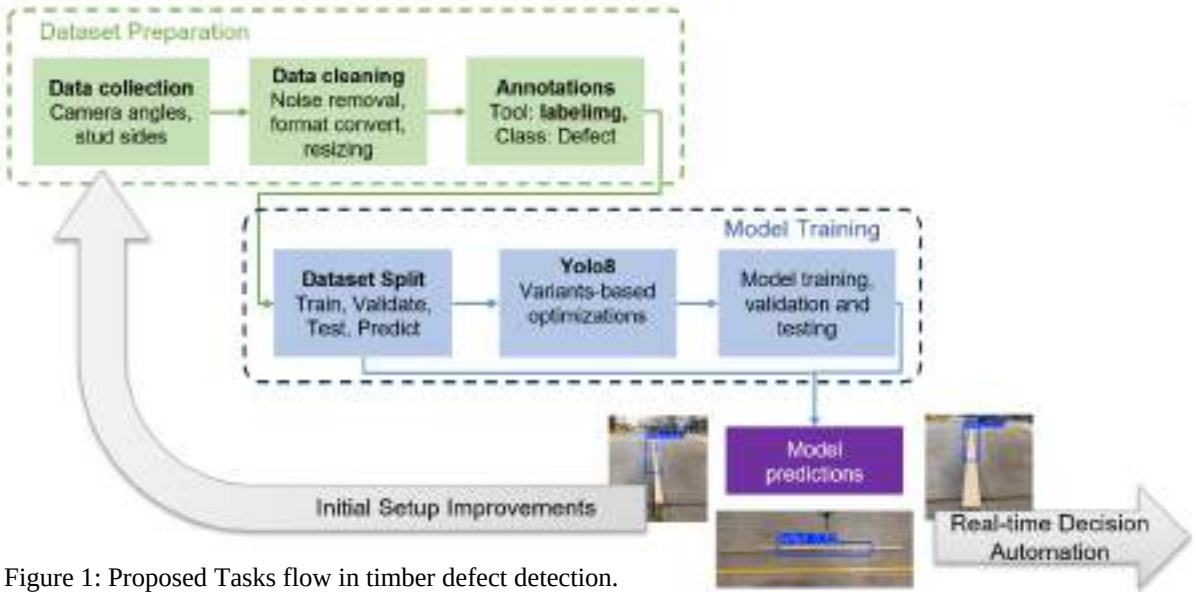

Figure 1: Proposed Tasks flow in timber defect detection.

capture the pictures of a stud on both sides (face and edge). A total of 15 studs, with 12 defective and 3 non-defective, are used to generate 400 multi-dimensional images. These images are manually cleaned to remove irrelevant details and are resized to 640 x 640 sizes to be fed to the YOLOv8 models. LabelImg [28] is a tool for ground truth generation for popular image detectors and is used here to annotate the dataset, creating defect class bounding boxes. The images showing no defect are not assigned to the defect class and are passed to the model training as background images. After cleaning and annotations, the final dataset comprising 285 images with defects and 65 background images is split stud-wise for training, validation, testing, and prediction at 65%, 15%, 15%, and 5%, respectively.

The dataset generation and model training for structural defects is tricky, as a defect visible on the face side at a particular angle may not be detectable across the edge and vice versa. The complexity of the task can be seen in Figure 2, which shows some real instances from the dataset generated.

Table 1: Timber Stud Surface Defect Detection Dataset preparation steps.

Phase	Parameter	Value
Initial Setup	Stud sides	2 (face, edge)
	Camera heights	3 (2 feet, 6 feet, 18 feet)
Data collection	Total studs	15
	Defective studs	12
	Non-defective studs	3
	Total images	400 (varying dimensions)
Resizing, cleaning, and annotations	Total images after data cleaning	350 (640 x 640)
	Background images	65
	Annotated with class: Defect	285
Model training	Training (65 %)	10 studs, 234 images
	Validation (15 %)	2 studs, 48 images
	Testing (15 %)	2 studs, 48 images
	Prediction (5%)	1 stud, 20 images

3 YOLOv8 Method

YOLO is a one-stage detection model that combines the predecessor's functionalities into improved architecture in its version series. YOLOv8 [2] is an adaptable and efficient model comprising three main modules. The initial backbone is a variant of CSPDarknet, used for multi-scale feature extraction in the model. The second unit, called the neck, implements the PAN-FPN module for feature aggregation, and finally, the head contributes to object classification and bounding box regression. One powerful feature of YOLOv8 is the real-time prediction generation that supports inspection-based applications for faster, lightweight, and more accurate real-time detections. The trade-off between speed and accuracy is well-managed in YOLOv8, which provides precise detections at the rate of high throughput. Moreover, the refined multi-scale feature fusion of this model makes it best suited for the current case of structural defect detection where the images are captured from different heights, offering multi-sized imperfection instances.

As the available dataset is of small size, the training is run on different variants of YOLOv8 to achieve high performance, considering factors of resource optimization, overfitting avoidance, comparative performance analysis, scalability and adaptation. These variants are YOLOv8 nano, YOLOv8 small, YOLOv8 medium, YOLOv8 large, and YOLOv8 extra-large, exhibiting different training speeds, computational requirements, and number of trainable parameters. From nano to large, these variants differ based on the layer count, sizes, and trainable parameters, and support limited to industry real-time applications.

4 Model Training

After the dataset preparation and splitting of the dataset, the data is passed to YOLOv8 variants for training and validation. Table 2 discusses the training machine specifications. The model is trained with the generated dataset on a machine with Central Processing Unit (CPU) Intel(R) Core(TM) Ultra 9 185H 2.50 GHz, Graphics Processing Unit (GPU) NVIDIA GeForce RTX 4070 Laptop GPU (8,188 MiB VRAM), 64 GB RAM (Random Access Memory), with installed version of CUDA 11.2, python 3.9.20 and Pytorch 2.5.1+cu121.

Table 2: Training machine specifications.

Property	Value
CPU	Intel(R) Core(TM) Ultra 9 185H 2.50 GHz
GPU	NVIDIA GeForce RTX 4070 Laptop GPU (8,188 MiB VRAM)
CUDA version	11.2
Operating System	Windows 11 Home
RAM	64 GB
Python version	3.9.20
PyTorch version	2.5.1+cu121

Table 3: Model Training parameters on YOLOv8

Parameter	Value	Parameter	Value
Image Size	640 x 640	Epochs	250
Batch Size	8	Augmentation	hsv_h=0.015
Learning rate	0.001		hsv_s=0.7
Momentum	0.937		hsv_v=0.4
Weight Decay	0.0005		mosaic=1.0

As the generated timber stud structural defect detection dataset is small and multifaceted, the training was performed on different hyperparameters to choose the best settings suitable for better accuracy, and Table 3 shows the carefully selected set of model training parameters on YOLOv8 variants. These hyperparameters were chosen to balance generalizability and computational efficiency, given the dataset constraints. The input image size is 640 x 640 with a batch size kept at 8 trained for 250 epochs during each model training. The batch size was selected based on the GPU availability to avoid any computational instability. The learning rate is initiated with 0.001, momentum of 0.937, and weight decay of 0.0005 to achieve a smoother convergence. The training was also set to early stopping to save the best-trained parameters for inference. During real-time image capturing for real-time inference, the brightness and hues vary greatly depending on the workshop environment and lighting conditions. To make the training robust of inference time conditions, the data augmentation is kept true during the training, and the augmentation parameters are passed as hue 0.015, saturation 0.7, and value 0.4, and the mosaic set is kept on. These data augmentation settings can avoid the overfitting of smaller datasets, making the model resilient to surrounding conditions by slightly changing the picture effects during training.

5 Evaluation Metrics

Typically, YOLOv8 does not support model testing on a different dataset. Instead, it generates the model predictions based on the trained weights. However, to assist the optimization study and hyperparameter evaluation, this study used a separate model testing mechanism by passing the unseen test images to a separate model evaluation method. This proved effective for understanding the real model accuracies and finetuning accordingly.

Table 4: Variants of YOLOv8 and their specifications

YOLOV8 Variants	#Layers	#Params	Val Precision (%)	Test Precision (%)	Val Recall (%)	Test Recall (%)
YOLO8nano	225	3,011,043	79.5	62.8	63.0	72.3
YOLO8sml	225	11,135,987	74.1	60.9	67.4	74.5
YOLO8med	295	25,856,899	93.0	74.8	60.9	72.3
YOLO8lg	365	43,630,611	85.7	79.8	60.9	67.1
YOLO8x_lrg	365	68,153,571	84.1	66.3	57.4	62.8

The evaluation metrics used for the inspection of model training and testing are precision (P), recall (R), and mean average precision (mAP) of the predicted bounding box of defects. Precision counts the correct predictions from all prediction instances, whereas recall counts the correct predictions out of all actual predictions. The formula for precision and recall is given in Equation (1) and Equation (2).

$$P = \frac{TP}{TP + FP} \quad (1)$$

$$R = \frac{TP}{TP + FN} \quad (2)$$

In Equation (1), *P* indicates precision, whereas *TP* and *FP* donate true positives and false positives, respectively. In Equation (2), *R* represents recall, and *TP* and *FN* present true positives and false negatives.

Mean average precision (mAP) considers the classification and location accuracy, and mAP.50 and mAP.5:.95 are reported here. mAP.50 reports the average precision of the model when the intersection over the union (IOU) threshold is 50% or up between predicted and ground truth bounding boxes. mAP@.50:.95 is another metric that computes the average precision for IoU thresholds ranging from 0.50 to 0.95 in 0.05-step increments. This metric is more critical than mAP@.50 since it penalizes projections far from ground truths and displays the model's ability to precisely locate objects. A high mAP@.50:.95 value indicates greater performance in localization and classification.

6 Discussion of Results

As indicated in Table 4, the number of layers and trainable parameters are increasing from YOLOv8nano to larger models. The validation and test results indicate varying accuracies of these trained models on the timber defect dataset. The validation and test precision for YOLOv8 nano, YOLOv8 small (sml), YOLOv8 medium (med), YOLOv8 large (lrg), and YOLOv8 extra-large (x_lrg) are 79.5% and 62.8%, 74.1% and 60.9%, 93.0% and 74.8%, 85.7% and 79.8%, 84.1% and 66.3% accordingly. The validation and test recall for YOLOv8 nano, YOLOv8 small, YOLOv8 medium, YOLOv8 large, and YOLOv8 extra-large are 63.0% and 72.3%, 67.4% and 74.5%, 60.9% and 72.3%, 60.9% and 67.1%, 57.4% and 62.8% accordingly. These results indicate that YOLOv8 medium and YOLOv8 large are best suitable for the current detection task, as the precision is high for these models, which means the model is detecting true instances and recall is comparatively better, demonstrating fewer missed detections.

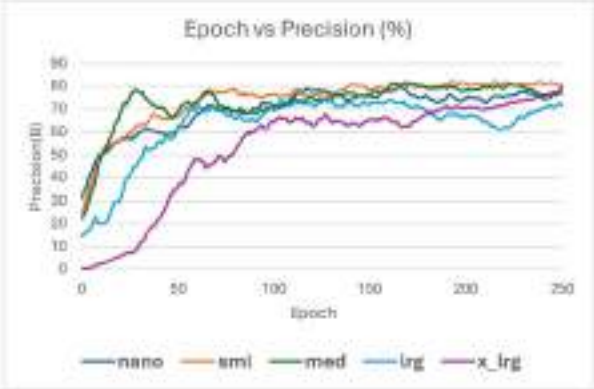

Figure 3: Training Precision in percentage

The training precision is shown in Figure 3, and it is visible that all models try to converge between 100-200 epochs with a slight increase in precision afterward, but the YOLOv8 large training curve indicates a loss in accuracy in later epochs, indicating that the model is still trying to learn new parameters due to its large size.

The training mAP.5 (B) and mAP.5:.95 (B) for all models in Figures 4 (a) and (b), respectively, indicate a similar pattern as precision(B) where models can achieve between 63% to 73% metrics for mAP.5 and between 35 % to 40% mAP.5-.95. These converged graphs show that models are neither over-fitting nor under-fitting, provided the toughness, small-scaled and complexity of the dataset.

Moreover, the final validation and test mAP.5 (B) and mAP.5:.95 (B) for all models are presented in Figure 5. This comparative graph indicates around 75% and 70% of validation and test mAP.5 (B) and around 45% and 38% achieve validation and test mAP.5:.95 (B). These values

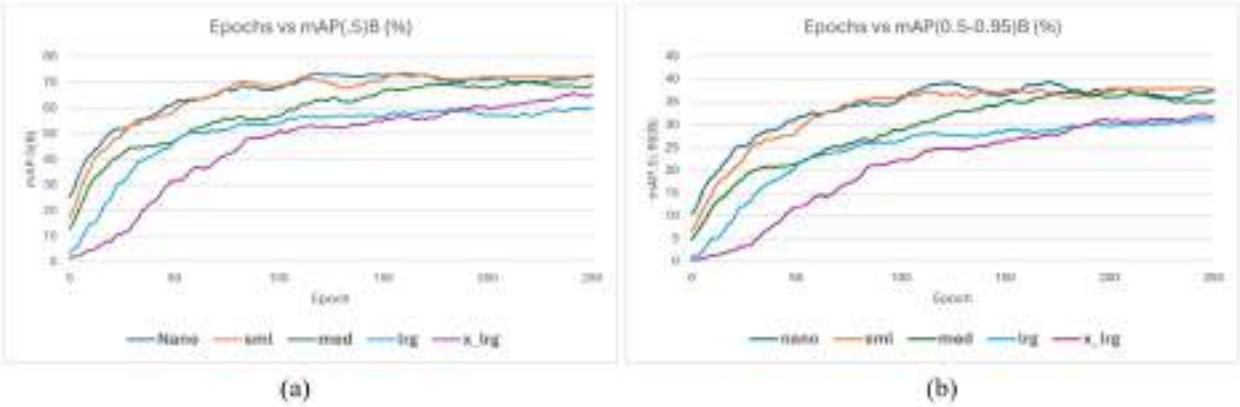

Figure 4: (a) Training mAP(.5)(B) in percentages (b) Training mAP(0.5-0.95)(B) in percentages

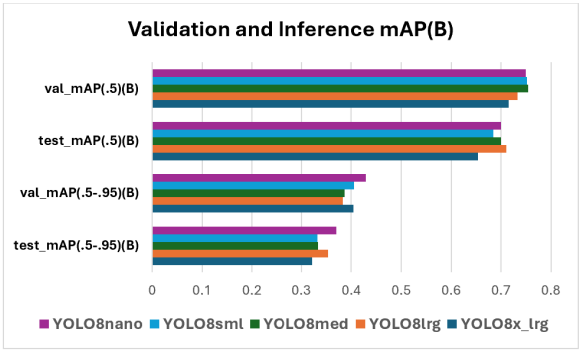

Figure 5: Validation and Inference results on YOLOv8 variants

demonstrate effective learning and consistently high capabilities, indicating that the models are generalized well on unseen data. Moreover, YOLOv8 medium and large are two modules that consistently achieved superior accuracies and precision, which confirms their ability to perform reliably in real-world scenarios.

Based on the collected results, YOLOv8 medium-trained weights are selected for model inference so that the images from one defective stud are passed to generate predictions, presented in Figure 6. The model generates predictions for the same defective studs differently when different angles of images are provided. The instances captured from 2 feet height generated a bounding box with high accuracy (a,b,c), but the top views 6 feet and 16 feet high indicate a gradual decrease in precision (d,e).

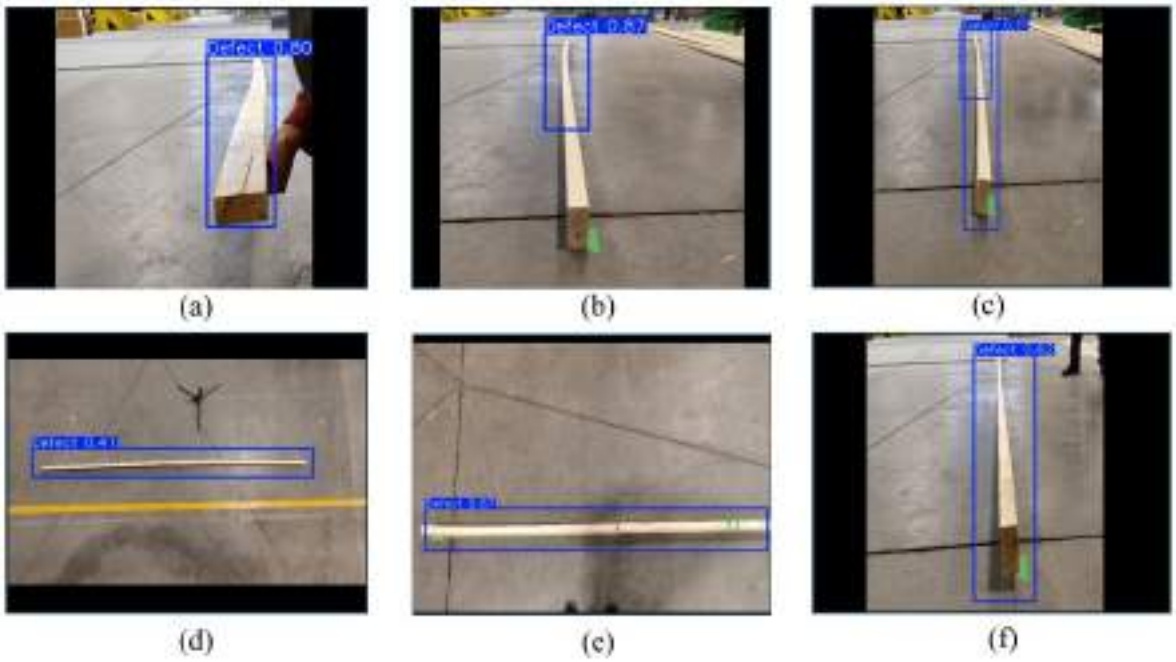

Figure 6: The difference in prediction accuracies based on different camera angles.

These observations provide valuable insight into the number of cameras, optimized camera installation location, and images needed for effective real-world predictions using the provided setup and methods.

As the number of defective studs in a working industrial setting is limited, so based on data availability, the number of defective and non-defective studs was adjusted to create a balanced trainable dataset, totalling 15 studs. The smaller datasets are highly prone to overfitting issues, compromising overall model authenticity and generalizability. To tackle this issue, a careful selection of hyperparameters and data augmentation was adopted while training with different modules of YOLOv8. In the future, this research can extend to collect and expand the dataset length to enhance accuracy and attain better results. Further, a performance comparison between other state-of-the-art and latest image detection training models can also be conducted.

7 Conclusion

This research discussed timber stud structural defect detection dataset preparation steps followed by the extensive model training on YOLOv8 variants, specifically focusing on detecting bends, twists, and wraps in timber studs used in wood house construction. The quantitative results indicated a balance between accuracy and computational efficiency, whereas YOLOv8 medium and YOLOv8 large demonstrated the high validation and test precision of 93.0%, and 74.8%, 85.7%, and 79.8%, respectively. The predictions generated provided knowledge about the best device placement and total frames for real-time prediction precision, and the predicted defect bounding boxes can be used for precise automated cutting of defective parts. This research will help reduce carbon emissions through resource utilization optimization and waste mitigation in the construction industry. Moreover, it advances computer vision and robotic automation in the Canadian wood construction industry. The proposed methods can be expanded to accommodate other types of timber defects, expand the dataset, and automate other pre- and post-manufacturing inspection steps.

Abstract

For progress monitoring in the construction industry, understanding the state of construction sites is crucial. However, traditional manual inspection methods are labor-intensive and time-consuming. To address these challenges, various methods for creating 3D models of job sites have been explored. Professional equipment such as LiDAR and laser scanners offer the most accurate means of generating point clouds (PCDs) and constructing 3D models. However, these tools are expensive, cumbersome, and often impractical for frequent use in dynamic construction environments. Recently, with the advancement of deep learning, 3D reconstruction techniques have been extensively studied and applied across various fields. Among these, Structure from Motion (SfM) stands out as a method capable of generating PCDs and estimating camera poses. Based on advancing capabilities of SfM, many research has been conducted to measure progress monitoring in construction field. However, most studies that have utilized SfM for progress monitoring have acquired a large number of images and ensured significant overlap in input data to enhance the robustness of the 3D model. While this approach provides a highly accurate 3D reconstruction, the image acquisition process itself introduces additional labor-intensive tasks. Therefore, this study aims to adhere to the fundamental nature of 3D reconstruction by evaluating the performance of various SfM models using only 26 images captured from a brief video recording at a construction site. The findings aim to evaluate the applicability of various SfM technologies with limited data, in real-world construction scenarios and finally provide insights into their potential and future directions.

Keywords –

Progress Monitoring, Structure from Motion, COLMAP, VGGSfM

1 Introduction

In the construction industry, progress monitoring is essential to ensure project efficiency, quality, and adherence to timelines. Traditional monitoring methods often rely on manual inspections and reports, which can be time-consuming, error-prone, and inconsistent. As a solution, 3D modeling techniques have gained attention for their ability to provide comprehensive information of construction sites [1, 2, 3].

To generate 3D models of construction sites, equipment such as LiDAR and laser scanners are widely used, offering the ability to produce highly accurate and dense point clouds (PCDs). For instance, Hu et al. utilized LiDAR to scan 3D surfaces of opencast quarries, enabling the analysis of slope stability. Similarly, Wang et al. employed laser scanners to rapidly perceive heavy construction equipment such as tower crane, improving safety and productivity in construction environments. Despite their accuracy and utility, these tools are expensive, bulky, require extensive training to operate, and involve significant time for scanning, making them less practical for dynamic and fast-paced construction site conditions [3, 4, 5].

These challenges have driven researchers to explore alternative methods for 3D reconstruction. With the advancement of deep learning and computer vision, techniques using 2D images to create 3D models have garnered significant interest [1]. While such methods may compromise lower accuracy compared to specialized equipment, their accessibility, ease of implementation, and reduced scanning time make them a promising alternative [1, 4]. Among these approaches, Structure from Motion (SfM) stands out as a photogrammetric technique capable of not only constructing 3D models from 2D images taken from varying perspectives, but also estimating camera poses which include their positions and orientations [6].

Using these strengths of SfM, research on progress monitoring based on SfM in the construction field has been actively conducted. However, these studies

focusing on the 3D reconstruction of actual construction sites, particularly interior environments, remain insufficiently explored. Additionally, achieving higher accuracy in SfM models often requires a large number of images and to be overlapped to some extend. Hence, acquiring such extensive image datasets in complex construction sites is challenging and may lead to even more cumbersome issues.

By utilizing image data captured within a very short time frame and comparing multiple SfM frameworks, this study aims to identify the challenges and opportunities of applying SfM in construction environments, thereby contributing to a deeper understanding of its potential in the industry.

2 Literature Review

2.1 Structure from Motion (SfM)

Structure-from-Motion (SfM) is a technique that builds 3D point clouds (structure) from cameras (motion). SfM is typically categorized into incremental and global approaches. In incremental SfM, the process begins by aligning an initial pair of images, followed by the gradual addition of new images. This method iteratively performs feature matching and bundle adjustment (BA), progressively constructing the 3D structure. In contrast, global SfM employs deep learning-based feature matching across multiple images, enabling a faster and more efficient reconstruction process. This approach estimates camera poses and reconstructs the 3D structure in a global, batch-wise manner rather than incrementally.

COLMAP [7] is one of the dominant incremental SfM tool in computer vision field due to its robustness and efficiency. It employs the Scale-Invariant Feature Transform (SIFT) algorithm, which ensures reliable feature matching even under image rotations and lighting variations. Furthermore, COLMAP uses the Ceres Solver-based BA to reduce accumulated errors, thereby enhancing reconstruction accuracy. As mentioned before, with the advancement of deep learning, global SfM methods also have been developed.

VGGSfM [8], one of the newest global SfM model, has been developed as an alternative to traditional incremental SfM methods. Unlike conventional approaches, VGGSfM jointly estimates all camera poses using a Transformer-based architecture, offering a simpler and more differentiable process compared to the combinatorial correspondence chaining step. Additionally, for BA, VGGSfM replaces the nondifferentiable Ceres Solver with the fully differentiable second-order Theseus Solver, further improving computational efficiency and scalability.

2.2 SfM in Construction Site

Although SfM cannot build 3D models as accurately as TLS or LiDAR, it has been widely studied due to its affordability, accessibility, and ability to perform spatial mapping to a certain extent. Ding et al. explored indoor scene understanding using 304 images captured with a widely used consumer-level camera and conducted 3D reconstruction using VisualSfM [5]. The strong 3D reconstruction capability significantly contributes to scene understanding, which has led to extensive research on its applications in progress monitoring.

Studies have also been conducted to evaluate COLMAP's powerful performance within the construction domain, emphasizing its potential applicability in this field. Keyvanfar et al. applied nine different 3D reconstruction models, including COLMAP, to visualize construction sites [9]. In their study, they utilized 138 images captured using an Unmanned Aerial Vehicle (UAV), ensuring a more robust 3D reconstruction by acquiring images with 60–80% overlap.

In addition to studies that solely utilized SfM for progress monitoring, research integrating SfM with other technologies has also been conducted. Mahami et al. and Han et al. employed SfM combined with Multi-View Stereo (MVS) to construct 3D models and align them with as-built Building Information Model (BIM) elements for progress monitoring [10, 11]. Additionally, some studies have leveraged SfM-based camera pose estimation to generate denser 3D models. For instance, Pal et al. developed an SfM-MVS-based 3D reconstruction pipeline to estimate camera parameters from 2D images and incorporated Neural Radiance Field (NeRF) and semantic segmentation to predict progress completion [1].

Although numerous studies have explored the application of SfM in the construction industry, many of these approaches have prioritized achieving more robust and dense 3D reconstructions by utilizing high-resolution cameras or capturing images with significant overlap to enhance feature matching. Consequently, rather than fully exploiting SfM's inherent advantages, these methods introduce constraints related to data acquisition, limiting their practical applicability.

3 Case Study

3.1 Overview

To conduct a 3D reconstruction study in a real construction environment, we visited a construction site located in Seongdong-gu, Seoul, and acquired image data. A specific room within the construction site was selected to compare the performance of different 3D reconstruction methods. Image acquisition was

performed using the Insta ONE X2 fisheye camera, which facilitated rapid data collection by capturing images in all directions with a single shot. The captured footage was converted into perspective images, and a total of 26 images from the selected room were used for the comparative analysis between COLMAP and VGGSfM. All of the converted images have resolution of 4320 × 2880. The workstation used for the case study was equipped with 32 GB of RAM, a Core i7-12700KF CPU, NVIDIA GeForce RTX 3080 Ti GPU and CUDA version 11.3 was utilized for GPU acceleration.

3.2 Evaluation Metrics

To quantitatively compare the results of 3D reconstruction, not only the number of 3D points and processing time but also three key metrics were used: mean track length (MTL), mean observations per image (MOI), and mean reprojection error (MRE). These metrics provide insights into the robustness, contribution, and accuracy of the reconstruction process [12].

MTL is the average number of images in which a 3D point is observed. It measures the frequency with which 3D points are visible across the set of input images, providing insight into the robustness of feature matching and triangulation in the reconstruction process.

$$\mathrm{MTL} = \frac{\sum_{i=1}^{N} L_i}{N} \tag{1}$$

Where N denotes total number of 3D points in reconstruction, L_i the number of images in which the i-th 3D point is observed.

MOI is the average number of 3D points observed per image. This metric evaluates how much each image contributes to the 3D reconstruction, indicating the distribution of feature matches across the dataset.

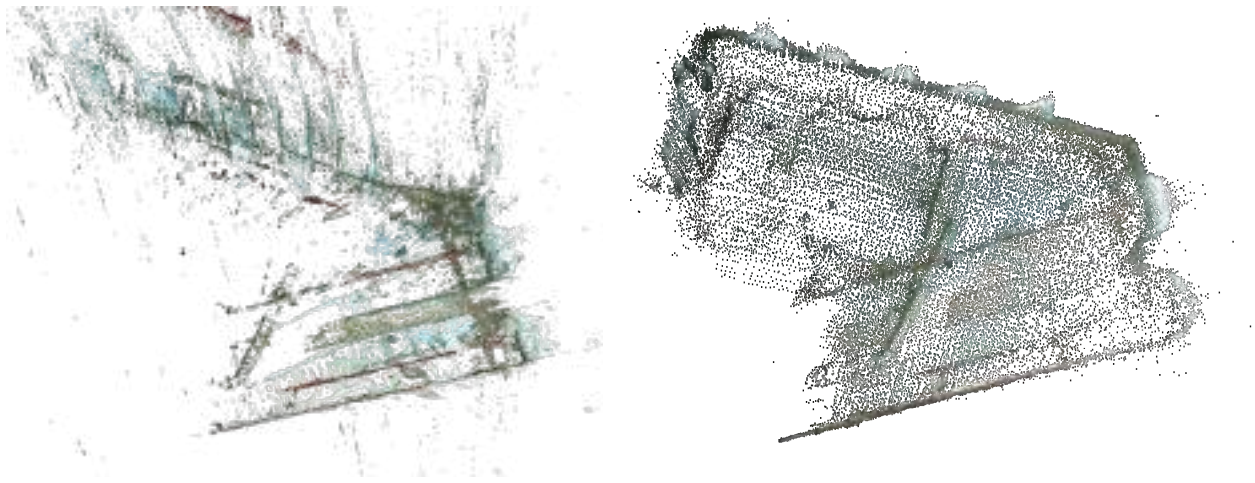
$$\mathrm{MOI} = \frac{\text{Total Observations}}{\text{Number of Images}} \tag{2}$$

MRE quantifies the average distance, in pixels, between the observed 2D points and their corresponding 2D projections from the 3D points. It serves as a key indicator of the accuracy of the reconstruction and the quality of the camera parameters.

$$\mathrm{MRE} = \frac{\sum_{i=1}^{N} |\boldsymbol{p_i} - \widehat{\boldsymbol{p}_i}|}{N} \tag{3}$$

Where N denotes total number of 2D points, p_i the observed 2D coordinates of the i-th point, $\hat{p}_i$ the reprojected 2D coordinates of the i-th point obtained from the estimated 3D point and camera parameters.

4 Result Analysis



4.1 Quantitative analysis

The quantitative comparison of COLMAP and VGGSfM using the aforementioned metrics is summarized in the following Table 1.

Table 1. Summary of quantitative comparison of COLMAP and VGGSfM

Metrics	COLMAP	VGGSfM
Number of 3D points	13,765	**69,612**
Processing time	30m 33s	**10m 35s**
MTL	**1.22082**	0.66221
MOI	1,377.38	**1,993**
MRE	1.08028	**0.01852**

* Bold values indicate better performance

(a) COLMAP (b) VGGSfM

Figure 1 Top view perspective of 3D reconstruction model of COLMAP(a) and VGGSfM(b)

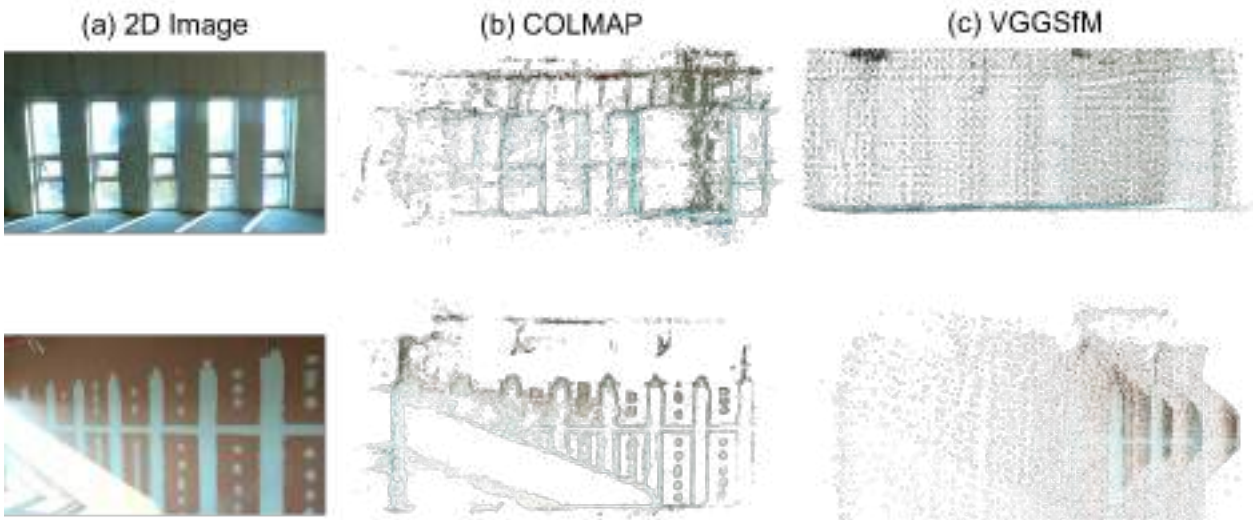


Figure 2 Reconstruction outputs of wall: (a) 2D image of wall (b) COLMAP (c) VGGSfM

The number of generated PCDs was significantly higher for VGGSfM, with 69,612 PCDs compared to 13,765 PCDs for COLMAP, a difference of approximately 55,000 points. In terms of processing time, VGGSfM was approximately 20 minutes faster than COLMAP, completing the task in 10 minutes and 35 seconds compared to COLMAP's 30 minutes and 33 seconds.

While MTL was 0.6 higher for COLMAP, for MOI, VGGSfM showed a higher value by about 600, indicating that images contributed more effectively to PCD generation. Moreover, the MRE for VGGSfM was about 1 lower than COLMAP, suggesting that VGGSfM's PCDs better explain the observed data.

Overall, VGGSfM demonstrated superior performance compared to COLMAP in all metrics except for MTL, which can be attributed to dataset-specific characteristics rather than model performance.

4.2 Qualitive analysis

Figure 1 presents the results of 3D reconstruction projected from a top-view perspective. In the case of COLMAP (Figure 1(a)), the room's shape appears inconsistent and scattered compared to VGGSfM (Figure 1(b)). Additionally, the floor area in the middle of the room is poorly reconstructed in COLMAP, whereas VGGSfM provides a more complete representation.

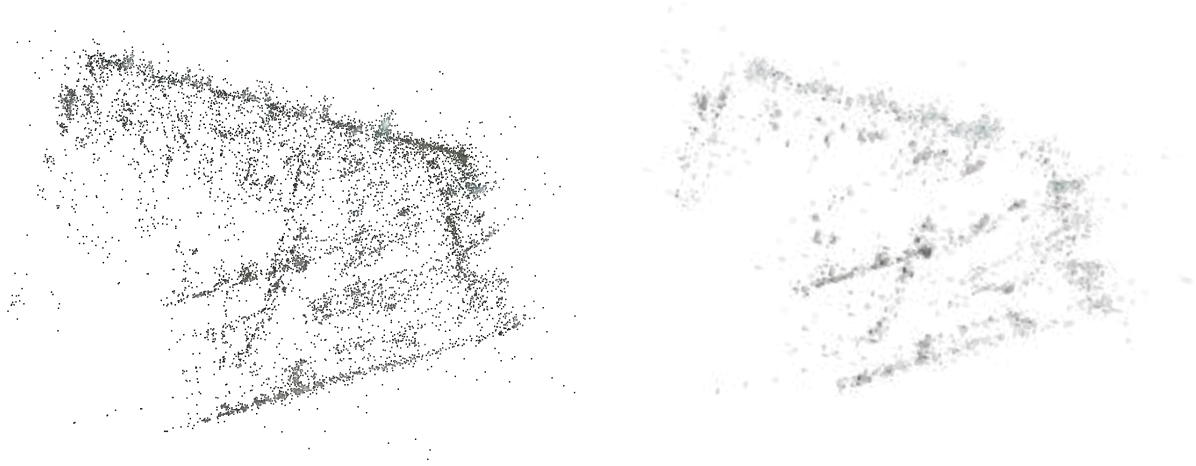

Figure 2 compares the reconstruction outputs of a wall using a 2D image (Figure 2(a)) as input, with results from COLMAP (Figure 2(b)) and VGGSfM (Figure 2(c)). As shown, COLMAP effectively captures distinctive lines and patterns, demonstrating its strength in feature-specific reconstruction. In contrast, VGGSfM produces a more uniformly distributed PCDs, reflecting a balanced and comprehensive reconstruction.

On the other hand, both models share a common limitation compared to laser scanners, as they rely solely on 2D input data for reconstruction. This constraint results in missing information in areas with bright occlusion or insufficient feature data.

5 Discussion

In this section, we compare not only COLMAP and VGGSfM but also various other SfM models. Meshroom [13] is an incremental SfM model that offers ease of use through a graphical user interface (GUI), whereas OpenMVG [14] is a global SfM model based on a command-line interface (CLI). The same set of 26 images used in the case study was used as input data for both models.

The processing time for Meshroom was approximately 21 seconds, while OpenMVG took 19 seconds. The number of generated 3D points was 8,587 for Meshroom and 3,174 for OpenMVG. Although both models demonstrated significantly faster processing times compared to COLMAP and VGGSfM, their reconstructed 3D models were insufficient for scene understanding, as shown in Figure 3. On the other hand, considering the perspective of SfM's camera pose estimation accompanying with fast processing speed, these models can serve as effective preprocessing tools for generating dense 3D models using methods such as MVS or NeRF. Their ability to provide camera positions makes them suitable for applications where precise pose estimation is essential for subsequent reconstruction processes.

Metrics	Meshroom	OpenMVG
Number of 3D points	**8,587**	3,174
Processing time	21s	**19s**

* Bold values indicate better performance

6 Conclusion

In this study, we explored the applicability of SfM models, in real construction environments. For this purpose, we compared two SfM models: COLMAP, one of the most widely used SfM models, and VGGSfM, a more recently developed framework. Comparison revealed that VGGSfM outperformed COLMAP in terms of the number of 3D points and processing time. Additionally, VGGSfM demonstrated superior performance in all metrics except for MTL.

Qualitative comparisons also highlighted VGGSfM's advantages. VGGSfM more accurately depicted the arrangement of windows and walls, whereas COLMAP exhibited scattered and poorly defined spaces. In contrast, VGGSfM effectively delineated a finite outline of the room, successfully reconstructing the enclosed space.

In discussion section, we also utilized two more SfM model of Meshroom and OpenMVG. These SfM has highly faster processing time of no more than 1 min, however, their number of 3D points were in proportion to the processing time. This result indicates that these models are not adequate for 3D reconstruction of scene understanding, on the other hand, in the perspective of preprocessing for building dense 3D models, they can serve camera poses of images in a short time.

Besides, this study remains certain limitations. Since SfM relies solely on 2D images as input, bright occlusions can lead to a lack of PCDs. Also, the 3D reconstruction was conducted for a single room within the construction site. When attempting to reconstruct multiple rooms, challenges arise due to the inability to extract overlapping features from images capturing transitions through openings, such as doors. Consequently, reconstructing an entire construction site remains a challenge. Future studies will focus on overcoming these limitations by developing methods to integrate reconstructions of multiple rooms, ultimately facilitating a comprehensive understanding of construction sites and contributing to progress monitoring efforts.

Abstract

The 3D building reconstruction from point clouds and images has significant applications in the field of built environment. Previous studies have investigated the methods of the indoor environment reconstruction and other studies explored the building façade reconstruction. However, limited studies have been conducted on aligningindoor and outdoor elements from point cloud data, which is critical for the building energy analysis and retrofitting plan during the operation stage. This research aims to develop a method that can automatically align the indoor building and façade elements from point cloud data. The results can enable the integration of buildings through the identified openings on both indoor and façade. The proposed method is validated on a real case and the experiment results show the effectiveness of the method. This research contributes to 3D reconstruction of the buildings with more details for automating building energy analysis and retrofitting design.

Keywords –

Point Cloud; Indoor Environment; Building Façade; 3D Reconstruction; Opening Detection

1 Introduction

Building reconstruction from point clouds and images has significant applications in the field of built environment, such as facility management, building performance analysis, and retrofitting design [1, 2]. Previous studies have investigated the methods of the indoor environment reconstruction and other studies explored the building façade reconstruction. For example, [3] proposed methods to reconstruct the indoor structural elements and generate geometric digital twin models. [4] presented method for the extraction of façade features from point cloud data. These methods are mainly focused on either indoor or façade data. Limited studies have been conducted to link the indoor and façade and integrate the building point cloud data as a whole.

3D laser scanning has been leveraged to capture the accurate as-is conditions of buildings, providing high-resolution spatial data that supports advanced modeling [5]. The BIM model can be then generated with processed point cloud clusters, which is known as the scan-to-BIM process [6]. Many studies have explored in this field to quickly and automatically generate BIM models from the point cloud data. For example, [7] presents the mobile laser scanning in reconstructing the indoor building environment and conduct semantic point cloud segmentation to reconstruct the buildings.

Despite advances in point cloud and image processing, as well as BIM-based workflows, detailed geometrical representations of indoor buildings often lackconnecting the indoor environment with building envelope enrichment. The integration of geometrical and spatial relationships between indoor spaces and façades into digital twin models remains a significant challenge. Achieving such integration is crucial for developing a more holistic understanding of buildings, enabling applications such as automated building energy analysis and retrofitting design. This research addresses this gap by proposing a novel method to align indoor building and façade elements from point cloud data, thereby contributing to more detailed and interconnected 3D building reconstructions.

2 Background

Previous studies have developed automatic methods for reconstructing indoor environments, primarily focusing on structural elements. For example, [3] proposed a method for creating geometric digital twins of buildings using a void-growing approach, which effectively identifies walls, ceilings, windows, floors,

and doors. Similarly, [8] reconstructed indoor environments from point clouds collected by mobile laser scanners. Structural elements such as doors, windows, walls, floors, and ceilings were extracted based on geometric and semantic features. Furthermore, [9] presented an automatic approach for segmenting indoor point clouds and performing parametric reconstruction of structural elements, such as walls and floors. In summary, the segmentation of indoor point clouds has been extensively explored, with numerous algorithms and approaches proposed for identifying structural elements.

Other studies have investigated building façade reconstruction from point cloud data. For example, [4] identified openings in façades made of reflective materials and estimated their geometric properties and locations. [10] introduced a large-scale 3D point cloud dataset of building façades for semantic segmentation, enabling the identification of façade features. Additionally, [11] developed a method for generating building façade geometry from point clouds and implemented an automatic approach for building energy performance simulation. In summary, previous research has explored the extraction of building façades from point cloud data, with a focus on identifying façade openings.

The 3D reconstruction of the physical environment into a digital format enables multiple use cases, such as VR-based room tour, distant visualization of tourist spots and conservation of dilapidated cultural heritage sites. However, several challenges are faced when aligning outdoor and indoor point cloud data (PCD). Firstly, it is difficult to find common overlapping between indoor and outdoor environments since they are often disconnected [12-14]. Another challenge is the significant lighting variations when transitioning between outdoor and indoor environments [15, 16]. Traditionally, geometric models are constructed by laser scanning and photogrammetry. For example, Scianna and La Guardia [17] re-created the 3D model of the Manfredonic Castle of Mussomeli in Sicily leveraging the photos collected from drones. Despite the generation of the castle in 3D format, it focused solely on the external layout of the castle and had not yet connected to the internal castle features due to complexities and technical barriers. Kaminsky, Snavely [18] presented a preliminary algorithm that aligned indoor and outdoor structures observed in satellite photos and floor plans. Geotags were then assigned to the photos to match their locations.

After detecting common areas between indoor and outdoor elements, rough estimations were computed to match the scenes using an objective function. In order to match the indoor and outdoor environments, Yang, Fang [19] put forward a Semantic-Geometric Descriptor (SGD) that utilized both semantic and spatial information obtained from PCD. An indoor and outdoor alignment framework was presented after conducting empirical experiments with their experimental PCD and public PCD. It showcased the possibilities to align both indoor and outdoor areas by some shared building features, such as windows and doors which enhanced the accuracy and speed. To tackle slow and error-prone manual generation of as-built BIM models, Tang, Huber [20] reviewed the state-of-the-art as-built BIM model generation methods in recent years. Object recognition, parametric modelling and relationship modelling are the most common methodologies for as-built BIM automation. Although significant works have been carried out to reconstruct the indoor room layout inside BIM, there is still a gap to integrate the indoor room layout into the outdoor environment. Cohen, Schönberger [15] exploited the semantic information from detecting windows in various scenes by a pre-trained classifier. Separate window projections were computed altogether to enhance consistency and the results were evaluated by a cost function in their 3D reconstruction.

In conclusion, limited studies have been conducted on aligning indoor and outdoor elements from the point cloud data, which is critical for the building energy analysis and retrofitting plan during the operation stage. This research aims to develop a method that can automatically align the indoor building and façade elements from point cloud data.

3 Methodology

This research proposes an automatic openings detection and align the indoor and outdoor together from point cloud data. This alignment is based on the openings (e.g., windows and doors) between outdoor and indoor point clouds.

3.1 Wall Segmentation

The input of the proposed method consists of façade point cloud data and the indoor point cloud data. The first step is to identify the walls and separate the walls into individual planes. The region growing and RANSAC algorithms are adopted to segment the point cloud and identify the walls [21]. Since there are typically more walls in the indoor environment, the segmented façade walls are used as a reference to select the corresponding walls in the indoor environment PCD. The walls, after filtering, are then used for further detection of openings. This process is conducted for both the indoor and outdoor data. After the processing, the input point cloud data are processed to segmented walls with the openings.

3.2 Openings Detection

The second step is to detect the openings on the walls for both indoor and outdoor point cloud data. Compared

with the indoor environment, the openings on the façade are more obvious than the openings in the indoor environment [4]. This is because there is more furniture in the indoor environment and can cause more occlusions of the point cloud. This makes it more difficult to identify openings in indoor environments.

Therefore, the proposed method starts by identifying the openings from the façade point cloud data, after the opening detection and the configuration of the openings on the façade, the results will be used to assist the refinement detection results of the openings detection in the indoor environment. The underlying principle of the opening detection is that openings appear as areas with no or very sparse points. Therefore, this research uses grid representation to detect the boundary of the openings.

To improve the accuracy of indoor environment data processing, a key step is to identify the openings from indoor and outdoor point cloud data. Since walls have a certain thickness, their indoor and outdoor surfaces represent two sides of the same structural element. The matching of indoor and outdoor point cloud data is based on their geometry features, such as the normal vector of the wall, and the coordinate position [19].

3.3 Openings Alignment

The final step is to align the openings on the same wall from indoor and outdoor point cloud data. Therefore, the indoor and outdoor building elements can be accurately matched. This aligned point cloud data can be further used for the 3D building reconstruction. Figure 1 presents the pipeline of the alignment of the indoor building and façade elements from point cloud data.

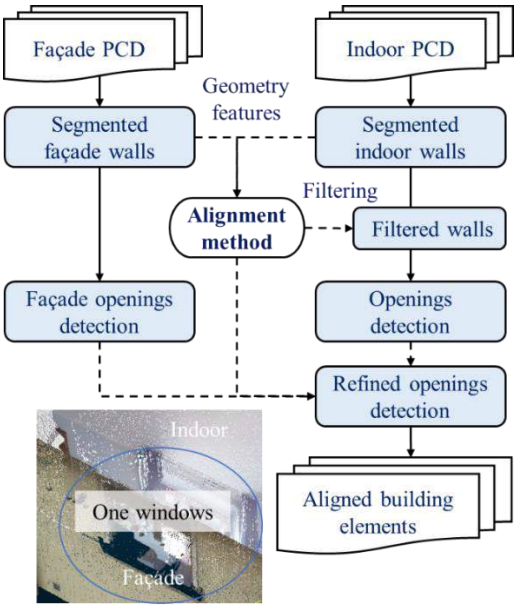

Figure 1. Pipeline of the proposed method

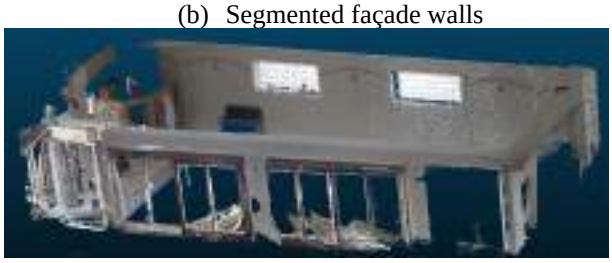
4 Experiments and Results

4.1 Case Background

The data used in this research is the point cloud data of the house building in the European. The materials used to build the building constructed in 1980 are concrete for the structure and bricks for the facades combined with windows in aluminum. The retrofitting proposed for the building is aimed to provide renewable energy to cover all the energy requirements from a single family, to reduce the energy demand acting in the insulation of the envelope and improving the air quality/heating/cooling by including a new heating/cooling/ ventilation system in the facade. Improved air quality and comfort in the different spaces will be the main objectives of the proposed. The project will retrofit completely the envelope of the building. Apart from this, a new ventilation/heating/cooling system will be integrated in the façade and connected to the heat pumps with the possibility to heat/cool the building depending on the requirements. The first floor of the case is used for the experiments to validate the effectiveness of the proposed method.

The point cloud data is collected by using the Leica BLK360 imaging scanner [22]. The registration of point clouds collected from multiple stations was done with the Leica Cyclone REGISTER 360 PLUS [23].

4.2 Indoor Wall Segmentation



After the region growing and RANSAC algorithms, the walls in the indoor environment PCD and façade PCD are segmented into individual and separate point clusters, which represent the walls of the building. The results of the segmented walls for the two PCD datasets are presented in the Figure 2. Figure 2a presents the original point cloud data of the ground floor. Figure 2b shows the segmentation results of the façade walls while Figure 2c shows the results of the indoor walls after segmentation. For the indoor environment PCD, there are more walls than the façade datasets. After the filtering process, the filtered walls that are connected to the façade are presented in Figure 2d.

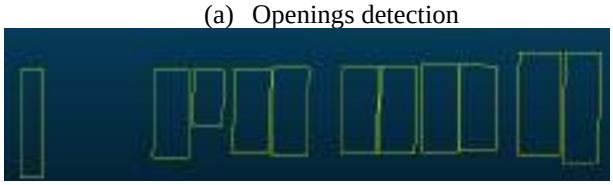
(a) Original point cloud data

(b) Segmented façade walls

(c) Segmented indoor walls

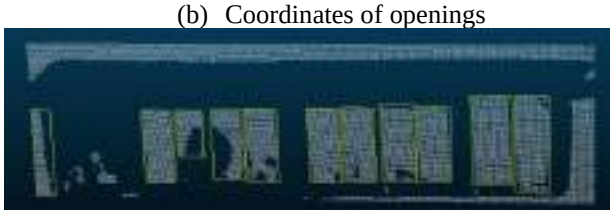
(d) Filtered indoor walls

Figure 2. Segmented walls. (a). Original point cloud data, (b). Segmented façade walls, (c) segmented indoor walls, (d) Filtered indoor walls.



The results of the point cloud segmentation show that the indoor segmentation resulted in more walls as it has more rooms inside while the façade was an envelope of the building point cloud. By comparing the normal vectors of the wall clusters using RANSAC [24], the walls with similar normal vectors will be grouped as the same wall and will be remained. Therefore, the rest walls were filtered and removed. Only the walls that can match with the façade point cloud were further processed for the opening detection.

4.3 Façade Openings Detection



After the wall identification, the openings of the façade are detected using the opening detection method. The results of the opening detection of the façade are given in figure 3. Figure 3a presents the point cloud data for opening detection. Figure 3b shows the results of the detected openings. Figure 3c presents the geometry and the position of the openings. The results are obtained in the rectangle format, which contain the four corner coordinates of the openings. Therefore, the location and the geometry information can be computed with the rectangle information representing the openings.

(b) Coordinates of openings

(c) Detected openings

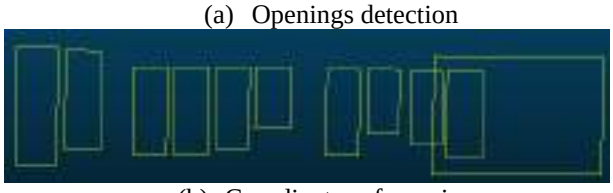

Figure 3. Façade openings detection

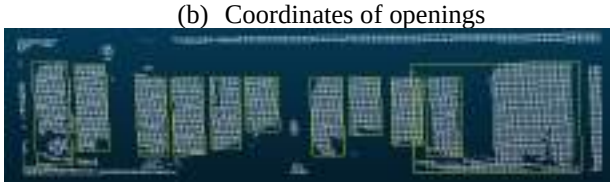
4.4 Indoor Openings Detection



Similarly, the openings on the indoor point cloud can be obtained. The results of the opening detection of the façade are given in figure 4. Figure 4a presents the point cloud data for opening detection. Figure 4b shows the results of the detected openings. Figure 4c presents the geometry and the position of the openings.

(b) Coordinates of openings

(c) Detected openings

Figure 4. Indoor openings detection

4.5 Aligned Building Elements

The last step is to align the results of the openings on the indoor openings detection with the detection results of façade point cloud. Figure 5 shows the alignment

results of the openings on both point cloud. The detected openings are aligned based on their coordinates of the rectangles representing the openings. The red points represent openings detected in the façade point cloud, and white points correspond to openings identified in the indoor point cloud. The alignment is performed based on the similarity of detected openings, considering both the least distance between corresponding openings and their overall layout. By matching openings with minimal spatial deviation and maintaining consistency in their distribution, the method ensures accurate geometric integration of indoor and façade elements.

Figure 5. Aligned openings in indoor and façade point clouds

4.6 Discussions

The detection results presented in Figures 3 and 4 highlight key issues that contribute to errors and reduced accuracy. Notably, in Figure 4c, the largest rectangle detected is not a window. This error is attributed to occlusion in the point cloud, which occurred during data collection in the indoor environment. Occlusion is a common challenge in such settings, as furniture and other building elements obstruct the view of certain features, leading to incomplete or misinterpreted data [25].Improved noise filtering techniques, such as adaptive thresholding or advanced denoising algorithms, can help retain useful points while minimizing the impact of noise [26]. Additionally, data augmentation methods, including multi-view point cloud merging and the integration of photogrammetry with LiDAR, can enhance the reconstruction of occluded areas [27].

Another significant issue arises from the reflection points of glass in windows. These reflections create ambiguities in the data and are almost unavoidable when capturing point cloud data of windows. The reflective surfaces interfere with accurate feature extraction and increase detection errors. Machine learning-based segmentation methods could be trained to differentiate between real structural features and reflection artifacts in windows [28].

In addition, the inherent noise within the point cloud data further impacts detection accuracy. While algorithms designed to filter out noise can enhance overall data quality, they may inadvertently remove some useful points. This, in turn, affects the detection of openings and reduces the geometric accuracy of identified features. It is challenging to preserve essential data while removing noise.

Addressing these issues requires enhanced data preprocessing methods, improved algorithms for handling occlusions in point cloud data, and techniques to minimize the impact of reflective surfaces during data acquisition [29]. Deep learning techniques, such as convolutional neural networks and transformer-based segmentation models, have shown promising results in point cloud processing. Examples such as KPConv [30] and Point Net [31] have been widely used for point cloud segmentation and feature extraction.

The point cloud data used in this study were collected using a terrestrial laser scanner, which provides higher data quality and accuracy and is recommended for data collection when applying this method. However, while this study successfully demonstrates the feasibility of detecting openings using point cloud data, the façade surface area analyzed is relatively small and lacks significant geometric variations. Since the proposed method focuses on identifying the presence of openings rather than reconstructing their precise shape, it has the potential to be extended to a wider range of building structures. To ensure its generalizability, further validation across diverse building types, including those with complex façade geometries and irregular opening configurations, is necessary.

Although the case study validates the proposed method's feasibility, the lack of a quantitative comparison with existing point cloud alignment methods remains a limitation. A systematic performance evaluation would provide a more comprehensive assessment of the method's effectiveness. Future research will address this by incorporating quantitative evaluations, specifically assessing accuracy and computational efficiency, to strengthen the validation and facilitate comparisons with alternative approaches. Additionally, expanding the range of case studies will be essential to evaluate the method's scalability and reliability under different architectural and environmental conditions, further enhancing its applicability to real-world scenarios.

5 Conclusions

This research introduces a method for automatically aligning indoor building elements with façade features using point cloud data. The approach emphasizes the identification and integration of openings, such as windows and doors, to seamlessly connect indoor and outdoor geometries. The validation conducted through a real-world case study highlights the effectiveness of the proposed method.

The results demonstrate that façade point cloud data effectively improves indoor opening detection and

achieves accurate alignment, significantly contributing to detailed 3D building reconstruction. This enhanced reconstruction not only improves the representation of building geometry but also supports advanced applications such as automated building energy analysis and retrofitting design.

However, there are still some limitations, including occlusions, noises, and reflective surfaces, which are common challenges in indoor point cloud data collection and processing. Future work will focus on refining the algorithms to better handle noise and occlusions, particularly in complex indoor environments, and further minimizing the impact of reflective surfaces during data acquisition. Additionally, integrating advanced preprocessing techniques could enhance detection accuracy and expand the applicability of the method to a wider range of building scenarios.

Abstract -

This paper presents a novel method for generating microscale digital twins of rubble stone masonry walls using a robotic construction pipeline. The pipeline integrates stone stock digitalization, stone layout planning, robotic stone assembly, and a dynamic digital twinning process. To validate the approach, a $0.7 \times 0.7 \times 0.4$ m^3 wall was physically constructed in the lab alongside its digital twin, which provided a precise representation of the wall's microstructures. The results show that the proposed pipeline achieved accurate stone assembly with an averaged ±1.2 cm tolerance, producing walls comparable to traditional masonry in terms of compressive strength.

1 Introduction

The construction industry urgently requires innovative solutions to reduce its environmental impact. Utilizing locally available natural materials, such as stone, offers a sustainable path by minimizing energy inputs and carbon emissions associated with material production and transportation [1, 2]. However, traditional stone construction poses challenges for the structural analysis. The irregular shapes of stone units and their placement based on local masonry practices create a highly variable microstructure, which directly impacts the structural behavior of stone masonry building [3]. Current practice for the structural analysis of rubble stone masonry buildings rely on fixed-length classifications based on typologies, which are subjective and introduce ambiguity in the analysis [3].

With advancements in digital technologies, it is now possible to create a digital twin, a 3D model of a physical asset. In masonry structures, digital twinning at the building level—where entire structures are scanned, digitized, and used for numerical analysis—has been explored by several works [4, 5, 6]. However, digital twinning at the stone-level, capturing the as-built microstructure [3], remains rare. This lack of detailed digital twins for stone masonry microstructures poses a significant bottleneck in the development of micro-scale numerical methods for analyzing rubble stone masonry structures [3].

This paper introduces an end-to-end pipeline for generating the microscale digital twin of stone masonry structures, utilizing a novel construction method that eliminates the need for masons. It starts from digitalizing the irregular shape of stones using photogrammetry. The 3D geometry of stones is used by a planning algorithm to determine the positions and orientation of stones. The execution of the plan, i.e., placing stones from the initial position to the final position in the wall, is carried out by a robotic system composed of a vacuum gripper, an on-site scanning system, and a robotic arm. A digital twining pipeline is carried out at the same time as the physical construction, recording the as-built position of stones, which feedbacks the planning algorithm to achieve a more precise and accurate construction.

2 Method

This section presents the main components of the proposed pipeline for the digital construction of mortar-joint stone masonry walls. Section 2.1 presents the methods and results of using photogrammetry to build the digital stone stock. The construction process is explained in Section 2.2, which includes the optimization of the stone layout, the physical construction, and the creation of the digital twin.

2.1 Digitization of initial stone stock

. We scanned 150 stones that were recycled from the demolition waste of stone masonry walls built by masons. The stones were scanned by capturing 100 photographs of one side, then flipping them over and taking an additional 100 photos of the opposite side. The photos were taken with a robotic arm that rotates around the object and takes photos at every 18-degree interval. The 200 photos were used for 3D model reconstruction with the software Agisoft Metashape [7]. A scaled bar is also visible in all photos with specific markers supported by Agisoft Metashape [7]. Figure 1 shows the distribution of stone shapes and stone sizes in the initial stock. Stones that are not placed in the constructed wall are indicated by circles in Figure 1. Stone flatness is measured by the ratio of the shortest

dimension to the intermediate dimension, and elongation is measured by the ratio of the intermediate dimension to the longest dimension, with dimension sizes determined through the principal component analysis [8].

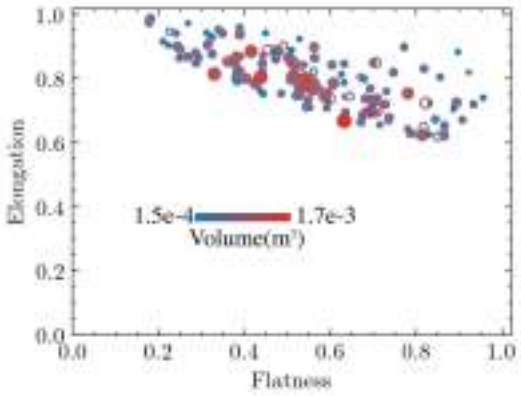

Figure 1. Elongation, flatness, and volume of stones in the initial stock. Stones not used in the final wall are shown by unfilled circles, while others are shown by filled points.

2.2 Microscale digital twinning by segment-wise construction

We propose a segment-wise construction and digital twinning process, where one segment corresponds to elevating the wall with a certain height according to the construction progress during the day. Figure 2 presents the steps for constructing one segment. Before the physical construction of a segment, the layout planning algorithm determines the stone layout for the current segment considering the current landscape, which is composed of the digital twin of previous segments and the boundary condition. The planning of stone layout is followed by the physical construction, where a robotic arm places stones to their planned positions. The robotic assembly of stones is paused every time a new layer of stones was placed on top of an existing one. During the pause, the physical wall is scanned by taking photos around it to capture the as-built positions of stones. We generate the digital twin of the segment based on the scanned layers, which serves as the input for planning and constructing the subsequent segments. Mortar layers are applied manually between layers. We will present in the following sections the details regarding the layout planning, robotic construction, and digital twinning.

2.2.1 Stone layout planning

To generate the stone layout in each segment, the planning algorithm developed in our previous work [9, 10] is used. We adapt the algorithm for segment-wise planning by including two additional functions. One is to apply a mask on top of every segment to avoid stones being placed beyond the segment height. It constrains the algorithm to find feasible positions only below the upper bound. The mask is implemented as assigning the value 1 to voxels above the current segment in the landscape occupancy tensor $L_{\text{occupancy}}$. The other improvement is to use the digital twin of stones from previous segments instead of using their planned positions to account for deviations of stone positions that can arise during the physical construction. As an example, Figure 3 shows the landscape for constructing one segment, composed of five parts: the as-built position of already placed stones from previous segments (in green), the planning positions of stones of the current segment (in blue), the boundaries of the wall (in grey), and the mask for limiting the upper bound (in black).

2.2.2 Robotic stone assembly

We choose a vacuum gripper instead of the conventional two-finger gripper due to its flexibility in handling objects with varying lengths and widths. After analyzing the shape of the stone, considering its curvature, center of gravity, suction area, and avoidance of collisions with stones placed previously, we determined the optimal picking planes for the stones. A team member manually attaches the stone to the gripper at the calculated position, after which we re-scan the stone to precisely locate its position and orientation relative to the robot end-effector. This data enables accurate calculation of the robot's placement trajectory.

2.2.3 Digital twinning

After placing each layer of stones, we scan the half-built wall with photogrammetry and reconstruct the 3D model with Agisoft Metashape [7]. The mesh is then transformed and rescaled according to the positions of markers in the robot frame, measured at the beginning of the construction. We register the stone mesh (a complete stone mesh) to the landscape mesh (where stones can be observed partially) using ICP [11], transforming the stone from the planning position to the as-built position, as shown in Figure 4.

3 Results

We applied the proposed digital construction pipeline to build a stone masonry wall of size $0.7 \times 0.7 \times 0.4$ m^3. The dimensions were chosen to match the size of mason-built walls of a similar typology, as in [3], ensuring a fair comparison of construction results. Figure 5 shows a photo and the 3D surface mesh of the final wall, as well

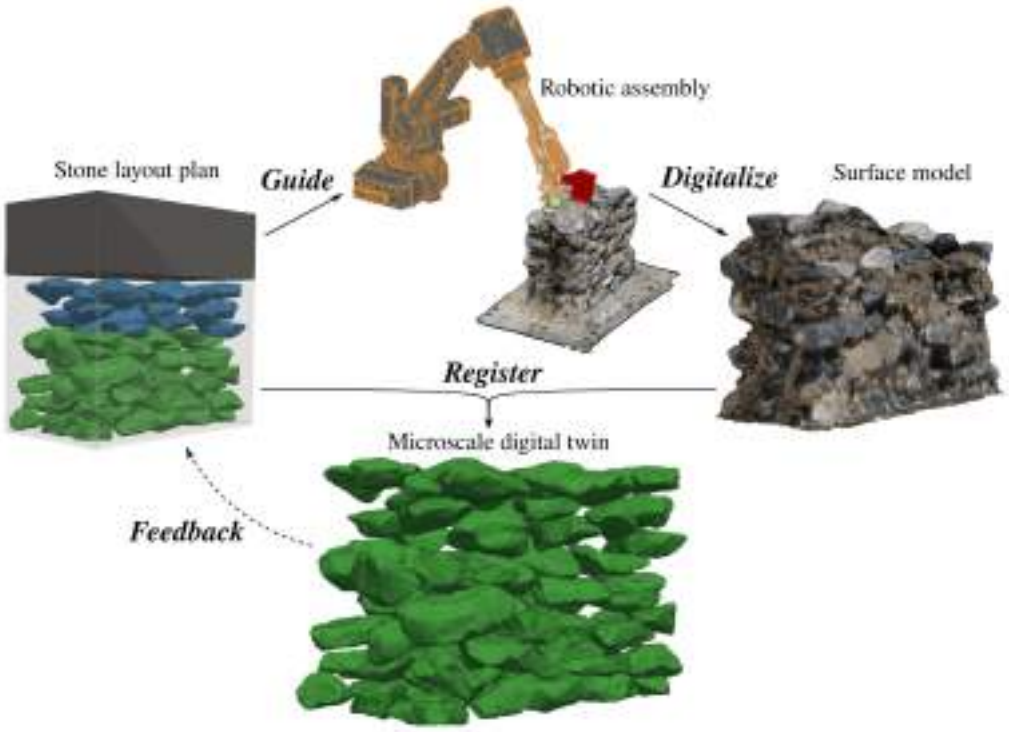

Figure 2. Microscale digital twinning process: starting with the generation of the stone layout plan, followed by robotic assembly guided by the plan, digitalization of the wall surface, and finally, registering the planned stones to the digitized wall to create the microscale digital twin of the as-built stone layout.

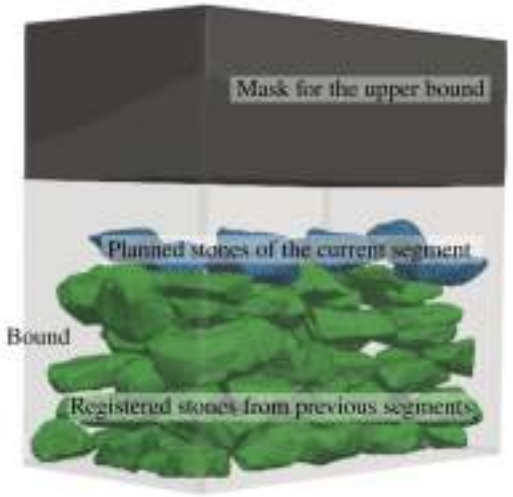

Figure 3. Landscape for planning one segment.

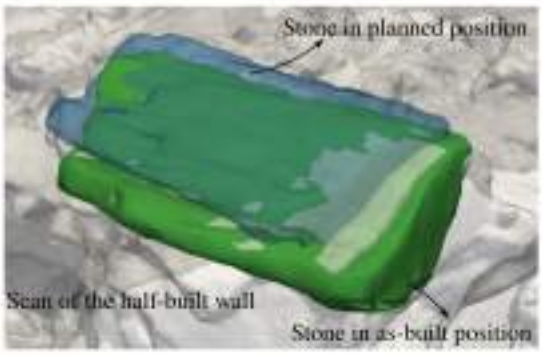

Figure 4. Transforming stones from planned position to as-built position by registering the stone mesh to the landscape mesh.

as its microscale digital twin composed of stone meshes in their as-built positions.

3.1 Simple compression test of the constructed wall

In masonry construction, walls primarily support compressive forces from the weight of the structure above. In this case, compressive strength is a crucial index that directly reflects their load-bearing capacity and resistance to failure under vertical loads. To obtain the compressive strength of the constructed wall, a simple compression test with no confinements at the top and bottom of the specimen was conducted according to the described procedures in EN1015-Part 1 [12]. In the compression tests, three loading/unloading cycles were applied before the peak force. The Young's modulus was derived by fitting a line to each of the three stress–strain cycles and taking the average value of the three slopes as presented in [13]. We obtained a compressive strength of 0.74 MPa, and a Young's modulus of 263 MPa. The strength is within the range reported in [14], between 0.43 MPa and 0.82 MPa.

3.2 Precision in stone assembly

To quantify the precision of the stone assembly process, we made use of the microscale digital twin obtained as the end of the construction, measuring the distances between the as-built positions of stones and their planned positions. We observed an averaged distance between stone centers of 0.012 m and a root mean square error of 0.014 m. The difference between the as-built geometry and planned geometry can be attributed to the following reasons:

1. When the robot reaches the force limit, it will release the stone before it arrives to its planned position.
2. The planned position of the stone is not necessarily a stable position. The stone can move under gravity after robot release it.
3. There are systematic errors in the digital twinning process, including the downsampling of stone meshes for robotic planning and layout planning, the registration of stone mesh to gripping position, the reconstruction of landscape mesh, and the registration of stone mesh to landscape mesh.

Situation 1 consistently happened when placing the first layer of stones. This is because the planning assumes the foundation to be perfectly flat, while the small bumps on the foundation stop the stone placement earlier. The error didn't propagate to the next segment of stones as the planning algorithm considered an updated landscape. For the following layers, stones were mostly placed below their planned position due to the effect of gravity, especially stones on the corners.

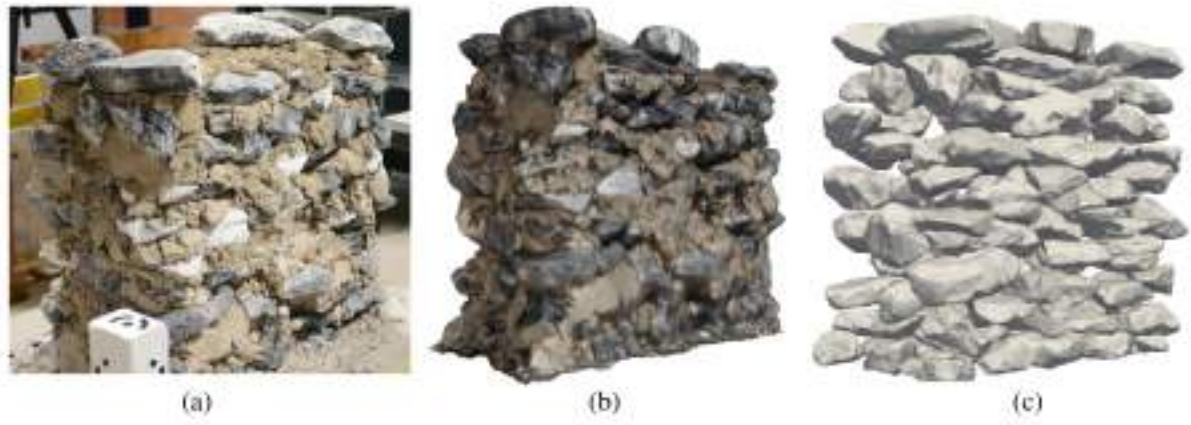

Figure 5. The constructed wall. (a) Photo of the constructed wall. (b) 3D surface model of the final wall. (c) Stones in the final wall on their as-built positions.

4 Conclusions

The traditional construction of masonry structures using natural stones often faces challenges in structural analysis due to the uncertainty and variability of the microstructure. This study introduces a pioneering pipeline for generating the microscale digital twin of stone masonry walls, which replicates the microstructure of physical walls. The pipeline makes use of the recent advance in stone layout optimization [9], to instruct a robotic system for stone assembly. The microscale digital twin is created at the same time of the physical construction, providing dynamic feedback for the construction process.

A three-leaf masonry wall was built as a case study to show the feasibility of the proposed method. Results show that the constructed wall achieved compressive strength of 0.74 MPa, and the digital twinning process had an averaged distance error of 0.012 m. While this work demonstrates the feasibility of digital masonry construction, further advancements in the digitalization of mortar are essential to fully realize the pipeline's potential.

Abstract –

Building Information Modelling (BIM) has wide application in building construction; however, its adoption in road construction remains limited. Although some studies have investigated the integration of BIM and photogrammetry, this integration remains largely an under-explored and overlooked area in specific environment of road infrastructure construction, with significant gaps in research and application. The novelty of this study lies in bridging this research gap by exploring the practical integration of BIM and photogrammetry, leveraging commercial-grade drone technology to develop a BIM-enabled Digital Twin (DT) tailored to road infrastructure construction. In this study, a 3D BIM model of a 500-meter-long road project was developed using Autodesk InfraWorks 360. The modeling process was followed by the acquisition and processing of 816 high-resolution images, captured over four separate drone flights on different dates, using a DJI Mavic 3 Enterprise commercial drone. The photogrammetric data was processed in Agisoft Metashape, yielding a dense point cloud, a Digital Elevation Model (DEM), and ortho-mosaics. These ortho-mosaics were integrated into BIM model to create a DT. The synchronization of multimodal data demonstrated that a BIM-enabled DT powered by photogrammetry not only enhanced visualization but also proved to be a promising tool for reliable and efficient monitoring of road construction progress.

Keywords –

Digital Twin; BIM; Ortho mosaic; Drone; UAV

1 Introduction

The demand for road infrastructure has grown significantly because these initiatives are vital to a nation's competitiveness, economy, health, education, and quality of life [1]. Road projects frequently face challenges such as schedule delays, cost overruns, and inadequate construction monitoring. These issues compromise the projects' capacity to succeed [2]. Road infrastructure projects consistently perform behind project baseline, resulting in an estimated $82.6 billion in annual cost overruns worldwide [3]. To mitigate these issues, efficient monitoring of construction progress is essential. However, conventional manual tracking methods are often inefficient, time-consuming, and susceptible to errors [4, 5]. These traditional methods generally rely on checklists and daily reports, which are open to subjective interpretation and can fail to provide accurate physical measurements of on-site work, keeping progress monitoring largely a 2D process [6].

While Building Information Modelling (BIM) has been widely adopted in vertical construction, its application in road infrastructure remains limited, leading to missed opportunities for efficiency and cost-effectiveness. Global acceptance of BIM as a management approach and digital construction tool has grown, and it is increasingly becoming an important tool in project management [7]. The foundation of a Digital Twin (DT) lies in its digital representation, with BIM serving as the crucial technology to construct this representation. BIM can be integrated with advanced technologies such as laser scanning, photogrammetry, drones, and sensors to improve the accuracy, efficiency, and real-time updating of site information [8].

The most common data collection technologies include robotic total stations, the Global Navigation Satellite System (GNSS) receivers, Light Detection and Ranging (LiDAR) scanners, and aerial photogrammetry etc. However, the scale of most linear transportation projects requires methods that can efficiently survey large areas with sufficient accuracy and resolution [9]. Photogrammetry has emerged as a cost-effective, rapidly

deployable data collection technology with numerous applications in different fields [9, 10].

Rapid advancements in drone technology have enabled wider and enhanced utilization of photogrammetry in construction projects. Drones are flying robots that fall under the category of Unmanned Aerial vehicles (UAVs). UAVs have become a popular and recognized technology in recent years because of their outstanding ability and flexibility [11]. They can be operated remotely by people or by software using pre-programmed flight plans [12]. UAVs have a range of applications, including aerial photography, and are utilized across many industries [13].

Using UAVs in combination with photogrammetry offers an efficient solution for digital mapping of projects [14]. By taking overlapping, georeferenced vertical and oblique photos, drone-based image acquisition makes large-scale surveys easier and quicker. These photos can then be utilized to produce precise, dense three-dimensional models. This approach is significantly more cost-effective than LiDAR and often achieves higher spatial resolution. Additionally, the portability of the hardware allows access to a greater variety of sites.

2 Related Work

Photogrammetry techniques can be used to generate a 3D model from data collected from drone pictures, while point clouds from 3D scanning of a construction site can also be used to create 3D models [8]. Then, during different phases of construction, this "drone model" can be compared with the Building Information Model to track and evaluate the status of the project [15]. Ortho-mosaic maps and 3D models produced through photogrammetry enhance visualization, providing clear and detailed visual representations of the site that support more informed decision-making. The shared model brings together engineers, contractors, and owners [16].

For effective progress monitoring, it is essential to integrate and visualize both as-planned and as-built information to gain a comprehensive overview of all construction processes. A visualization technique using BIM and Photogrammetry highlights progress deviations by superimposing an as-planned model onto real-time-lapsed photographs, resulting in a single, comprehensive visual representation [17].

While many studies have investigated the integration of BIM and photogrammetry for construction monitoring, they still have limitations and gaps that warrant further research. A review of 134 previous studies by Castañeda, Sánchez [8] aimed at identifying key complementary technologies to BIM in road projects found that photogrammetry was examined in merely eight (8) studies. This finding underscores that integration of photogrammetry with BIM remains a largely overlooked area in the specific context of road infrastructure projects.

Turkan, Bosche [4] developed a system that integrated spatial data collected from 3D laser scanning with schedule data for construction progress tracking; however, it was limited to vertical construction and it neither extended to linear projects like roads nor incorporated photogrammetry. Vick and Brilakis [9] and Lo, Zhang [5] conducted studies on utilization of aerial photogrammetry for road layer construction progress monitoring, but their studies did not integrate the point cloud data into a BIM model to create a DT, and they did not use a commercial-grade UAV. Puri and Turkan [18] proposed a framework using mobile LiDAR and 4D design models, but their study focused primarily on bridge construction only and lacked photogrammetry.

Jacob-Loyola, Muñoz-La Rivera [19] conducted a study on construction progress tracking by periodically recording physical site conditions using UAVs and generating point clouds through photogrammetry. The data was then integrated with 4D BIM for monitoring purposes. However, a key limitation of the study was its primary focus on vertical construction, limiting its applicability to linear infrastructure projects.

Foregoing in view, this study is aimed at addressing the limitations and gaps in previous research by focusing on the integration of BIM and aerial photogrammetry for road infrastructure using a commercial-level drone and the concept of DT—a novel approach that remains overlooked in existing literature.

3 Proposed Framework

This study aims to investigate the integration of BIM with photogrammetry in the specific context of road infrastructure construction using commercial-grade drone. This framework for BIM integration with road infrastructure is shown in Figure 1 and outlined as under:

- Selection of an under-construction road project, collection of relevant drawings, and development of a 3D BIM model using Autodesk InfraWorks 360.
- Acquisition of 816 images of the project through photogrammetry using DJI Mavic 3 Enterprise, spanned over four flights on different dates.
- Processing photogrammetric data using Agisoft Metashape to obtain high-resolution ortho-mosaic.
- Integration of ortho-mosaic with 3D BIM Model in Autodesk InfraWorks 360 to create a DT.
- Synchronization of data between actual project and DT.

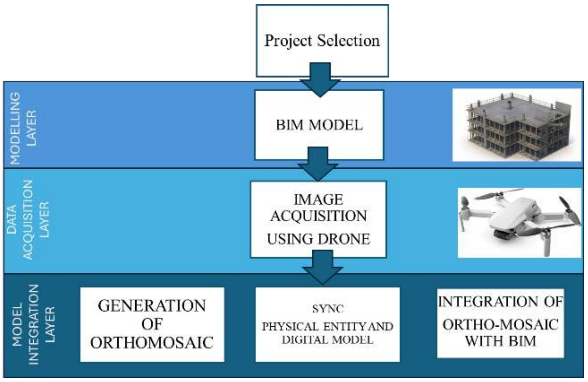

Figure 1. Proposed BIM-Photogrammetry framework for road construction monitoring.

3.1 Data Collection

The DJI Mavic 3 Enterprise was selected for capturing high-resolution images of the construction site due to its affordability, reliability, and capability to cover large areas efficiently. Specifically designed for high-precision surveying and mapping, this drone features a real-time kinematic (RTK) system, which uses satellite navigation to obtain accurate positional data. Other features include: a mechanical shutter, 56× zoom camera, 20MP sensor, and RTK module, all integrated into a compact and mobile platform. Additionally, the camera's ability to capture images at intervals of 0.7 seconds significantly enhances the efficiency of mapping operations, enabling faster data collection [20].

3.1.1 Flight Planning

Flight planning is performed to ensure that manual input is not necessary for acquisition of data, ensure reproducibility of results and limiting the effect of data on the skill of operator. A flight plan outlines the specific route and procedures that the UAV will adhere to during its flight. First, the mission was planned through DJI Remote Control by logging into DJI application. Subsequently, a spacious, obstacle-free launch area was carefully selected. The equipment was meticulously assembled, with all propellers securely fastened. The batteries for both the drone and the remote control were thoroughly inspected to ensure they were fully charged. Once the remote control and the drone were powered on, their connection was verified to confirm proper functionality.

Prior to take-off, the system validated the availability of an adequate number of satellites to ensure a stable and reliable flight. Figure 2 shows a snapshot of flight planning. All necessary permissions required for operation of done were acquired before the conduct of flight and a professional drone pilot was tasked to overview safe operation of the drone.

Figure 2. UAV flight planning for photogrammetry-based monitoring

3.1.2 Image Acquisition

UAV flights were conducted over the study area on four separate dates: 26th August, 6th September, 30th September and 15th October 2024. Each flight was executed with a consistent flying altitude of 60 meters to ensure uniform data collection across all sessions. A total of 816 images (204 images per flight) were captured at a resolution of 1.87cm/pixel, providing high-detail visuals necessary for precise analysis of the project's development over time.

Figure 3 presents a series of high-resolution images captured over the study area from a 90-degree angle. Each image contained detailed geospatial data reflecting the current state of the site, highlighting key features such as access routes, construction modules, and the terrain's topography. Additionally, these images provided essential georeferencing information, facilitating the integration of data for creating a precise point cloud model.

Figure 3. High Resolution images acquired using UAV

3.2 Image Processing

The process of generating ortho-mosaics from the high-resolution drone images was carried out in multiple steps using Agisoft Metashape, which is a robust photogrammetry tool commonly used for 3D reconstruction from 2D images [21].

4 Case Study

The study area selected for this research is a 500-meter linear stretch of the service road located parallel to the Islamabad Expressway in Islamabad, Pakistan. Figure 4 shows the study area. The site is part of an interchange project at Islamabad Highway. The images were taken on site for further processing and integration with BIM for progress monitoring. The coordinates marking the boundaries of the study area are 33°33'19.01"N, 73°10'0.23"E at one end, and 33°33'3.62"N, 73°10'11.52"E at the other end.

Figure 4. Geographic representation of the 500-meter study area along the Islamabad Expressway.

The process of generating ortho-mosaics from the high-resolution drone images was carried out in multiple steps elaborated as follows.

4.1.1 Data Import

The data processing began by importing the captured images into Metashape, ensuring that all high-resolution images, captured at a consistent altitude with a side overlap ratio of 70% and a frontal overlap ratio of 80%, were prepared for further processing.

4.1.2 Image Alignment

The next step involved image alignment, where Structure-from-Motion (SfM) algorithms were utilized to reconstruct the relative positions of the images based on their overlapping features. These algorithms detect matching key points across multiple images, allowing the software to calculate their spatial relationships and reconstruct the 3D geometry of the scene. This process relies on bundle adjustment, an optimization technique that refines the camera positions and orientations to minimize errors and ensure alignment accuracy [22]. Incorporation of RTK positioning data significantly enhanced this process by providing precise geospatial information. The RTK module embedded in the drone ensured centimetre-level accuracy for the positional data of each image, eliminating the need for a large number of Ground Control Points (GCPs).

4.1.3 Point Cloud Data

After image alignment, a dense point cloud was generated for three-dimensional representation of the scanned area. This process first produced a sparse point cloud, containing fewer points spread across the scene, which was used for initial alignment. Once the alignment was complete, the point cloud was refined into a dense point cloud, containing a higher density of points that more accurately reflected the physical environment. These dense point clouds provided finer details of the site, crucial for accurate modeling and progress monitoring.

The data obtained from the point cloud included essential information about the terrain and site structures, offering a foundation for further steps in the workflow. Following the generation of the point cloud, a Digital Elevation Model (DEM) was created to represent the terrain's surface without any objects, such as buildings or vegetation, and was used to understand the topographical aspects of the study area.

4.2 Development of Ortho-Mosaics

Finally, the ortho-mosaics were created from the images. These high-resolution, geometrically corrected images provided a comprehensive view of the entire site, ensuring that every pixel was aligned with its true ground position. Figure 5 shows the DEM and corresponding ortho-mosaics for two out of the four data collection intervals.

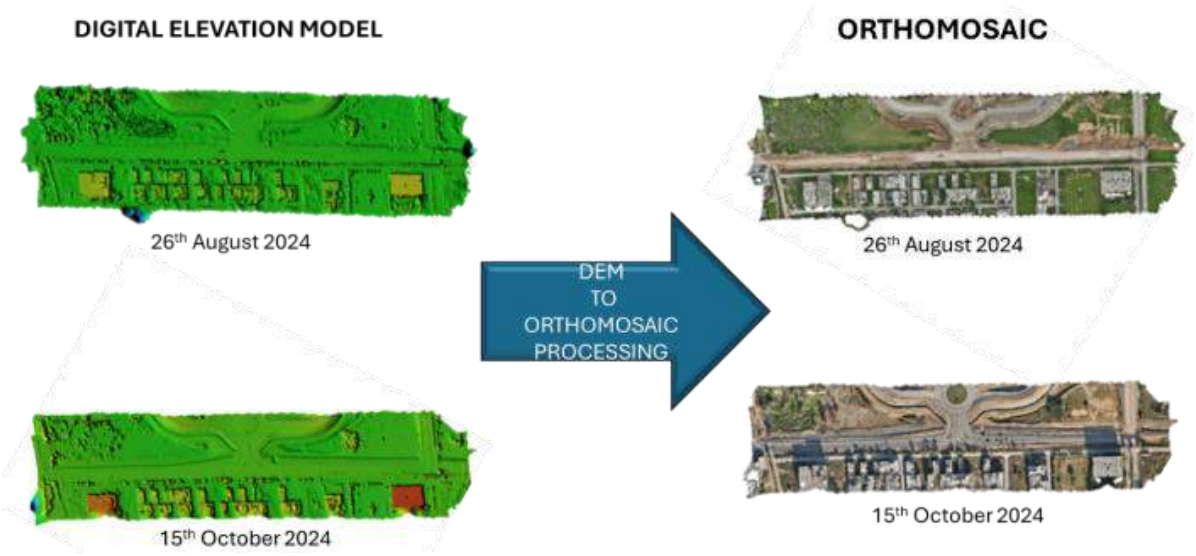

Figure 5. DEM and Ortho mosaic of data acquired on 26th August and 15th October

4.3 Integration with BIM

The processed ortho-mosaic data was exported in formats compatible with various BIM software applications to ensure seamless integration with project workflows. One of the primary formats used for export was TIFF (.tiff), which is widely supported across many Geographic Information System (GIS) and BIM platforms due to its high-resolution capabilities and geospatial referencing attributes. This export process enabled the ortho-mosaic to be incorporated into BIM environments for enhanced visualization, design, and analysis. By exporting the data in such formats, it allowed precise geospatial data into BIM models, improving the accuracy of site planning, progress monitoring, and decision-making throughout the project's lifecycle.

The processed photogrammetry data was integrated into the 3D BIM model using Autodesk InfraWorks 360. This process involved overlaying the high-resolution ortho-mosaic onto the 3D BIM model of the road, enabling precise mapping of the current site conditions. The ortho-mosaic was imported and georeferenced within the InfraWorks environment, creating a comprehensive DTof the construction site.

The creation of layers in the BIM model enabled effective monitoring of the progress of the project. The road layers, such as the base course, sub-base course, and surface course were carefully mapped and tracked to assess their completion status. This integration facilitated a visual comparison of the planned design with the actual progress on-site, enabling accurate and reliable progress monitoring. The combination of photogrammetry data and the BIM model enhanced and ensured the alignment between the planned design and evolving site conditions.

4.3.1 Data Synchronization

Regular updates to the BIM model were conducted by integrating the latest photogrammetry data after each drone flight. This was pivotal in enabling the DT of the project, ensuring that the BIM model accurately reflected the current state of the construction site. By continually synchronizing the model with multimodal real-time data, it provided an up-to-date visualization that enabled effective monitoring of progress and site conditions. Table 1 depicts construction progress on the dates of data acquisition, and Figure 6 shows the digital representation.

Table 1. Construction progress of pavement computed through Digital Twin

Date	Layer	Area (m^2)	Volume (m^3)
26th August 2024	Sub-base	2,461	492
	Base	6,171	1,234
6th September 2024	Base	8,632	1,726
30th September 2024	Base	3,953	791
	Surface	4,726	945
15th October 2024	Surface	8,632	1,726

The end result is represented in Figure 7 where the DT is rendered in 3D along with its environment.

Figure 7. 3D visualization of a preliminary digital twin platform

5 Discussion

Although numerous studies have explored the integration of BIM and photogrammetry, its application in road infrastructure construction remains largely under-explored and overlooked. This study addresses the mentioned research gap by integrating BIM and photogrammetry in the specific environment of road infrastructure and showing practical application in progress monitoring using existing technologies.

The development of 3D BIM model was based on construction drawings of the project. Model development process was followed by the collection of data through aerial photogrammetry technology using a commercial grade drone. Utilization of such RTK-equipped drone ensured precise geospatial information and high resolution of the collected data i.e. 1.87cm/pixel. Moreover, such drones are capable of being used on large-scale projects such as roads which are generally spread over numerous kilometers. The photogrammetric data was processed yielding a dense point cloud and DEM. The data obtained from the point cloud included essential information about project terrain offering a solid foundation for further steps in the workflow.

The DEM was processed to subsequently generate ortho-mosaics. A BIM-enabled Digital Twin (DT) was then developed by integrating high-resolution ortho-mosaic images into Autodesk InfraWorks at regular intervals. The DT was used for successfully computing and monitoring construction progress of road layers.

Previous studies, such as Turkan, Bosche [4] have used photogrammetry and UAV for progress measurement, However, most research has focused on vertical infrastructure, lacking BIM and DT integration. This study leveraged ortho-mosaics to build a reliable and dynamic representation of the project site, adding to its novelty. This study found photogrammetric data collection technology to be cost-effective as well as rapidly deployable. While data interoperability issues were not faced during data collection and processing, such challenges cannot be ruled out if BIM-enabled DT of the road is fed with further data related to scheduling and cost data etc.

6 Conclusion

This study has several notable contributions to the body of knowledge. First, it confirms the extent to which the integration of photogrammetry data and BIM can be successfully implemented in the road construction environment. Additionally, it demonstrates how DTs can be effectively utilized in road construction using existing technological capabilities. Furthermore, it verifies that BIM-enabled DT powered by photogrammetry can not

only facilitate effective road visualization but also help in reliable monitoring and measurement of progress across large-scale construction sites efficiently. Finally, it highlights how commercial-grade drones can be efficiently utilized in road construction for applications that extend far beyond basic videography, offering significant practical benefits.

Future research should explore the integration of Artificial Intelligence (AI) with BIM-Photogrammetry in the specific environment of road construction. Future research can also explore how BIM-Photogrammetry integration can be leveraged for addressing challenges related to construction quality of roads.

Abstract -

The construction industry has long explored robotics and computer vision, yet their deployment on construction sites remains very limited. These technologies have the potential to revolutionize traditional workflows by enhancing accuracy, efficiency, and safety in construction management. Ground robots equipped with advanced vision systems could automate tasks such as monitoring mechanical, electrical, and plumbing (MEP) systems. The present research evaluates the applicability of open-vocabulary vision-language models compared to fine-tuned, lightweight, closed-set object detectors for detecting MEP components using a mobile ground robotic platform. A dataset collected with cameras mounted on a ground robot was manually annotated and analyzed to compare model performance. The results demonstrate that, despite the versatility of vision-language models, fine-tuned lightweight models still largely outperform them in specialized environments and for domain-specific tasks.

Robotics; MEP Detection; Open-Vocabulary Models

1 Introduction

Recent surveys highlight the growing adoption of mobile robots in the construction industry as a means to address labor shortages and improve safety [1]. Despite these advancements, significant challenges remain for real-world deployment. As noted by [2], collaboration between developers and construction firms is essential to ensure these technologies contribute effectively to productivity and safety. Among the most repetitive and time-consuming tasks in construction workflows, site surveys—critical for monitoring progress and supporting decision-making—are still largely performed manually [3]. Robust detection technologies could significantly enhance the automation of these processes, but detecting Mechanical, Electrical, and Plumbing (MEP) systems remains a complex challenge.

MEP monitoring involves tracking and assessing the installation and functionality of critical systems during construction. This process is essential for identifying potential issues early, preventing costly rework, and avoiding delays [4]. While supervised learning algorithms, particularly convolutional neural networks (CNNs), have significantly advanced object detection in construction, these methods face limitations in dynamic and unstructured environments [5]. Models like YOLO (You Only Look Once) have shown success in controlled conditions but struggle with occlusions, variable lighting, and the introduction of novel objects often encountered on construction sites [6, 7].

Figure 1. Our Journeybot platform for data collection: a Jackal rover base from Clearpath equipped with several cameras and LiDARs (not used in this study).

Open vocabulary object detection presents an alternative approach, offering the ability to generalize across diverse datasets and identify objects not seen during training [8]. These open-vocabulary models, which integrate Large Language Models (LLMs) with computer vision, have demonstrated potential in tasks such as generating detailed inspection reports and monitoring construction sites [9]. Another example, Omni-Scan2BIM [10], employs open-vocabulary models to recognize and segment MEP components for automatic as-built BIM generation. However, their focus on specific classes, such as pipes and ducts, limits their applicability to broader MEP monitoring tasks. Trained on diverse datasets, open-vocabulary models can adapt to new environments and identify emerging components and materials [11], an essential capability for dynamic construction sites where variability is high.

This paper evaluates the potential of open vocabulary

object detection models for MEP monitoring in construction environments. To this end, we constructed a real-world dataset of MEP components using a mobile robot equipped with multiple sensors. The dataset was used to train and evaluate a fine-tuned supervised object detection model, YOLO11 [12], which as a closed-set detector works only for the specific classes that it was trained or fine-tuned on. Then, compare its performance with three open vocabulary object detection models: Grounding-SAM2 [13], Grounding DINO [14], and DETIC [15]. This comparative analysis provides a comprehensive assessment of fine-tuned, lightweight closed-set detectors versus pre-trained open-vocabulary models in real-world MEP monitoring tasks. Our findings offer valuable insights into the effectiveness of deploying open-vocabulary models compared to smaller, task-specific models for dynamic construction environments. As LLMs and open-vocabulary models continue to evolve, this work contributes to understanding their role in advancing construction site automation.

2 Experimental Setup

Robotic Platform: This study utilized the Journeybot robotic platform, a four-wheeled unmanned ground vehicle (UGV) equipped with a hybrid vision and laser sensing system (Figure 1). While capable of semi-autonomous navigation, the robot was manually operated during data collection for safety reasons.

The sensing system was tailored for comprehensive environmental monitoring and digital twin data collection. It included four Intel Realsense D435i stereo cameras covering all sides of the robot, with one facing upward, and a front-facing Intel Realsense T265 tracking camera for enhanced localization. Depth images from the D435i supported collision avoidance, together with a horizontally mounted Velodyne Puck 32MR LiDAR. An Ouster LiDAR augmented the data collection system, but both LiDARs are not covered by this work. Wheel encoder data and IMU readings were synchronized with detection sensors by an NVidia Jetson computer.

Dataset: The dataset was collected at an active construction site provided by an industrial partner, with a primary focus on MEP assets. Using the Robot Operating System (ROS), our robotic platform was manually teleoperated through the site, capturing data stored as *rosbags*. Images were extracted at a rate of 10 Hz from the rosbags, followed by a filtering process to remove redundant and blurred frames. The remaining images were annotated for the 10 specific MEP components listed in Table 1 using an online annotation tool. The dataset is shared online.

The final annotated dataset was divided into 70% training, 20% validation, and 10% testing splits. Table 1 also presents the number of images and instances per class. Example images are shown in the results section (Figure 3), illustrating the challenges posed by real-world data collection on a mobile platform. These include objects appearing at varying distances, being partially occluded, or blurred due to motion, reflecting the dynamic and unpredictable nature of construction site environments.

Table 1. Dataset details with number of images (and instances) per each class.

No.	Class	Images(instances)
	All	8885(14064)
1	Boiler	768(769)
2	Cable Tray fitting	252(317)
3	Electrical Panel	658(1022)
4	Fire Alarm Detector	872(877)
5	Pipe Fitting	3625(5014)
6	Valve	610(906)
7	Electrical Outlet	786(1023)
8	Generator	124(124)
9	Light	1992(2168)
10	Pump	1536(1844)

Evaluation Procedure: For quantitative evaluation, we assessed the performance of a lightweight object detector (YOLO11 Nano pre-trained on COCO [16]) fine-tuned (200 epochs) on our dataset, comparing its best performing weights (on the validation split) against three pre-trained large open-vocabulary models without fine-tuning: Grounding DINO, Grounded SAM2, and DETIC. The evaluation metrics included precision, recall, and F1 score (All measured on the testing split at 0.5 intersection over union).

3 Results and Discussion

Table 2 depicts the results of F1 score for YOLO11 Nano compared to the open-vocabulary models GSAM2, GDINO, and DETIC, evaluated on the test dataset. YOLO11 achieved a total precision of 0.87, outperforming GSAM2, GDINO, and DETIC, which scored 0.018, 0.02, and 0.015, respectively. Similarly, YOLO11 exhibited superior recall at 0.901, compared to 0.042, 0.084, and 0.018 for the open-vocabulary models.

Table 2. F1 score total and per class for each model evaluated in the testing dataset split

Class	YOLO11	GSAM2	GDINO	DETIC
all	0.89	0.018	0.032	0.014
1	0.94	0.01	0	0.005
2	0.86	0	0	0
3	0.9	0.045	0.059	0.043
4	0.94	0.036	0.026	0.063
5	0.86	0.01	0.013	0.013
6	0.87	0.005	0.007	0
7	0.82	0.005	0.003	0
8	0.92	0	0.006	0
9	0.81	0.038	0.027	0
10	0.93	0.014	0.123	0.013

The results underscore the superior performance of YOLO11 Nano, with improvements exceeding 85% in

precision, 82% in recall, and 86% in F1 score compared to the best-performing open-vocabulary model (GDINO). YOLO11 also achieved consistent detection across all classes, including class 2 (Cable Tray Fitting), which none of the open-vocabulary models detected. The failure of these models in detecting such specialized classes likely stems from their reliance on large, generic datasets like COCO [16] and LVIS [17], which lack adequate representation of MEP-specific components. DETIC exhibited the poorest performance, failing in five out of ten classes, while GSAM2 and GDINO each failed in two classes.

Figure 2 presents the normalized confusion matrix for YOLO11 Nano's predictions, demonstrating robust performance even for less-represented classes, such as generators, with a detection accuracy of 91%. This emphasizes YOLO11's capability to handle imbalanced datasets, a common challenge in domain-specific applications.

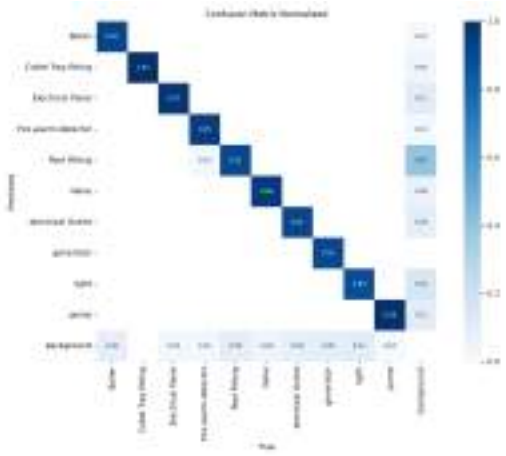

Figure 2. YOLO11 normalized confusion matrix for its predictions on the testing dataset split.

Figure 3 provides qualitative examples of YOLO11 Nano's predictions, displaying predicted classes, bounding boxes, and confidence scores. In some cases, the model outperformed human annotations, identifying overlooked objects like valves in the bottom-right corner of an image. Conversely, in instances of blurred images, the model avoided false positives, aligning with human annotators' limitations. However, false detections occasionally occurred, particularly for reflective surfaces, which resembled target classes like light sources.

These findings highlight the limitations of general-purpose open-vocabulary models in specialized environments like construction sites, where dynamic conditions, specialized components, and unique visual contexts demand fine-tuned, domain-specific approaches.

Real-world Applicability: Assessing the applicability of open-vocabulary models for real-world robotic systems compared to lightweight object detectors like YOLO11

Figure 3. Qualitative examples of YOLO11 Nano's performance, displaying predicted classes, bounding boxes, and confidence scores.

Nano requires careful consideration of model size and memory requirements. Model size, expressed in terms of parameters, is a critical factor influencing memory usage and computational efficiency, especially on resource-constrained platforms. Among the evaluated models, GSAM2 exhibited the largest memory footprint with 910 million parameters—350 times larger than YOLO11 Nano, which has just 2.6 million. GDINO followed, with a parameter count 67 times larger than YOLO11 Nano, while DETIC, the smallest open-vocabulary model, required 164 million parameters, making it 63 times larger than YOLO11 Nano.

Computational efficiency is equally crucial for deployment on real-time robotic systems. YOLO11 Nano was specifically evaluated on an NVIDIA Jetson Orin Nano, processing image samples from the testing dataset at a speed of 23.36 frames per second. This performance meets the requirements for real-time applications, demonstrating that YOLO11 Nano is highly suited for resource-constrained environments, unlike larger open-vocabulary models whose significant computational demands make them less practical for such applications.

4 Conclusion

This study compared the performance of pre-trained open-vocabulary detection models and fine-tuned lightweight detectors for robotic MEP detection in construction sites. Using a dataset collected with a tele-operated robotic platform, we demonstrated that fine-tuned models like YOLO11 Nano significantly outperformed open-vocabulary models in detection accuracy, computational efficiency, and real-time applicability. While open-vocabulary models offer promising generalization capabilities, their performance on domain-specific tasks remains

limited.

With the huge advancements in vision-language models, we hope this work encourages research on narrowing this gap, possibly, by fine-tuning open-vocabulary models on specialized datasets, potentially combining their adaptability with the precision of supervised models. Another direction could be to design construction-related prompts to adapt the open-vocabulary detectors.

Abstract -

Building Information Modeling (BIM) plays an important role in building design and construction, particularly for achieving energy-efficient retrofits. Building envelope retrofits using panelized prefabricated system, such as those popularized by the Energiesprong program, need accurate as-built dimensions of facade features (windows, doors, etc.) to achieve the desired thermal and air tightness. Traditionally, building surveying is done manually, resulting in a time-consuming and labor-intensive process. Recently, 3D point clouds from terrestrial LiDAR have been used to automate the generation of as-built dimensions of existing buildings. However, automated BIM using LiDAR relies on solving the point cloud semantic segmentation (PCSS) problem. In this work, we propose a robust pipeline for solving the PCSS problem using deep neural networks, focusing on overcoming challenges posed by imbalanced datasets and complex architectural features. We introduce the first high-density, labeled, and validated building envelope point cloud dataset derived from multiple building scans, specifically curated to tackle challenges in facade-level segmentation. Results from the trained neural networks show that advanced attention-based architectures and incorporating radiometry (light intensity and RGB) features significantly boost segmentation accuracy for windows and doors.

point cloud, semantic segmentation, supervised learning

1 Introduction

More than 40% of the buildings in the United States were constructed prior to 1980, when energy regulations were in place [1]. Building envelope retrofits using prefabricated overclad panels offer a promising solution to increase the energy efficiency of these older buildings. Moreover, this process minimizes occupant disruption and has a high potential for automation, shortening assembly time at the job site and increasing overall construction quality. However, this type of retrofit requires precise as-built dimensions of the building to effectively design and manufacture the overclad panels, highlighting the need for Building Information Modeling (BIM) to create a digital twin. Creating an as-built retrofit BIM involves measuring the geometry of building facade features, such as windows and doors, to produce a dimensional digital twin that facilitates the design and installation of prefabricated overclad panels. However, this process is often time-consuming, labor intensive, and susceptible to errors. Therefore, automating this process has substantial benefits when trying to achieve building envelope retrofits at a large scale [2].

Recent advancements in 3D LiDAR scanning technologies have enabled the acquisition of high-density point cloud data, providing detailed geometric representations of scanned structures. However, point clouds are inherently unstructured, making the extraction of semantic information—such as identifying facades, windows, and doors—a complex but essential task for creating BIM-ready datasets [3]. This process can be automated by solving the Point Cloud Semantic Segmentation (PCSS) problem, revolutionizing building surveying by eliminating the need for manual annotation and generated dimensional twins in real time. Despite its promise, several challenges remain, particularly for datasets with imbalanced class distributions and complex architectural features [4]. This study focuses on improving facade segmentation for retrofitting applications by introducing a labeled and validated high-density facade dataset, curated from multiple building scans. This dataset bridges a critical gap in resources required for evaluating advanced neural network for solving the PCSS problem.

Two deep learning models were evaluated: PointNet++, based on a multi-layer perceptron (MLP) architecture [5], and the Superpoint Transformer (SPT), a transformer-inspired model leveraging hierarchical feature learning and attention mechanisms [6]. These models were fine-tuned by training them on additional radiometry features, enabling richer feature representations and achieving superior segmentation accuracy. Furthermore, to address the

inherent challenges of imbalanced datasets, where walls dominate and classes such as windows and doors are underrepresented, we employ a combination of sampling techniques and weighted loss functions.

The structure of the paper is as follows. Section 2 reviews related work on PCSS in the construction industry, highlighting the need for labeled data. Section 3 details the dataset collection, labeling validation, post-processing procedures, and the class distribution within the dataset. Section 4 discusses the deep neural network architectures used and their evaluation metrics. Finally, Section 5 presents the results, while Section 6 presents the conclusions and future work.

2 Related Works

2.1 PCSS applications in construction

Recent breakthroughs in deep neural networks have led to the development of powerful deep learning models which can capture and learn texture, shape, and contextual information from images, accelerating the use of computer vision in various applications. Semantic segmentation is a widely used technique in computer vision, which is the process of assigning a label to every pixel in an image, indicating which category the corresponding pixel belongs to. This helps in better scene understanding of 2D images. Among various scene understanding problems, 3D semantic segmentation is helpful in determining accurate object boundaries with similar patterns along with their labels [7]. Unlike 2D images, 3D data generated by laser scanners are unordered and invariant to permutations, making it difficult for the deep neural networks to learn the desired features [3]. Due to its inherent nature, point clouds are subject to outliers and noise. In addition, non-uniform point densities in various regions affect point cloud feature learning. Deep learning (DL)-based segmentation for point clouds has been used in various applications such as robotics, industrial automation, autonomous driving [4] and 3D scene understanding, enabling automated decision making in three-dimensional space[8] . Datasets like KITTI[9] and nuScenes [10] are widely used in benchmarking point cloud segmentation algorithms and their performance in autonomous driving in real world scenarios.

Given that, in general, old buildings lack an as-built, or even an as-designed BIM, point cloud data has become popular within the construction sector for 3D BIM generation. Recently, innovative methods have been developed to efficiently create as-built BIMs for various construction projects, including envelope retrofits, re-cladding, and window replacements. [11]. PCSS can be used to generate accurate as-built BIMs from 3D laser scans of the building, where the accuracy depends mainly on the sensor and range. However, the efficiency of supervised machine learning used in PCSS is heavily dependant on the available labeled training data. Currently, the amount and variety of open source point cloud datasets to train, validate, and compare new neural network architectures are mainly limited to the autonomous driving industry. Beyond autonomous driving, numerous datasets like S3DIS featuring residential and commercial buildings focus on indoor room and office scenes captured using RGB-D devices [12]. Building exterior envelopes, however, usually correspond to sparse urban datasets like Semantic3D[13] and Toronto3D[14] collected using mobile/aerial laser scanning technology and those featuring [15] and [16] facade-level classes are of sparse density. Therefore, it is essential to address the scarcity of dense, accurately labeled point cloud data of exterior building envelopes, specifically designed for semantic segmentation tasks aimed at enhancing productivity and reducing costs in retrofit and new construction projects.

2.2 Class imbalance in real-world datasets

The performance of DL classification models is heavily impacted by how well the data is distributed across the different classes.[17] To achieve optimal performance, and avoid overfitting on individual classes, the model has to be trained on datasets that are as balanced as possible [7]. In a real-world point cloud scan of a building exterior envelope, as much as 80% of elements can be classified as walls points, while the rest correspond to features such as windows and doors.

Standard learning algorithms assume balanced class distributions and severe imbalances like our application, can lead to biased decision boundaries on under-represented minority classes. This study[18] systematically analyzed how imbalanced data skews model predictions towards majority classes, leading to biased decision boundaries. Due to the large presence of the wall points in real world facade dataset like ours, the model can be heavily skewed and can learn to over classify the majority group. Furthermore, class imbalance can distort the performance evaluation when using metrics such as accuracy, as correctly classifying the major classes may yield high scores that incorrectly indicate good performance [19].

3 Dataset Collection and Labeling

For data collection, we used the Leica MultiStation MS60 to scan buildings across the ORNL campus. The MS60 is a terrestrial laser scanner (TLS) that allows users to customize scan density, enabling the collection of dense scans with high accuracy. The lidar scanner returns the Cartesian coordinates x, y, z and the light intensity I of a point on a surface measured by the laser. In addition, the TLS is equipped with a 5 MPx RGB camera fea-

Figure 1. Sample facades used for DeeP-CuBES

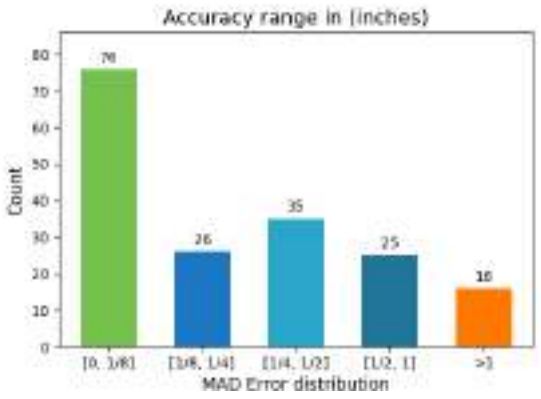

Figure 2. Error distribution for window dimensions

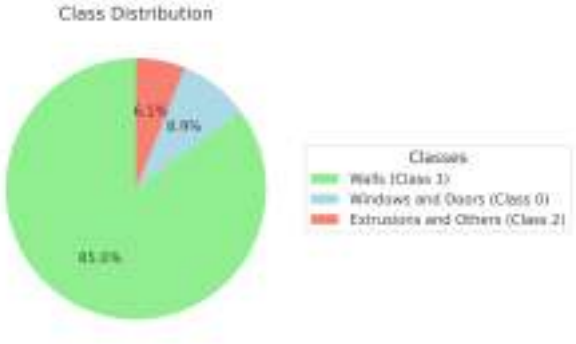
turing a CMOS sensor which takes captures images of the scanned area to later interpolate the points with the pixel RGB values. Therefore, the final raw point cloud belongs to a seven-dimensional space with coordinates $\begin{bmatrix} x & y & z & I & r & g & b \end{bmatrix}$. A total of 25 building facades across the ORNL campus were scanned and the point clouds were initially cleaned to remove outliers such as trees and other occlusions using CloudCompare [20]. A subset of the facades collected is shown in Figure 1.

With the cleaned, pre-processed data of different individual facades, we used the ORNL-developed Automatic point Cloud Building Envelope Segmentation (Auto-CuBES) algorithm to accelerate data labeling [21]. Auto-CuBES uses a sequence of unsupervised machine learning methods, such as k-means and DBSCAN, to segment the building envelope into wall points, windows points, door points, and other categories (building extrusions) with an accuracy of 3mm. Although Auto-CuBES is significantly faster than manual segmentation, it requires several segmentation steps which involve calibrating various parameter values to segment window and door openings from the wall points. The segmentation results from all building scans were grouped into three classes: windows+doors, walls, and others. The results from Auto-CuBES were validated by comparing them to manual measurements of the window dimensions (length and height) using the TLS laser. Figure 2 shows the distribution of Mean Absolute Deviation (MAD) observed in our dataset. Note that most of the error distribution is heavily skewed toward lower values (ranging between 0 to 1/8 in), as indicated by the high count in the first bin. Also note that the manual measurements are not the actual ground truth, as it may be subject to human inaccuracies. This result suggests that the segmentation is accurate for most cases, with less than 10% of the dataset having a MAD error greater than 1 inch. After labeling and validation, we created the Oak Ridge National Laboratory Building Envelope Library (ORNOBEL) for exterior building envelopes.



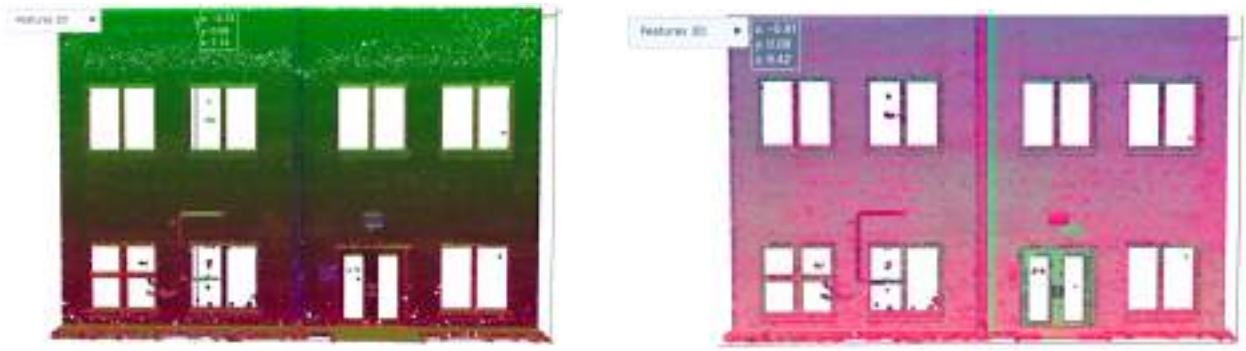


Figure 3. Distribution of 223 million points within the Oak Ridge National Laboratory Building Envelope Library (ORNOBEL)

The ORNOBEL dataset consists of dense facade scans of 25 different multistory buildings with 3mm accuracy and more than 220 million points of labeled data. Figure 3 shows the distribution of the three classes used, namely windows+doors, walls, and others. These categories can be further subdivided in the future. Note that 85% of the data consists of wall points, creating a significant imbalance that can affect the performance of any trained model.

3.1 Post processing and preparing the data

To ensure the point cloud data is standardized, aligned, and ready for neural network model training, we implemented a series of pre-processing steps, as outlined below:

- **Spatial Centering & Intensity Normalization:** The origin of each facade point cloud was moved to the geometric center of its minimum bounding box. This ensures consistency of the spatial positioning of all walls and openings (windows and doors) facilitating easier model interpretation. Light intensity was normalized to avoid large values observed in the raw data.

(a) Default feature map without radiometry features

(b) Fine tuned feature map with added radiometry features

Figure 4. Comparison of fine tuned feature partition map for SPT.

To handle outliers in intensity values, we employed the *Robust Z-Score* normalization method:

$$I_{\text{robust}} = 0.6745 \cdot \frac{I - \text{Median}(I)}{\text{MAD}} \tag{1}$$

where I is the raw intensity value, Median(I) is the median intensity, and MAD is the Median Absolute Deviation. This ensures that the intensity values are scaled robustly, particularly across facade surfaces and doesn't skew the model training.

- **PCA-Based Alignment:** For facade-specific data preparation, Principal Component Analysis (PCA) was applied to the wall points using scikit-learn to establish a consistent reference axis [22]. Subsequently, point clouds representing windows and doors were aligned to this PCA-derived axis to standardize their orientations. This alignment step is crucial for facade datasets collected without a common TLS orientation, as it ensures uniformity, allowing models to concentrate on geometric features such as coplanarity without being influenced by variations in orientation.

- **Output Format:** RGB color values were left unchanged, as they can serve as additional radiometric features for identifying facade components. The preprocessed point clouds, with spatial centering, normalized intensity, PCA alignment, and original RGB values, were exported in standard h5 formats. This approach ensures that the data is directly usable for neural network training.

4 Deep Neural Networks applied to PCSS

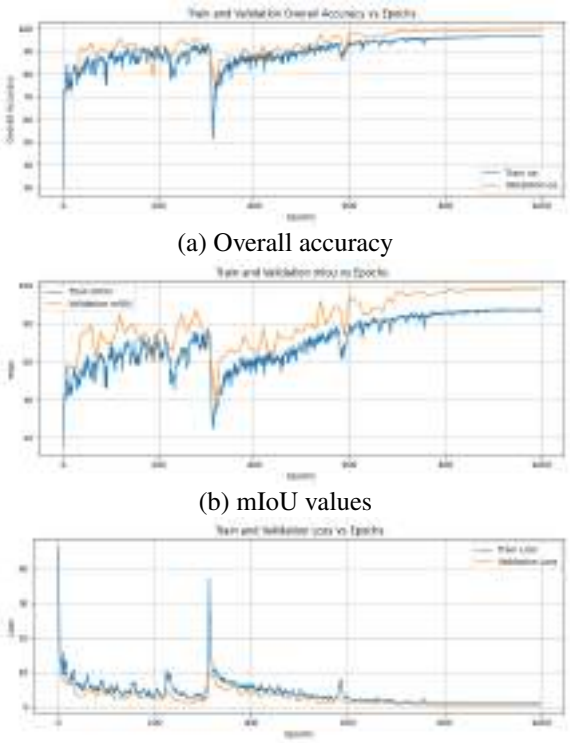
PointNet++ was a groundbreaking model introduced in 2017 to solve the Point Cloud Semantic Segmentation(PCSS) problem [5]. The algorithm pioneered the hierarchical learning of both local and global features directly from unordered point clouds. Given its historical significance, we used PointNet++ as a baseline to evaluate the PCSS accuracy on our dataset. PointNet++ uses a Multi Layer Perceptron (MLP) architecture and processes point clouds hierarchically, using set abstraction implemented by multiple MLP layers to capture local and global features. However, it only uses the xyz coordinates for feature learning, ignoring other informative attributes like light intensity and RGB. When trained and tested on the ORNOBEL dataset, the model performed poorly in capturing spatial relationships for minority classes such as windows and doors, highlighting the difficulty of dealing in imbalanced classes.

We have implemented Superpoint Transformer (SPT) neural network architecture [6], an advanced model which uses additional feature sets and super point partitions to improvise feature learning. This model draws inspiration from the U-Net convolutional architecture [23], which has been groundbreaking in 2D image segmentation. By integrating transformer-based self-attention mechanisms, which has seen breakthroughs in language understanding, SPT effectively captures the spatial dependencies between unordered points, while its U-Net-like encoder-decoder structure allows for multi-scale feature learning. Additionally, its compact size, with fewer parameters, ensures computational efficiency, making it an ideal choice for dense point cloud segmentation of building envelopes.

4.1 Superpoints features

Superpoints are groups of points clustered together based on their local geometric properties. The Superpoint Transformer outperforms PointNet++ by leveraging a more sophisticated architecture inspired by U-Net and superpoint graphs. Unlike PointNet++, SPT uses a combination of xyz coordinates, light intensity, and RGB values to construct a rich, hierarchical feature map. These features are used to construct a meaningful hierarchical partition with adjacency relationship with neighboring points. Subsequently, SPT organizes the point clouds with feature

maps into superpoints (i.e., clusters of points with adaptive and shared local features) enabling efficient and structured feature aggregation.



The transformer encoder-decoder architecture with self-attention allows SPT to learn spatial dependencies between points effectively, which is critical for capturing complex facade openings and features. SPT integrates MLP layers to extract point-wise features and project them onto higher dimensions before applying attention. This combines the strengths of both MLPs and transformers. Our fine-tuning process involved customizing SPT to optimize its ability to learn facade-specific features as shown in Figure 4. With the appropriate calibrated parameters in SPT, classification accuracy across all metrics was improved compared with the PointNet++ baseline results, particularly for correctly classifying minority classes.

4.2 Deep neural networks training

To establish a point of comparison for improvements, we generated a baseline models using PointNet++. The original PointNet++ model was trained without implementing any sampling methods or dataset balancing, relying solely on xyz coordinates for feature learning (no radiometry features like intensity or RGB were used). The model performed poorly across all classes due to the dataset's inherent imbalance. To address this, we used a combination of sampling methods: weighted cross-entropy loss as a passive sampling method and downsampling majority class as an active approach. While these techniques significantly improved the model's performance, the generalization to non-downsampled wall points remained poor. This highlighted the limitations of addressing class imbalance solely by downsampling a single class, which is impractical for real-world applications.

The Superpoint Transformer model was initially trained on the ORNOBEL dataset without fine-tuning or incorporating intensity and RGB features. Moreover, the SPT was trained directly on the class-imbalanced dataset, providing a more robust and effective solution to the challenges posed by the dataset's structure. The model performed extremely well, yielding a significant boost over the Pointnet++ model's results. To effectively train our neural networks, we employed cross-entropy loss functions. Specifically, for the PointNet++ model, we applied a weighted cross-entropy loss to explicitly handle class imbalance within the dataset. For the SuperPoint Transformer model, the standard categorical cross-entropy loss was sufficient enough.

Overall Accuracy: measures the ratio of correctly classified points across the entire dataset. While accuracy was recorded, it is misleading for imbalanced datasets as it disproportionately favors the majority class (wall points in our case)

(a) Overall accuracy

(b) mIoU values

(c) Model Loss

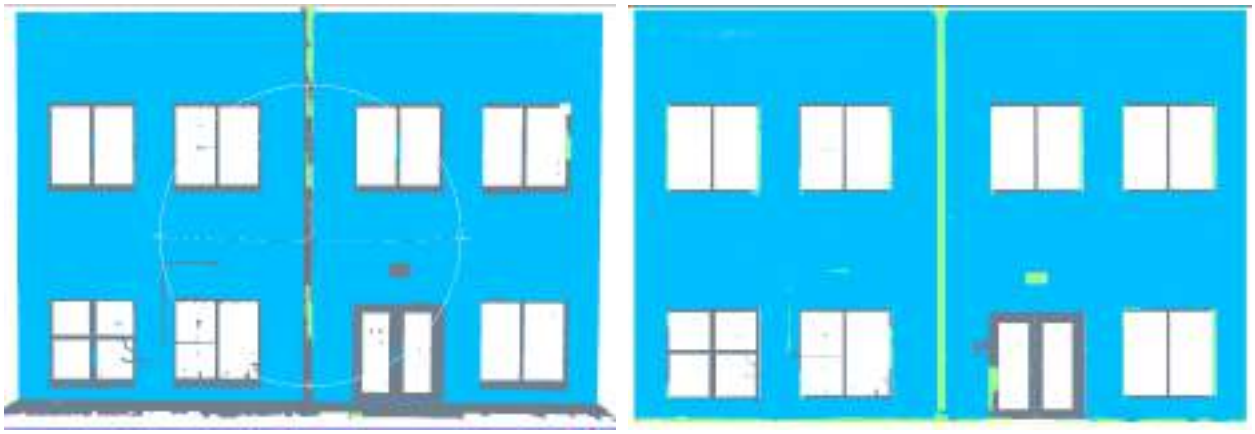


Figure 5. Comparison of training metrics from SPT

mean Intersection over Union (mIoU): this metric provides a class-wise measure of segmentation accuracy. This metric is particularly effective for semantic segmentation, as it evaluates the overlap between predicted and ground-truth points for each class.

The SPT model was trained for up to 1000 epochs with an early stopping criterion to prevent over-fitting. Pointnet++, on the other hand, was trained for 50 epochs. A standard batch size of 32 was utilized for both models, balancing computational efficiency and effective gradient updates. Figure 5 shows the three different aforementioned metrics during the training process of the SPT model for baseline comparisons. It is noteworthy that overall accuracy quickly reaches a high value >80% largely due to the bias towards wall points. Meanwhile, the mIoU values do not reach their maximum until the end of the training phase.

5 Results and Discussion

The training and testing experiments were conducted on a system equipped with an NVIDIA RTX 6000 Ada Generation GPU, Intel Xeon Gold 6442Y CPU, and 128 GB of RAM. Training times varied depending on the model complexity and number of epochs, with PointNet++ com-

(a) Pointnet++ prediction on down-sampled wall points

(b) SPT prediction on actual points

Figure 6. Comparison of model predictions.

pleting in approximately 3 hours per run and Superpoint Transformer taking around 2 hours per run. From our experiments, we observed that well-represented classes with planar geometries (such as walls) are correctly segmented in most of the instances. Figure 6b shows, the segmentation results for the Pointnet++ (left) and SPT (right). The improved segmentation accuracy of SPT model resulted from careful feature fine-tuning, where additional point features (such as RGB, intensity, and elevation) were integrated beyond the default set used in the original implementation.

Note that, in general, the wall points (denoted in blue color) are well identified in both models. However, opening points (grey color) were more accurately segmented using SPT. In the case of Pointnet++, such points were not distinctly separated from the third class (green color)which corresponded to other protrusions, such as gutters or ground platforms. The testing error metrics shown in Table 1 demonstrates that the SPT has a superior performance for solving the PCSS problem for building envelopes. This improved performance is primarily attributed to the SPT's attention-based architecture, which effectively captures detailed spatial relationships and long-range contextual features. Additionally, incorporating radiometric information, such as RGB and intensity values, enables richer feature representations, significantly improving segmentation accuracy for facade elements like windows and doors. It is important to note, however, that RGB features do not inherently resolve class imbalance; instead, the enhanced accuracy from radiometric features improve overall model performance.

After the PCSS problem is solved, the digital twin of the building envelope is created by finding the minimum bounding box of the different classes. Figure 7 shows the bounding box for each opening. Note that the SPT model struggled with accurate predictions along the boundaries of windows and doors, where the transition between classes introduces ambiguities leading to partition errors that cannot be fully corrected with the current model. This boundary defines the transition between classes and lacks a distinct geometric or feature discontinuities where two or more classes intersect. Table 2 compares the dimensions of the digital twin extracted using the SPT model versus the original one defined using the Auto-CuBES algorithm. The opening are number from 1 to 8, going from left to right, and from bottom to top. Note that the bottom openings show the largest errors, while the top openings show a low height error and large width error. Upon close inspection, the errors are mainly due to outliers in the opening classes. One of the last steps in Auto-CuBES involve removing outliers from each identified cluster, drastically increasing its accuracy. The SPT model, on the other hand, its very efficient at identifying the main points belonging to a particular cluster, but cannot completely remove the outliers within a cluster. This exemplifies the limitations of relying solely on a deep learning model, and directs our research towards a more robust PCSS solution that uses both neural networks and unsupervised clustering techniques.

Table 1. Testing error metrics on ORNOBEL Dataset

Metrics	mIOU	OA%

signed for building exterior envelopes, addressing the lack of labeled datasets for building retrofitting applications. Our findings highlight the potential of 3D PCSS in generating precise Building Information Models (BIMs) for retrofitting applications, particularly for designing and deploying prefabricated overclad panels to enhance building energy efficiency. Based on the observations from 2D image-based facade segmentation domain [24, 2], we believe that our 3D facade segmentation dataset will contribute to the further development of 3D facade-oriented methods for construction domain. Results from the deep learning models tested show that a transformer-based architecture has a good potential for solving the semantic segmentation problem in dense building envelope point clouds. However, we plan to extend our work by further training on more state-of-the-art models in combination with various sampling methods and clustering techniques to further address our current limitations. For future work, we aim to expand our dataset by including additional building scans with diverse architectural styles and materials, removing PCA to generalize and address class boundary limitations. Additionally, we will open-source our dataset to address the lack of labeled resources in this domain, fostering collaboration and innovation in 3D facade segmentation. Future exploration will also involve developing methods for faster and improved real-time segmentation capabilities for on-site retrofitting applications through accelerated pipelines.

MAP: A Versatile Platform for Predictive Algorithms in Construction and Beyond

Ramyani Sengupta[1], Emad Elwakil[1] and Yi Jiang[1]

[1]School of Construction Management Technology, Purdue University, USA
sengup11@purdue.edu, eelwakil@purdue.edu, jiang2@purdue.edu

Abstract– The construction industry in North America is a dynamic and rapidly evolving sector characterized by its fast-paced operations and constantly shifting demands. Despite its significance, the industry has been slow to adopt emerging technologies compared to other fields. This lag extends to the integration of artificial intelligence (AI), where vast opportunities for innovation remain underutilized. While large, well-funded firms have begun leveraging AI to develop proprietary applications capable of analyzing historical data to predict patterns and trends, smaller firms often encounter significant barriers, including limited resources and technical expertise, which hinder their ability to adopt such advanced tools.

This study introduces a robust, user-friendly platform that integrates commonly employed machine learning algorithms. The platform empowers smaller firms by enabling them to train, validate, and test their data effectively without requiring extensive technical expertise. Beyond addressing the immediate needs of the construction sector, the platform is intentionally designed for versatility and adaptability, making it applicable across various industries. It supports tasks such as pattern recognition and data visualization, providing a reliable solution for non-experts to evaluate and select the most suitable models for their unique datasets and variables.

Keywords – Modeling, Algorithms, Machine learning; Simple Neural Network, Multi-Layer Perceptron, Support Vector Machine, Random Forest, Regression, Construction

1 Introduction

The construction industry in North America has become a dynamic and rapidly growing sector, with its profits soaring to an impressive $1.8 trillion in 2023 [1] and contributing to 4.4% of the GDP in the United States in 2023 [1]. This remarkable growth highlights the industry's critical role in driving regional economic development and infrastructure advancements. However, in an environment of increasing competition and evolving market demands, every organization within the industry must strive to carve out a distinctive edge that sets it apart from its closest competitors. This differentiation often hinges on how companies embrace and integrate innovative technologies into their operations. Technology adoption has emerged as a key factor in determining which firms can stay ahead of the curve, enhancing overall performance [2]. In an industry where traditional methods and opinions can still hold considerable sway in many areas, the construction industry has often fallen behind in this area [3], and today, the ability to leverage cutting-edge tools and systems can be the most defining characteristic of successful organizations.

Alongside automation, robotics, and drone technology, to name a few, artificial intelligence or 'AI' algorithms has become a quickly growing technology across all industries. Adopting it within the construction industry can help improve efficiency, safety, and overall project outcomes by streamlining project planning, resource management, and real-time decision-making. Currently, available AI tools can improve performance, make firms more competitive, and thus give them an 'edge' [4]. As more and more US construction companies invest in in-house AI algorithms for their historical data to predict project timelines and future issues, this paper aims to streamline the process by creating a platform with different ML algorithms. As it can be challenging to determine which algorithm works best for different types of data, the 'Modelling and Prediction Platform ('MAP' platform) application can help determine the best-fit model for the data. Users can run their data through MAP and easily choose among six different machine learning algorithms (a simple neural network, multi-layer perceptron, support vector machine with five different kernel options, random forest, ridge regression, and lasso regression) to determine which model – with the least amount of error – best fits the data and predicts a pattern between the variables. Certain algorithms have additional parameters that can be used to customize the users' choices. This application can be used for datasets beyond the construction industry, as its visualization, modeling,

and predictive techniques are not limited to construction datasets or project management.

2 AI and Construction

Although challenging, multiple attempts have been made to define AI and its function. "*A being concerned with methods of achieving goals in situations in which the information available has a certain complex character*" was used by McCarthy in a 1988 textbook as an attempt to define artificial intelligence. Since then, its definition has constantly evolved, and its functions have surpassed expectations. Although it can still be termed a comparatively modern form of technology [5], the number of companies using AI technologies has increased by 270% between 2014 and 2018, almost a three-fold increase [6]. This begs the obvious question today: *if everyone is using it, how does it lend a competitive edge*? Mikalef and others, in their 2021 study, argue that in-house tools, i.e., AI capabilities developed by firms themselves, can enhance performance and give companies an edge [4]. Such engineered solutions can allow project managers to track project progress, resolve conflicts and issues, and make informed decisions from any location. A good example of such 'in-house' tools is using historical data for predictions. Some of the heavyweight construction firms in the country, such as Turner Construction, Suffolk Construction, DPR Construction, and AECOM, among others, routinely train AI algorithms nowadays on their proprietary company data from previous decades to predict future scheduling timelines, delay causes, project performance, etc. The idea is that such algorithms can quickly be trained to analyze historical data to detect current issues a*nd predict potential issues* in construction projects. Many of the top 10 construction companies in the US (big names in the industry such as Turner, AECOM, Suffolk, etc.) have investing 'wings' within their firm that heavily research these topics and then infuse capital into startups focusing on specific tools that can improve their projects. This can help enable proactive planning and resource allocation within the company *before* such issues arise. Due to budget constraints and lack of manpower, smaller names often fall behind, and the tool described in this study may help them compete.

2.1 Background on AI Adoption

Case studies can significantly help strengthen the argument that incorporating AI techniques and tools improve company performance and can reiterate the importance of more compact firms having access to such technology. A 2020 study including 150 firms of various sizes investigated the use of eleven types of AI capabilities (generic AI such as task and decision automation, machine learning algorithms, deep learning algorithms, cognitive, cognitive cyber security, natural language processing, robotic personal assistant, pattern recognition, chatbots, neural networks, and virtual companions). The study found that AI use within firms had an incredibly positive result with increased organizational performance at the company level, and process-related variables also improved the company [7]. Professional readiness and AI technologies correlate as well [8]. Another 2022 study investigated 299 Scandinavian countries and found that AI platforms strongly impact organizational performance, whether in the social aspect or financial performance [2]. A 2021 study among 530 employees across Indian telecommunication companies (Vodafone, Idea Telecom, Bharti Airtel, Reliance Jio, etc.) reported that using AI applications and algorithms helps managerial employees get real-time data on employee performance quite effectively and that automated processes and other AI tools can influence performance. Companies can "overachieve", "deliver sustainable results", "optimize resources better", and "do the right thing" far more often if they use AI tools to drive performance [9]. Another empirical study from 2022 among 380 employees of Dubai-based companies found that AI use had positive relationships with organizational structure, process innovation, and employee expertise/performance.

When combined with onsite tools/field work, AI technologies can use technologies like tracking and computer vision algorithms for remote inspection while also maintaining quality assurance/quality control (QA/QC) [10]. Construction robotics and automation also transform how resources are used on construction sites [11]. Robotic systems can perform repetitive or dangerous tasks, such as bricklaying, concrete pouring, or welding, with greater precision and speed than human workers [10, 12, 13]. This increases productivity and reduces the risk of human error and accidents. Today, a combination of sensors and algorithms can be used for cranes (e.g., versatile.ai), which connect to a local IoT system for easy tracking by all stakeholders in a project. Currently, versatile.ai is almost unanimously favored by the top construction companies in the US for site work and remote supervision.

AI technologies, thus, show promise when used for a myriad of onsite and offsite work in construction. It is no surprise that large firms across North America are spending millions of dollars on AI tools for all kinds of construction-related variables – from office productivity to onsite safety and PPI use. As discussed earlier, not all firms are large enough to fund decades of AI research, and the platform discussed in this paper can help smaller firms overcome the labor of building complex tools for their historical project data – a platform like MAP can help them determine which algorithms can help predict and highlight any existing patterns in their datasets.

3 The 'MAP' Platform

Six algorithms were chosen for this platform due to their already well-established status in data analysis – they are well-documented in literature and can work for varying data types. The application, named 'Modelling & Prediction Platform' or 'MAP,' displays an error histogram and a graph between the actual data and predicted data alongside the Mean Squared Error and R-squared coefficient values. This can be used to predict future technology adoption within the industry. The findings can help offer a new appreciation for the challenges and opportunities that may be analogous to adopting AI in construction. The application is currently in its testing phase, and a case study conducted with MAP and real construction data is ongoing and thus is beyond the scope of the current discussion.

3.1 Algorithms in MAP

Keeping in mind the dynamic needs of the construction industry, the following six algorithms have since been encoded into the MAP UI (written in Python ver3.12.6, with sci-kit-learn and Matplotlib – discussed later in this section):

- Simple Neural Network
- Multi-layer Perceptron
- Support Vector Machine (with five kernel functions the user can choose from – linear, polynomial, sigmoid, precomputed, and radial basis function or rbf)
- Random Forest
- Ridge Regression
- Lasso Regression.

A Simple Neural Network is great for learning patterns in data that traditional algorithms might miss. Its main advantage is flexibility—it can adapt to many types of data, like images, text, or numerical data [14] (*in the current version of the MAP UI, however, only numerical data can be used as input and/or training and/or test variables*). It is also quite robust to noise, meaning it can handle data that is not perfectly clean (*again, it is advised to use cleaned data for the MAP platform for good visualizations*). With the right training, it can generalize well to predict new, unseen data. The Multi-Layer Perceptron can be considered a powerful extension of simple neural networks. Its biggest benefit is its ability to model complex relationships by using multiple layers of interconnected nodes. MLPs can solve problems that are not linearly separable, making them ideal for tasks like image classification or natural language processing [15]. They also perform well with large and diverse datasets, which can be helpful for construction companies.

Support Vector Machines, or SVMs, are highly effective for classification and regression tasks. SVMs are particularly good with small to medium-sized datasets and are less prone to overfitting. One of their strengths is the flexibility provided by kernel functions, which lets them work well with both linear and non-linear data [16, 17]. Kernel functions help to convert input data into the required hyperplane/ multidimensional space, and the five kernels that are included in the current version of the MAP model (that can be chosen with ease by the user, depending on their dataset, variable types and/or any modeling requirements) are:

- The linear kernel is an ideal option for simple, linearly separable data,
- The Polynomial kernel excels at capturing complex relationships,
- The sigmoid kernel mimics the activation function in neural networks,
- The precomputed kernel allows customization based on prior knowledge and
- The Radial Basis Function (RBF) is versatile for non-linear patterns.

Random Forest is a versatile and reliable algorithm with extensive uses in classification and regression. Its primary benefit is robustness – it combines the predictions of many decision trees to improve the overall accuracy of the output and reduce overfitting. It also does well at handling missing data and can work with numerical and categorical variables [17]. Additionally, Random Forest provides feature importance scores, helping identify which features matter most [17, 18]. Ridge Regression improves upon linear regression by adding a penalty to large coefficients, and its key benefit is reducing overfitting, which makes it ideal for datasets with many correlated features [19]. This regularization ensures that the model generalizes new data better. Ridge Regression can be particularly useful when all input features contribute to the outcome but need their influence 'moderated' to a certain extent [20]. The final algorithm, called 'Lasso Regression,' is similar to Ridge Regression but has an additional benefit: it can select features by shrinking some coefficients to zero. This makes it a great choice for simplifying models and improving interpretability, especially when dealing with datasets that have many irrelevant features [21]. Thus, the model can be computationally efficient while excelling in identifying the most important variables. All machine learning models in MAP were encoded into the platform using 'sci-kit-learn' (also referred to as 'sklearn'), a freely available and easy-to-use open-source machine learning library kit for the Python programming language, and all visualization techniques were incorporated into the platform by using 'Matplotlib' (a blend of 'MATLAB' – the popular programming environment, 'plot', and 'library') which is another commonly used free, open-source plotting library for the Python programming

language. The user interface was built entirely with Python (the code editor was Visual Studio Code). The user interface (or 'UI') was built to import a comma-separated values (csv) file, read and identify each variable from each column, and then automatically display them in a window for the user to choose input and output variables. The following section discusses the UI in detail.

3.2 Methodology of MAP

The following sections outline the processes behind the user interface design, each option in the application window, the algorithms and their testing alongside the function of each output window.

3.2.1 The UI

The MAP platform is designed to take in a .csv file as an entry (toggle *1. Select .csv file*), parsing the variable list and automatically identifying the variables. Once the file is chosen, the window beneath this option will display a complete list of all the variables. The user can then choose which variables to choose as 'input' options and which elements are to be displayed as 'output' options, and they appear in the next two terminals (underneath the buttons '*2. Choose input variables'* and '*3. Choose output variables'*). A list of algorithms is provided on the right (*4. Choose a model*) from which the user can select any option to train and validate data from the .csv file of their choosing. The figure below shows what the interface of the modeling platform looks like:

Figure 1. The MAP Platform

As discussed earlier, certain algorithms require the user to make further choices. Additional parameters appear in windows like the one below (Figure 2 below shows an example if the user chooses the Support Vector Machine option):

Figure 2. Supplementary parameters for some algorithms

The platform also provides a terminal window (Figure 1) that displays the mean squared error and R-squared values to the user. This can be particularly useful to quickly check if the chosen model suits the user's data or if the parameters need to be customized to fit their needs. Since values for both the training and validation datasets are displayed, it can help the user understand if a different modeling algorithm should be tested.

3.2.2 Model testing and validation

As seen in Figure 1, the platform allows each dataset to be split into two sets for training and validation. Depending on the user and the type of model they choose, one can split the data into any ratios (*they must add up to 1.0 to utilize the entire dataset – in the example figure (Figure 1), the ratios are 0.8 and 0.2*). For example, historical project data can be used for training, while current data can be used for the output.

3.2.3 Output windows

The final output is divided into two graphs, one for the error histogram of the output variable and another for the actual data vs predicted data for the chosen output variable. In the actual output, the error histogram is displayed toward the left of the final output window instead of the top, and the graph of actual vs. predicted values is displayed toward the right side of the output window. Output images from a test training and validation set (using a synthetic dataset for preliminary work) are displayed below in Figures 3 and 4 for a fictional variable from a test dataset:

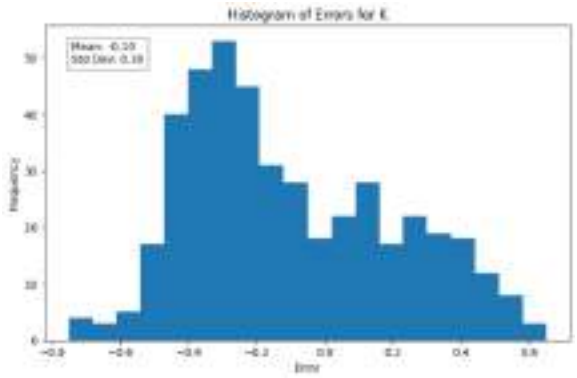

Figure 3. Test output showing an error histogram for a fictional variable '*K*' from a test dataset

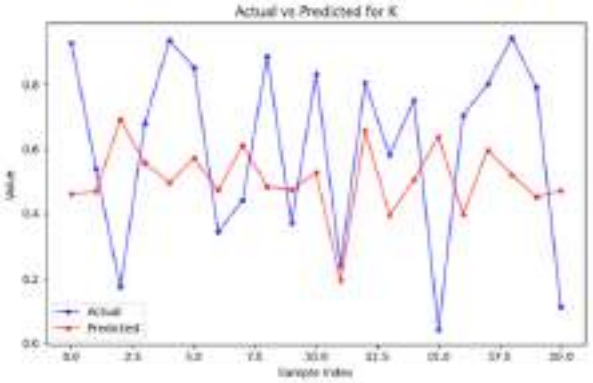

Figure 4. Test output showing the actual vs. predicted data plot for a fictional variable '*K*' from a test dataset

The test dataset shows a weak resemblance between the actual and predicted values, as the dummy dataset does not have identifiable relationships between the variables and were used purely for testing each algorithm. Data from the error histogram was used as one of many identifiers of whether the algorithm is a good choice for the dataset. The values of standard deviation and mean squared and R-squared error (pictured in the top left corner of the error histogram – Figure 3 alongside the terminal window – in Figure 1) also contribute to the user being able to determine of the model is a good fit for their chosen dataset.

4 Conclusion

In stark contrast to other industries, despite such clear positives, stakeholders and investors in this industry are still quite unsure of the potential benefits and overall financial worth of the construction and AI team-up [22]. As the industry changes and adjusts, investigating and investing in AI technologies will be crucial to maintaining competitiveness and meeting the increasing demand for smarter and greener projects. The future of construction lies in the successful adoption of AI, making this an essential area of exploration for the industry. Accurate information from real employees in the industry is crucial for researchers to gain more perspective on the usefulness of AI in construction.

While addressing the current needs of the construction industry, the platform's design is also simple, versatile, customizable, and adaptable, allowing it to be used in a wide range of other industries for tasks such as pattern recognition and data visualization. The platform's customization options also enable users to tailor its functionalities to suit their specific datasets and variables. This flexibility makes it particularly appealing for users who are not overly familiar with ML algorithms, as it provides an accessible way to experiment with different models and determine which one performs best for their unique business needs. The simplicity of the interface also ensures that using it requires little training and can be mostly intuitive. By bridging the gap between AI capabilities and practical usability, this platform offers smaller firms an opportunity to compete on a level playing field with their larger counterparts while encouraging broader AI adoption across various industries. Such algorithms hold immense potential to revolutionize small construction companies, as they can provide firms with evidence-based, data-driven insights that were previously only accessible to larger firms. MAP can help more compact companies optimize their project timelines by using their historical data, similar to the larger firms, and then predict any probable delays or other issues. It can also help to improve estimation by identifying patterns (if any) in past projects, helping employees build more accurate and competitive bids. Most importantly, platforms like MAP need not be limited to any singular industry; the application can be used to predict patterns in other firms looking for a simple application to test out predictive algorithms for their data. Future and ongoing work on MAP includes testing and validating it on real-world construction data from construction companies across the continent.

Abstract

Rising global temperatures and more frequent extreme weather events have made air conditioning systems essential for maintaining indoor thermal comfort. Building engineers often rely on real-time data to optimize energy retrofits that can also help improve building thermal resilience against these extreme climate events. However, older buildings often lack the automation commonly found in new structures with wired/wireless sensory networks, making retrofitting both costly and labor-intensive. Therefore, this paper introduces a novel framework that combines Building Information Modeling (BIM) with semi-autonomous mobile robots for efficient real-time indoor ambient data collection. BIM serves as a centralized knowledge base for spatial maps and navigation plans for unmanned ground mobile robot (UGR) equipped with sensors. These robots use advanced navigation and drift-correction algorithms to efficiently collect indoor environmental data, including temperature, humidity, and CO_2 levels, in complex indoor environments. The collected data is visualized on a web-based platform, enabling facility managers to make informed decisions and remotely control HVAC systems for greater operational flexibility. This framework was implemented in a case study demonstrating its capability for collecting spatial and temporal ambient data and visualizing them to support human-centered energy-efficient building operations. The results emphasize the framework's scalability, cost-effectiveness, and use case in various building types.

Keywords:
BIM; IoT; Mobile Robot; UGR; Indoor Environmental Quality

1 Introduction

The growing global demand for energy-efficient indoor environments highlights the critical need for innovative approaches to managing Heating, Ventilation, and Air Conditioning (HVAC) systems, which are among the most energy-intensive components of buildings. With individuals spending nearly 80% of their time indoors [1], buildings account for 40% of total global electricity use [2]. According to the International Energy Agency (IEA), 3.6 billion cooling appliances are currently in use worldwide. This number is projected to surge to 14 billion by 2050 if equitable access to cooling is provided [3]. Additionally, the frequency of extreme weather events is expected to rise and there is a need to address thermal resilience in buildings against these climate events through new construction and retrofitting. These highlight the urgent need for more innovative approaches in the built environment and more efficient and adaptive active and passive building systems. In this context, there is an opportunity to explore technologies that can optimize building energy performance and occupant thermal comfort through advanced monitoring and data-driven control strategies.

The effective optimization of building energy use and thermal comfort requires a holistic understanding of various interconnected systems, including the building's mechanical and electrical components, occupant behaviors, as well as external factors like weather patterns. To achieve this, a significant amount of data must be continuously gathered, analyzed, and managed at different scales (e.g., granular levels such as individual rooms and floors). Prior research has shown that whether in real-time, near real-time, or through batch processing, data-driven insights can enhance energy efficiency and occupant comfort [4]. However, the challenge lies in the efficient collection of high-quality spatial and temporal data, particularly in existing buildings where constraints

on system retrofitting can limit the implementation of modern energy management strategies.

The use of wired and wireless sensor technologies has revolutionized data collection in building [5]. Traditionally, inspectors manually collected data through time-intensive processes that yielded limited information. With the integration of wired and wireless sensors into Building Automation Systems (BAS), the need for manual inspections has been greatly reduced. In newly constructed buildings, sensors are often pre-installed and integrated into the operational infrastructure. However, for older buildings, retrofitting such systems is challenging due to high installation costs, labor-intensive processes, and limitations on building closure for such retrofitting [6]. Wired systems, commonly used in applications like video surveillance, are particularly costly and less feasible for larger structures such as dormitories and office complexes, where extensive wiring and installation efforts are required [7]. These challenges necessitate innovative and technological solutions for cost-effective and flexible data collection. UGR provides a promising alternative, offering a versatile and cost-effective approach to collect real-time data without the need for extensive building updates in existing buildings to understand the existing conditions to make informed decisions. By navigating through building interiors autonomously, these robots can gather critical environmental data, overcoming the constraints of traditional wired systems and manual inspections.

2 Background

The use of sensors for indoor environmental data collection is a fundamental approach to improving energy efficiency and thermal comfort in buildings, particularly in regions with extreme climates. In tropical regions, where the adoption of air conditioning systems is on the rise due to the increase in extreme heat events, sensor networks are essential for optimizing HVAC operations. Sensors such as temperature, humidity, Particulate Matter (PM), Carbon Dioxide (CO_2), and occupancy detectors enable real-time monitoring of indoor environmental conditions, allowing for more precise control of air conditioning systems [8], [9]. Research has demonstrated that sensor-based systems can significantly reduce energy consumption by providing actionable data for adjusting HVAC settings based on actual environmental conditions rather than static, user-determined settings [10]. However, in tropical climates, a common issue is that users tend to "over-control" temperature settings, leading to inefficiencies such as excessive compressor operation, which increases power consumption without necessarily improving comfort [11]. The integration of more intelligent sensor systems can help mitigate such over-control by providing data-driven insights and optimizing temperature regulation.

Building Information Modeling (BIM) combined with robotics is an emerging approach for real-time ambient data collection in buildings, especially in complex or older environments where traditional sensor installation might be challenging due to cost, labor, or installation time requirement [12]. UGR, equipped with sensors, can autonomously navigate indoor spaces to collect data on temperature, humidity, and air quality, feeding this information into BIM and Building Energy Modeling (BEM) tools for analysis and optimization. This integration allows for the creation of detailed, dynamic simulation models that provide accurate spatial and environmental insights, which can then be used to tune building operations (e.g., operation of HVAC systems) [13]. Additionally, UGR can access areas that are difficult or impractical for human intervention, making data collection more efficient and comprehensive. Studies have shown that this approach not only improves thermal comfort but also supports energy-efficient building management, particularly in older structures that lack required levels of automation.

The integration of BIM, sensors, and robotics has the potential to revolutionize building management by offering a holistic solution to the challenges of ambient data collection and energy optimization. Recent studies highlight the interactions between these technologies, where BIM provides a comprehensive spatial framework, sensors deliver real-time environmental data, and robotics ensure efficient and flexible data collection in difficult-to-reach areas [14]. Hu et al. developed "AirScope," a robotic system using distributed deep Q-learning to monitor indoor air quality, effectively reducing data latency and optimizing cooperative route planning [15]. Cao et al. proposed an intelligent construction robot system using BIM-based navigation maps, camera calibration, and A* and TEB algorithms for autonomous navigation and obstacle avoidance, demonstrating its feasibility for advancing construction automation [16].

This paper presents a novel framework integrating BIM with UGR for real-time indoor environmental data collection in indoor spaces, particularly addressing the challenges of retrofitting in older buildings that do not have modern Building Management System (BMS). In this study, spatial maps and navigation plans are generated from the building's BIM model for UGR equipped with lightweight sensors. These UGRs efficiently navigate complex environments to collect critical data such as temperature, humidity, PM and CO_2 levels. The collected data is processed and visualized on a web-based platform, providing facility managers with actionable insights for optimizing HVAC systems. An experimental case study demonstrates the framework's

effectiveness, showcasing its scalability, cost-efficiency, and suitability for diverse building types. The results highlight the framework's potential to transform building operation management practices in existing buildings with minimal infrastructure investments, contributing to global sustainability goals.

3 Research Methodology

This section outlines the conceptual framework and methodology of the study, detailing different phases and system implementation. The study integrates BIM, Internet of Things (IoT) sensors, and semi-autonomous robotics in a case study. BIM semantic data is used for navigation, allowing the UGR to move autonomously. The robot, equipped with IoT sensors, collects environmental data, which is stored in a cloud database and visualized on a web-based BIM platform.

3.1 Framework

The framework begins with the extraction of data from an Industry Foundation Classes (IFC) file, which represents the building's geometry and structure within BIM. This data is processed to create a spatial map of the building, defining key building components such as walls, doors, and rooms. The spatial map enables a semi-autonomous robot equipped with IoT sensors to navigate through the building and collect environmental data, including temperature, humidity, PM, and CO_2 levels. This information is stored in a cloud-based database and accessed via a REST API for visualization on the BIM web platform, allowing facility managers to make real-time adjustments to HVAC systems in order to improve energy efficiency, occupant thermal comfort, and indoor air quality. Figure 1 provides an overview of the framework.

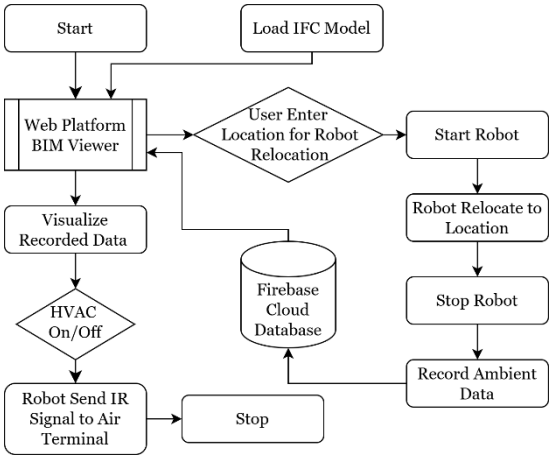

Figure 1. Overview of the proposed framework.

The process begins with loading an IFC file onto the web platform. The user then specifies the robot's starting location, from which it autonomously moves through the building, collecting and uploading data to the Firebase Cloud database. The retrieved data is displayed on the platform in a user-friendly interface, enabling informed, data-driven decisions to enhance building operations and indoor environmental quality.

3.2 Web Platform

The web platform for data visualization and control is built with IFC.js, a JavaScript library that enables the visualization of IFC data in web applications. It displays building geometry, sensor data, and system performance in an intuitive and user-friendly interface. The backend is powered by a Node.js server that runs Python scripts for processing navigation maps and retrieving sensor data from the cloud database to the web platform. For cloud data storage, the platform uses Firebase's Database, a cloud-based NoSQL solution. Firebase's real-time data syncing capabilities ensure instant updates across all connected devices, critical for real-time monitoring applications. Using a combination of TypeScript and Python, the platform offers a scalable solution for monitoring building conditions, allowing facility managers to optimize HVAC operations and remotely control the robot. Figure 2 shows a snapshot of the web platform with two windows: one for visualizing sensor data and controlling HVAC operations, and the other one for robot control and navigation plan.

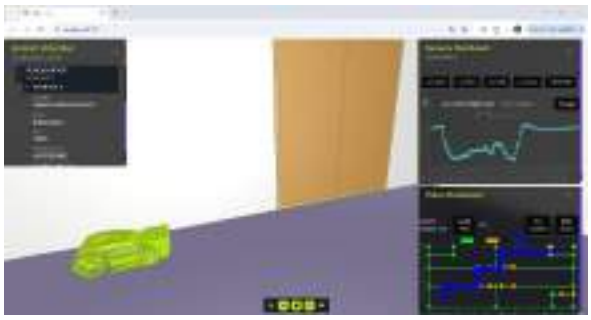

Figure 2. User interface for developed web platform for robot control and ambient data visualization.

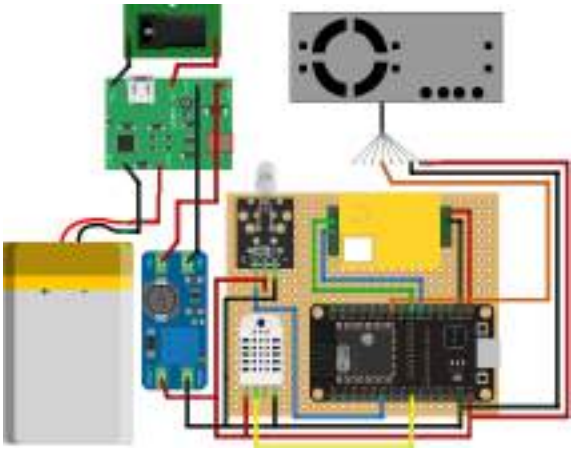
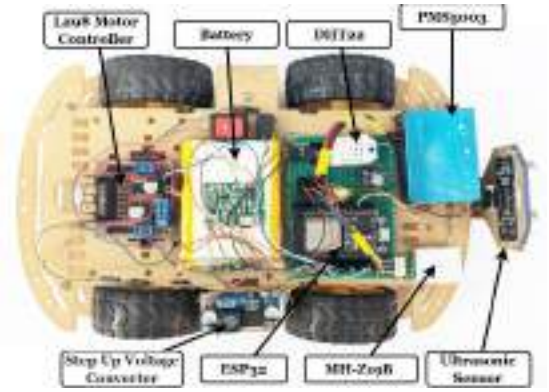
3.3 UGR and Sensor Module Development



A. UGR Robot Development

The UGR is a compact and efficient platform for autonomous ambient data collection. It features a 256 × 150 × 2 mm chassis with a 500 g load capacity, ensuring a lightweight and durable build. Equipped with 65 mm wheels, it offers smooth mobility across indoor surfaces. The robot is powered by a 3.7V, 5000mAh lithium-ion battery with a step-up converter to supply the required



voltage for motors and sensors, providing a runtime of up to 4 hours on a full charge. ESP32-WROOM microcontroller enables wireless communication and real-time sensor data processing, making it an effective solution for environmental monitoring and smart automation applications.

B. Sensing Module Development

The framework includes IoT-based sensors installed on a UGR for ambient data collection. It includes a DHT22 for temperature and humidity recording, PMS5003 for particulate matter measurement, and the MH-Z19B sensor for CO_2 measurement. The DHT22 sensor provides high accuracy for temperature and humidity measurements, with a temperature accuracy range of ±0.5°C and a humidity accuracy of ±2-5%. This makes it ideal for indoor climate monitoring [17]. The PMS5003 sensor delivers real-time particulate matter (PM2.5 and PM10) data with an accuracy of ±10 µg/m³, ensuring a healthy indoor environment [18]. The MH-Z19B is a reliable sensor for measuring CO_2 concentrations, offering an accuracy of ±50 ppm in the range of 400-5000 ppm, contributing to comprehensive indoor air quality monitoring [19]. These sensors are connected to an ESP32-WROOM microcontroller, which interfaces with a Wi-Fi network. Data recorded by the sensors is first stored locally on the ESP32 and then transmitted to a Firebase database via HTTP POST requests, ensuring efficient and reliable data management. Figure 3 illustrates the circuit diagram of the sensor setup and their installation locations on the UGR, providing a clear overview of the system's hardware integration.

(a)

(b)

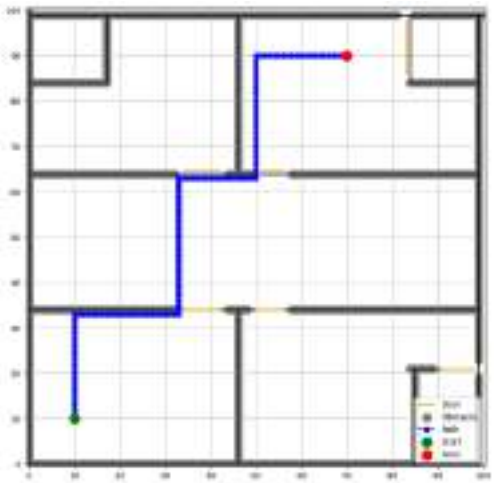
Figure 3a. Circuit diagram of the sensors installed on UGR; b. Sensors configuration on UGR.

3.4 Navigation Algorithms

The navigation of the UGR adopted in this study is based on the study by Chen et al. [20], which employs the A* algorithm, a widely applied pathfinding method in robotics. A* combines the strengths of Dijkstra's Algorithm and Greedy Best-First Search, enabling efficient navigation in complex environments [21]. This approach allows the robot to balance exploring the shortest paths while considering a heuristic to direct movement toward a target location. The process begins when a user uploads an IFC file to the platform, where different components (e.g., walls, doors, and furnishing) are extracted from the building model. Walls and furnishing are treated as obstacles, while doors are identified as access points, crucial for allowing the robot to navigate between different rooms and spaces.

When the user inputs the target room or location on the developed web platform, the target coordinates are sent to a Python script via a HTTP POST request. The algorithm then calculates the optimal path from the robot's current location to the target destination, ensuring that obstacles are avoided and that the robot can efficiently move to the target point. Once the path is identified, the Python code computes the distances and angles required for navigation. The path is displayed on a 2D graph for the user's review. Upon user acceptance of the path, the path data is uploaded to the cloud database. This data includes the distance the UGR needs to traverse and the angles at which it must turn. Once the path data is successfully stored, the robot initiates its movement towards the targeted location, which may be a space, room, corridor, or other predefined area. Upon arrival at the target location, the robot begins recording relevant data, which is subsequently stored in the cloud database for further analysis and processing. Figure 4. provided shows a building plan where walls are represented as obstacles and doors as access points. The robot's path is illustrated with blue lines, highlighting the

optimal route calculated by the A* algorithm from the starting location to the target room. The figure highlights how the robot navigates around obstacles and through access points, offering a clear representation of its motion path within the building layout.



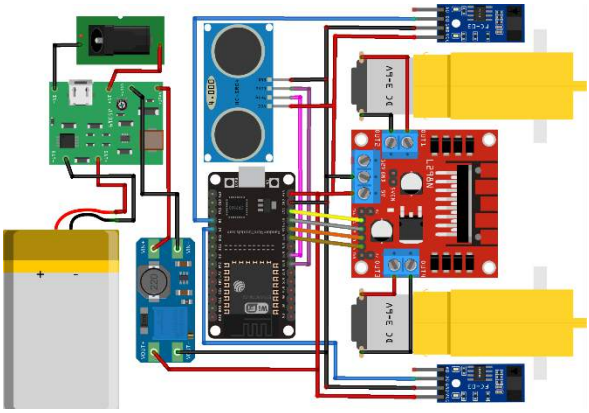


Figure 4. UGR Navigation Path in a 2D Building Layout with Obstacles and Access Points.

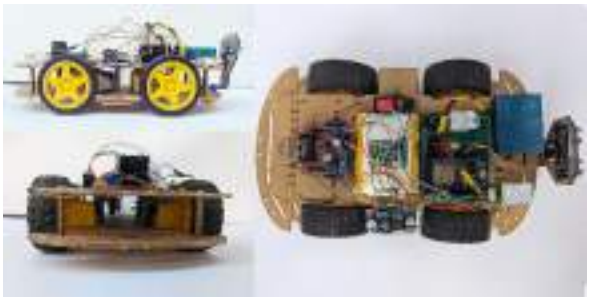

3.5 Robot Working

The UGR used for data collection is a four-wheel-drive vehicle powered by gear motors with speed encoders and is controlled via an LM298 motor driver [22], [23]. The robot's movements are managed by the motor driver and an ESP microcontroller. In addition to motor control, an ultrasonic sensor is employed in front of the robot for obstacle detection, ensuring the robot can avoid unexpected objects and navigate safely in dynamic environments [24]. Given the low-cost nature of the prototype, the dynamic obstacle avoidance approach is simple yet effective. When an obstacle appears in the robot's path, it initially pauses and waits for the obstruction to clear. If the obstacle remains stationary, the UGV adjusts its path by turning left or right to navigate around it, ensuring continued movement without complex real-time mapping. Once the A* algorithm sets the path, the distance and angle the robot needs to cover are stored in a cloud database. When the user clicks the "Start Robot" button on the platform, the ESP retrieves this data and directs the robot to travel the specified distance and angle. The speed encoder counts the wheel revolutions to ensure the robot stops after covering the required distance. The LM298 motor driver enables bidirectional control, allowing the robot to move forward, backward, or rotate, while the speed controller ensures smooth and precise movement.

This cost-effective setup allows the robot to navigate complex indoor environments and collect environmental data efficiently, with minimal disruption. Figure 5a shows the circuit diagram of the developed UGR, illustrating the connections between the ESP, LM298 motor driver, motors, speed encoders, and the power circuit, while Figure 5b displays images of the developed robot, highlighting the configuration of all sensors and hardware components in the actual setup.

4 Result and Discussion

4.1 Experimental Setup of Case Study

To test the accuracy and efficiency of the developed framework, an experimental study was conducted in a 9x12m indoor space comprising four rooms. The robot successfully navigated through the test environment, using its integration with BIM to access accurate spatial maps. This integration allowed the robot to traverse complex indoor layouts with ease. The A* algorithm, combined with drift-correction mechanisms, ensured optimized movement, achieving precise path planning and time-efficient navigation. Upon reaching designated locations, the robot began collecting real-time environmental data on temperature, humidity, PM2.5,

PM10, and CO_2 levels. The results demonstrated the framework's reliability, as the robot's trajectory closely followed the planned navigation path in dynamic indoor conditions. However, since the current system relies on non-autonomous navigation, it lacks real-time path adaptation and localization. This odometry-based approach is susceptible to cumulative drift and relies on predefined paths, limiting its ability to handle unexpected obstacles or environmental changes. While effective in structured environments, its performance can be affected in dynamic settings, where real-time localization and adaptive path planning would improve overall navigation accuracy.

4.2 Results and Interpretations

The environmental data collected by the robot was continuously logged over a 24-hour period, with measurements taken every 5 minutes. As shown in Figure 6, the temperature and humidity levels are plotted on a dual-axis graph, clearly illustrating the inverse relationship between these two parameters. The general trend in the data can also be observed with 3rd-degree polynomial illustrated in the graph. The temperature showed moderate fluctuations, ranging from a minimum of 10.1°C to a maximum of 14.0°C, with an average of 12.2°C. In contrast, the humidity remained relatively stable, fluctuating between 50.0% and 72.5%, with an average of 67.6%. This automated data collection ensured accuracy and consistency, eliminating the need for manual measurements and providing a comprehensive dataset.

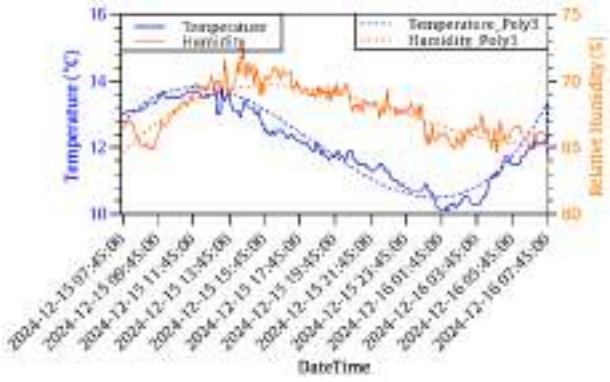

Figure 6. Recorded temperature (°C) and humidity (%) data over 24 hours.

Air quality data, including PM2.5 and PM10, are depicted in Figure 7. The graph demonstrates distinct spikes in particulate matter concentrations at specific times, likely corresponding to activities such as cleaning or movement within the test environment. Despite these occasional fluctuations, the overall air quality remained within acceptable indoor thresholds based on WHO standards. PM2.5 levels for the recorded data ranged from 13.9 to 41.6 µg/m³, with a 24-hour average of 28.7 µg/m³, slightly exceeding the WHO interim target of 25 µg/m³. PM10 levels varied between 15.6 and 47.8 µg/m³, with a 24-hour mean of 33.0 µg/m³, well within the WHO guideline limit of 50 µg/m³. The generalized trend observed in the data is shown using a 3rd-degree polynomial on the graph. These values reflect indoor air quality for the test space, where particulate matter concentrations can vary slightly throughout the day. The use of a dual-axis scale in this graph effectively highlights the differences in magnitude and trends between PM2.5 and PM10 levels, providing a clear representation of the data.

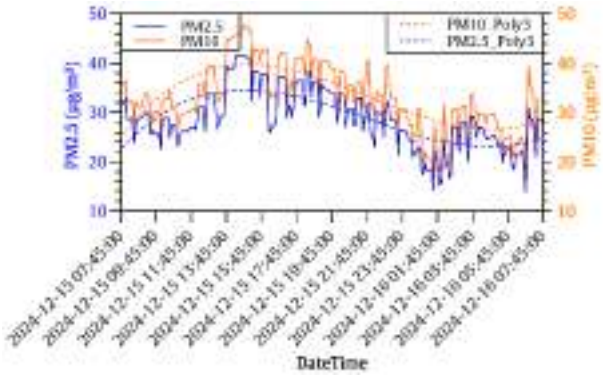

Figure 7. Recorded PM2.5 and PM10 (µg/m³) concentrations over 24 hours.

Figure 8 shows the CO_2 levels, revealing moderate fluctuation, peaking at 1022 ppm with 75% value at 719 ppm. These trends emphasize the importance of adequate ventilation in maintaining healthy indoor air quality. The CO_2 levels in collected data ranged from 446 to 1022 ppm, with an average of 666 ppm, indicating moderate fluctuations throughout the day. Though there are higher fluctuation in data; the overall trend shown on the graph confirms that CO_2 levels remained below critical thresholds, reflecting good ventilation in the test space. The observed indoor environmental data trends not only showcase the robot's ability to collect accurate and real-time data but also provide valuable insights into environmental dynamics over time.

These results highlight the potential of using a UGV for ambient data collection, particularly in retrofit building applications where installing stationary sensors can be costly and labour-intensive. A mobile robot offers a more flexible and cost-effective solution by measuring the spatial distribution of air quality, temperature and humidity across different locations. However, unlike fixed sensors that provide continuous data at a single point, the UGV collects data at intervals as it moves, which may lead to gaps in capturing sudden environmental changes. To mitigate this limitation, the sampling approach should be optimized to balance

spatial coverage and data collection frequency, ensuring a more reliable analysis.

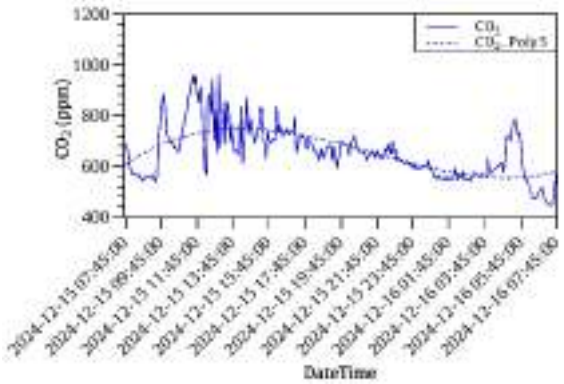

Figure 8. Recorded CO_2 levels (ppm) over 24 hours.

4.3 Limitations

While the framework exhibited promising results, several limitations exist. One notable issue is the robot's reliance on pre-uploaded updated BIM data, which can lead to navigation or data collection inaccuracies if the models are outdated or incomplete. This is certainly an important aspect to be addressed in future work for buildings without any prior BIM documentation. Additionally, the system's performance in highly dynamic or crowded environments has not been fully tested, and testing in such environments may shed light on further adaption to rapid changes or irregular conditions by improving the state-of-the-art algorithms. Another critical limitation is the need for continuous wireless internet access, as the robot depends on real-time data transmission and communication with the server for data processing and navigation updates.

The current sensor setup is limited to a small set of environmental parameters such as temperature, humidity, PM2.5, PM10, and CO_2. Expanding the range of measurable parameters by incorporating additional sensors comparing the data with that from stationary sensors installed in various spaces could provide a more holistic environmental analysis. Furthermore, the accuracy of the robot may vary, as odometry is prone to surface slippage and wheel malfunction, leading to cumulative errors over time. Future research is needed to focus on enhancing navigation algorithms, expanding sensor capabilities, and addressing the requirement for continuous internet access to ensure seamless operation in diverse and dynamic environments.

5 Conclusion

The study presents a novel framework that integrates BIM and semi-autonomous mobile robots to address the challenges of real-time ambient data collection in older buildings with limited automation infrastructure. By using BIM for spatial mapping and navigation, the proposed system enables efficient robot movement and accurate environmental monitoring. The framework demonstrated its ability to collect minimum critical indoor environmental data parameters, including temperature, humidity, particulate matter, and CO_2 levels, in a scalable and cost-effective manner. The real-time data visualization on a web platform further empowers facility managers to optimize HVAC operations, improving both energy efficiency and occupant thermal comfort. Results from the case study confirmed the system's reliability, with consistent data accuracy and efficient robot navigation, even in complex indoor layouts.

While the findings highlight the potential of this framework to transform building management practices, certain limitations must be addressed. The reliance on updated BIM models and consistent wireless connectivity poses challenges for dynamic or crowded environments. Additionally, the limited range of sensors restricts the scope of environmental analysis. Future research should focus on enhancing navigation algorithms for greater adaptability, expanding the sensor suite to cover more environmental parameters, and developing offline capabilities to mitigate connectivity issues. Despite these limitations, this study provides a solid foundation for scalable, real-time ambient data collection, contributing to sustainable and resilient building operations.

Abstract –

The construction industry is undergoing a rapid transformation through the integration of digital technologies and construction. These advancements drive methods like object detection, enabling applications such as progress monitoring and material reuse to support sustainability goals. By fostering innovation, reducing material waste, and promoting circular economy principles, these technologies hold immense potential to revolutionize construction practices. However, the scarcity of dataset availability significantly hinders the development of effective machine learning (ML) applications in construction. Manual data collection remains resource-intensive, error-prone, and time-consuming, creating further barriers. This study introduces an automated methodology that combines web scraping and Large Multimodal Models (LMMs) to address these limitations. Using the Gemini Vision model, over 55,000 images were collected, including 2,691 identified as containing structural steel components—such as beams, columns, trusses, steel frames, and steel structures. Metadata generation achieved 94.8% accuracy, enabling efficient categorization through a rule-based filtering approach. The proposed methodology bridges significant gaps in the current literature by delivering a scalable, reusable framework for dataset development tailored to construction applications. By automating data acquisition and metadata generation, it enhances dataset usability for methods like object detection and applications such as progress monitoring. This research establishes a foundation for advancing AI-driven solutions in construction automation and sustainability, contributing to the industry's digital transformation.

Data Acquisition; Web Scraping; Construction Automation; Large Multimodal Models (LMMs); Metadata Generation; Dataset Scalability; Structural Steel Components; Automated Dataset Development.

1 Introduction

The construction industry is undergoing a transformation by the integration of digital and automated technologies. The advancements enhance efficiency, accuracy, and sustainability in tasks in tasks such as object detection for progress monitoring and material reuse planning [1–3]. These technologies hold immense potential to improve construction workflows, reduce material waste, and promote circular economy principles [4–7]. However, fully leveraging these technologies is hindered by the scarcity of high-quality domain-specific datasets, i.e. structural steel components. This limitation hampers the development, validation, and deployment of machine learning (ML) models for critical applications, including structural steel reuse, deconstruction progress monitoring, and material tracking [8–10].

Existing studies underscore the importance of datasets for progress monitoring for accurately identifying and categorizing construction materials, such as structural steel components, based on their properties, dimensions, and suitability for reuse [11–13]. However, many available datasets suffer from limited scope, inadequate diversity, and insufficient annotation quality, making them unsuitable for training robust ML models. For instance, datasets for structural steel applications often lack crucial elements such as component geometries, detailed metadata, and standardized classifications—key requirements for ML-driven solutions [14]. Moreover, manual data collection methods frequently used in this domain are labor-intensive, time-consuming, and prone to inconsistencies, further compounding the issue [15–17]. These challenges highlight the vital need for automated, scalable methodologies to develop precise and standardized datasets for ML applications.

Web scraping has emerged as a powerful tool to address these challenges by automating the collection of large datasets from diverse online sources [18] This technique has been successfully applied in domains such as healthcare and

natural disaster monitoring, demonstrating its scalability and efficiency [19,20]. In construction, web scraping has shown promise in aggregating information on materials, components, and project designs, offering a viable alternative to manual data collection [21,22]. By scraping images and metadata of structural steel components from online sources, this approach can create datasets with sufficient volume and diversity to support advanced ML applications. Additionally, web scraping addresses challenges like inconsistent webpage structures and data cleaning, ensuring comprehensive and high-quality datasets [23–25].

Recent advancements in artificial intelligence, particularly in Multimodal Models derived from Large Language Models (LLMs) such as GPT-4 and Gemini Vision, further enhance the potential for dataset generation [26]. Multimodal models combine visual and textual processing capabilities, making them uniquely suited for tasks such as metadata generation and image classification [27]. These models analyze both image content and contextual text to produce descriptive metadata, enabling hierarchical organization and effective classification [28,29]. Unlike manual annotation methods, which are error-prone and inefficient, multimodal models offer unparalleled accuracy and scalability when processing large datasets [20]. Furthermore, their ability to analyze and generate structured descriptions from unstructured data makes them indispensable for research in this domain [20,30].

Despite these advancements, three critical gaps remain: (1) a lack of scalable, automated methodologies for creating domain-specific datasets in construction; (2) underutilization of multimodal models for metadata generation and hierarchical organization; and (3) insufficient exploration of the broader potential of datasets, such as their reuse in deconstruction, material tracking, or progress monitoring to support sustainability goals. Addressing these gaps is essential to advancing the field and enabling meaningful applications in construction automation, precision engineering, and sustainable practices.

This study addresses these challenges by presenting an automated methodology that integrates web scraping, multimodal models, and data organization techniques to create a scalable and reusable dataset for structural steel components. By automating the entire process—from data collection to organization—this methodology establishes a robust foundation for training ML models tailored to construction applications. Furthermore, the structured and annotated dataset produced by this study directly supports circular economy principles by facilitating material reuse, reducing waste, and optimizing resource utilization. These contributions align with sustainability goals by minimizing the environmental impact of construction practices and promoting efficient workflows, offering valuable solutions for the industry's transition toward more sustainable operations[31].

2 Objectives

This study presents an automated methodology that integrates web scraping and Large Multimodal Models (LMMs) to generate standardized, structured datasets for construction. The methodology addresses critical challenges of dataset scalability, usability, and annotation quality, with a focus on consistent and accurate component type labeling. The key objectives include: (1) develop an automated web scraping pipeline to efficiently collect construction-related images from diverse online sources; (2) utilize multimodal LMMs to generate descriptive metadata for each image, enabling precise identification and classification of construction components; (3) implement a keyword rule-based categorization system to filter and organize images into a hierarchical folder structure that represents unique construction components, improving the usability and accessibility of the dataset; and (4) preparing a dataset with unique identifiers for each image to ensure consistency, standardization, and usability for downstream applications, such as training object detection models and supporting progress monitoring and sustainability-driven practices.

3 Methodology

This study employed a systematic, multi-phase methodology to acquire, process, and categorize data related to structural steel components. Each phase was carefully designed to ensure quality, reliability, and scalability while addressing the challenges posed by diverse and large-scale datasets. The workflow depicted in Figure 1 comprises four main steps: (1) data acquisition, (2) metadata generation, (3) dataset categorization, and (4) standardization.

3.1 Phase 1: Data Acquisition

The first phase aimed to automate the acquisition of structural steel images and metadata from online repositories and websites. This required developing a robust web scraping pipeline capable of navigating diverse and often unstructured web sources.

3.1.1 Web Scraping Implementation

The web scraping pipeline was implemented in Python, incorporating the following core libraries: *BeautifulSoup* for parsing *HTML* and *XML* documents, and *Requests* for sending *HTTP* requests and retrieving webpage content, and *Urllib* for *URL* parsing and management. Figure 2 illustrates the pseudocode for the web scraping pipeline, detailing its core components; URL sanitization, dynamic crawling, image downloading, and data organization. The pipeline included:

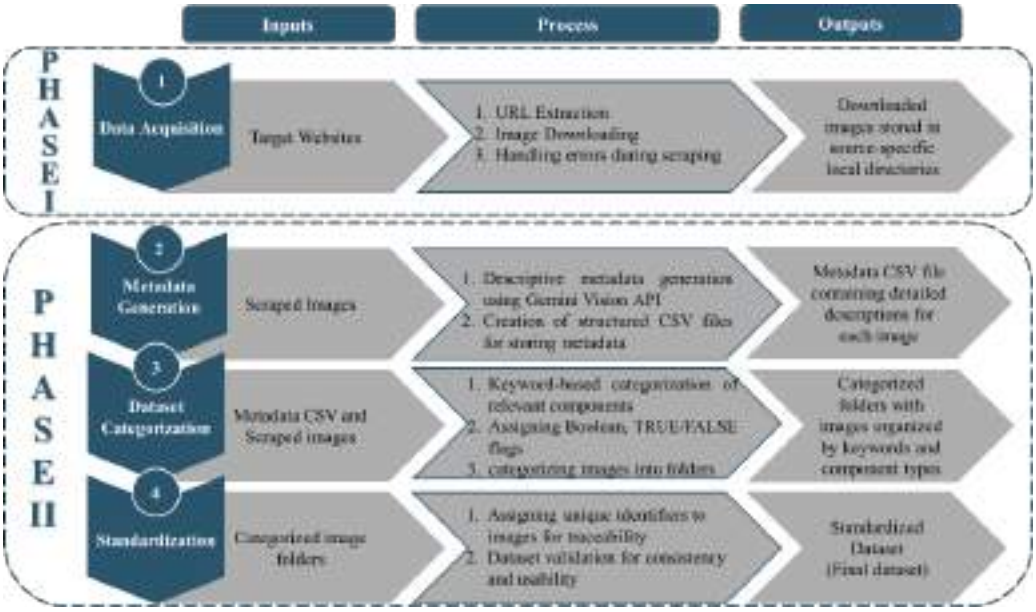

Figure 1. Workflow for Automated Dataset Generation Using Web Scraping and Large Multimodal Models

1. Sanitizing URLs and Filenames*:* A custom function, *sanitize_filename*, was designed to remove invalid characters from filenames and URLs, ensuring compatibility with file storage systems. This was achieved using Python's *re* module to apply regular expressions.
2. Dynamic Website Crawling*:* The *crawl_website* function recursively traversed web pages to retrieve images. *BeautifulSoup* was used to extract <*img*> tags, and a custom user-agent header mimicked a browser request, reducing IP blocking risks. A retry mechanism handled timeouts or rate-limit errors (HTTP 429) with randomized delays.
3. Downloading Images*:* image collection process relied on a targeted web scraping pipeline designed to extract domain-specific images related to structural steel. Relevant websites, including construction-focused repositories, engineering resources, and online catalogs featuring structural steel components (e.g., trusses, beams, columns, and frames), were identified and prioritized. Specific keywords such as "structural steel components," "steel trusses," "steel beams," and "steel frames" were used to guide the search and refine the scraping process. The *download_image* function saved images from extracted URLs into source-specific directories to facilitate later validation and traceability.
4. Handling Large-Scale Data**:** The pipeline could handle up to 100 pages per website and included delays between requests to avoid server flags. The *os* library was used to create a structured directory system for efficient data management.

```
IMPORT required libraries: requests, BeautifulSoup, os, re, random
  SET base_url and target folder for image downloads
  DEFINE User-Agent for headers

DEFINE FUNCTION sanitize_filename(filename):
    REMOVE invalid characters using regex
    RETURN cleaned filename

DEFINE FUNCTION download_image(url, folder):
    SEND GET request with headers
    IF successful:
      SAVE image to the target folder with sanitized filename

DEFINE FUNCTION scrape_images(page_content, folder):
    PARSE page content using BeautifulSoup
    EXTRACT image URLs and call download_image()

DEFINE FUNCTION crawl_website(base_url, folder):
    FETCH page content
    CALL scrape_images()
    RECURSE for linked pages

DEFINE MAIN FUNCTION():
    SET base_url and target folder
    CALL crawl_website(base_url, target folder)

CALL MAIN FUNCTION() to execute the web scraping process
```

Figure 2. Pseudocode illustrating the automated web scraping pipeline.

3.1.2 Data Volume and Storage

The scraping process collected 55,926 images, organized into source-specific folders. Each image's metadata (e.g., source URL and filename) was logged for validation, ensuring efficient management and traceability in subsequent phases. Figure 1 provides a high-level overview of this process.

3.2 Phase 2: Metadata Generation, Categorization, and Standardization

The second phase aimed to enhance the collected images with detailed metadata, categorize the data, and prepare a standardized dataset for downstream applications. This phase covered Steps 2–4 of the methodology.

3.2.1 Metadata Generation

Metadata for the dataset was generated using Gemini Vision, a state-of-the-art Large Multimodal Model (LMM) designed for analyzing visual content and generating textual descriptions. The metadata generation process was implemented in Python and executed on Google Colab, leveraging its computational capabilities for efficient large-scale processing. The Gemini Vision API was used for descriptive text generation, as illustrated in Figure 3.

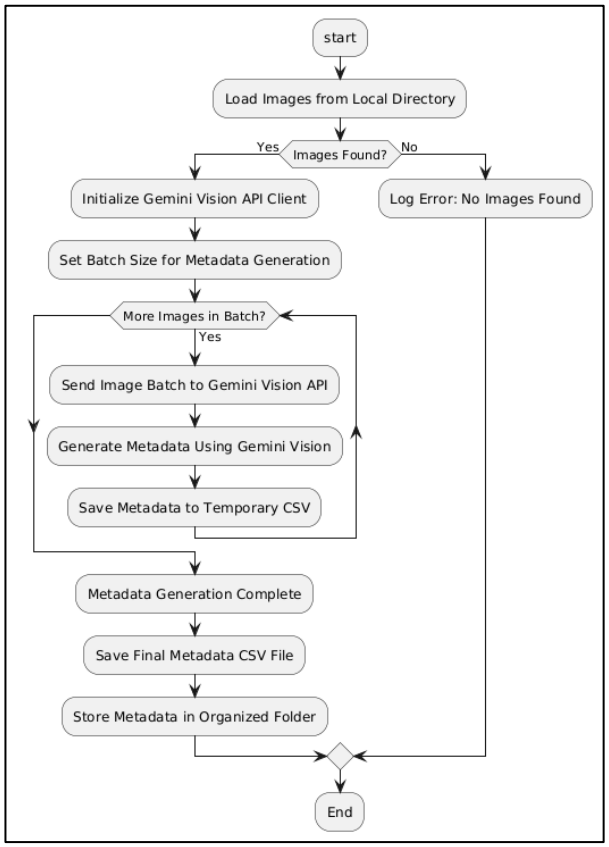

Figure 3 Workflow for metadata generation using Gemini Vision

1. Parallel Processing: To handle the large-scale dataset effectively, the *process_images_in_folder* function utilized Python's *ThreadPoolExecutor* for parallel processing. This approach distributed the workload across multiple system cores, significantly reducing processing time while ensuring scalability.
2. Error Handling: The system incorporated robust error-handling mechanisms. Issues such as corrupted image files or API timeouts were intercepted and logged with detailed error messages. Failed images were either skipped or re-queued for reprocessing, ensuring minimal data loss.
3. Metadata Validation: he metadata descriptions generated by Gemini Vision were stored in a structured Pandas DataFrame, paired with unique image IDs for traceability. To ensure accuracy, random samples (5% of the dataset) were manually reviewed, verifying their consistency with the actual visual content.

3.2.2 Metadata Example and Storage

Each metadata record included two essential fields; image ID: a unique identifier for each image, ensuring traceability, and description: a textual description generated by Gemini Vision, detailing the image's content. The final metadata was exported to a structured CSV file (*image_dataset_preparation.csv*) to facilitate seamless integration into downstream processes. This standardized file format ensured seamless integration into subsequent phases, enabling efficient accessibility and usability.

3.2.3 Rule-Based Categorization

A Python function, *extract_steel_structures*, scanned metadata descriptions for keywords indicating structural steel components (e.g., "beam," "column," "truss," "steel frame"). The categorization steps were (as illustrated in Figure 4):

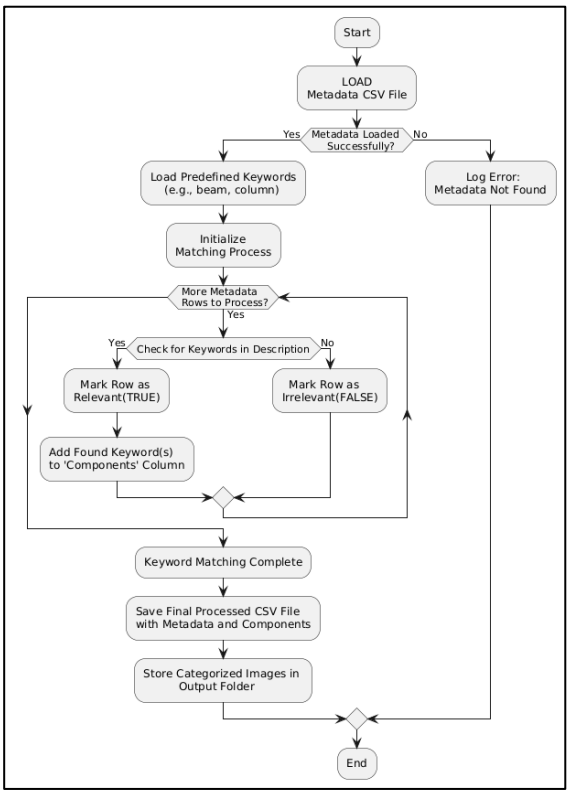

Figure 4 Keyword Matching Flowchart

1. Keyword Matching: Regular expressions were employed to identify variations in phrasing, such as "steel trusses" and "trusses of steel."
2. Field Assignment: Two fields were populated for each image: "*steel_structure"* a Boolean field *(TRUE/FALSE)* indicating the presence of structural steel components and "*components"* which is a list of matched keywords representing specific structural elements.

3.2.4 Validation and Refinement

To ensure the dataset's accuracy and reliability, a validation and refinement process was conducted. A diverse 5% sample of the dataset was manually inspected for categorization accuracy. Discrepancies, such as false positives and ambiguous descriptions, were analyzed to refine keyword matching rules. This iterative process improved classification precision and enhanced the overall quality of the dataset.

3.2.5 Final Dataset

The final dataset included 2,691 images, each labeled as TRUE for containing structural steel components. These images were categorized into the following components: beams: 1,716 images; columns: 554 images; steel frames: 169 images; trusses: 116 images; and steel structures: 506 images.

4 Results and Discussions

The proposed methodology successfully generated a comprehensive dataset of 2,691 structural steel images from an initial pool of 55,926 images retrieved from various online sources. This process demonstrated the robustness and effectiveness of the methodology in automating large-scale data acquisition, metadata generation, and dataset standardization, specifically tailored for construction applications. Each stage of the workflow addressed critical challenges, including data scarcity, inconsistent metadata, and the need for scalable solutions to support machine learning applications in the construction sector.

The web scraping process retrieved 55,926 images from diverse online sources using a pipeline optimized for dynamic website structures and large-scale data handling. Following keyword-based filtering and metadata validation, 53,235 images were excluded due to irrelevance or insufficient metadata descriptions, resulting in 2,691 images deemed relevant to structural steel components. These components were categorized into key structural elements: beams (63.8%), columns (20.6%), steel structures (18.8%), steel frames (6.3%), and trusses (4.3%). This categorization, summarized in Table 1, reflects the prevalence of these components in real-world structural steel usage, ensuring the dataset's practical applicability for construction applications.

Table 1. Categorization of Structural Steel Components in the dataset

Component type	Count	Percentage of Dataset
Beams	1,716	63.8%
Columns	554	20.6%
Steel Frames	168	6.3%.
Trusses	116	4.3%
Steel Structures	506	18.8%
Total number of images in the dataset		2,691

The metadata generation phase utilized Gemini Vision's Large Multimodal Model (LMM) to produce detailed descriptions for each image. A sample of 5% of the dataset, approximately 135 images, was manually inspected to verify metadata accuracy and categorization reliability. Observed discrepancies, including 7 false positives caused by ambiguous descriptions, informed iterative refinements of keyword matching rules and metadata prompts. These adjustments ensured alignment between generated metadata and visual content, resulting in a high accuracy rate of 94.8%. Approximately 5.2% of the metadata required manual correction due to ambiguity or incomplete details. Examples of metadata descriptions and their associated categorization are presented in Figure 5.

The metadata generation process, as summarized in Table 2, was completed in 11 hours and 42 minutes. This time refers exclusively to the metadata generation process, including image annotation and description. The workflow was implemented using Python on Google Colab, leveraging Python's *ThreadPoolExecutor* for parallel processing to efficiently handle the large-scale dataset. The computing environment included a Google Colab Pro+ subscription, providing access to an NVIDIA Tesla P100 GPU and 16 GB of RAM, which ensured sufficient computational power for metadata generation. This setup facilitated concurrent processing of multiple images, significantly reducing runtime. Dynamic crawling and retry mechanisms effectively mitigated errors caused by website structures and rate limits. This dataset provides valuable insights into structural steel components, including the unique geometries of trusses and steel frames frequently used for load distribution in roofing systems and other applications. It supports downstream machine learning applications, such as object detection models for automated progress monitoring on construction sites. Additionally, the categorized dataset holds potential for circular economy practices, enabling the identification and reuse of structural steel components during deconstruction and other sustainability-focused activities.

1	Image ID	Description	steel_structure	components
125	ecf40e32-07a5-4f44-ae42-599650b07b7e	The image shows a steel structure of a building under construction.	TRUE	steel structure
126	f935743a-4731-4c00-b64a-c19de3f474c3	The image shows a metal framework of a building under construction. There are many steel beams and girders, and the ceiling is made of corrugated metal.	TRUE	beam
127	d8e96038-154c-4474-9549-de60d88b449e	The image shows a steel structure of a building under construction. The structure consists of columns, beams, and trusses. The columns are vertical members that support the beams. The beams are horizontal members that span between the columns. The trusses are triangular members that support the roof.	TRUE	beam, column, truss
128	8e37c727-c9c4-4a5b-b422-233621258bb6	A steel frame of a container, likely used for shipping or storage.	FALSE	
129	670de234-a2c0-41dd-9a05-3374b1984fb4	The image shows a steel structure of a building under construction. There are a lot of steel beams and columns. The beams are connected to the columns with bolts and nuts. The columns are supported by the foundation. The roof is made of metal sheets.	TRUE	beam, column
130	798a0f3a-5469-40f9-b33d-11db971a0f60	The image shows a metal frame that could be used as the base for a table, bench, or other piece of furniture.	FALSE	

Figure 5 Metadata and Categorization of Structural Steel Images

Table 2 Key performance Metrics of dataset Preparation

Metric	Value	Description
Total Images Collected	55,926	Number of images retrieved from diverse online sources.
Filtered Images	2,691	Number of images retained after keyword-based filtering.
Excluded Images	53,235	Images excluded due to irrelevance or insufficient metadata.
Metadata Accuracy (For 5% of data)	94.8%	Percentage of descriptions accurately matching image content.
Processing Speed	1.33 images/ second	Average speed achieved during scraping and metadata generation.
Time Taken	11 hours, 42 minutes	Total time taken for web scraping and dataset preparation.

The methodology demonstrated significant scalability and flexibility, overcoming challenges such as dynamic webpage structures, redundant data, and linguistic inconsistencies in metadata descriptions. Iterative refinements to scraping algorithms, metadata prompts, and keyword-based categorization rules ensured a high-quality dataset, ready for diverse construction applications. These results establish a robust framework for generating high-quality datasets and pave the way for future advancements, such as integrating real-time data acquisition and expanding to other construction materials like concrete and timber. This scalable approach sets a benchmark for automated dataset generation, enhancing the adoption of AI in construction practices.

5 Summary and Concluding Remarks

This study demonstrates how web scraping and Large Multimodal Models (LMMs) can effectively create a scalable, structured dataset tailored for construction applications. By automating data collection, metadata generation, and dataset organization, the methodology overcomes inefficiencies in manual data gathering, limited dataset availability, and insufficient annotation quality. Using Gemini Vision, descriptive metadata for 2,691 structural steel images were generated with 94.8% accuracy, selected from an initial pool of over 55,000 images. These images were categorized into beams, columns, trusses, steel frames, and steel structures, enabling streamlined tasks like object detection for progress monitoring and construction automation.

Key contributions of this study include: (1) developing an automated web scraping pipeline to

efficiently collect construction-related images from diverse online sources; (2) utilizing Gemini Vision for high-quality metadata generation to enable precise identification and classification of construction components; (3) implementing a keyword-based categorization system to organize and filter the dataset, using a rule-based approach with Boolean labels and hierarchical folder structures; (4) delivering a reusable dataset with standardized records and unique image identifiers to support downstream applications like progress monitoring and circular economy initiatives; and (5) establishing a scalable framework adaptable to construction materials beyond structural steel, including concrete, timber, and composites, to address broader dataset challenges.

While this study focuses on structural steel, the methodology is adaptable to other construction materials, offering potential for broader applications. However, the selection of websites might favor commonly available components, and keyword choices could introduce bias, influencing dataset composition. To minimize this bias, careful source selection and validation were implemented, along with a comprehensive keyword strategy designed to capture diverse naming conventions, ensuring balanced representation.

To ensure the robustness of the dataset. Future work should address discrepancies, such as false positives and overlooked false negatives, and explore cost-effective LMMs and open-source alternatives for wider adoption. Additional enhancements, such as real-time data acquisition from active construction sites and expanding the dataset to include diverse materials, would improve dataset usability and diversity. These developments would further AI-driven advancements in construction automation and sustainability initiatives. Overall, this study establishes a robust methodology for automated data generation and AI applications in construction. By addressing scalability, usability, and annotation challenges, it accelerates digital transformation, promotes sustainable practices, and lays the groundwork for future innovations in the built environment.

Abstract

Construction workers frequently encounter substantial mental stress due to the high demands of their roles, including tight deadlines and challenging environmental conditions. Although electrodermal activity (EDA) sensors offer a promising solution for monitoring stress levels, traditional designs are often inflexible, leading to issues such as poor skin contact, elevated contact impedance, and motion artifacts that compromise the quality of the collected signals. To overcome these challenges, this paper introduces a stretchable EDA sensor featuring a Peano-Gosper fractal design aimed at enhancing adaptability and minimizing motion-related interference. Through a finite element analysis, several design variations were assessed, with the fractal pattern demonstrating superior skin contact and reduced mechanical strain, making it highly suitable for real-world applications. Experimental results indicated significant advancements in signal-to-noise ratio (SNR), with the fractal-designed sensor achieving nearly 8 dB improvement compared to conventional EDA sensors during experimental construction activities. This development enhances the reliability of EDA measurements and corresponding mental stress monitoring, ultimately contributing to improved health and safety outcomes for construction workers.

EMG ; Flexible Sensor; EDA; Motion Artifact; Physiological Monitoring

1 Introduction

The construction industry has long grappled with the pervasive issue of mental stress among its workforce, a problem that has far-reaching consequences for both individual health and overall project outcomes [1]. Recent studies have indicated that construction workers experience some of the highest rates of stress-related mental health issues across all industries, with an estimated 35% reporting symptoms of anxiety or depression. This chronic exposure to occupational stress not only impacts worker well-being but also significantly increases the risk of serious health complications, including cardiovascular diseases and musculoskeletal disorders [2]. Moreover, stress-induced cognitive impairments can lead to decreased situational awareness and decision-making abilities, potentially compromising worksite safety and productivity [3,4].

Electrodermal activity (EDA) has emerged as a promising biomarker for quantifying sympathetic nervous system activation, which is closely linked to stress responses [5]. EDA measurements, which capture changes in skin conductance resulting from sweat gland activity, have shown a robust correlation ($r = 0.78$) with self-reported stress levels in controlled laboratory settings. In the context of construction, preliminary field studies utilizing commercial EDA sensors have demonstrated the potential for real-time stress monitoring [6]. However, the dynamic and physically demanding nature of construction environments presents unique challenges that often result in degraded sensor performance, with reduced SNR compared to stationary conditions.

The widespread adoption of wearable health monitoring technologies in the construction sector has been hindered by limitations in current sensor designs [7]. While significant advancements have been made in data processing algorithms and machine learning models for stress detection, the underlying hardware often fails to meet the specific demands of construction tasks [8]. Commercial EDA sensors, typically designed for general-purpose physiological monitoring, employ rigid materials and standardized form factors that are ill-suited for the diverse and strenuous activities inherent to construction work. These design shortcomings manifest in several critical issues, including increased contact

impedance due to poor skin conformity, motion artifacts from sensor displacement, and user discomfort during prolonged wear [9].

To address these challenges, this paper proposes a novel solution: a fractal-based, patch-type flexible EDA sensor specifically engineered for use in construction environments. The innovative fractal design offers enhanced skin conformity, potentially reducing contact impedance and increased SNR. This approach not only minimizes motion artifacts but also improves overall signal quality and user comfort. By leveraging advanced materials and optimized geometries, the proposed sensor aims to maintain consistent performance across a wide range of construction activities, from repetitive tasks to sudden, high-intensity movements. This tailored solution has the potential to revolutionize real-time stress monitoring in construction workers, providing more accurate and reliable data for both immediate intervention and long-term occupational health strategies.

The paper is structured as follows: In Section 2, a brief literature review is provided, focusing on flexible EDA sensors and health monitoring applications of EDA sensors. Section 3 describes the proposed methodology, including the technical details of the design and fabrication techniques. In Section 4, a case study is presented, which includes details of the experiments conducted to develop and evaluate the developed sensor. The results are analyzed and discussed in Sections 5 and 6. Finally, Section 7 concludes the paper.

2 Background and Related Work

2.1 Stress, the Sympathetic Nervous System, and EDA

Stress triggers a complex cascade of physiological responses, primarily mediated by the autonomic nervous system (ANS). The ANS comprises two main branches: the sympathetic nervous system (SNS), which initiates the "fight-or-flight" response, and the parasympathetic nervous system, responsible for "rest-and-digest" functions [10]. During stress, the SNS becomes dominant, leading to a range of physiological changes aimed at mobilizing energy resources and preparing the body for action [11].

The skin, particularly its sweat glands and vasculature, is exclusively innervated by the SNS, making it an ideal target for assessing sympathetic activation. Electrodermal activity (EDA), which measures changes in skin electrical properties due to sweat gland activity, provides a direct and relatively unambiguous index of SNS arousal [12]. This contrasts with other physiological measures, such as heart rate variability, which reflect the complex interplay between both SNS and PNS influences.

EDA is typically quantified through skin conductance measurements, which are proportional to sweat secretion. The palmar surfaces of hands and feet, with their high density of eccrine sweat glands , are preferred measurement sites. The EDA signal comprises two main components: tonic skin conductance level (SCL) and phasic skin conductance responses (SCRs). SCL represents the slowly changing baseline level of electrical conductivity, reflecting overall psychophysiological activation [13]. SCRs are rapid, transient increases in conductance, occurring either in response to specific stimuli (specific SCRs) or spontaneously (non-specific SCRs or NS.SCRs).

Specific SCRs typically manifest 1 to 6 seconds post-stimulus and are characterized by several key parameters: amplitude (magnitude of conductance change), latency (time between stimulus onset and SCR initiation), rise time (duration from SCR onset to peak), and half-recovery time (time for amplitude to decrease by 50% from peak). NS.SCRs, while morphologically similar to specific SCRs, occur in the absence of identifiable external stimuli. The frequency and mean amplitude of NS.SCRs serve as additional indicators of psychophysiological arousal [14].

Importantly, both SCL and SCR patterns exhibit significant inter-individual variability, necessitating careful baseline establishment and within-subject comparisons in experimental designs. Numerous studies have demonstrated the superior sensitivity of EDA measures, particularly SCL and NS.SCR frequency, in tracking stress responses compared to other physiological indicators. This sensitivity, combined with the relatively straightforward interpretation of EDA in terms of SNS activity, makes it a valuable tool for real-time stress monitoring in dynamic environments such as construction sites.

2.2 Flexible EDA sensors

Flexible electrodermal activity (EDA) sensors represent a significant advancement in wearable biomonitoring technology, offering potential solutions to the longstanding challenges associated with traditional rigid sensor designs [15]. The development of these sensors is driven by the need for more reliable and comfortable continuous monitoring systems, particularly in dynamic environments such as construction sites [9,16,17].

One of the primary advantages of flexible EDA sensors is their ability to maintain consistent skin contact during movement, potentially reducing motion artifacts that plague inflexible commercial sensors. These artifacts, which can significantly distort physiological signals, are particularly problematic in occupational settings where workers engage in varied physical activities. While algorithmic approaches such as adaptive filtering and

machine learning techniques have shown promise in mitigating motion artifacts, they are inherently limited by the quality of the raw signal input [7,8]. Flexible sensors address this issue at the hardware level, potentially improving signal fidelity before any software processing occurs.

Recent advancements in materials science have enabled the development of novel flexible sensor substrates and electrode materials. Conductive polymers, carbon nanotubes, and metallic nanowires have been successfully incorporated into stretchable matrices, creating sensors capable of withstanding substantial deformation while maintaining electrical performance [18]. These materials often exhibit unique electromechanical properties, such as increased conductivity under strain, which can be leveraged to enhance sensor sensitivity and resilience. The design of flexible EDA sensors also allows for innovative electrode patterns and geometries that were previously unfeasible with rigid substrates. Fractal-inspired designs, for instance, have shown promise in optimizing the tradeoff between mechanical flexibility and electrical performance [19]. These intricate patterns can potentially increase the effective surface area for EDA measurement while allowing the sensor to conform to the complex topography of human skin, particularly in areas with high curvature or frequent movement.

3 Materials and Methodology

The overview of the proposed methodology is presented in Figure 1, In the first step, we 3D model 8 different variations of fractal curves with varying order and shapes to fit within a square patch of length 5 mm. Here we model Hilbert, Moore, z-space and Peano-Gosper curves. In the second stage we perform static analysis subjecting the 3D models to varying tensile forces and evaluate stress/strain characteristics. We calculate von-mises stress, strain values, and geometric characteristics such as overage area. Based on the results, we choose Peano-Gosper order 4 curve for fabrication. During fabrication, we use Silver Nanoparticle modified ink to print in into a flexible polyimide surface using a piezoelectric printing mechanism. After printing the Ag-NP surface is UV-treated using sintering. Then, the developed electrode is evaluated and compared with the commercially available electrodes for noise reduction.

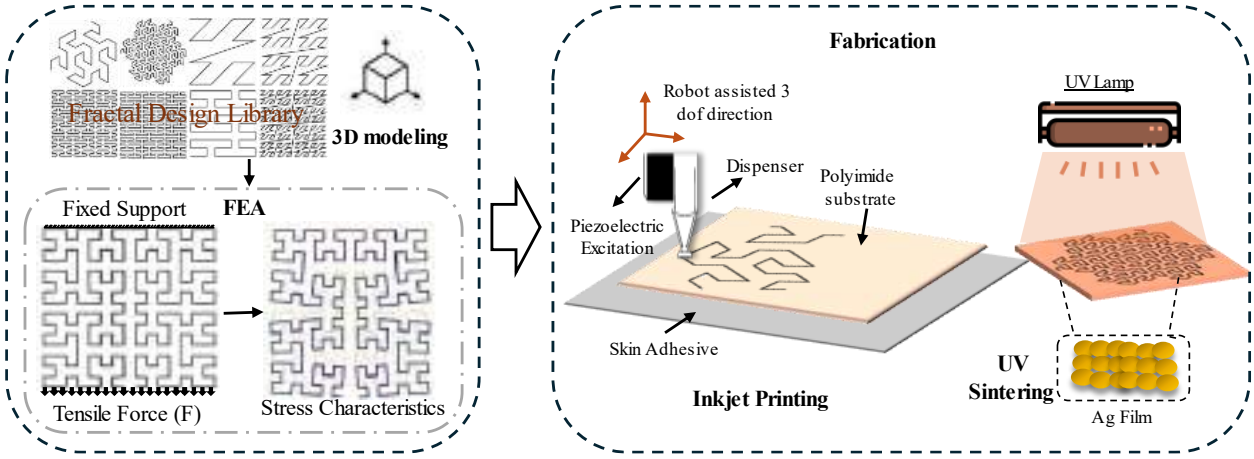

Figure 1: Overview of the methodology. Multiple Fractal designs are 3D modeled and then analyzed for mechanical properties using finite element analysis. The best one is selected based on a mixture of von Mises stress, strain, and geometric properties like coverage to surface area ratio. The selected design is printed using AgNP ink into a flexible polyimide substrate followed by polyimide

3.1 Design and FEM evaluation of Flexible Electrodes

Eight different fractal curve variations were modeled in 3D, including Hilbert, Moore, Z-space, and Peano curves of varying orders, each confined within a 5 mm square patch. The Peano-Gosper curve, originally termed the flow-snake, represents a sophisticated space-filling pattern that exhibits unique hexagonal characteristics. When implemented in second and third orders, this curve generates intricate self-replicating structures that optimize both spatial utilization and mechanical adaptability.

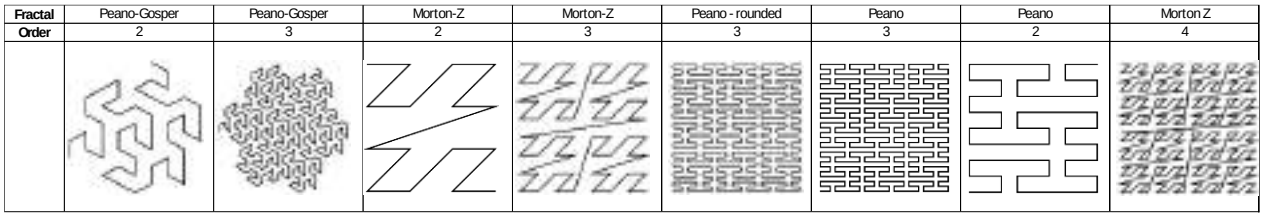

Figure 2: Fractal curves with respective order analysed for this study.

The Morton Z-curve, alternatively known as the Z-order curve, employs an innovative approach to dimensional mapping, effectively transforming two-dimensional spatial relationships into linear sequences while maintaining proximity correlations. Implemented across orders 2, 3, and 4, this pattern creates a hierarchical arrangement that achieves an optimal equilibrium between connectivity and coverage. The Z-curve's architecture proves particularly advantageous in applications requiring efficient spatial data organization and multidimensional query optimization.

Among these patterns, the Peano curve demonstrates the mathematical possibility of continuous coverage across a complete unit square. Its modified variant, the Peano-rounded design, incorporates strategic curvature elements to enhance mechanical performance. These modifications serve multiple purposes: they minimize stress concentration at junction points, preserve continuous surface coverage, and significantly improve the structure's overall flexibility and stretchability characteristics.

These models were subjected to static analysis simulating tensile forces ranging from 0.5 N to 2 N, representing the spectrum of mechanical stresses encountered during typical construction activities. The FEA simulation utilized a non-linear large deformation model to account for the elastic behavior of the flexible substrate. The material properties of the silver nanoparticle (AgNP) conductive ink and the polyimide substrate were incorporated into the model, with particular attention to the interface between these materials.

$$\sigma_v = \sqrt{\frac{1}{2}\left[\sum_{x,y,z}\left(\sigma_x - \sigma_y\right)^2\right] + 3\left(\tau_{xy}^2 + \tau_{yz}^2 + \tau_{zx}^2\right)} \quad (1)$$

$$Ku = F, \qquad \in = \frac{\Delta l}{l_0} \quad (2)$$

where, $\sigma_x, \sigma_y, and\ \sigma_z$ are the normal stresses along the x,y, and z axes, respectively and $\tau_{xy}, \tau_{yz}, and\ \tau_{zx}$ are the shear stresses in the respective planes.

3.2 Sensor Fabrication and Sintering

The sensor electrodes were designed to fit comfortably on human skin, optimized for flexibility and durability in field environments. Polyimide, selected as the substrate, provides a balance of lightweight structure and flexibility similar to the tensile qualities of human skin, allowing the sensor to conform to body contours with minimal discomfort. This Kapton HN polyimide film offers high elongation capacity, low thermal expansion, and favourable tensile strength, making it an ideal foundation for wearable sensors that experience frequent motion. The selected thickness (0.125 mm) of this film supports the sensor's resilience while maintaining a minimal profile for improved adhesion and reduced interference during movement.

The electrodes were created using Ag nano-ink, chosen for its excellent conductivity and mechanical robustness, essential for clear and stable signal transmission. This ink, consisting of silver nanoparticles (AgNPs), combines a high-weight percentage of Ag with properties suited for high-resolution printing. The small particle size allows smooth deposition without clogging, while the moderate viscosity ensures steady flow through the printer's micro-dispensing system. These factors together enhance the ink's adherence to the polyimide surface, resulting in conductive pathways with low resistance after sintering. This choice of material ensures the electrodes can perform reliably under various physical strains while keeping the overall structure lightweight and thin $V(t) = V_0\ sin(\omega t) = V_0\ sin(2\pi f t)$. The printing process employed a SonoPlot Microplotter proto, utilizing an ultrasonic fluid injection mechanism to achieve precise electrode patterning. This technique relies on a piezoelectric-controlled glass dispenser, where AC-induced vibrations allow controlled dispensing of the Ag nano-ink onto the substrate. By adjusting the frequency of the AC signal, the fluid's flow rate is precisely managed, creating a serpentine pattern optimized for flexibility and durability. Following the printing phase, UV sintering with a pulsed light system (X-1100:XENON) was applied to solidify the AgNPs without overheating the polyimide film. This sintering process removed solvents and bound the particles into a stable, conductive layer, completing the sensor's

formation with minimal thermal impact on the flexible substrate.

4 Experimental Case Study

To study the artifact reduction in the developed EDA sensor roofing construction task was used (Figure 2). The EDA signals were recorded between the index and ring finger. In one scenario, the subjects were asked to stay static without moving their fingers to record the base-line signals and analyze the noise properties in the static position. To induce motion, a hammering-based construction task was used. During the hammering task, the subjects hammered shingles into a prebuilt roof structure. This task was performed for both the commercial and developed electrodes. The detailed results are presented in Section 5.

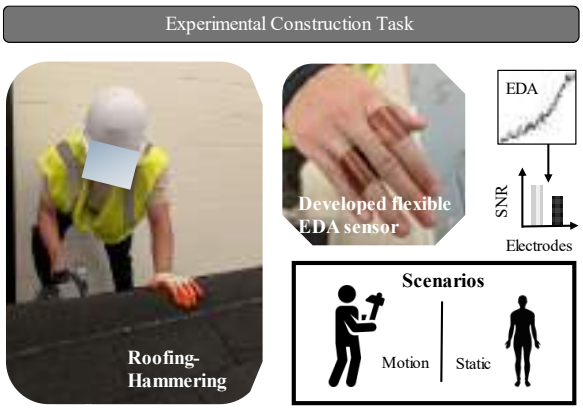

Figure 3: Experimental setup comprises two scenarios with and without motion. For inducing motion hammering task is used where the subject hammers shingles into a prebuilt roof structure. The signals are acquired for developed and commercial electrodes.

The signals acquired from the EDA sensors were amplified using bio-amplifier from AD-Instruments. Signals were acquired at the range of 100 Hz.

5 Results and Discussion

The comparative analysis of the various fractal-based electrode designs revealed significant performance variations across mechanical properties and signal quality metrics. The results demonstrate the superior characteristics of higher-order fractal patterns, particularly in terms of stress distribution and motion artifact reduction.

5.1 Mechanical Performance Analysis

The finite element analysis revealed distinctive mechanical behaviors across the various fractal patterns tested. The Peano-Gosper curve of order 2 initially showed the highest von Mises stress at 5.5E+10 N/m², while its order 3 counterpart demonstrated a dramatic improvement, with stress levels dropping to 3.9E+08 N/m². This significant reduction in stress indicates that higher-order Peano-Gosper patterns effectively distribute mechanical loads throughout their structure.

The Morton Z-curve patterns exhibited consistent mechanical performance across different orders, with stress levels stabilizing around 2.0E+10 N/m². The order 3 and 4 variations maintained relatively uniform stress distribution, suggesting reliable mechanical stability. These patterns demonstrated better structural integrity while accommodating deformation, with strain values ranging between 0.1 and 0.2.

The Peano and Peano-rounded variations demonstrated notably different characteristics. The Peano-rounded design of order 3 achieved moderate stress levels of approximately 1.5E+10 N/m² and maintained relatively low strain values of around 0.15. The rounded corners incorporated into this design proved effective in mitigating stress concentration points, a common challenge in angular fractal patterns. The standard Peano curve showed similar stress characteristics but with slightly higher strain values, indicating that the rounded modifications successfully improved the overall mechanical performance.

Strain analysis across all patterns revealed a consistent trend where higher-order patterns generally exhibited better strain management. The Peano-Gosper order 2 design showed the highest strain at 0.55, while its order 3 variant demonstrated remarkably lower strain values (0.004). This pattern was consistent across all designs, with higher-order variations consistently outperforming their lower-order counterparts in strain management. The Morton Z-curve patterns, particularly in orders 3 and 4, maintained moderate strain levels, suggesting good deformation characteristics under applied loads.

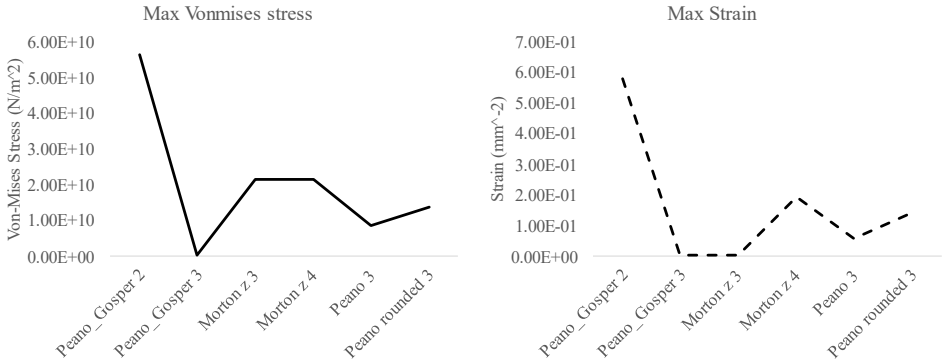

Figure 4: Max Von-mises stress and maximum strain for the given loading conditions.

The comprehensive analysis of both stress and strain characteristics indicates that while higher-order patterns generally offer superior mechanical properties, the optimal design must balance performance with manufacturing feasibility. The Peano-gosper order 3 pattern emerged as a particularly promising candidate, offering an excellent compromise between stress distribution, strain management, and practical implementation considerations. Based on this comparison, Peano-Gosper 3 was selected for the fabrication and further analysis.

5.2 Motion Artifact Reduction

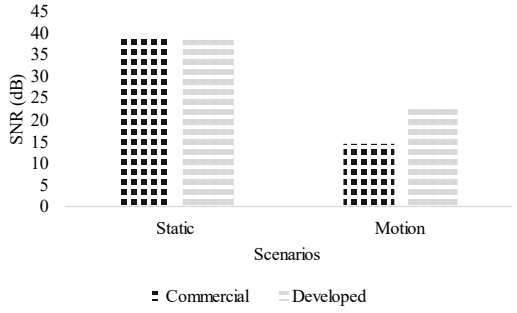

Figure 5: The developed electrodes provide significant improvement in SNR for the hammering task which induces significant motion.

To compare the performance of the developed electrode with the existing commercial modules we used bipolar finger electrodes made from brightly polished stainless steel plates (ADInstruments). As shown in Figure 5, the designed serpentine electrode exhibits a significantly higher SNR of approximately 23 dB compared to the commercial electrode, which has an SNR of around 15 dB. This difference in SNR performance can be attributed to the optimized electrode design and manufacturing process employed for the serpentine structure. We also compared the SNR both during static position (rest) and dynamic position (hammering with the sensing hand) to assess the difference during dynamic activities. While both electrodes provide similar performance during rest ($|SNR| < 1db$) the performance during dynamic activity (hammering) the SNR improvement is significant (8 db). The enhanced SNR indicates that the designed electrode is capable of providing cleaner, more reliable EDA signals, which is a critical requirement for accurate physiological monitoring in wearable health applications.

6 Conclusions

This research develops and analyses flexible sensor technology through the development of fractal-based electrodes for EDA monitoring applications. The comprehensive mechanical analysis of various fractal patterns has yielded significant insights into their performance characteristics and potential for wearable sensing applications. The finite element analysis results demonstrate remarkable improvements in mechanical stability and stress distribution across different fractal designs.

The investigation revealed that higher-order fractal patterns consistently outperform their lower-order counterparts. The Peano-Gosper pattern showed the most dramatic improvement, with von Mises stress reduction from 5.5E+10 N/m² in order 2 to 3.9E+8 N/m² in order 3. Similarly, the Morton Z-curve patterns maintained consistent stress levels around 2.0E+10 N/m², demonstrating reliable mechanical stability across orders 3 and 4. The fabricated sensor of the Peano-Gosper order 3 demonstrated an 8db of SNR improvement when compared to commercial sensors while performing construction tasks.

These advancements address critical limitations in current wearable sensor technology, particularly in maintaining stable electrode-skin contact during dynamic activities. However, several challenges remain for future

investigation. The integration of flexible amplification circuits and wireless communication systems would enhance the sensor's practical applicability. Additionally, further research into surface modification techniques could improve long-term durability and signal stability.

Future work should focus on expanding this fractal-based design methodology to other physiological monitoring applications and developing automated manufacturing processes for complex patterns. The potential applications extend beyond EDA sensing to include other biomonitoring systems, suggesting broader implications for wearable health monitoring technology. Despite current limitations in system integration and long-term durability, this research establishes a promising foundation for next-generation flexible sensors that combine mechanical reliability with enhanced signal quality.

Abstract -

Mobile Laser Scanner (MLS) technology enables the acquisition of high-precision three-dimensional lidar point cloud data of roadside infrastructure elements, including traffic signs and street poles. This research presents an innovative and computationally efficient algorithm for the extraction of pole-shaped objects from MLS point clouds. The methodology addresses the computational challenges associated with large-scale point cloud processing through a trajectory-based segmentation and ground point filtering. The algorithm implements geometric descriptors, specifically linearity and verticality to identify potential pole structures. Subsequently, the statistical outlier removal (SOR) filter is applied to refine the candidate pole detection results. The final classification of true pole objects is achieved through the application of ground clearance criteria. The algorithm's effectiveness was validated through empirical testing across three distinct urban and suburban environments, utilizing data acquired from two different MLS systems. The experimental results demonstrated successful performance metrics, achieving mean precision and recall rates of 97.21.

Keywords -

Road, Linearity, Verticality, Trajectory, LiDAR, Poles.

1 Introduction

Poles along roads are really important for new technologies like self-driving cars and creating 3D maps [1]. By knowing exactly where these poles are located, we can better understand road conditions and improve how we design and manage transportation infrastructure [2]. While traditional inspection methods involving manual ground-based assessment are resource-intensive and laborious, there is a critical need for expedited, fully automated inspection protocols for roadside infrastructure evaluation [3].

MLS systems have emerged as powerful tools in this field, offering significant advantages over other remote sensing technologies [2]. Unlike optical imaging, which struggles with illumination variations, laser scanning systems can measure distance information directly without being adversely affected by ambient lighting or shadows [4] , [5]. These systems generate three-dimensional spatial information of object surfaces, eliminating the time-intensive computational processes typically required for deriving 3D coordinates from imagery [6].

Previous research has explored various techniques for extracting pole-shaped objects from point clouds, including voxel-based procedures and adaptive radius cylinder models [7]. However, existing approaches often face limitations such as dependence on complex voxel transformations, suboptimal thresholding parameters, and requirements for extensive training datasets and computational resources.

In response to these challenges, the research proposes a novel and computationally efficient algorithm for pole-shaped object extraction from mobile laser scanning point clouds. The methodology introduces geometric descriptors for pole detection while maintaining computational efficiency through systematic data segmentation. By addressing the limitations of existing approaches, this research aims to advance automated infrastructure monitoring and environmental mapping technologies.

2 Proposed Method

2.1 Pre-processing

This subsection addresses the critical challenge of managing the vast volume of lidar point cloud data. It emphasizes the importance of effectively removing both noise and ground points, which is essential for reducing the overall data size and ensuring that only relevant information

is retained. This process plays a key role in minimizing unnecessary data, thereby enhancing the efficiency of subsequent data processing and analysis.

2.1.1 Sectioning

MLS systems leverages trajectory data to efficiently segment point cloud information by recording the vehicle's precise location throughout the scanning process. This trajectory data, which is inherently aligned with the point cloud coordinate system, allows for seamless segmentation of the scanned environment into uniform sections without requiring complex georeferencing. By dividing the trajectory into fixed-length segments—in this case, 90m—the corresponding point cloud data is simultaneously partitioned into equivalent sections, creating a systematic approach to processing large spatial datasets [2]. The primary advantage of this method lies in its ability to transform continuous, complex point cloud information into manageable, discrete units, significantly reducing computational complexity and enabling more focused spatial analysis. Since the trajectory data is substantially smaller in volume compared to the lidar point cloud data, this segmentation approach not only simplifies data processing but also improves overall implementation efficiency, making it an elegant solution for handling extensive MLS datasets. Figure 1-a illustrates the trajectory data overlaid on the collected LiDAR point clouds. It is important to note that an elevation shift is required due to the absence of elevation data in the trajectory. As shown in Figure 1-b, the sectioning of the collected data has been appropriately performed, with each section represented in a distinct color.

subcaption

2.1.2 Noisy Points Removal

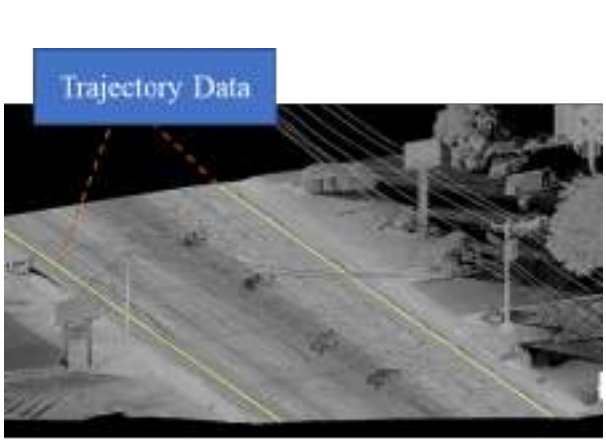
Noisy points (Figure 2) in MLS point clouds can arise from various sources, such as sensor imperfections, environmental noise, and surface reflectivity variations. These points typically exhibit abnormal elevations or low point density, which makes them distinguishable from the rest of the point cloud. The SOR method is a robust technique used to detect and eliminate these outliers by analyzing the statistical distribution of neighboring points [8].

The SOR algorithm operates by calculating the mean distance from each point to its neighboring points within a specified radius. In this study, the number of nearest neighbors (N) is set to 10. For each point in the point cloud, the mean distance to its 10 nearest neighbors is computed (Obtained based on trial and error). These mean distances are then used to define a threshold, which is typically based on the global mean and standard deviation of the mean distances across the entire dataset. Points that have a mean distance significantly larger than the average (i.e., those that fall outside a certain multiple of the standard deviation) are considered statistical outliers. These outliers are likely to be noisy or erroneous, as they do not align with the expected spatial distribution of neighboring points. The general formula for the SOR algorithm can be expressed as [8]:

$$D_i = \frac{1}{N} \sum_{j=1}^{N} |P_i - P_j| \tag{1}$$

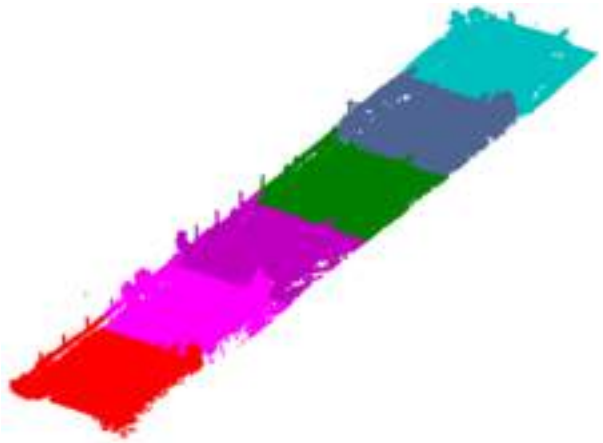
where D_i is the mean distance from point P_i to its nearest neighbors P_j, and N is the number of neighbors (in this case, 10). For each point P_i, the algorithm calculates the mean distance to its neighbors and compares it to the overall distribution of mean distances in the dataset. Points with a mean distance greater than a threshold defined as $\mu + k\sigma$ (where μ is the mean and σ is the standard deviation of all mean distances, and k is a defined constant) are flagged as outliers.

xcolor



2.1.3 Ground Points Removal

The Cloth Simulation Filter (CSF) method [9] offers an innovative approach to ground point removal in MLS point clouds, addressing the critical challenge of data volume reduction for efficient processing and analysis. By simulating a cloth-like surface that drapes over the point cloud, the algorithm mimics gravitational effects, effectively classifying points as ground or non-ground based on their position relative to this simulated surface. This method demonstrates remarkable versatility, capable of handling diverse terrains including both steep and flat areas, making it particularly valuable for large-scale point cloud datasets.



The CSF algorithm's effectiveness hinges on two key parameters: grid size and classification threshold. The grid size, which determines the resolution of the cloth mesh, plays a crucial role in capturing terrain features accurately—in this study, a 0.31m grid size was selected to optimize detail and efficiency. By carefully tuning these parameters, the method can dramatically reduce point cloud volume, as evidenced by its ability to remove approximately 4.5 million ground points from a 5-million-point dataset in just 3 seconds. This computational efficiency, combined with the algorithm's ability to model complex terrain variations, makes the CSF method a powerful tool for preprocessing lidar point cloud data across various environmental contexts.

2.2 Detecting Candidate Poles

This step aims to identify pole-shaped objects among the remaining point clouds, which include various objects

(a) Displaying the trajectory data on the LiDAR point clouds (an elevation shift is needed).

(b) Created sections which partition the point cloud for efficient processing.

Figure 1. (a) Trajectory data overlaid on the LiDAR point clouds, requiring an elevation shift for alignment, and (b) resulting sections dividing the data into manageable units.

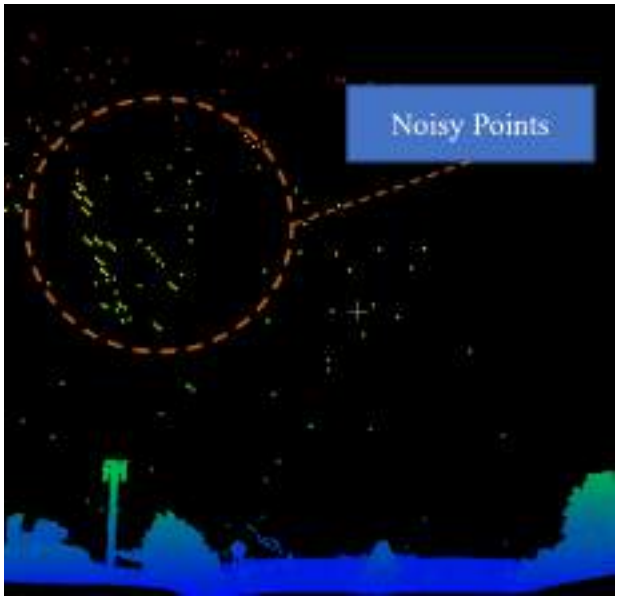


Figure 2. Displaying the noisy points.

that lack meaningful information in isolation. By analyzing the surrounding neighborhood points, we aim to assign meaningful descriptors to each point. For instance, we know that power lines typically exhibit thin, lengthy linear structures, while objects such as poles tend to have a long, vertical shape. To distinguish between these types of objects, rule-based descriptors of linearity and verticality are employed. These two geometric features—verticality and linearity—are particularly effective for characterizing poles. The descriptors are quantified using the eigenvalues obtained from the Principal Component Analysis (PCA) procedure, which captures the directional properties of the point cloud and provides a means to differentiate between vertical and linear structures.

These descriptors are computed for each point in the filtered point cloud dataset after ground point removal. Let $P(i)$ represent the set of points, where i is the index of each point. The descriptors are computed based on eigenvalues derived from PCA of the covariance matrix.

2.2.1 Verticality and Linearity Descriptors

The verticality descriptor $V(i)$ is defined as [2]:

$$V(i) = \frac{\lambda_1}{\lambda_1 + \lambda_2 + \lambda_3} \tag{2}$$

where λ_1, λ_2, λ_3 are the eigenvalues of the covariance matrix, and λ_1 is associated with the dominant vertical direction of the point cloud.

The linearity descriptor $L(i)$ is computed as:

$$L(i) = \frac{\lambda_2}{\lambda_1 + \lambda_2 + \lambda_3} \tag{3}$$

where λ_2 corresponds to the direction of the linearity of the point cloud.

2.2.2 Neighborhood Selection and Thresholding

For each point index i, the neighborhood points are selected based on a spherical neighborhood with radius $r = 0.9$ meters. This can be expressed as:

$$N(i) = \{P(j) \mid \|P(i) - P(j)\| \leq r\} \tag{4}$$

where $N(i)$ is the set of neighboring points for point $P(i)$, and r is the radius for point selection.

2.3 DBSCAN-based Point Cloud Clustering

To detect pole-shaped objects in a point cloud using an unsupervised approach, we employ the DBSCAN (Density-Based Spatial Clustering of Applications with Noise) algorithm, which clusters points based on their geometric characteristics [10]. The input to DBSCAN consists of feature vectors for each point, which include the 3D coordinates as well as additional descriptors, such as linearity and verticality. Each point $P(i)$ is represented by a feature vector:

$$\mathbf{x}(i) = \{x_i, y_i, z_i, \text{linearity}_i, \text{verticality}_i\} \tag{5}$$

where x_i, y_i, z_i denote the 3D coordinates of point $P(i)$, and linearity_i and verticality_i are the calculated descriptors based on the local neighborhood and PCA. These descriptors serve as indicators of whether a point is part of a pole-like object or not.

The DBSCAN algorithm requires two parameters: the maximum distance ϵ and the minimum number of points MinPts. The distance threshold ϵ determines the maximum allowed distance between two points for them to be considered as neighbors, and MinPts defines the minimum number of points required in a neighborhood for a point to be classified as a core point. The neighborhood of a point $P(i)$ is defined as the set of points $N_\epsilon(i)$ within a distance of ϵ:

$$N_\epsilon(i) = \{P(j) \mid \|\mathbf{x}(i) - \mathbf{x}(j)\| \leq \epsilon\} \tag{6}$$

where $\|\mathbf{x}(i) - \mathbf{x}(j)\|$ is the Euclidean distance between points $P(i)$ and $P(j)$. If the number of points within this neighborhood is greater than or equal to MinPts, then $P(i)$ is considered a core point, which is a point around which a cluster can form. This is mathematically represented as:

$$|N_\epsilon(i)| \geq \text{MinPts} \tag{7}$$

Points that lie within the neighborhood of a core point but do not themselves have enough points to form a cluster are classified as border points. Border points are included in the same cluster as the core points they are associated with. Any point that is not a core point or a border point is classified as noise.

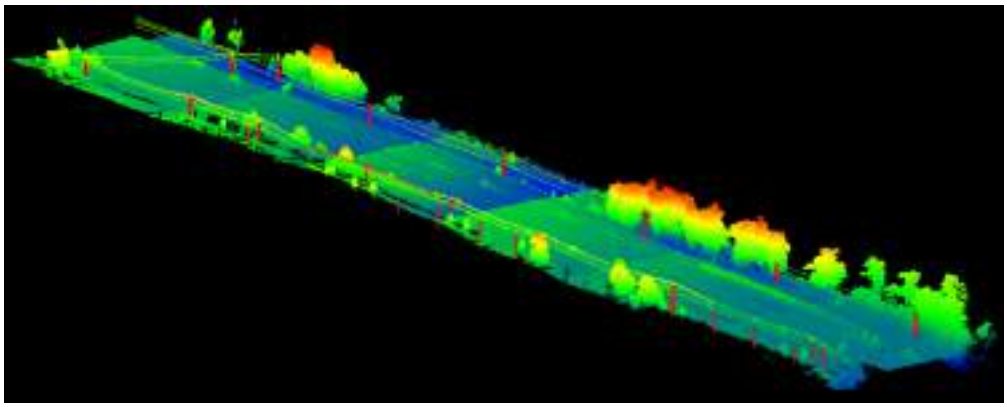
DBSCAN assigns each core point and its corresponding neighborhood to a cluster, and the final output is a set of clusters $C_1, C_2, \ldots, C_k$, where each cluster contains densely connected points. Points that are classified as noise are not included in any cluster. The overall output of the DBSCAN algorithm is given by:

$$\text{DBSCAN}(\epsilon, \text{MinPts}) = \{C_1, C_2, \ldots, C_k\} \tag{8}$$

where $C_1, C_2, \ldots, C_k$ are the detected clusters corresponding to potential pole-shaped objects. This clustering approach enables the identification of pole-like structures based on their geometric properties without the need for labeled data.

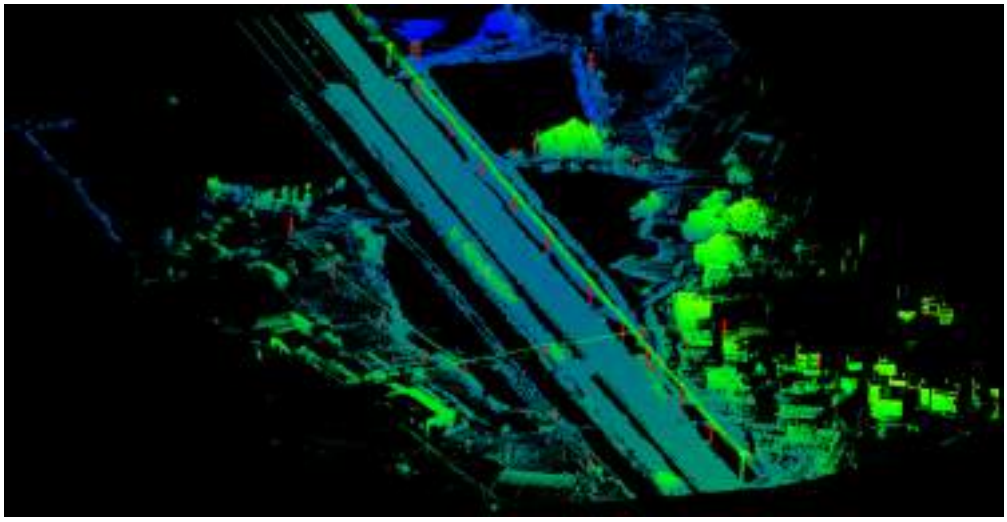
3 Experiment and Results

3.1 Study Area and Results



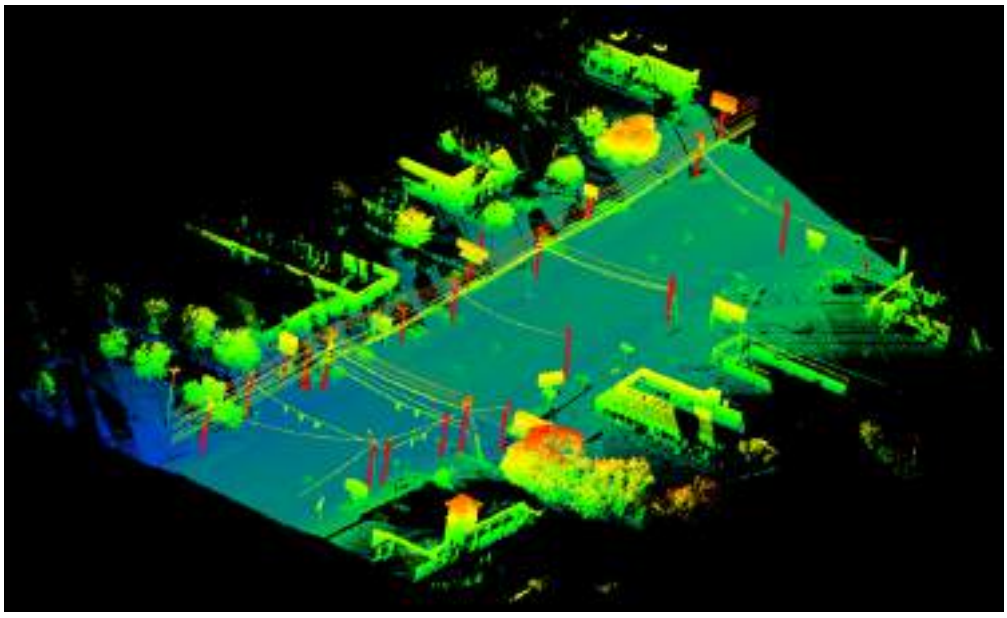
The evaluation of the proposed algorithm is based on datasets from diverse environments, each presenting unique challenges for accurate analysis. The urban region in the USA, with its high object density and reflective surfaces, complicates the distinction of pole-shaped structures due to overlapping vertical objects, occlusions, and varying point densities. The suburban USA region, while less dense, still presents challenges with trees, power lines, and scattered buildings, requiring the algorithm to manage a large dataset with 45 million points and efficiently classify pole-shaped objects. The suburban region in China adds complexity due to geographical differences, sensor calibration variations, and environmental factors like vegetation and local infrastructure. Across all datasets, challenges include point density variations, occlusions, environmental factors, and geographical variability, which demand a robust, adaptive algorithm.

The algorithm demonstrated strong performance (Figure 3) across the test regions, particularly in the suburban USA area where it successfully detected 33,490 pole points with only 796 points undetected and 953 false positives, achieving approximately 97 percent recall accuracy (Table 1). In urban environments, additional challenges arose from phone lines attached to poles and traffic signs, which occasionally led to misclassification. While the algorithm showed reduced accuracy in detecting transmission line pylons and poles with additional equipment such as transformers, its adaptability to various environmental conditions proved effective. The presence of dense trees, cables, and varied building types added complexity to the detection process, yet the algorithm maintained robust performance across different regions, efficiently processing large lidar datasets and adapting to diverse urban and suburban landscapes.



4 Discussion

4.1 Computation System



The proposed method presents significant advantages over previous approaches, particularly in terms of system implementation, runtime efficiency, input data requirements, and overall efficiency. Unlike many prior studies that rely on expensive cloud computing systems, the method was executed on an affordable laptop featuring an Intel Core i5 processor, 12 GB of RAM, and an Nvidia GeForce graphics card. This economical setup still

(a) Suburban USA

(b) Suburban China

(c) Urban USA

Figure 3. Visualising the output of the algorithm (the extracted poles are displayed in red color): (a) Suburban USA, (b) Suburban China, (c) Urban USA.

Table 1. Performance metrics of the proposed algorithm across three datasets, with average values.

Dataset	Length (m)	Points (million)	Precision (%)	Recall (%)	F1 Score (%)	Time (s)
Suburban USA	550	45	97.68	97.23	97.45	104
Suburban China	500	19	97.00	95.84	96.42	93
Urban USA	200	15	96.96	94.97	95.95	115
Average	–	–	97.21	96.01	96.61	–

achieved satisfactory performance, making it accessible for practitioners without high-end infrastructure, and particularly suitable for resource-constrained environments like field-based applications or small-scale projects. Additionally, the runtime efficiency of the method is a key strength, processing data in approximately 312 seconds, which is significantly faster than other methods—up to 20 times faster in some cases.

4.2 Datasets

In terms of input data, the method has the advantage of relying solely on 3D lidar point clouds and trajectory data, simplifying the data acquisition process compared to other methods that require additional data sources such as scanlines or labeled training datasets. This makes the algorithm more flexible and easier to implement in situations where such data is difficult or costly to obtain. The method's versatility is further demonstrated by its ability to handle data from multiple MLS platforms and operate effectively in both urban and suburban environments. This adaptability enhances the algorithm's robustness and broadens its applicability across diverse geographic locations and point cloud characteristics. Overall, the proposed algorithm outperforms existing methods by providing high performance on affordable hardware, efficient processing, minimal data requirements, and flexibility across different platforms, making it a practical and valuable tool for pole detection in lidar point clouds.

4.3 Parameter Selection and Optimization

The effectiveness of the proposed algorithm relies on several key parameters, whose values were carefully selected to optimize performance across diverse MLS datasets. While the primary parameters—segmentation length (90 m), SOR nearest neighbors ($N = 10$), and CSF grid size (0.31 m)—were justified in the methodology, additional parameters such as the spherical neighborhood radius ($r = 0.9$ m), DBSCAN clustering parameters ($\epsilon = 0.5$ m, MinPts = 10), and ground clearance threshold (0.5 m) also warrant discussion to elucidate their optimality.

The spherical neighborhood radius of 0.9 meters, used for computing verticality and linearity descriptors, was chosen to encapsulate the local geometry of pole-shaped objects while minimizing interference from adjacent structures. Given that poles in the datasets typically have diameters of 0.2–0.5 meters, a 0.9-meter radius ensures sufficient point inclusion for robust PCA-based eigenvalue computation, capturing vertical extents of 2–3 meters. Empirical trials showed that smaller radii (e.g., 0.5 m) yielded unstable descriptors in sparse regions, whereas larger radii (e.g., 1.5 m) incorporated noise from nearby objects, reducing specificity. This value proved effective across urban and suburban environments, balancing sensitivity and precision.

For DBSCAN clustering, the maximum distance $\epsilon = 0.5$ m and minimum points MinPts = 10 were selected to group points into coherent pole structures. The 0.5-meterϵ aligns with the physical scale of poles and the point density of the MLS data (100–1000 points/m^2), ensuring that points along a single pole are clustered without merging with unrelated objects spaced further apart. A smaller ϵ (e.g., 0.2 m) fragmented poles, while a larger value (e.g., 1.0 m) over-clustered with non-pole features. Similarly,MinPts = 10 reflects the expected point count within a pole's neighborhood, filtering out noise while retaining valid clusters. This combination was iteratively refined to maximize recall and precision, as evidenced by the 97.21% average precision reported in Table 1.

The ground clearance threshold of 0.5 meters, applied as a final classification criterion, distinguishes pole bases from ground-level clutter. This value accommodates terrain variations and sensor height offsets, ensuring that poles are correctly identified above residual ground points post-CSF filtering. Testing revealed that a lower threshold (e.g., 0.2 m) misclassified low vegetation, while a higher threshold (e.g., 1.0 m) missed valid pole bases in uneven areas. The 0.5-meter criterion proved robust across the datasets, enhancing the algorithm's adaptability to diverse landscapes.

These parameter choices were informed by empirical optimization, practical constraints (e.g., computational efficiency on standard hardware), and the physical characteristics of pole-shaped objects in MLS point clouds. While the selected values yielded high performance (average F1 score of 96.61%), future work could explore adaptive parameter tuning based on local point density or environmental context to further enhance generalizability. Nonetheless, the current settings provide a practical and effective baseline for pole detection, as demonstrated by the experimental results.

4.4 Comparison with Baseline Methods

The proposed approach, leveraging trajectory-based segmentation and geometric descriptors, is designed to offer improved efficiency over existing techniques for pole-shaped object extraction from MLS point clouds. While Section 1 highlights limitations of baseline methods—such as voxel-based pole extraction techniques and adaptive radius cylinder models—this subsection provides a qualitative comparison to contextualize our method's advantages.

Unlike voxel-based methods, which rely on computationally intensive grid construction and transformations, our approach uses trajectory data to segment point clouds directly, simplifying preprocessing and reducing computational overhead. Similarly, adaptive radius cylinder models (e.g.,[6]) often require iterative optimization and extensive parameter tuning, whereas our method employs straightforward geometric descriptors (linearity and verticality) to achieve rapid pole detection. A key strength of our algorithm is its independence from labeled training data, a common requirement in many baseline techniques that increases preparation time and resource demands. By contrast, our reliance on raw 3D point clouds and trajectory information enables efficient processing on standard hardware, as demonstrated across diverse urban and suburban datasets (Section 2).

While baseline methods may offer robustness in specific scenarios, such as handling complex occlusions or varying object densities, they typically incur higher computational costs and preparatory complexity. Our approach prioritizes speed and simplicity, achieving high performance (e.g., 97.21% average precision, Table 1 without sacrificing accuracy. This efficiency is particularly valuable for real-time or resource-constrained applications, distinguishing our method from existing techniques that often trade off speed for additional data dependencies or processing steps. Future work could explore quantitative benchmarks against these baselines to further validate these advantages, though the current results underscore the practical benefits of our streamlined design.

4.5 Analysis of Misclassified Cases

While the proposed algorithm demonstrated robust performance across diverse datasets, achieving an average precision of 97.21% and recall of 96.01% Table 1, a small number of misclassified cases warrant critical discussion to understand limitations and guide future improvements. Notably, the algorithm missed two pole-shaped objects in the experimental evaluation, as observed in the suburban USA dataset (Section 3.1), where 796 points were undetected out of 33,490 true pole points.

Several factors may contribute to these misses. First, occlusion by dense vegetation or overlapping infrastructure (e.g., power lines or traffic signs) likely obscured the geometric signatures of these poles. In urban and suburban environments, poles are often situated near trees or cables, which can disrupt the continuity of point cloud data, reducing the effectiveness of linearity and verticality descriptors (Section 2.2). For instance, a pole partially occluded by foliage may exhibit insufficient vertical point density within the 0.9 m spherical neighborhood, failing to meet the DBSCAN clustering criteria ($\epsilon = 0.5$ m, MinPts = 10). Second, poles with non-standard configurations—such as those with attached equipment (e.g., transformers) or irregular bases—may deviate from the expected geometric profile, leading to their exclusion during the ground clearance (0.5 m) or statistical outlier removal stages (Section 2.1.2). The suburban USA dataset, with its mix of trees, power lines, and varied pole designs, presented such challenges, as noted in Section 3.1.

These misclassifications have implications for the algorithm's applicability. In scenarios requiring exhaustive pole detection (e.g., autonomous navigation), missing even a small fraction of poles could impact reliability. However, the low false negative rate (e.g., 796 undetected points versus 33,490 detected) suggests that the algorithm remains highly effective for most practical purposes, such as infrastructure mapping, where near-complete detection suffices. The trade-off between sensitivity and specificity is evident here: stricter geometric and clustering criteria enhance precision (97.21%) by rejecting ambiguous cases but may overlook edge cases like the two missed poles.

To address these limitations, future enhancements could include adaptive neighborhood sizing based on local point density to better handle occlusions, or the integration of contextual features (e.g., pole-top equipment recognition) to improve detection of non-standard poles. Additionally, incorporating multi-pass clustering or post-processing to recover missed candidates could mitigate false negatives, though at the cost of increased computational complexity. These insights, derived from analyzing the misclassified cases, underscore the algorithm's strengths in typical scenarios while highlighting areas for refinement in challenging environments.

5 Conclusion and Future Works

The paper introduces an innovative algorithm for extracting pole-shaped objects from lidar point clouds, addressing the challenges of large-volume spatial data processing in urban and suburban environments. By systematically partitioning point cloud data and employing geometric features like verticality and linearity, the method efficiently identifies and clusters pole-like objects. The algorithm's robustness is demonstrated through extensive testing on complex datasets totaling 1.3 kilometers and 80

million points, achieving an impressive average F1 score of 96.61 percent. Its key advantages include simplicity of implementation, rapid extraction time, independence from training data, and compatibility with various MLS systems. While the results are promising, the authors suggest further validation across different lidar platforms such as airborne or terrestrial laser scanners to comprehensively assess the algorithm's adaptability and performance in diverse environmental conditions.

Abstract

Additive construction by extrusion addresses challenges such as labor shortages and inconsistent quality in traditional construction methods by offering automation, precision, and reduced waste. However, it remains challenging for large scale implementation due to dynamic printing conditions and environmental influences. Real-time control can be greatly beneficial in addressing these variations, which relies on a comprehensive and accurate real-time monitoring system. In this paper, we describe our ongoing work on developing a real-time multimodal sensing system that integrates thermal, depth and RGB data. By combining these sensors, the system can capture surface temperature and geometric data of extruded material, providing detailed feedback on its strength, extrudability and buildability. It provides new insights and information for quality monitoring systems in additive construction by extrusion, achieving a better balance between detailed detection and real-time monitoring. The methodology includes RGB-thermal image alignment, automated sample detection, and structured light-based depth sensing to refine geometric and temperature data. This system lays the groundwork for future advancements in predictive analysis and dynamic real-time printing control.

1 Introduction

Additive construction by extrusion offers solutions that can help alleviate issues such as labor shortages and hard-to-control quality within the construction industry. [1]. It shortens construction time through continuous layer-by-layer deposition, parallel operations, and reduced reliance on curing delays[2]. Specifically, labor demand is reduced by automating processes such as material deposition and eliminating the need for formwork, which traditionally requires intensive manual effort. The precision of additive ensures consistent material distribution, minimizes human error, and enables high-quality results even for complex, customized designs. Furthermore, it optimizes material usage by precisely allocating resources, reduces waste and promotes sustainability by incorporating eco-friendly materials, making it a cost-effective and environmentally conscious solution[3].

Additive construction by extrusion faces a number of challenges when it comes to large scale implementation. First, the printing process is highly dynamic. The complex interplay of parameters such as material rheology, extrusion speed and mechanical motion can lead to unpredictable variations, making it difficult to fully rely on pre-programmed paths and prone to geometric defects. Secondly, printed structures exhibit a high degree of vulnerability to changes in material properties. Even small fluctuations in viscosity or ratios can trigger interlayer destabilization or even lead to structural collapse[4]. In addition, environmental factors such as temperature, humidity, and solar irradiance can affect early-age and final properties of concrete, including strength and durability[5, 6]. These uncertainties highlight the need for a real-time feedback and control system capable of dynamically adjusting printing parameters to efficiently maintain print quality during construction. Such a system requires accurate, fast-response, and highly automated monitoring capabilities, with the ability to capture complex variations, including geometric features and temperature differences.

In this paper, we present the development of a real-time multimodal sensing system designed to address these challenges. The proposed system aims to establish a comprehensive near real-time quality inspection framework to monitor both geometric fidelity and abnormal temperature variations. This approach enables

automatic measurement of geometric deformations and concrete surface temperature shortly after deposition, with the results reported to the operator for informed decision-making. The system lays the foundation for real-time control in additive construction by extrusion. The next section provides a brief review of existing literature on reality capture and non-contact inspection methods in the field of additive construction by extrusion.

2 Related Work

Geometry Monitoring for Real-Time Control: Numerous real-time monitoring and control systems for additive construction by extrusion employ vision-based approaches, utilizing 2D RGB cameras to capture and analyze geometric features. These systems typically position cameras either directly above or at an angle overlooking the printed samples, providing continuous image acquisition of the concrete layers. For example, Kazemian[7] developed a system using a 720p camera to monitor samples with a width of 40 mm, achieving width measurements with an error margin of ±1.7 mm using the OpenCV package. Similarly, Barjuei[8] employed an industrial camera to establish a real-time vision-based control framework for layer-width monitoring demonstrating good adaptability and low error rates. Another study by Jhun[9] utilized a 2D laser and camera module to monitor thickness, width, and cross-sectional area, forming the basis of a real-time geometric quality monitoring system. Additionally, Martin[10] implemented a low-cost depth camera for real-time quality monitoring, focusing on the width and height of layers. The system improved accuracy significantly after applying a statistical filter. While these systems excel in monitoring specific geometric parameters such as width or height, providing detailed feedback on more intricate aspects of concrete, such as collapse or deformation, presents additional challenges.

To enhance the automation of geometric detail monitoring, some researchers have explored the potential of AI technologies and advanced instruments. For instance, Davtalab[11] trained a Convolutional Neural Network (CNN) to detect layer deformation, achieving an accuracy and F1 score greater than 90%. Similarly, Senthilnathan[12] utilized computer vision to analyze images containing detailed deformations by converting them into two-bin linear binary patterns. Deformations were detected using information entropy, demonstrating high sensitivity in identifying defects. Furthermore, Xu[13] employed high-precision structured light scanning to inspect 3D-printed concrete structures, achieving highly accurate geometric monitoring and introducing a novel method for evaluating printing quality. While these methods offer high-precision geometric inspection, their processing times can be relatively extended, which may make them more commonly applied to post-printing quality assessment rather than real-time monitoring.

Exploring Beyond Geometric Features: In addition to geometric features, some researchers have explored other variables as the focus of sensing and monitoring systems for quality control. For instance, Kazemian[14] compared several variables, including power consumption of the agitator motor, extrusion pressure, electrical resistivity, and computer vision, to assess their effectiveness in ensuring printing quality. The results indicated that computer vision-based methods were the most effective for controlling printing parameters and maintaining quality, while electricity consumption was the least effective. Similarly, Rehman[15] developed an integrated sensor-printer system for real-time quality control, which monitors penetration, compression, shear, and tensile tests during the printing process to provide feedback on the performance of freshly extruded concrete. Additionally, Banijamali[16] proposed a novel index combining electrical resistivity and temperature to rapidly evaluate the strength of 3D-printed concrete structures, providing an innovative method for early-age strength monitoring. While these studies provide valuable insights into strength prediction and real-time quality control, their emphasis on mechanical properties leaves opportunities to further explore the role of environmental and material temperatures in influencing extrudability and buildability during the early stages of the printing process

Temperature has been identified as a critical factor affecting the quality of extruded sample. Both environmental temperature and the heat generated during curing influence the structural integrity of the printed concrete[17]. While elevated temperatures can impact strength[18], curing times and heat-induced stresses may lead to deformation and affect bonding characteristics[19, 20]. More critically, temperature directly governs the fresh properties of concrete, including viscosity, yield strength, and flowability, which are fundamental in determining its extrudability and buildability during the 3D printing process[21].

Therefore, real-time monitoring of temperature is essential, as it directly correlates with key printing parameters such as nozzle traveling speed and interval time between layers and/or material dosing. However, the potential of temperature monitoring for real-time quality control in 3D concrete printing has yet to be fully explored.

Summary and Research Gap: Despite significant advancements in geometry monitoring and real-time control for additive construction by extrusion, existing methods, which often rely on single-sensor setups with

relatively focused data sources, may benefit from further enhancements to achieve greater comprehensiveness in observed data dimensions, detail levels, and accuracy. Vision-based approaches effectively monitor parameters like width and height but may have limitations in capturing finer deformations or collapse. While advanced techniques such as AI models and structured light scanning demonstrate high precision, they are often more commonly applied to post-printing quality checks. Additionally, the potential of real-time temperature monitoring, which affects fresh material properties and plays a crucial role in early strength gain, influencing both extrudability and buildability, has yet to be fully explored. To address these shortcomings, this study proposes a multi-modal system that integrates thermal, depth, and RGB data, enabling the automated extraction of detailed, accurate geometric and temperature information to support real-time control.

3 Multimodal sensing system setup

The developed system integrates a FLIR Lepton 3.5 thermal camera and an Astra 2 RGB-depth camera to provide comprehensive monitoring of surface temperature and sample geometry during the concrete printing process. The thermal camera operates with a resolution of 160 x 120 pixels, an operational range of -10°C to 80°C, a dynamic range of -10°C to 400°C, a framerate of 8 fps, and a horizontal field of view of 57º, enabling real-time thermal data acquisition. The Astra 2 RGB-depth camera captures high-resolution RGB images at 1920 x 1080 pixels with a framerate of 30 fps and a horizontal field of view of 74.7º, while its depth function provides depth data with a resolution of 1600 x 1200 pixels at 30 fps. The depth camera employs a structured light sensor with a horizontal and vertical field of view of 58.2° and 45.2°, respectively, operating within a range of 0.6 m to 8 m and achieving a precision of $\leqslant 0.16\%$ at 1 m. Structured light technology projects a patterned field of light onto the surface, capturing deformations caused by surface geometry to reconstruct detailed 3D shapes, which is particularly effective for complex geometries [13].

Figure 1. (a)Setting of the thermal-RGB-depth camera (b)Setting of the system

The thermal camera is securely mounted on top of the RGB-depth camera using a fixed bracket, positioned 5 cm above it, as shown in Figure 1(a). This combined setup is mounted on a movable platform, located 30 cm away from the extruder and angled at 60 degrees relative to the printing platform, providing a comprehensive overview of the printing process and the sample, as illustrated in Figure 1(b). This integrated multi-modal

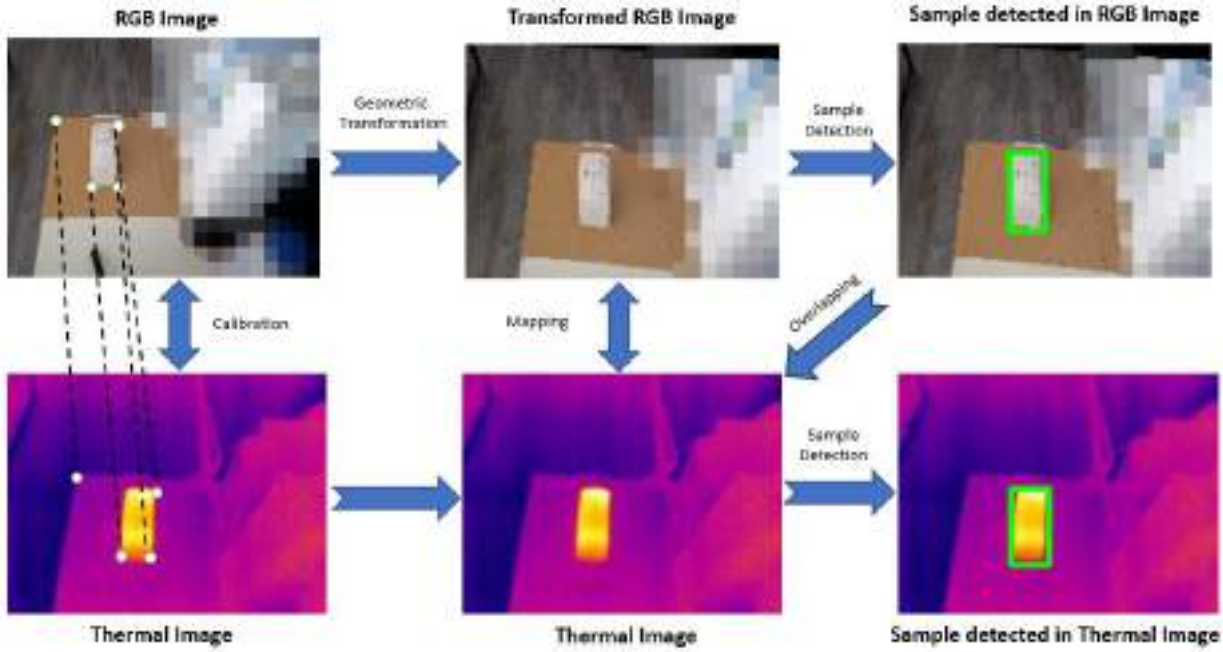

Figure 2. Thermal-RGB data alignment

sensing system enables the automated capture of detailed geometric and temperature data, supporting real-time control and enhancing the precision and effectiveness of the monitoring process during 3D concrete printing.

3.1 Surface temperature capturing

The automated process for capturing the surface temperature of a sample is as follows (shown in Figure 2): First, thermal and RGB images are captured simultaneously at a frame rate of 8 FPS, determined by the lower frame rate of the two cameras. Due to differences in the field of view (FOV) and resolution, the RGB image undergoes a geometric transformation to align its perspective and scale with that of the thermal image. This transformation is guided by a calibration process. Next, a series of image processing steps is applied to the RGB image to identify the sample's contour. The detected sample location in the transformed RGB image is then mapped onto the thermal image, enabling precise localization of the sample within the thermal image. Finally, the temperature data from the selected region in the thermal image is extracted as the sample's surface temperature. The details of each step are explained in the following paragraphs.

Geometric transformation: The RGB images undergoes a calibration process to align with the thermal images. To calibrate it more precisely, we put 4 heating points as calibration points on the printing platform so that they are obvious to identify in both RGB and thermal images. Once the calibration points are identified, the perspective transformation matrix H can be calculated by the OpenCV's package [21]. Then each pixel in the destination image to corresponding pixel in the source image can be calculated using:

$$\begin{bmatrix} x' \\ y' \\ \omega' \end{bmatrix} = H \cdot \begin{bmatrix} x \\ y \\ 1 \end{bmatrix} \quad (1)$$

Where (x, y) are the coordinates in the source image, (x', y') are the coordinates in the destination image, ω' is the scaling factor for normalization.

The main problems encountered during image transformations involve the extrapolation of non-existing pixels and the interpolation of pixel values. In cases where pixels in the destination image map to out-of-bound coordinates in the source image, extrapolation method which ensures that such pixels remain unmodified in the destination image is employed. Additionally, because the mapped coordinates are often fractional values, bilinear interpolation is used to estimate the pixel values at these fractional coordinates.

Sample detection: to automate the process of sample detection, there are 4 steps as follows: 1) Grayscale conversion, 2) Edge detection, 3) Contour detection, 4) Sample detection. First, the transformed RGB image is converted into a single-channel grayscale image, suitable for edge detection algorithms. The grayscale intensity is given by:

$$I_{gray}(x, y) = 0.2989 \cdot R(x, y) + 0.5870 \cdot G(x, y) + 0.1140 \cdot B(x, y) \quad (2)$$

Where $R(x, y)$, $G(x, y)$, $B(x, y)$ are the red, green and blue intensity values at pixel (x, y). $I_{gray}(x, y)$ is the grayscale intensity.

Then, Canny algorithm[22] is adopted to detect edges. This algorithm identifies regions of rapid intensity change, which often correspond to object boundaries. The gradient of the grayscale image is computed in the x- and y- directions using Sobel filters:

$$G_x = \frac{\partial I_{gray}}{\partial x}, \quad G_y = \frac{\partial I_{gray}}{\partial y} \quad (3)$$

The gradient magnitude and direction are then calculated by:

$$G = \sqrt{G_x^2 + G_y^2} \quad (4)$$

$$\theta = \arctan\left(\frac{G_y}{G_x}\right) \quad (5)$$

Then, Non-Maximum Suppression process eliminates spurious responses by retaining only the strongest gradient magnitudes along the direction of the edge. Through Double Thresholding, pixels with gradient magnitudes above the upper threshold are classified as strong edges, and those below a lower threshold are discarded. Pixels between the thresholds are treated as weak edges. Finally, Edge Tracking by Hysteresis preserves weak edges that are connected to strong edges while suppressing isolated weak edges, producing a binary edge map. Then, contours are

Figure 3. Steps to detect sample in RGB images

detected in the binary edge map. A contour is defined as a curve joining all continuous points along a boundary with the same intensity. The contour with the largest area is selected as the sample's contour. The contour detection example is shown in Figure 3.

Alignment and capturing: after detecting the sample region in the transformed RGB image, a rectangular bounding box is generated and directly applied to the thermal image. The temperature data in each pixel within the bounding box are then extracted and recorded as surface temperature.

3.2 Geometry monitoring

The system for sample geometry monitoring uses the same camera with depth mode.

Point clouds generation: The monitoring process utilizes the in-built point cloud mode, which generates a point cloud based on the depth map and the camera's intrinsic parameters. The (x, y, z) coordinate of each point are computed using the following equations:

$$x = (u - cx) \cdot \frac{z}{f_x} \quad (6)$$

$$y = (v - cy) \cdot \frac{z}{f_y} \quad (7)$$

$$z = depth(u, v) \quad (8)$$

Where u, v are the pixel coordinates in the 2D image, z is the depth value. cx, cy are the center of the optical axis. f_x, $f_x$are the focal length of the camera.

Background filtering: Once the point cloud is generated, an initial coordinate-based filter is applied to remove the background. Given the fixed relative position between the sample and the camera, the filter coordinates can be predefined as constant values. After applying the background filtering, the remaining point cloud consists solely of the platform and the monitored sample.

Plane identification and filtering: The processed point cloud undergoes a plane segmentation and filtering step to isolate the sample. The RANSAC (Random Sample Consensus)[23] algorithm is employed to identify the primary plane, which corresponds to the printing platform. Through iterative random sampling of points, potential planes are generated, and the distances between the points and these planes are calculated. Points within a predefined distance threshold are classified as inliers of a given plane. After 1000 iterations, the plane with the largest number of inliers is identified as the platform plane. To further refine the results, additional points within the threshold distance to the identified plane are included as part of the platform to remove noise. Once the platform points are filtered out, the remaining points in the point cloud are considered to represent the sample.

Outlier filtering: After the removal of the platform plane, some outliers may still remain in the point cloud. To address this, Statistical Outlier Removal (SOR) is employed to filter out these noise points. This process begins by calculating the average distance between each point and its neighboring points (e.g., the 20 nearest neighbors) to establish the global distance distribution, including the mean and standard deviation. Points with distances exceeding two standard deviations from the mean are identified as outliers and subsequently removed from the dataset. This approach, based on detecting local density variations in the point cloud, effectively eliminates noise in sparsely populated regions, resulting in a refined and clean point cloud. The process of the point clouds processing is shown in Figure 4.

4 Discussion

This system emphasizes detailed geometric and temperature inspections, delivering comprehensive and refined data to enhance real-time control in 3D concrete printing. The integration of the thermal and RGB data can extract temperature and enable continuous and automated surface temperature measurement. With its sensor refresh rate capable of handling printing speeds up to 30 cm/s, the system supports most industrial printing conditions[24-26]. Integrated with an established model of material and process parameters, the monitoring system facilitates early identification of conditions that balance the critical aspects of extrudability and buildability.

Early changes in layer geometries during the printing process can be influenced by key process parameters, such as printing speed, extrusion rate, nozzle deposition

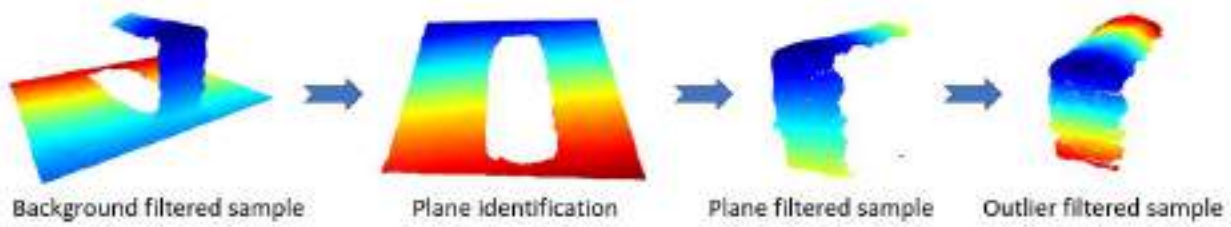

Figure 4. Point clouds processing and filtering

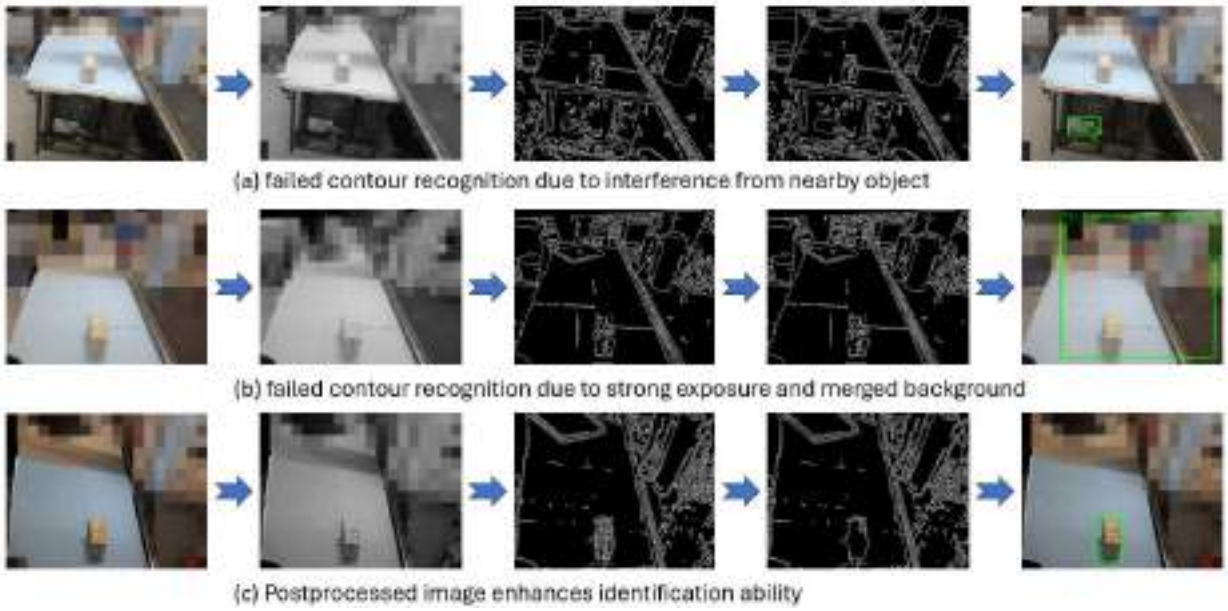

Figure 5. Object identification under different scenarios

height, and material properties like yield stress, stiffness, and early-age strength gain. However, geometry alone may not be sufficient to pinpoint parameters requiring adjustment. By combining object temperature - which reflects on green material properties and concrete hydration behavior - the combined data set could provide insights into which material and/or process parameters may need modification. For instance, localized temperature anomalies, such as excessive gradient or out-of-range values, combined with a slight change in layer height could indicate the potential for future excessive layer deformation or inadequate interlayer bonding, thus enabling predictive interventions on process parameters or material dosing. This comprehensive approach supports dynamic refinements to printing parameters ensuring precision, stability, and structural integrity throughout the 3D printing process.

One of the main challenges of this system lies in the automatic recognition of geometric features in images, which is sensitive to background settings and lighting conditions. When contrast is insufficient, such as under strong lighting, high exposure, or when the sample color closely matches the background, contour detection may fail. For instance, in Figure 5(b), strong exposure caused the background and sample to merge visually, resulting in failed contour recognition. Similarly, Figure 5(a) illustrates interference from other high-contrast contours in the background, which disrupted sample detection. To overcome these challenges, it is necessary to eliminate environmental interferences and enhance recognition accuracy. Techniques such as reducing brightness, increasing contrast, or applying filters can significantly improve detection performance. For example, as shown in Figure 5(c), post-processing the image to enhance contrast led to a substantial improvement in contour recognition, demonstrating the potential of post-processing in ensuring reliable image-based monitoring. These enhancements are essential for maintaining the robustness of the system in diverse operational environments.

The geometry monitoring system developed in this study provides valuable support for real-time quality control in 3D concrete printing. In terms of measurement accuracy, the system shows better performance in width measurements compared to height measurements. As shown in Table 1, the width measurement error is approximately 3.5 mm, while the height measurement error is around 5.4 mm. While these results may not surpass those of some existing systems, the approach offers distinct advantages. By using depth information to generate point clouds, the system captures more detailed geometric features than standard 2D RGB cameras. For example, at a distance of 0.7 m, it can detect deformations as small as 5 mm, which is helpful for identifying potential concrete layer deformations. Figure 6 demonstrates the system's ability to detect complex height deformations, enabling operators to monitor and adjust the printing process as needed.

Table 1 Measurement of sample width and height

Type	Captured(mm)	Actual(mm)
Width	62.4	58.9
Height	89.1	94.5

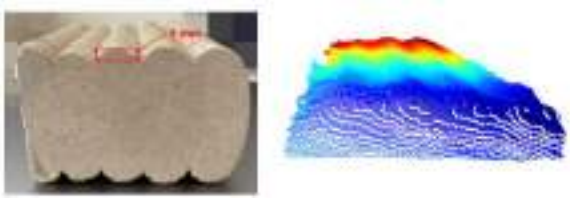

Figure 6. Sample with point clouds image

The use of a structured light-based depth sensor for geometric measurements enables high-resolution data capture but comes with several limitations in various environmental conditions. One major challenge is its sensitivity to lighting conditions, particularly in outdoor applications. In regions with strong solar radiation, the projected infrared pattern used by structured light sensors can be significantly disrupted, leading to reduced measurement accuracy or data loss. This constraint limits their effectiveness in open construction sites or large-scale outdoor 3D printing operations where environmental light fluctuations are unavoidable.

Additionally, the performance of the selected depth sensors is constrained by their frame rate, which is not particularly high. In large-scale applications, such as continuous 3D concrete printing over expansive areas, this limitation may hinder its ability to track fast-moving printing nozzles or dynamically adjust extrusion parameters in real time.

Another practical challenge arises from the presence of extraneous objects in real-world construction environments. Debris, scaffolding, and other surrounding elements can introduce noise in the captured data, making object detection more difficult. These distractions can degrade the reliability of geometric measurements and increase the risk of false detections, which is critical for autonomous or semi-automated construction processes.

From an industrial application perspective, future development should focus on selecting more advanced sensors with enhanced robustness against environmental disturbances. LIDAR-based sensors, for example, are less affected by ambient lighting and could serve as an alternative for outdoor applications, though at a higher cost [27, 28]. Additionally, improving the robustness of object detection algorithms through deep learning-based techniques could mitigate the impact of background clutter and ensure reliable detection of the printed structure. These advancements will be crucial for enabling fully autonomous and scalable 3D concrete printing systems in real-world industrial settings.

5 Conclusion

This study presents the development of a multi-modal sensing system designed to enhance real-time quality control for additive construction by extrusion by integrating thermal, depth and RGB data. As work in progress, we described the system and methodology we use to capture these data. The system aims to provide detailed feedback on geometric features and sample surface temperature. It provides new insights and information for quality monitoring, achieving a better balance between detailed geometric detection and real-time monitoring. Future work will focus on improving the system's resiliency to adapt to various outdoor scenarios and industrial environments. Additionally, future efforts will also involve developing an AI-based framework to process the captured data, enabling real-time adjustment of printing parameters and the ability to predict potential risks, ensuring improved construction quality.

Abstract –

Scaffolding safety is a critical challenge in the construction industry, often compromised by accidents caused by improper assembly and missing components. This study introduces an automated pipeline for scaffold safety monitoring, integrating robot-assisted point cloud data acquisition, deep learning-based segmentation, scaffold component detection, and safety verification. A quadruped robot equipped with terrestrial LiDAR is utilized to acquire point cloud data, which is then segmented using a deep learning model. The scaffold components are detected through a patch-based algorithm, followed by 3D transformation, clustering, and Delaunay triangulation. The process culminates in the generation of a 3D CAD model, enabling safety evaluations to identify issues such as missing platforms and improperly installed horizontal members. The experimental results demonstrated high performance in CAD model generation and successfully identified structural anomalies in scaffolds, with the proposed method achieving an F1 score of 97.44% in CAD modeling. This approach shows substantial potential for improving scaffolding safety through effective monitoring and early hazard detection.

Scaffold Monitoring; Robotic Data Acquisition; Point Cloud Data; Deep Learning; 3D CAD Modeling; Safety Evaluation

1 Introduction

Scaffolds are vital temporary structures in construction sites, ensuring worker safety while enhancing operational efficiency. However, accidents occurring during the installation of scaffolds remain a significant safety concern, often attributed to missing components or improper assembly [1]. To prevent such accidents, safety guidelines are established to regulate scaffold installation, but ensuring compliance remains a challenge [2]. In practice, adherence to these guidelines relies heavily on manual inspections by supervisors, making it difficult to consistently enforce strict safety protocols. To address these issues, there is a growing demand for the development of automated technologies that can monitor scaffolding conditions and evaluate their safety.

Recent studies have highlighted the potential of using 3D point cloud data for scaffold safety monitoring. With its ability to provide precise spatial information about structures, 3D point cloud data can serve as a valuable tool for detecting and analyzing scaffold components. Luo et al. [3] applied least-squares fitting and random sample consensus (RANSAC) to scaffold point clouds acquired through mobile laser scanning (MLS) to extract scaffold pipes and monitor their deformation. Wang [4] utilized algorithms such as clustering, RANSAC, and m-estimator sample consensus to extract scaffold components from point clouds and verify compliance with installation regulations. Advancements in deep learning have further improved the accuracy of scaffold recognition. Kim et al. [5] developed a scaffold monitoring pipeline that includes data acquisition using a quadruped robot equipped with MLS, deep learning-based point cloud segmentation, and 3D CAD model generation. Kim et al. [6] proposed an algorithm that leverages deep learning techniques to interpret terrestrial laser scanning (TLS) point cloud data and performed regulation checks on scaffold installations.

However, there has been a lack of comprehensive research for scaffold safety monitoring presenting a complete pipeline that encompasses all stages, from data acquisition to 3D model generation and anomaly detection. Furthermore, existing methods for scaffold component detection have often demonstrated reduced performance when applied to different scaffold sites. In previous studies, scaffold component detection methods projected point clouds into 2D before applying techniques such as RANSAC and peak finding. However, this approach results in the loss of 3D geometric

information of the components. A patch-based detection approach could offer a more effective alternative by preserving and utilizing the 3D structure of the components.

This study addresses these limitations by proposing a robust pipeline specifically designed for scaffold monitoring. As shown in Figure 1, the proposed approach integrates efficient point cloud data acquisition using a quadruped robot, deep learning-based point cloud segmentation, scaffold component detection, 3D CAD model generation, and automated anomaly detection into a unified framework. Notably, the method enhances robustness in scaffold component detection through processes such as 3D transformation, patch-based component detection, and Delaunay triangulation for scaffold unit identification.

During the scaffold installation phase, major factors contributing to scaffold accidents include errors in falsework design, incorrect connections, missing components, and improper assembly [7]. However, this study focuses on automatically detecting missing components and improper assembly. The proposed method detects these anomalies by segmenting scaffold point clouds, identifying structural components, and verifying their geometric correctness within the 3D CAD model. By addressing improper assembly and missing components, the framework ensures proactive safety monitoring, enabling early detection of hazardous scaffold conditions. If further refined, the proposed method is expected to contribute significantly to preventing accidents and improving safety conditions in construction environments.

2 Methodology

2.1 Point Cloud Acquisition and Segmentation

As shown in Figure 1(a), a mobile laser scanning system was constructed by mounting a TLS LiDAR (FARO Focus M70) and a mini PC (Intel NUC 11) onto a quadruped robot (Unitree Aliengo). The robot was remotely controlled for movement and point cloud data acquisition. Figure 1(b) illustrates the analysis of the acquired point cloud data using RandLA-Net [8], a deep learning-based 3D segmentation model. The model classifies the point cloud data into seven categories: vertical members, horizontal members, platforms, stairs, rakers, bracings, and background.

2.2 Scaffold Component Detection

In the scaffold component detection step illustrated in Figure 1(c), vertical members, horizontal members, and platforms are extracted from the segmented point clouds. These three components are essential elements of scaffolds and are therefore subject to safety verification; other components are excluded from the assessment as they do not directly affect structural stability.

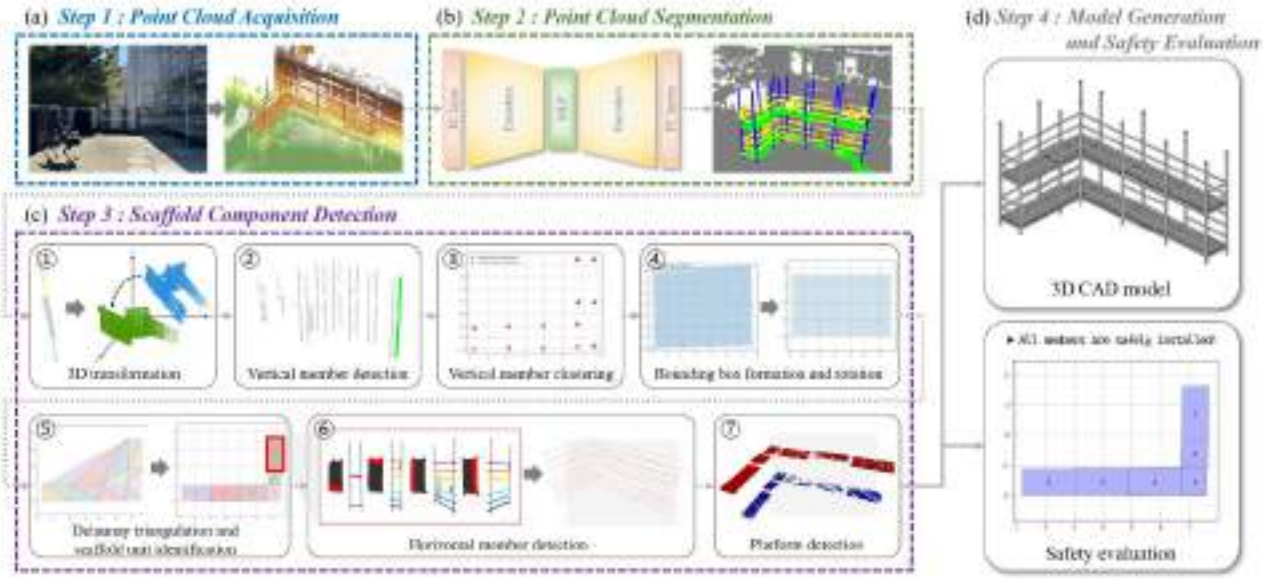

Figure 1. Overview of the scaffold safety monitoring pipeline; (a) robot-assisted point cloud data acquisition, (b) point cloud segmentation using a deep learning-based model, (c) scaffold component detection, and (d) 3D CAD model generation and scaffold safety evaluation.

(a) (b) (c)

Figure 2. 3D patch representation of scaffold components; 3D patches for (a) vertical members, (b) horizontal members, and (c) platforms.

Vertical members, horizontal members, and platforms are identified using a patch-based component matching algorithm proposed by Kim et al. [9]. A 3D patch similar in size and shape to each component is generated and traverses across the target region within the point cloud. If the distance between the points in the patch and the target point cloud is below a predefined threshold, the presence of the component is confirmed. Figures 2(a), 2(b), and 2(c) show green points representing the generated 3D patches for vertical members, horizontal members, and platforms, respectively.

Once the point cloud data are segmented, the largest cluster of vertical member points is identified using density-based spatial clustering of applications with noise (DBSCAN). The entire point cloud is then aligned through a 3D transformation to ensure that the largest vertical member cluster is perpendicular to the XY plane (Figure 1(c), Step 1). This alignment effectively handles tilted scaffold point cloud data. The patch-based component matching algorithm is then applied to the segmented vertical member points to detect vertical components (Figure 1(c), Step 2), using patches measuring 0.1 m × 0.1 m × 4 m. Overlapping vertical members are merged through DBSCAN clustering (Figure 1(c), Step 3). Subsequently, a bounding box is created around the projected vertical member points on the XY plane, and the points are rotated so that the bounding box aligns with the X and Y axes (Figure 1(c), Step 4). Delaunay triangulation is applied using the X and Y coordinates of the vertical members to partition the space. From the partitioned areas, regions forming right-angled rectangles are identified as individual scaffold units (Figure 1(c), Step 5). This scaffold unit identification method is robust and performs effectively regardless of the scaffold's shape or size. Finally, within each scaffold unit, horizontal members and platforms are detected using patches (Figure 1(c), Steps 6 and 7). The dimensions of the patches used to detect these components are determined based on the size of the corresponding scaffold unit, with a patch thickness set at 0.1 m.

2.3 Model Generation and Anomaly Detection

As shown in Figure 1(d), once the scaffold components are detected, their positional information is extracted to generate a 3D CAD model. For example, in Step 6 of Figure 1(c), if a horizontal member is detected using a patch measuring 0.1 m × 0.1 m × 1 m, a pipe with a length of 1 m is created at the corresponding position. The CAD model is automatically generated using the FreeCAD modeler with a Python-based script. The detected vertical and horizontal members are represented as cylindrical CAD objects in FreeCAD, while platforms are modeled as rectangular box-shaped objects. The final CAD model is then exported in FCStd format.

This model can serve as a visual resource for site managers to monitor the installation status of scaffolds and facilitate structural stability analysis. The obtained component information can also be used to directly evaluate the safety of the scaffold. In this study, the presence of platforms and the abnormal lengths of horizontal members in each scaffold unit are identified.

3 Experiments and Results

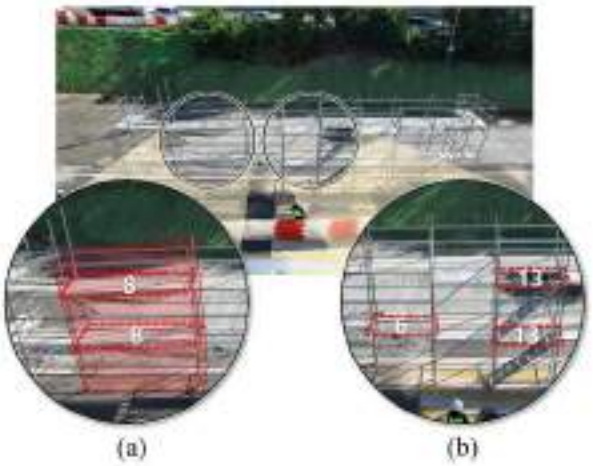
3.1 Datasets

In this study, the RandLA-Net model pretrained on the dataset from Kim et al. [6] was used for point cloud data segmentation. To validate the proposed method, point cloud data were acquired from an actual scaffold site. Figures 3(a) and 3(b) show the scaffold site where the data were acquired and the quadruped robot used for data acquisition, respectively. A total of 23 point cloud datasets were acquired as the robot moved across the site, and these datasets were registered using FARO SCENE software.

(a) (b)

Figure 3. Data acquisition at the scaffold site; (a) scaffold site where point cloud data were acquired, and (b) quadruped robot used for data acquisition.

To evaluate the performance of the proposed method for scaffold safety verification, components were deliberately installed incorrectly at the scaffold site depicted in Figure 3. As shown in Figure 4(a), the horizontal members of scaffold Unit 8 were installed with an abnormally long length, and their platforms were improperly secured and tilted. Additionally, as shown in Figure 4(b), platforms were missing from scaffold Units 6 and 13.



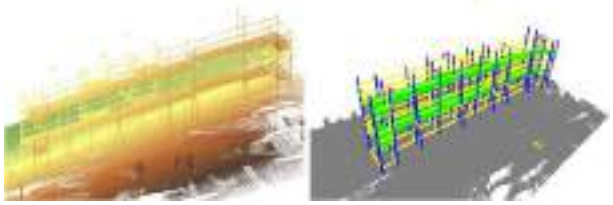


Figure 4. Examples of structural anomalies in scaffolds; (a) improperly installed horizontal members and tilted platforms in scaffold Unit 8, and (b) missing platforms in scaffold Units 6 and 13.

3.2 Experimental Results

3.2.1 3D Semantic Segmentation Results

Figure 5(a) shows the registered point cloud data of scaffolds acquired using the robot. The acquired point cloud data were segmented using a deep learning-based approach, as shown in Figure 5(b). As indicated in Table 1, the segmentation achieved an average F1 score of 91.08%.

(a) (b)

Figure 5. Scaffold point cloud registration and segmentation; (a) registered scaffold point cloud data acquired using the robot, and (b) segmentation results based on the deep learning-based approach.

Table 1. Segmentation performance for scaffold point cloud data.

Scaffold component	Precision	Recall	F1 score
Vertical member	83.14%	99.44%	90.56%
Horizontal member	96.24%	70.46%	81.36%
Platform	88.40%	97.16%	92.57%
Background	99.77%	99.92%	99.84%
Average	91.89%	91.75%	91.08%

3.2.2 Scaffold Component Detection Results

Patch-based detection was performed on the segmented point cloud data to identify points corresponding to vertical members (Figure 6(a)). The detected vertical members were consolidated through clustering (Figure 6(b)) and then rotated to align with the X and Y axes (Figure 6(c)). Using the X and Y coordinates of the vertical members as reference points, Delaunay triangulation was applied to partition the space (Figure 6(d)). From the partitioned areas, scaffold units were estimated (Figure 6(e)). For each scaffold unit, horizontal members and platforms were detected using the patch-based approach (Figures 6(f) and 6(g)).

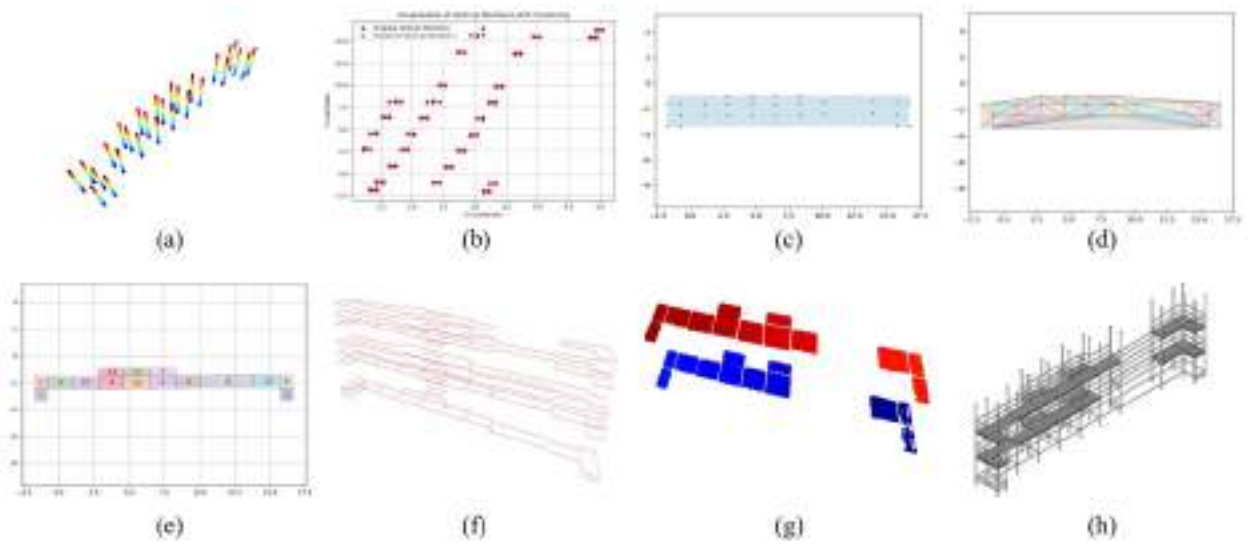

Figure 6. The process of scaffold component detection; (a) patch-based vertical member detection in the segmented point cloud, (b) clustering of detected vertical members, (c) rotation of vertical members to align with the X and Y axes, (d) Delaunay triangulation for space partitioning based on vertical member coordinates, (e) estimation of scaffold units from partitioned areas, (f) horizontal member detection in scaffold units, (g) platform detection in scaffold units, and (h) 3D CAD model generation.

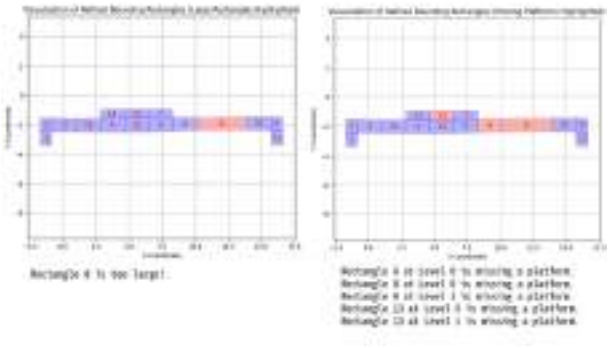

3.2.3 3D CAD Model Generation and Anomaly Detection Results

Figure 6(h) shows the 3D CAD model generated based on the detected scaffold component information. As shown in Table 2, the scaffold components were represented in the 3D CAD model with an F1 score of 97.44%. Although the segmentation of the scaffold point cloud achieved lower performance (Table 1), the modeling accuracy improved by utilizing the raw point cloud data within the scaffold units during the extraction of horizontal members and platforms.

Table 2. Performance of 3D model generation for scaffold components.

Scaffold component	Precision	Recall	F1 score
Vertical member	100%	100%	100%
Horizontal member	95.71%	98.05%	96.87%
Platform	100%	91.30%	95.45%
Average	98.57%	96.45%	97.44%

Figure 7 shows the evaluation and visualization of the scaffold's safety status based on the component information. As shown in Figure 7(a), the algorithm successfully detected the abnormally long horizontal members in scaffold Unit 8. An abnormally long horizontal member must be detected in advance, as it compromises structural stability and increases the risk of collapse. Additionally, Figure 7(b) demonstrates that the algorithm accurately identified the missing platforms in scaffold Units 6 and 13. As shown in Figure 7(b), the platforms in scaffold Unit 8 were abnormally installed at a tilt and were therefore detected as missing.

(a) (b)

Figure 7. Evaluation and visualization of scaffold safety status; (a) detection of abnormally long horizontal members, and (b) identification of missing platforms.

3.3 Discussion

3.3.1 Challenges in CAD Modeling Accuracy

Figure 8(a) highlights the factors that led to the decreased precision in horizontal member representation within the CAD modeling results (Table 2). As shown in the figure, multiple horizontal members at the lowest level were incorrectly detected. This issue arose because noise points acquired near the ground were misclassified as horizontal members. To address this, a preprocessing step to filter out ground noise points could be introduced.

Figure 8(b) illustrates the factors contributing to the decreased recall in CAD modeling of horizontal members. The figure shows Unit 8 of the scaffold, where an abnormally long horizontal members were installed. The installation caused a slight tilt, leading to the failure of the patch-based component matching algorithm. Since the patches move parallel to the X or Y axes, they are less effective in detecting tilted components.

The causes of the reduced recall in platform modeling are demonstrated in the example shown in Figure 8(c). Although platforms were present, they were installed at an angle, similar to the situation in Figure 8(b), and therefore were not detected. However, such improper platform installation poses a significant risk of falls, making the detection of these anomalies in the safety evaluation results meaningful.

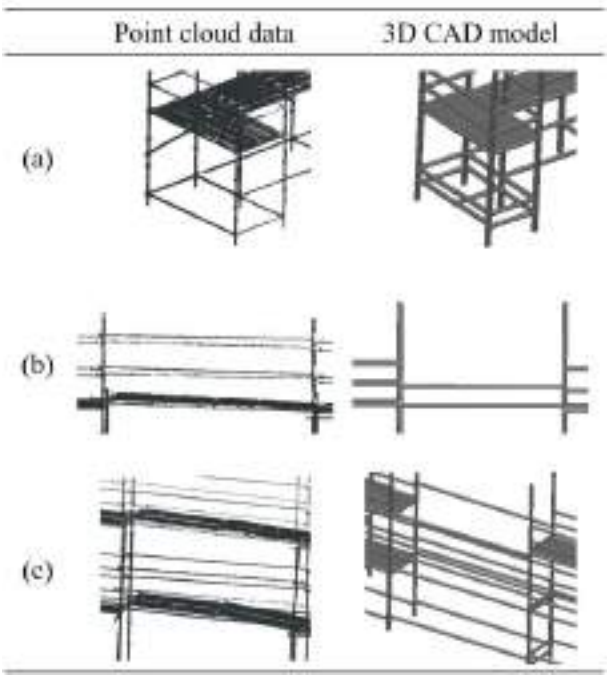

Figure 8. Analysis of false detection issues in CAD modeling for scaffold components; (a) incorrect detection of horizontal members, (b) undetected horizontal members, and (c) undetected platforms.

3.3.2 Future Directions

To achieve comprehensive structural monitoring of scaffolds, it is essential to detect not only improper assembly and missing components but also incorrect connections, such as base plates and joints. However, since these connections are highly localized features, they are difficult to segment using point cloud data alone. Therefore, future studies could explore a sensor fusion approach that integrates image and point cloud data to enable more accurate connection monitoring.

In this study, scaffold safety monitoring was conducted by detecting improper assembly and missing components. The proposed method was validated using abnormally long horizontal members as an example of improper assembly and missing platforms as an example of missing components. However, many additional subcategories exist. For instance, the improper assembly category could include tilted components or elements installed with irregular spacing. Similarly, the missing component category could be expanded to include missing horizontal and vertical members. To enhance the practical applicability of the proposed method, future research will apply and validate the method on scaffolds with a wider range of defects.

Although the proposed method was validated in a testbed environment, future studies should focus on applying and refining the method in real construction sites. This would require acquiring a larger and more diverse scaffold point cloud dataset to further improve 3D segmentation performance. Additionally, to address real-world challenges such as noise and occlusion in point cloud acquisition, techniques such as noise removal and point cloud upsampling should be integrated into the workflow.

4 Conclusion

This study proposed a comprehensive pipeline for scaffold safety monitoring, consisting of robot-assisted point cloud data acquisition, deep learning-based point cloud segmentation, scaffold component detection, CAD model generation, and safety evaluation. Experimental results confirmed that the proposed method effectively detected scaffold components, and generated high-accuracy 3D CAD models. Furthermore, the method successfully detected missing platforms and abnormal horizontal member installations in scaffold units, contributing to the visual assessment of safety conditions. However, the false detection cases of some components suggest the need for further research into noise point cloud preprocessing and the improvement of tilted component detection. For the generalization of the method, further improvement is needed through its application to construction sites with a wider variety of

scaffold shapes and sizes. The proposed method has significant potential for effectively monitoring the installation status and verifying the safety of scaffolds, and is expected to play a key role in improving safety conditions at construction sites.

Abstract -

Rooftop 3D reconstruction using UAV-based photogrammetry offers a promising solution for infrastructure assessment, but existing methods often require high percentages of image overlap and extended flight times to ensure model accuracy when using autonomous flight paths. This study systematically evaluates key flight parameters—ground sampling distance (GSD) and image overlap—to optimize the 3D reconstruction of complex rooftop infrastructure. Controlled UAV flights were conducted over a multi-segment rooftop at Queen's University using a DJI Phantom 4 Pro V2, with varied GSD and overlap settings. The collected data were processed using Reality Capture software and evaluated against ground truth models generated from UAV-based LiDAR and terrestrial laser scanning (TLS). Experimental results indicate that a GSD range of 0.75–1.26 cm combined with 85% image overlap achieves a high degree of model accuracy, while minimizing images collected and flight time. These findings provide guidance for planning autonomous UAV flight paths for efficient rooftop assessments.

Infrastructure Assessment; Photogrammetry; 3D Reconstruction; Uncrewed Aerial Vehicles; Roof Inspection

1 Introduction

The inspection of rooftops plays a critical role in assessing the structural integrity and maintenance needs of buildings. Traditionally, this task has been carried out by inspectors physically accessing rooftops to identify defects in the building envelope and rooftop equipment. This manual approach is inherently time-consuming, especially for large-scale commercial and industrial structures, and presents significant challenges for visualizing structures.

Advancements in Uncrewed Aerial Vehicle (UAV) technology and photogrammetry have opened new possibilities for building inspections. UAV's equipped with high-resolution cameras can capture images from locations inaccessible to inspectors, enabling comprehensive documentation of structures. These images can be processed using 3D reconstruction techniques to create digital models of the inspected structures. This not only facilitates better visualization of scale and defect locations, but also serves as a historical record for tracking structural changes over time.

Figure 1. LiDAR point cloud of Ellis Hall, Kingston, Ontario with labeled roof sections and height above ground level (AGL).

This study explores the use of autonomous flight paths for generating accurate 3D reconstructions for building inspections. Specifically, it investigates how varying flight parameters, such as image overlap (OL) and ground sampling distance (GSD), affect the accuracy of the reconstructed models. The intended outcome of this research is to be able to optimize these parameters to minimize the flight duration, computation time, and number of image captures - key factors for reducing inspection and processing time in commercial applications - while still maintaining accurate models. There are three primary contributions of this paper:

- Recommendations based on experimental testing for optimal UAV flight parameters in autonomous photogrammetry-based rooftop 3D reconstruction.
- Validation of a UAV-based LiDAR platform as a source of ground truth models using a high-resolution terrestrial laser scanner (TLS).
- Application of cloud-to-cloud comparisons and quantitative pointcloud analysis for infrastructure assessment applications.

2 Related Work

Related work was reviewed from two areas of research: (1) Influence factors for 3D reconstruction, and (2) Quantitative assessment of large-scale mesh models.

2.1 Influence factors for 3D reconstruction

Influence factors for UAV photogrammetry-based 3D reconstruction can be broadly grouped into three main categories: flight parameters, camera settings/image acquisition, and reconstruction methods. While camera settings and reconstruction methods can have significant impacts on reconstruction quality, they were out of the scope of this research and were kept constant throughout the testing. The influence of flight parameters on photogrammetry reconstruction quality has been investigated thoroughly. Several studies have confirmed that flight height, image overlap, ground control point (GCP) quantities/distribution, and georeferencing methods have a significant impact on reconstruction accuracy. GCP's are typically used in larger scale mapping applications such as forestry [1, 2] and glaciology [3], however there has also been research on GCP density and pattern on the reconstruction of dam infrastructure [4]. In this paper's application of building facade 3D reconstruction, there are enough unique features from the building characteristics that an adequate number of tie points can be achieved during feature extraction without the requirement of GCP's.

Flight height has been investigated individually [5, 6], and in combination with overlap and other parameters [7, 8, 7, 9, 10, 11] in various other applications, but less research has been done on how these parameters can influence the reconstruction quality of infrastructure assets. Altman et al. investigated how varying reconstruction methods, number of images, and number of control points (CP's) could influence the reconstruction quality of a church facade [12]. However, all data collected was from terrestrial sources.

2.2 Quantitative assessment of mesh models

Several methods have been established for quantitatively measuring model quality and accuracy. These methods can be broadly categorized into three areas: (1) Reconstruction metrics, (2) Discrete model metrics, and (3) Continuous model metrics. Metrics from the reconstruction process such as number of tie points and number of points in the dense cloud have been shown to correlate with lower control point RMSE values [2]. Discrete metrics consist of control points with known locations that can be used to determine vertical and horizontal error at various locations on the model. These methods can be used to indicate drift or misalignment, but they do not provide continuous information about mesh accuracy across the entire model surface. Continuous model metrics can be divided into measures of mesh visual quality and measures of global geometric accuracy. Mesh visual quality metrics such as local roughness, noise, curvature variation, and topology can be used to quantify the appearance of a mesh surface [13]. Continuous metrics for measuring mesh accuracy are less common in large-scale 3D reconstruction due to the requirement of a ground truth model (GT), which can be difficult to capture at high degrees of coverage and accuracy. Typically, a GT is captured using TLS systems that can produce point clouds at a high degree of accuracy and point density [12, 14, 13, 15].

Chen et al. outlined a workflow for the inspection of a masonry bridge through UAV-based data acquisition, 3D reconstruction, data quality evaluation, and damage detection [15]. They used a TLS point cloud to provide quality metrics for five different potential defects in the reconstructed photogrammetry model. They acknowledge the presence of occlusions in their TLS model due to obstacle-blocking and self-shadowing. These coverage-based defects would be exacerbated for roof reconstructions, where rooftop equipment and obstructions would limit the coverage of the TLS system to an even greater extent. In this paper, a two-stage GT method is proposed. A TLS is used on the rooftop to capture specific areas of high geometric complexity. This is used to validate a UAV-based LiDAR payload that collects data across the entire roof structure.

3 Background

Within the field of photogrammetry, the standard path for autonomous flights is a double-grid boustrophedon pattern using an oblique camera angle [7]. This involves the UAV making back and forth passes at a specified distance in perpendicular directions across the coverage area. This method allows non-horizontal surfaces to be captured from four directions and reduces the chance of occlusions. These paths can be defined with two flight parameters: the image overlap (OL), and (b) the GSD. Because of the oblique camera angle and the varying roof elevations, GSD was used as a variable parameter instead of flight height to better represent the distance between the camera and the target surface.

GSD refers to the resolution of the captured images relative to the real-world dimensions of the scene. GSD depends on the distance between the camera and the object being captured (Z), the camera focal length (f) and the size of a pixel on the sensor (p), which can be determined with the dimensions of the sensor and the image, i.e.,

$$\text{GSD} = \frac{Z}{f}\, p. \tag{1}$$

OL considers the area of shared coverage between two consecutive images. This is expressed as a percentage of

the entire image. Side OL can be determined using the distance between consecutive passes in the same direction. Front OL is defined as the following:

$$\mathrm{OL} = 100 \cdot \frac{\mathrm{GSD}\, w - v\, r_c}{\mathrm{GSD}\, w}, \tag{2}$$

where w is the image width, v is the UAV speed, and r_c is the capture rate of the camera.

4 Methodology

In this study, the approach in assessing flight parameters for 3D photogrammetry has three steps: 1. Data Collection: collected image data from 9 flights of the building in Figure 1 using a DJI Phantom 4 Pro V2. The research team collected UAV-based LiDAR data using a DJI Matrice 350 RTK, and TLS data using a FARO Focus. 2. Model Generation: generated 3D reconstructions using photogrammetry software Reality Capture [16]. LiDAR models are processed in DJI Terra [17], and TLS models are aligned using SCENE point cloud software [18]. 3. Model Evaluation: All models were trimmed, aligned, and compared using 3D point cloud processing software CloudCompare [19].

4.1 Data collection

Ellis Hall on the campus of Queen's University, Kingston, Ontario (latitude: 44.226, longitude: -76.496) was chosen as the test site for this experiment. The building features five distinct roof segments at AGL elevations ranging from 1.71 m to 14.16 m. The roof sections contain a variety of rooftop features, including an observatory dome, various HVAC equipment, fencing and barrier walls, and experimental testing equipment. This variance in elevation and subject matter provides unique levels of obstruction, lighting conditions, GSD, and feature complexity for the experiment.

Images for the photogrammetry reconstructions were collected using a DJI Phantom 4 Pro V2, a consumer multirotor UAV with an on-board 20M camera featuring an 84° field of view and an 8.8 mm focal length, capable of capturing 4k images. The goal of this research was to assess the photogrammetry reconstruction quality of fine details and unique rooftop features in real-world conditions. As such, a process was needed that would provide a continuous, global metric of model accuracy across the entire mesh surface. To do this, A 'ground truth' model (GT) was needed to assess the accuracy of the generated reconstructions. A LiDAR scan of the building was performed using a DJI Matrice 350 RTK, equipped with a Zenmuse L2 LiDAR sensor. The L2 features a frame-based LiDAR, internal IMU system, and an RGB mapping camera [20]. A D-RTK 2 Base Station and on-board RTK Module provide Real-time Kinematic Processing (RTK) for accurate localization during the flight, and Post Processing Kinematics (PPK) was done using DJI Terra [17]. The L2 specifications report a ranging accuracy of 2 cm at 150 m scanning distance, which is reported to improve at closer ranges. This paper proposes the use of a point cloud collected from the Zenmuse L2 as a GT model to provide quantitative evaluations of accuracy for the photogrammetry-based 3D reconstructions.

The UAV-based LiDAR point cloud was validated using the Faro Focus TLS platform. The TLS was placed in 14 locations across Roof Section B and Roof Section D. The Faro Focus produces a point cloud with 2 mm accuracy [21]. Ground control spheres were used to register the scans in Faro's SCENE 3D point cloud software. Three test segments of the roof were chosen to compare the TLS and LiDAR point cloud's. Areas of geometric complexity were chosen to highlight potential deficiencies in the UAV-based LiDAR's effectiveness as a GT model. A cloud-to-cloud (C2C) comparison was conducted between the two point clouds at each test segment. One of these comparisons can be seen in Figure 2. The test segments averaged an 85% F-score at a threshold value of 2 cm.

Figure 2. Recall scalar field for a cloud-to-cloud comparison of the UAV-based LiDAR and TLS point clouds.

4.2 Model generation

Photogrammetry models were generated using Reality Capture photogrammetry software [16]. Reality Capture uses a photogrammetry pipeline consisting of feature extract, feature matching, and a Structure-from-Motion (SfM) algorithm to establish a set of tie points. A meshing stage generates a geometric surface for the scene using a triangulation algorithm. Finally, a Coloring/Texturing stage estimates a color for each vertex based on the input images.

Reality Capture's settings were kept to their default values with the exception of the following alignment parameters: the maximum features per megapixel were increased from 10,000 to 20,000 and the maximum features per image was increased from 40,000 to 100,000. The prior hardness of position and the prior hardness of orientation were decreased from 1.0 to 0.1. Preselector features were

Table 1. Variable Flight Parameters, Flight Data, and Model Data

	Variable Parameters		Flight Data		Model Data	
Flight	GSD (cm)	OL (%)	Duration (min)	Captures	Compute Time (min)	Tie Points
Flight 1	0.51 - 1.01	60	4	42	55 sec	109 270
Flight 2	0.51 - 1.01	70	6.5	76	1 min 26 sec	637 177
Flight 3	0.51 - 1.01	80	9.5	198	2 min 55 sec	2 242 477

Flight 6	0.75 - 1.26	85	13.5	233	3 min 31 sec	4 571 844
Flight 7	0.75 - 1.26	90	32.5	482	11 min 31 sec	11 434 884
Flight 8	0.98 - 1.49	85	8.25	171	3 min 11 sec	3 073 278
Flight 9	0.98 - 1.49	90	23.5	360	6 min 15 sec	8 108 259

increased from 10,000 to 30,000 and the detector sensitivity was increased from medium to high.

4.3 Model evaluation

The models were evaluated using C2C distances between the photogrammetry-based models and the LiDAR point cloud. All point cloud analysis was done using CloudCompare [19]. The mesh models were sampled at 40,000 points per square meter. This was done to produce a dense point cloud that could accurately represent the mesh surface. All point clouds were then spatially subsampled with a minimum distance of 5 mm to ensure consistent uniform-density between models. The value of 5 mm was selected based on previous work on large-scale photogrammetry models [14].

Models were then trimmed of surrounding surfaces and divided into five rooftop sections. The models were roughly aligned using equivalent point pairs, before a fine alignment was done using an iterative closest point (ICP) algorithm. C2C distances were calculated using a quadratic height function as a local surface model, with a nearest neighbour radius of 10 cm. Three metrics were produced, following procedures in [14].

Precision is the measure of how accurately the points of the model align with the GT, represented as a percentage of points under a threshold distance d, and is defined as:

$$P(d) = \frac{100}{|R|} \sum_{r \in R} [\mathrm{e_{rg}} < d], \tag{3}$$

where R is the set of all points r in the reconstruction. e_{rg} is the distance between a given point r and its nearest point g in the GT point cloud.

Recall is a measure of the completeness of a reconstruction relative to a GT model. Recall is also represented as a percentage and is defined as:

$$R(d) = \frac{100}{|G|} \sum_{g \in G} [\mathrm{e_{gr}} < d], \tag{4}$$

where G is the set of all points g in the GT point cloud.

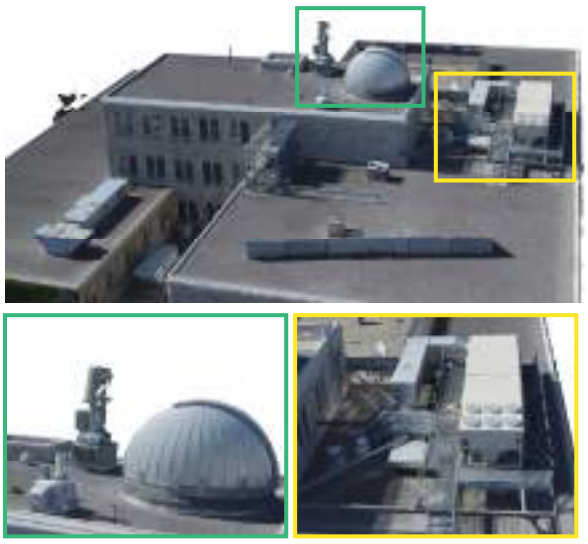
The third metric combines these two measures to provide a robust qualifier for model quality that considers accuracy and completeness. The F-Score, or harmonic mean, is defined as:

$$F(d) = \frac{2P(d)R(d)}{P(d) + R(d)}. \tag{5}$$

5 Results

Based on qualitative observations, it was observed that the flights at 60% and 70% OL produced models with large distortions, as seen in Figure 4a and F-Scores in Table 2. At these overlap percentages, even some flat rooftop surfaces were not accurately represented by the model. Because of this observation, these OL percentages where not used in future testing. Above 80% OL, models began to better represent the structure, but there were still variations in the reconstruction accuracy of fine details and complex geometry, as seen in Figure 3.

Some clear trends were observed from the C2C quantitative analysis conducted. The flights at 0.75 - 1.26 cm GSD generally outperformed the other flights, even when compared with flights that had significantly more images captured. This was observed for most roof sections: Flight 6 or Flight 7 had the highest F-score for four of the five roof sections. Another interesting observation is that Flight 5, having captured only 96 images, shared the third highest average rank with Flight 4 and Flight 9, which had 249 and 360 captures, respectively. It also had the lowest overlap of the three flights. The analysis also highlights the reduction in model quality for the lowest rooftop sections, D and E, at a higher GSD. At the same OL, Flight 9 had an F-Score that was 12.3% lower for Roof E and 15.9% lower for Roof D, when compared with Flight 7.



The precision and recall were also plotted across different threshold values for each of the roof sections. In Figure 4 and Figure 5, an example of this is shown for roof sections B, C, and D. It is clear the flights at 0.75 - 1.26 cm GSD (gold, turquoise, and pink on the diagram) consistently perform well across a range of threshold values. These plots also illustrate the under-performance of the 0.98 - 1.49 cm GSD flights on Roof D, shown in lime green and purple on the graphs in Figure 5 and Figure 6.

Table 2. F-Scores at 4cm Threshold

	Flight 1	Flight 2	Flight 3	Flight 4	Flight 5	Flight 6	Flight 7	Flight 8	Flight 9
Roof A	5.64	31.33	92.06	92.79	92.62	**95.82**	**95.64**	94.89	95.51
Roof B	43.55	77.18	90.80	90.56	91.04	**92.39**	**92.19**	90.98	91.56
Roof C	86.78	95.70	98.16	98.12	97.27	**98.17**	**98.80**	97.43	98.01
Roof D	12.63	85.19	84.56	86.36	**89.10**	**90.16**	88.53	70.46	84.36
Roof E	78.29	80.08	78.43	**88.92**	**86.22**	86.03	82.24	76.67	84.01
Mean	29.16	69.13	88.54	91.26	91.18	**92.41**	**91.30**	85.41	90.51
Rank	8.8	7.0	6.0	4.2	4.2	**1.6**	**2.6**	6.4	4.2

(a) Flight 4: 0.51 - 1.01 cm GSD, 85% OL

(b) Flight 6: 0.75 - 1.26 cm GSD, 85% OL

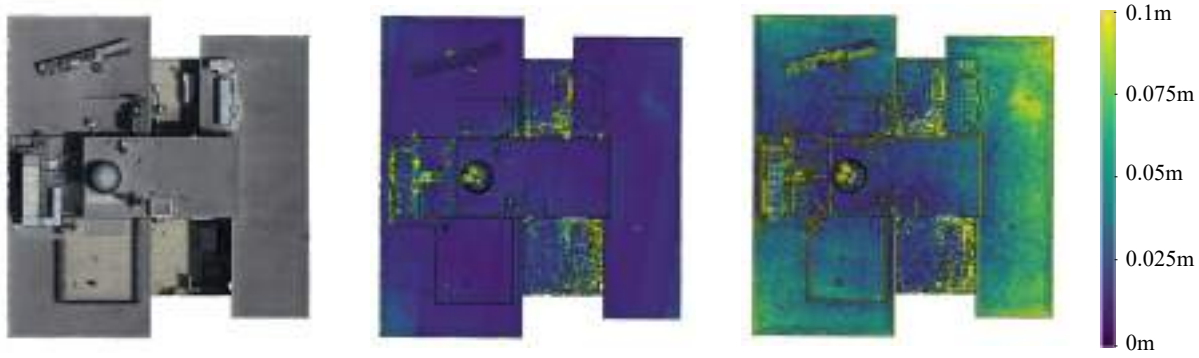
Figure 3. At the same OL, Flight 6 produces a more accurate model than Flight 4. Thin-walled surfaces feature less occlusions, seen in the exhaust ventilator on the left, and complex geometry was represented better, seen in the walkway on the right.

These figures also illustrate the separation in quality for more complex roof sections. Roof C, a section with minimal geometric complexity, features significantly less variation in F-Score across different flights. With the introduction of complex geometry (Roof B) and higher degrees of obstruction (Roof D), the flights begin to display a greater range in quality.

6 Discussion

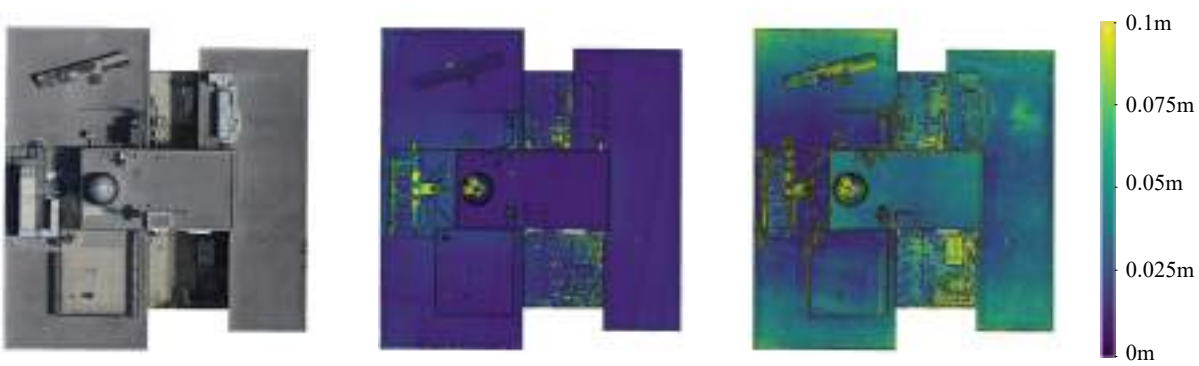
The models produced with 90% OL provided diminishing returns, or even decreasing quality, over the models at 85% OL. It was also evident that the 0.75 – 1.26 cm GSD flights produced more accurate reconstructions relative to the number of images collected, particularly for the roof sections at higher elevations. For general roof surfaces that have a moderate amount of geometric complexity and limited obstructions, these flight parameters will provide high-quality mesh models that accurately represent the real-world structure.

This paper provides three additional findings with regard to autonomous flight paths for rooftop 3D reconstruction:



- For roof sections that don't exhibit complex geometry, lower OL can still yield effective results while reducing flight time, image captures, and computation time. This can be seen in Roof C, where 70% OL produced a model with an F-score greater than 95% at a 4cm threshold.

- Thin-walled surfaces and fine details (e.g. chain-link fences, metal bar grating) were not captured accurately even at optimal OL and GSD values. Supplementary images would need to be captured manually around these features for accurate reconstruction.



- Lower roof sections exhibited a significant decrease in F-score relative to the other roof sections, regardless of GSD and OL parameters. This could be due to obstruction from other building sections and poorer lighting conditions.

(a) Flight 2: 0.51 - 1.01 cm GSD, 70% OL

(b) Flight 4: 0.51 - 1.01 cm GSD, 85% OL

(c) Flight 7: 0.75 - 1.26 cm GSD, 90% OL

Figure 4. RGB (left), precision (middle), and recall (right) scalar fields for three of the test flights. The model from Flight 2 data produced large regions of high error (>10 cm), and was unable to recreate simple building geometry. With higher overlap percentages, the error becomes primarily concentrated around regions of high detail, and the lower roof sections with poorer lighting and greater obstruction. Note that the rectangular area of high error on the observatory dome was due to rotation of the telescope prior to collection of the GT, however this is consistent across all test flights.

7 Future Work

The number of flights was kept relatively low due to the time-intensive data collection and C2C analysis processes. In future testing, a larger sample size of flights should be compared. Other flight parameters have also been shown to have an effect on reconstruction quality, including ground control points, camera angle, image parameters, camera settings, and georeferencing methods [7]. Future testing could investigate how these parameters may influence model quality in the context of building envelope 3D reconstruction. With added parameters and test flights, the main effects and interaction effects of these parameters can be observed using a statistic model.

The optimal parameters were also tested using other

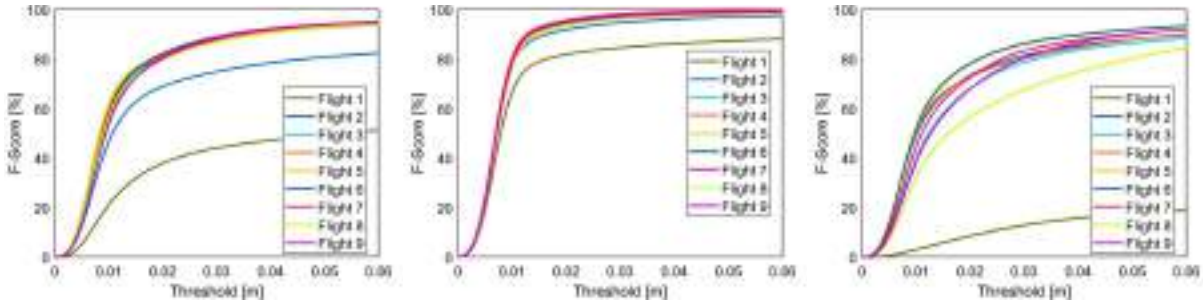


Figure 5. Precision at threshold values up to 6 cm for roof sections B, C, and D (left to right). For rooftops with less features, such as Roof C, the models remain fairly similar across different threshold values. As rooftop complexity is introduced, models begin to spread out.

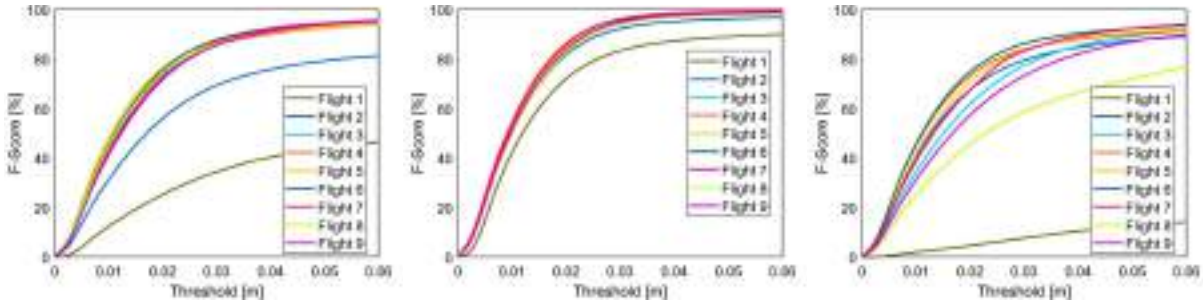

Figure 6. Recall at threshold values up to 6 cm for roof sections B, C, and D (left to right).

UAV platforms including the DJI Mavic 3 Enterprise and the DJI Mini 4 Pro. Flights were also conducted on other buildings, including residential and commercial structures. Future testing could involve quantitative evaluation for different UAV platforms and types of buildings.

8 Conclusion

This paper investigated how varying flight parameters can influence the reconstruction accuracy of rooftop 3D models. Through a series of field tests, the study demonstrated that GSD values of 0.75 - 1.26 cm and an overlap of 85% provided the most efficient flight path while maintaining a high degree of reconstruction accuracy. Using a rooftop TLS configuration, UAV-based LiDAR has been validated as an effective method for providing accurate rooftop point clouds that can be used as suitable ground-truth models for photogrammetry.

Abstract

Accurate assessment of tunnel conditions is vital for ensuring long-term safety and structural integrity, particularly in weak rock masses with complex geological conditions. This study introduces a methodology to analyze tunnel deformation and potential damage using point cloud data acquired in 2019, 2022, and 2024 through terrestrial laser scanning (TLS). The datasets were processed to remove outliers, irrelevant elements, and internal features, resulting in a clean representation of the tunnel's geometry. A novel algorithm integrates point cloud segmentation, centerline alignment, and projection techniques to derive tunnel profiles and monitor structural changes over time. The results demonstrate TLS's effectiveness in capturing high-resolution data for ovalization monitoring, revealing a consistent reduction in cross-sectional area throughout the tunnel and a rightward shift in the 2024 profiles. This approach underscores the potential of TLS for precise structural monitoring and deformation analysis in challenging environments.

Tunnel; Point cloud; Open3D

1 Introduction

Tunnel stability continues to be a major challenge in civil engineering. Various technologies have been applied to optimize monitoring processes, guaranteeing stability and minimizing the probability of tunnel failure throughout its useful life [1], [2]. Failures threatening the safety of tunnels constructed in soft or weak rock masses often occur throughout their long-term service periods [1], [3], [4]. The deformation and failure of rock masses are primarily influenced by discontinuities, which play a crucial role in determining their mechanical properties and overall stability [5]. Additionally, the mechanical behavior of tunnel structures is shaped by a combination of internal and external factors. While historical structural performance is an internal factor, external loads, such as temperature variations and water pressure, significantly affect the long-term properties and stability of the structure [3].

Therefore, ensuring the safe operation of tunnels is essential, as tunnel structures are highly susceptible to disasters due to the complex geological conditions in which they are situated [3]. However, traditional long-term monitoring methods are expensive, time-consuming, and highly dependent on operator subjectivity. These methods usually rely on one-dimensional random sampling, focusing only on limited areas, which leads to the omission of critical details [6], [7]. Additionally, traditional measurement approaches require surveyors to directly access hazardous geological areas. Despite these efforts, there are regions that cannot be manually measured, and the inherent risks involved in such measurements remain a major concern [8].

To address these challenges, many companies have invested in remote sensing technologies, including light detection and ranging (LiDAR), terrestrial laser scanning (TLS), digital photogrammetry, and unmanned aerial vehicles (UAVs) with 3D reconstruction capabilities [5]. For tunnel applications, laser scanning and photogrammetry are commonly employed, as both offer distinct technical advantages and potential value [6]. Firstly, these technologies enable rapid scanning of rock masses, such as temporarily exposed tunnel faces, significantly reducing survey time. Secondly, they allow geologists to perform measurements without physically approaching the tunnel face, thereby enhancing the safety of survey operations [5]. Additionally, sensor-based continuous monitoring techniques and analysis models are increasingly utilized to ensure tunnel functionality and maintain structural integrity over time [2].

Terrestrial Laser Scanning (TLS) offers high resolution and accuracy, making it a reliable method for data acquisition, often surpassing photogrammetry in precision while maintaining flexible measurement distances adaptable to various scenarios. Unlike photogrammetry, TLS does not require a light source, making it particularly suitable for dark underground environments such as tunnels. Its applications extend beyond tunnel monitoring to include stratigraphic

modeling, archaeological excavation, and ancient site exploration [5], [8]. In tunnel engineering, TLS is frequently employed for ovalization monitoring of shield tunnels, with results aligning closely with structural calculations. Additionally, advancements in laser scanning technology have enabled the development of 3D LiDAR point clouds, which have proven effective in monitoring tunnel displacements [9].

After obtaining the point cloud, it is essential to process the data to identify relevant features such as discontinuities. Automated algorithms typically rely on clustering techniques or region-growing approaches, operating on spherical local support regions and utilizing normal vectors to detect features. Clustering methods, such as k-means, fuzzy k-means, ISODATA, DBSCAN, and CFSFDP, often use parameters like dip angle and dip direction derived from normal vectors for discontinuity identification. Additionally, model fitting techniques, including the Hough Transform (HT), Random Sample Consensus (RANSAC), and Principal Component Analysis (PCA), are employed to construct geometric models and estimate optimal plane parameters, enabling precise feature extraction and analysis [5], [10].

In this research, several challenges were identified within the dataset, including outliers, the presence of elements inside the tunnel, and irregularities in the tunnel's shape. To address these issues, we propose an algorithm designed to analyze tunnel damage using point cloud data captured by a terrestrial laser scanner (TLS) over three different years.

The structure of this paper is as follows: Section 2 discusses the materials and methods used to acquire and process the point cloud datasets. Section 3 presents the results, including the extraction of tunnel profiles for each dataset and an analysis of their changes over time. Finally, Section 4 highlights the scientific contributions and conclusions of this study.

2 Materials and Methods

This study focused on a tunnel with vertical walls and an arched roof, located in the Peruvian jungle (see Fig. 1). The tunnel serves as a critical passageway for gas transmission pipelines, facilitating their traversal across mountainous terrain. The structure has an approximate height of 2.10m and a width of 2.50m. The internal profile of the tunnel is reinforced with a layer of shotcrete, providing structural stability and durability.

Figure 1. External view of the tunnel located in Peru.

2.1 Data Acquisition

The tunnel data were collected during three different years: 2019, 2022, and 2024. For the datasets from 2019 and 2022, a Leica C10 laser scanner was employed, while the most recent data from 2024 was acquired using a Trimble X7 3D laser scanner. Table 1 summarizes the technical specifications of the Trimble X7 scanner.

Table 1 Features of the Trimble X7 3D Laser Scanner

Features	Specification
Scan Speed	26,600 points/sec
Scanning Range	350m - 600m
Accuracy	2.5mm at 100m
Noise tolerance	1.5mm - 2.5mm

For data acquisition planning, given the tunnel's 300-meter length, data capture stations were placed every 5 meters. The laser scanner was positioned at a height of 1.8 meters to ensure the capture of all possible points, including those behind pipes. Although the tunnel had sufficient natural lighting, artificial lighting was used to enhance data quality (see Fig. 2).

Figure 2. Data acquisition process inside the tunnel.

After completing the data acquisition process, which required a single day of work with a team of three individuals, the collected data was processed using Trimble software to export the point cloud in .ptl format.

2.2 Data Processing

After data acquisition, the collected data was processed in Python due to its extensive libraries for point cloud data handling and analysis. The primary library utilized was Open3D, an open-source tool for 3D data processing [11]. This library provides robust functionality for working with various point cloud formats, making it a versatile choice for this study. The parameters for data processing were based on the tunnel's measurements, including its height and width, to accurately filter outlier points.

2.2.1 Importing data

The data from 2019 and 2022 were provided as .txt files. Using NumPy, these files were transformed into point clouds containing only positional data. For the 2024 dataset, it was necessary to identify the specific format of the point cloud before processing, in this was .pts.

Open3D provides two primary methods for creating a point cloud: tensors or geometry-based methods. In this study, the geometry-based approach was chosen as it offers a wider range of features for controlling and processing the point cloud effectively. Figure 3 illustrates the 2024 point cloud, visualized using Open3D.

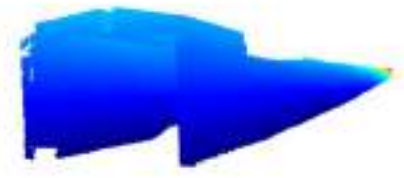

Figure 3. Visualization of the 2024-point cloud data processed in Open3D.

Finally, each dataset was uniformly downsampled using a specified voxel size. The points were grouped into voxels of 0.1m size, and each occupied voxel produced a single point by averaging all the points within it. Table 2 presents the results of the data import process.

Table 2 Summary of the Point Cloud Data

Year	Total points	Filtered Points	Retention Percentage
2019	70124628	348248	0.5%
2022	2259802	231868	10.26%
2024	4722696	208109	4.41%

Note: "Retention Percentage" represents the ratio of filtered points to total points, expressed as a percentage.

2.2.2 Cleaning data

As shown in Figure 3, the scanner captured points outside the tunnel, which are irrelevant to the objectives of this study. Similarly, within the tunnel, the presence of pipes required their removal, as the analysis focused solely on the contour profile. Additionally, several outlier points were identified during the scanning process. Figure 4 illustrates the interior of the tunnel, where the pipes and floor were captured.

Figure 4. The view of the tunnel's interior is represented in the point cloud.

To address these issues, a centerline representing the tunnel's overall geometry was first extracted. Subsequently, all points within a 1-meter distance from the centerline were removed. This process effectively eliminated the floor and the contour of the pipes from the point cloud (see Fig. 5). Next, the KDTree algorithm from the PyntCloud library was applied to identify neighboring points for each data point. Using this neighborhood information, the average distance from each point to its neighbors was computed. Points with an average distance greater than 0.20 meters were classified as outliers, and the corresponding neighboring points were eliminated. This iterative filtering process resulted in a clean point cloud that accurately represents the tunnel's contour shape.

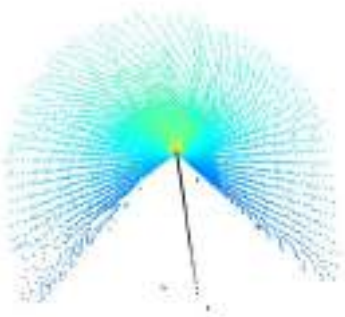

Figure 5. Point cloud after removing the floor and pipe shapes. The black line represents the centerline of the tunnel.

Then, Table 3 shows the number of points in each point cloud before and after the cleaning process, along with the corresponding percentage, which represents the ratio of points remaining after cleaning to the total points before cleaning.

Table 3. Summary of the point cloud data

Year	Downsampled points	Points after cleaning	Percentage
2019	348248	215646	61.9%
2022	231868	192832	83.2%
2024	208109	172915	83.1%

Since the structural movements are measured in millimeters, the focus is on removing outlier points generated near the tunnel floor. However, eliminating noise from the point cloud may impact the analysis of each section, as certain data points could be mistakenly discarded.

3 Results

3.1 Profiles

In this process, the centerline created during the data processing phase was divided into 2600 points. Using the direction of the line, a plane perpendicular to the line was created for each pair of adjacent points. This plane defined a region surrounding a specific number of points from each point cloud (see Fig. 6). With a voxel size of 0.10m, the minimum distance between each plane was also set to 0.10m.

Fig. 6. Points in the surrounding region are defined by the perpendicular planes.

After extracting the points from each region, the projection of each point onto the plane perpendicular to the centerline was calculated. Using the Matplotlib library, a plane was generated with all these points connected by a line, forming the tunnel’s contour (see Fig 7.).

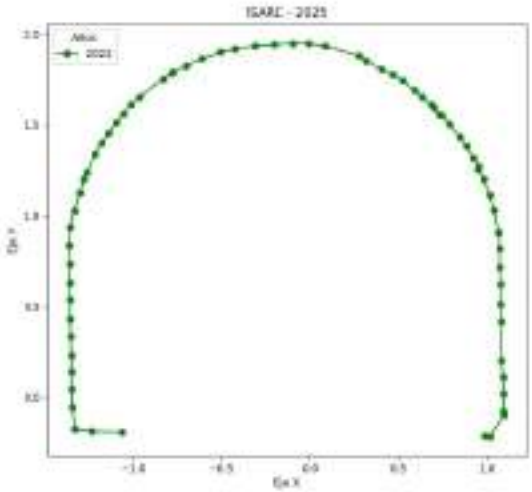

Fig. 7. Tunnel contour formed by points projected onto a plane perpendicular to the centerline.

Subsequently, all profiles were combined into a single 2D plane to analyze the variations in the tunnel's contour over time, highlighting changes observed across different years (see Fig. 8).

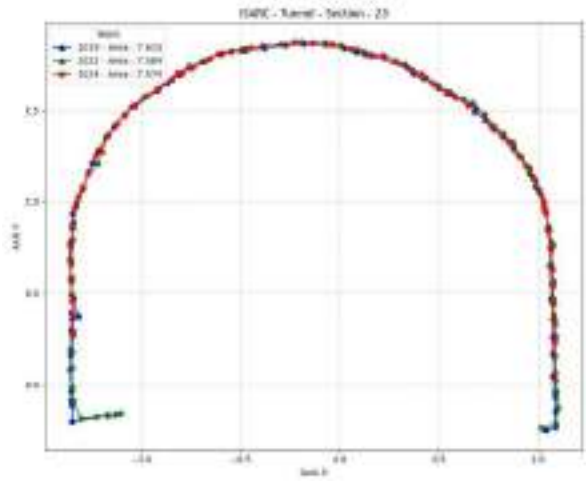

Fig. 7. Tunnel profiles from different years.

3.2 Damage identification

Using the three-point cloud datasets (2019, 2022, and 2024), each section was projected onto a 2D plane to analyze changes in the tunnel's cross-sectional area. Table 3 summarizes the reduction in area for a specific section, showing a consistent decrease over time. Additionally, the results indicate a reduction in tunnel width between 2019 and 2022 (see Fig. 8) and a consistent shift to the right across all sections over the years.

Table 4. Reduction in cross-sectional area

Year	Area (m2)	Percentage
2019	7.615	100%
2022	7.584	99.5%
2024	7.574	99.4%

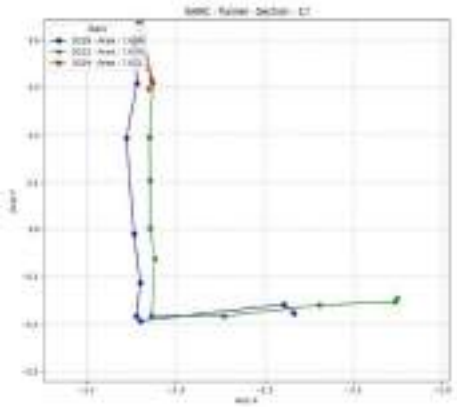

Fig. 8. Reduction observed in the lower-left section of the tunnel's cross-section.

An analysis was conducted along the entire tunnel, comparing cross-sectional areas from each year. The blue line represents the area from 2019, the green line corresponds to 2022, and the red line reflects 2024. The results reveal a noticeable reduction in the cross-sectional area of the tunnel over time, which may be attributed to ground movement or structural degradation of the tunnel. In Fig. 9, the comparison between 2019 and 2022 reveals noticeable changes in the tunnel's cross-sectional area, indicating structural modifications or deformation during this period. Similarly, Fig. 10 illustrates how the tunnel's sections in 2024 have shifted relative to 2022, showcasing continued changes over time

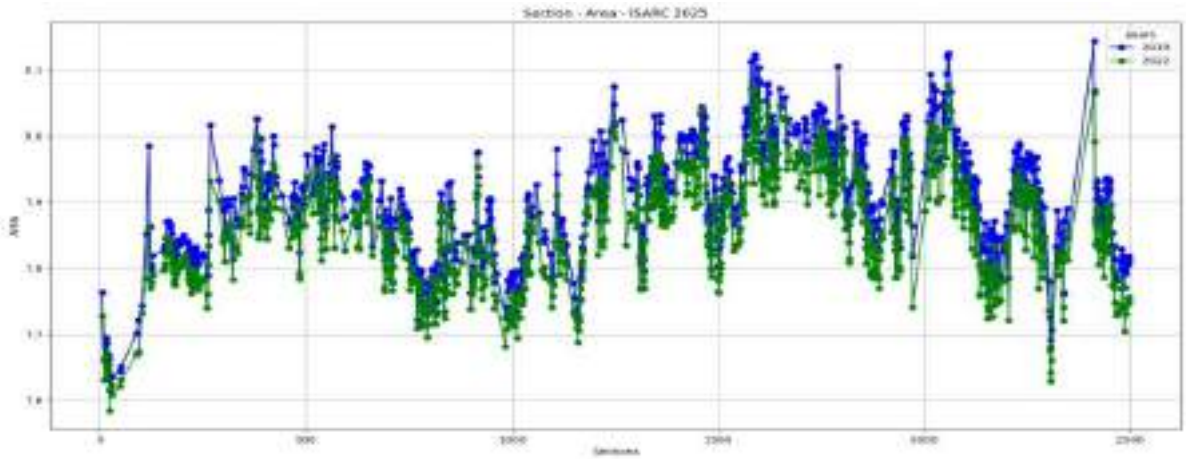

Fig. 9. Comparison of Tunnel Cross-Sections Between 2019 and 2022

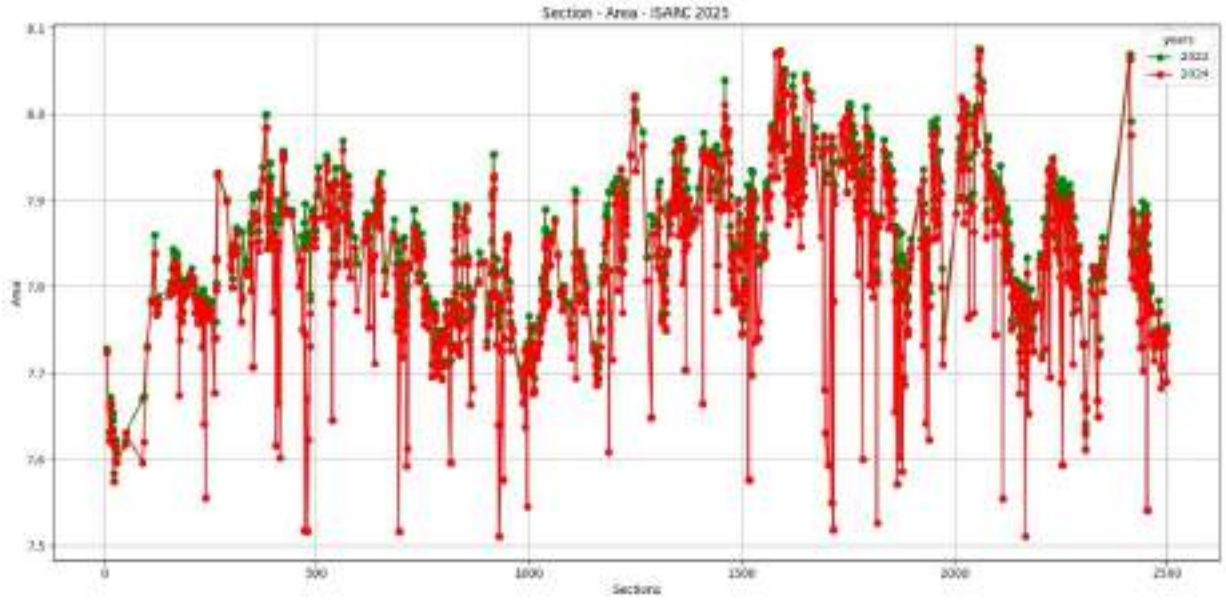

Fig. 10. Comparison of Tunnel Cross-Sections Between 2022 and 2024

4 Conclusions and Discussion

This study presents an innovative methodology for assessing tunnel deformation and structural changes over time using point cloud datasets acquired through terrestrial laser scanning (TLS) in 2019, 2022, and 2024. The following conclusions were derived:

- TLS has proven to be a reliable tool for capturing high-resolution data, facilitating detailed monitoring of the tunnel's structural changes. Its capacity to perform accurate measurements in challenging environments, such as dark underground tunnels, highlights its suitability for infrastructure assessment.
- Analysis of the tunnel profiles revealed a consistent reduction in cross-sectional area across all sections over the years. The results indicate a decline of 0.6% from 2019 to 2024, with notable deformation in specific regions, particularly the lower-left corner. This reduction may be attributed to geological movements or material degradation.
- A systematic rightward shift in the tunnel's cross-sections was observed over time. This movement underscores the need for continuous monitoring to identify and address potential instability risks associated with lateral displacement.
- The proposed algorithm effectively segmented the point cloud data, aligned it with the tunnel centerline, and projected profiles for comparative analysis. This approach enabled the detection of subtle changes in geometry, demonstrating its applicability for tunnel condition assessment.
- The findings highlight the importance of integrating advanced technologies, such as TLS and automated algorithms, into routine tunnel inspections. Such methods provide precise and actionable insights, reducing dependency on manual inspections and enhancing safety in hazardous conditions.

As observed, the findings have significant implications for structural monitoring and tunnel maintenance. Traditional tunnel monitoring techniques rely heavily on visual inspections, geodetic surveys and instrumentation-based systems. Although these methods have been widely used, they have limitations in terms of subjectivity, data resolution and safety. Visual inspections, for example, depend on the experience of engineers and can overlook subtle deformations. Geodetic surveys, which use total stations or leveling instruments, provide accurate measurements at discrete points, but require a lot of time and effort.

The progressive reduction of the cross-section indicates cumulative deformation that could compromise long-term stability. This problem could be due to the geomechanics of the area, such as ground movements, traffic loads in the area, or degradation of the tunnel materials. Early detection of deformations using TLS would allow engineers to implement preventive mitigation measures before critical failures occur. For instance, the use of metal trusses or increasing the thickness of shotcrete, the

characteristics of which must be carefully calculated. On the other hand, being able to detect these changes in the cross-section is a better alternative compared to visual identification or manual measurements, which are subjective and depend on the experience of the inspector. Automating TLS reports makes it possible to generate reports, facilitating informed decision-making for tunnel maintenance.

Abstract -

We developed a 3D measurement system for autonomous construction and conducted demonstration experiments of autonomous construction using OPERA (Open Platform for Earthwork with Robotics and Autonomy), which is a research and development platform developed by the Public Works Research Institute. As a use case, we carried out soil loading into a dump truck by a backhoe in a test field. In this paper, we give overviews of our system and the demonstration experiments.

Keywords -

1 Introduction

The Japanese construction industry is facing a labor shortage because of a declining birthrate, an aging population, and youth job disengagement. To address this issue, the Ministry of Land, Infrastructure, Transport and Tourism is promoting i-Construction 2.0 [1] in order to establish efficient construction processes based on digital technologies. The aim of i-Construction 2.0 is to revolutionize construction sites via three types of automation, namely, automation of construction work, automation of data linkage, and automation of construction management, the expectations being reduced labor and improved productivity.

Extensive research has been conducted on the development of autonomous construction machinery and the utilization of 3D data. R. Heikkilä et al. [2] investigated case studies of automated construction in Europe, highlighting the increasing use of methods that employ 3D data, which plays a critical role in automation. I. Niskanen et al. [3] implemented the 3D LiDAR on the boom of the backhoe to recognize the shape of soil loaded on the vessel of the dump truck. A. Assadzadeh et al. [4] have employed deep learning to estimate the posture of the backhoe using RGB image data captured by cameras installed at the site.

In support of the aforementioned efforts, our work involves automating construction work by using autonomous construction machinery. As an implementation of autonomous civil construction work, we target soil loading associated with shield tunneling as shown in Figure 1. Soil excavated from the shield tunnel is transported to an external soil pit via pipelines and conveyor belts and then loaded into a dump truck by a backhoe and transported to a treatment plant. The backhoe operates depends on when the dump truck arrives, which in turn depends on traffic conditions, and this often causes waiting time for the backhoe operator. Therefore, automating these soil-loading tasks would increase efficiency and productivity. Furthermore, in this case the locations of the backhoe, truck parking, and soil pit hardly ever change. We can install sensors in the environment to detect the shape of the earth mound in the soil pit and the position of the dump truck. This requires fewer sensors than in more-dynamic situations, and this system is applicable even if the dump truck has no sensors of its own. For these reasons, our aims were to automate the soil loading involved in shield tunneling and conduct demonstration experiments in a test field. In this paper, we give an overview of our system the experiments performed in the test field.

2 System overview

We have developed three components for realizing autonomous construction OPERA (Open Platform for Earthwork with Robotics and Autonomy), which is a platform for autonomous construction; ROS2-TMS for Construction, which is a management system for controlling construction machinery; and a 3D measurement system. Figure 2 shows an overview of the system, in which two LiDARs detect the shape of the earth mound and three LiDARs detect the dump truck. The three components

are on the same network and communicate using ROS 2 [5] to enable autonomous construction. In ROS 2, the communication method for sending and receiving commands and messages is called topic communication, and these commands and messages are called topics; sending topics is called publishing and receiving topics is called subscribing. In this paper, we use the same terminology.

2.1 OPERA

We use OPERA [6, 7] to control autonomous construction machines. Developed by the Public Works Research Institute (PWRI), OPERA is a research and development platform for automating earth works; it contains a set of common control signals, middleware, simulators, a demonstration environment, and autonomous construction machinery, and it is available on GitHub for open development [8]. Moreover, OPERA was developed in ROS 2, which allows construction machinery and sensors to be controlled by common commands independent of the manufacturer.

2.2 ROS2-TMS for Construction

We use ROS2-TMS for Construction [9] to manage the tasks of autonomous machinery developed by Kyushu University. This task management system enables the accumulation and management of environmental information from sensors in construction sites and machinery; it realizes autonomous construction by giving commands to robots and autonomous construction machinery based on the flowchart and data . TMS_IF for OPERA [10] is an interface developed to publish commands via OPERA based on the indicated tasks; it was also developed in ROS 2 and uses the open package Moveit2 [11] for motion planning and the open package Nav2 [12] for autonomous driving. We control the construction machinery by providing information from Mongo DB[13] as the database using ROS 2.

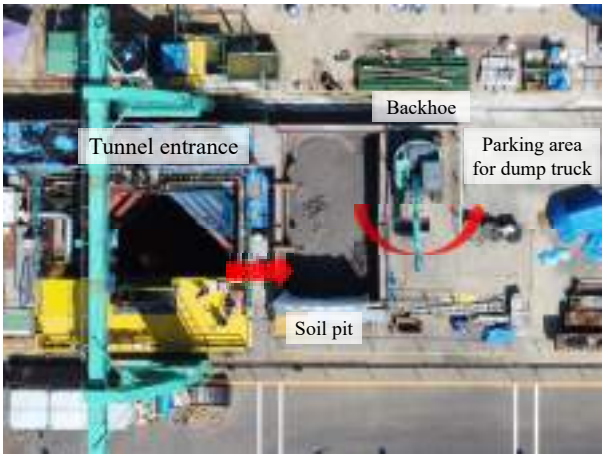

Figure 1. Use case.

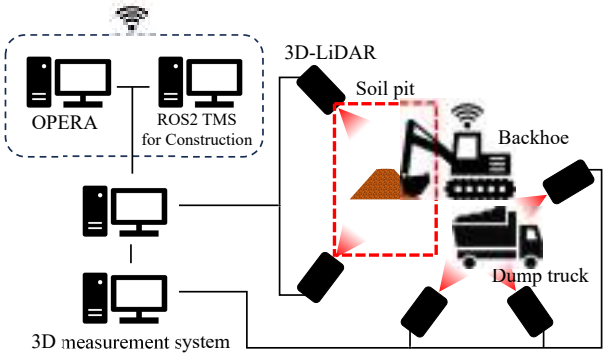

Figure 2. Overview of system.

2.3 3D measurement system

We developed the measurement system by using multiple 3D LiDARs to detect the shape of the earth mound and the location of the dump truck. The resulting point-cloud data enable accurate recognition of the shapes of the targets, and this allows calculation of the best position for the backhoe to excavate more soil. We explain the registration method for the point-cloud data from the multiple 3D LiDARs in Section 2.3.1, the excavation recognition methodology in Section 2.3.2, and the loading recognition methodology in Section 2.3.3.

2.3.1 Registration of point-cloud data

Because the LiDAR coordinate system uses the sensor center as the origin, the point-cloud data obtained by each LiDAR are in different coordinate systems. In this study, we define the center of the backhoe as the origin of the world coordinate system W, and we calculate the homogeneous transformation matrix $H_{L\to W}$ from each LiDAR coordinate system L to W.

As shown in Figure 3, we placed three spheres in the scan range of all the LiDARs , and we estimate the center coordinates of each sphere from the obtained point-cloud data as shown in Figure 4; Figure 4(b) shows the cropped point-cloud data around one of the spheres from Figure 4(a). Using four points selected randomly from the cropped point-cloud data of the sphere, we obtain its center coordinates $s(a, b, c)$ by solving the following equation:

$$\begin{pmatrix} x_1 - x_0 \\ x_2 - x_0 \\ x_3 - x_0 \end{pmatrix} \begin{pmatrix} a \\ b \\ c \end{pmatrix} = \begin{pmatrix} x_1^2 - x_0^2 + y_1^2 - y_0^2 + z_1^2 - z_0^2 \\ x_2^2 - x_0^2 + y_2^2 - y_0^2 + z_2^2 - z_0^2 \\ x_3^2 - x_0^2 + y_3^2 - y_0^2 + z_3^2 - z_0^2 \end{pmatrix} /2. \tag{1}$$

Next, we calculate the L_2 norm between s and each cloud point and count the points for which the L_2 norm is within threshold. This process is iterated 1000 times, after

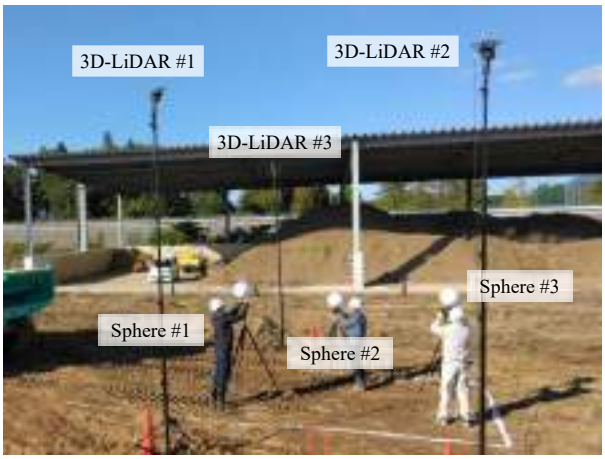

Figure 3. Installation of spheres.

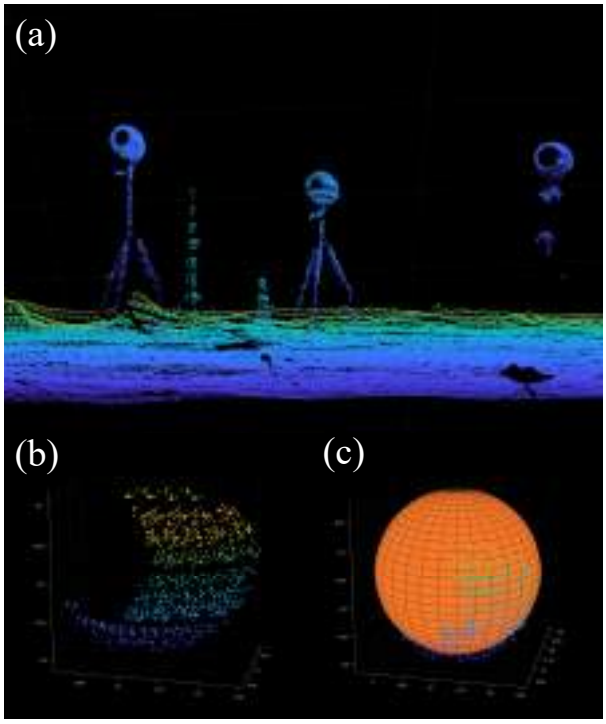

Figure 4. Point-cloud data of spheres: (a) LiDAR-obtained point-cloud data; (b) cropped point cloud of a sphere; (c) estimated sphere.

which the s with the most points is adopted. We estimate $S_L = \{s_1, s_2, s_3\}$ by calculating for the three spheres.

We then placed prisms at a mechanically known point on the backhoe and the center positions of the spheres. The sphere coordinates S_W in the world coordinate system were obtained by using a total station.

We obtain the homogeneous transformation matrix $H_{L \to W}$ from S_L and S_W and transform each LiDAR coordinate system into the world coordinate system. Figure 5 shows the point-cloud data transformed by the homogeneous transformation matrix.

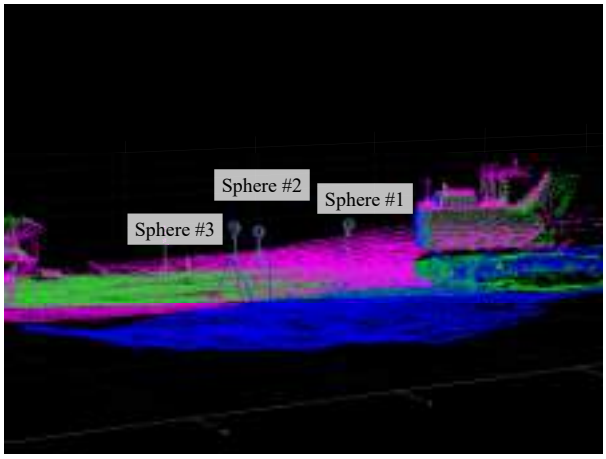

Figure 5. Integrated point-cloud data.

2.3.2 Recognition for excavation

We estimate the excavation points from the shape of the earth mound by using the point-cloud data transformed to the world coordinate system. We extract the point-cloud data in the soil pit and divide them into a planar grid. At each grid location, the lowest z coordinate is the height of the grid, and these grid data form the height map from which the highest grid point is estimated as being the excavation point. Figure 6 shows the height map of the earth mound. The excavation points are published constantly in the database of ROS2-TMS for Construction as the ROS 2 topics.

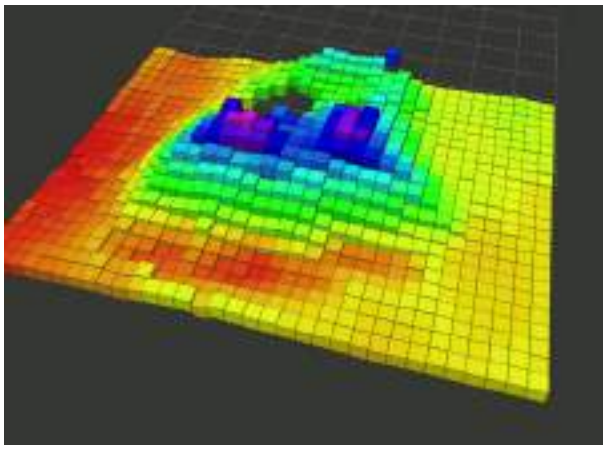

Figure 6. Height map of earth mound.

2.3.3 Recognition for loading

First, we estimate the current position of the dump truck. We obtain the point-cloud data of an empty dump truck P_d in advance and find the coordinates at the four corners of the vessel O_d from P_d. RANSAC is used to derive the homogeneous transformation matrix that converts P_d into the current point-cloud data P_r. By using the matrix to transform O_d, the current position of the dump truck is estimated as the current vessel coordinates O_c.

Next, we estimate the loading point by using O_c to extract the inlier point-cloud data in P_r, and the extracted point-cloud data are divided into a planar grid. The points with the highest z coordinate give the height of the grid, and these gird data form the height map. In this study, the grid map was padded and smoothed via convolution. From the height map, the lowest grid point is estimated as being the loading point. In addition, the loading volume inside the vessel is estimated by comparing P_d and P_r.

3 Overview of experiment

We conducted the task of excavating and loading soil with one autonomous backhoe (ZX200, Hitachi Construction Machinery Co., Ltd.) and one crawler carrier (IC200, Kato Works Co., Ltd.) at the PWRI DX field in Tsukuba City, Ibaraki Prefecture, Japan. Figure 7 shows the experiment. The earth mound was surrounded by pipes that simulated the soil pit. Five LiDARs (Livox) were installed to detect the shape of the earth mound and the location of the crawler carrier and estimate the excavation and loading points. Those points were then published to the database of ROS2-TMS for Construction as the ROS 2 topics. The backhoe generated a trajectory based on the target coordinates in the database and performed excavation and loading operations. When the inside of the vessel reached a certain loading capacity, a loading completion flag was published to the database, and the operation was completed.

3.1 Excavation test

Figure 8 shows the excavation by the backhoe, which avoided the pipes by us preparing walls as obstacles in the simulation environment in advance. Figure 8(a) shows the backhoe waiting for the start flag of ROS2-TMS for Construction, and Figure 8(b) shows the excavation task starting and the backhoe having subscribed the excavation point from the database. Figure 8(c)–(f) show the backhoe executing the excavation tasks twice and excavating the top of the earth mound. In the study of Niskanen et al.[3], the 3D LiDAR was installed on the boom of the backhoe to measure the vessel. In contrast, we install the 3D LiDAR at the site. By installing the 3D LiDAR at the site, it is possible to recognize the entire soil mound, including the backside, which cannot be observed from the backhoe. Additionally, since point cloud data of the soil mound can be continuously acquired regardless of the backhoe's posture, the backhoe can operate without waiting for measurement and estimation times.

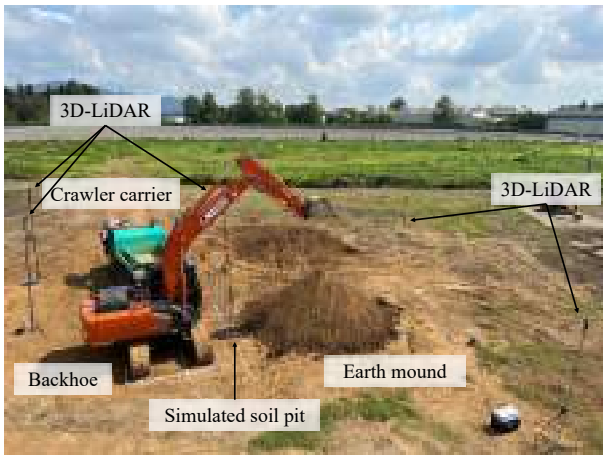

Figure 7. Overview of experiment.

In this study, the backhoe is assumed to remain stationary. Since the coordinate system of the backhoe is obtained through prism measurements, it is necessary to perform measurements each time the backhoe moves. This is our future work, and we will explore methods to automatically recognize the position and orientation of the backhoe in the future.

3.2 Loading test

Figure 9 shows the point-cloud data at different times; in each panel, the purple rectangle is the estimated outline of the vessel and the red sphere is the loading point at the relevant time. The vessel is recognized when the evaluation value exceeds a certain level from the registration results, and the lowest point inside the vessel is estimated as the loading point in the height map in this rectangle. By performing coordinate transformation from the position and orientation of the vessel, it is possible to continuously estimate the position and orientation of the dump truck. Acquiring point cloud data from multiple angles using three LiDARs improves the accuracy of registration, thereby stabilizing the estimation of position and orientation. The vessel is not recognized in Figure 9(a) but is recognized in Figure 9(b). In Figure 9(c), the loading point is estimated in the vessel and published to the database. In Figure 9(d)–(h), the position of the loading point changes as the soil is loaded. Figure 10 shows the inside of the vessel before and after loading, and the loading volume was estimated from the point-cloud data after the loading operation.

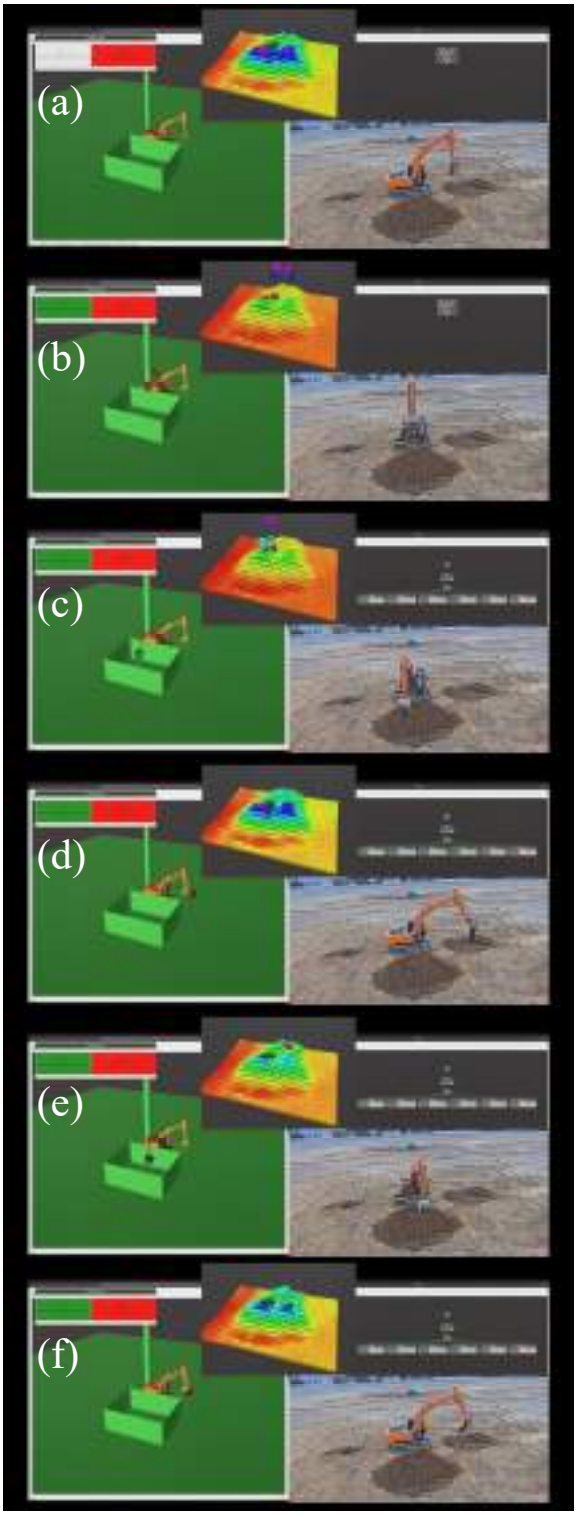

Figure 8. Each figure shows the simulation (left), the actual backhoe (right), and the height map (center).

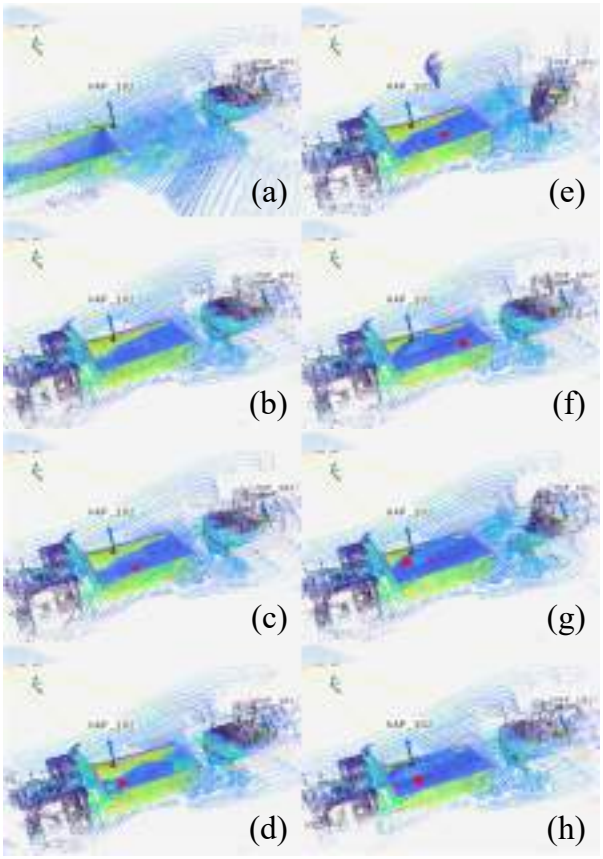

Figure 9. Estimating the loading point at each time. The purple rectangle is the estimated outline of the vessel and the red sphere is the loading point at each time.

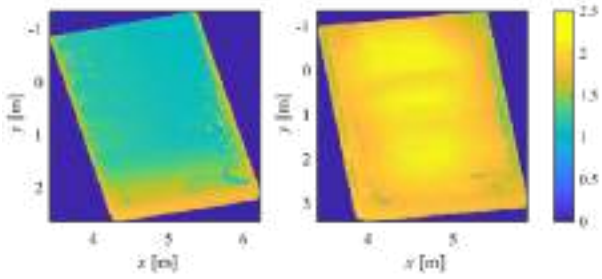

Figure 10. Inside of vessel.

4 Conclusion

We have developed a 3D measurement system for autonomous construction. We configured the task of loading soil into a dump truck by an autonomous backhoe as the use case, and we conducted demonstration experiments of this task in the test field.

Installing multiple LiDARs around the targets enabled the latter to be measured without any blind spots. The co-

ordinate transformation method using spheres facilitated registration of the point-cloud data obtained by the LiDARs.

The obtained point-cloud data allowed detection of the shape of the earth mound. The excavation points were published to ROS2-TMS for Construction as the task management system, and the backhoe excavated autonomously based on the excavation points.

The obtained point-cloud data allowed detection of the vessel position and the shape of the loaded soil. The loading points were also published to ROS2-TMS for Construction.

The integration of multiple point-cloud data which was achieved by our developed system, ensured reliable data acquisition. We will focus on exploring optimal excavation methods using the acquired data.

In this measurement system, the LiDAR-obtained point-cloud data are large and can overload the network. Therefore, in future work we will construct a robust network and continue to develop the system for application to actual construction sites.

Abstract

Vision-based indoor positioning approaches are increasingly gaining attention due to their cost-effectiveness and scalability. The core principle of vision-based indoor positioning is to identify the most visually similar space to the reference space images. A major challenge in previous vision-based indoor positioning methods arises from the need for large annotated datasets to ensure robust model performance, necessitating coverage of space images from various angles and points of view. To address this limitation, we propose a method that applies feature matching to 360-degree images, enabling indoor positioning with just a single reference image per space. This eliminates the need for multiple reference images by preprocessing the input image through feature-descriptor-based alignment and cube-map projection, allowing the image to be adjusted to better match the position and shape of the reference image. Experiments conducted on six different floor plans achieved an accuracy of 72.57% using only one reference image, confirming the feasibility and efficiency of this lightweight approach to indoor positioning.

Keywords –

360-degree photo; Image feature matching; Indoor positioning; Computer vision; Few-shot learning; One-shot learning

1 Introduction

Unlike outdoor positioning often relies on global positioning system (GPS) [1], indoor environments require different approaches because GPS signals cannot be received. The most common indoor positioning methods are signal-based techniques such as Wi-Fi [2], ultra-wideband (UWB) [3], and radio frequency identification (RFID) [4], which typically rely on triangulation methods and thereby offer robust performance. However, these techniques can be heavily influenced by indoor objects, such as furniture and walls, that interfere with signal propagation. Moreover, they require the installation of dedicated equipment, which can limit their applicability. In these contexts, vision-based indoor positioning methods present a more intuitive and robust alternative than signal-based methods [5].

Indoor positioning research based on visual information often involves extracting features from images and then determining proximity to predefined reference points [6]. Recent advances in machine learning and deep learning have enabled systems to automatically identify salient features from video frames, which can subsequently be used to estimate a user's location relative to these reference points. By harnessing visual cues, such systems can potentially overcome the limitations of wireless signal-based approaches, offering finer spatial resolution and rich contextual information about the surrounding environment.

Despite the advantages offered by vision-based indoor positioning methods, several challenges remain. A major issue is the heavy dependence on large, labeled image datasets; as the number of positioning reference points increases, so does the need for more extensive data collection. Another concern is the potential confusion arising in visually similar spaces [7]. Even in the same location, images can vary significantly depending on the camera's extrinsic parameters, making it difficult to distinguish between different areas that share analogous visual features. Therefore, to maintain the benefits of image-based indoor positioning while overcoming these challenges, methods are needed that can operate effectively with fewer images and reduce reliance on specific camera parameters.

In this paper, we propose a one-shot indoor positioning method for residential buildings that leverages 360-degree images. Because many residential buildings repeat the same floor plan on every floor, they offer an environment well-suited for vision-based indoor positioning. To address the conventional reliance on large-scale datasets, we advocate the use of 360-degree images instead of standard photographs. Compared to conventional images, 360-degree images exhibit lower dependence on camera angles and positions, and they can be manipulated through projection to highlight specific visual information [8]. Building on these advantages, we

prepare a single reference image for each room as training data and use a corresponding query image to determine the user's current location by comparing their visual similarity. As part of this process, we employ feature extraction to adjust the orientation of the 360-degree images. We then perform cube-map projections on the aligned images, segmenting them so that each direction can be compared directly. Through this approach, robust indoor positioning is achievable with only one representative 360-degree image per room.

2 Related Studies

2.1 Image-based Indoor Positioning System

Image-based positioning offers the advantage of leveraging dense visual information with minimal equipment while providing intuitive insights into spatial relationships. Traditionally, such methods have relied on feature-based techniques like the Scale-Invariant Feature Transform (SIFT) or Oriented FAST and Rotated BRIEF (ORB) [9] for keypoint detection and matching. By correlating extracted features with reference images or pre-built maps, researchers have demonstrated accurate localization even in the most intricate, multi-room settings. Concurrently, recent advances in neural network architectures have led to the widespread development of similarity-based methods [7]. Although these approaches share the overarching goal of precise localization, they primarily differ in how they extract and represent features from given images.

Despite their promise, these methods often require large-scale image datasets and carefully tuned parameters to ensure robustness under varying conditions. Keypoint-descriptor-based methods (e.g., SIFT, ORB) circumvent extensive training procedures, but tend to be highly sensitive to environmental changes in lighting or perspective [10]. Consequently, additional processes, such as rigorous parameter tuning or ensemble modelling, are often recommended to improve reliability. Moreover, in tall buildings where multiple floors replicate near-identical room layouts, distinguishing among different spaces becomes increasingly problematic. This issue is exacerbated by the limited field of view (FoV) in conventional images, which can capture only a fraction of the environment and thus yield inconsistent results when camera angles differ.

To overcome these challenges, 360-degree imaging has gained momentum as an alternative. By capturing the entire environment from a single vantage point, such images minimize the need for multiple photographs taken at various angles or distances [11]. Not only does this broader coverage enhance feature extraction, but it also simplifies the alignment process during positioning. Furthermore, positioning methods that employ scene understanding of 360-degree photos through segmentation-based techniques have also been introduced [12,13]. However, deep learning-based methods, particularly those leveraging convolutional neural networks and other advanced architectures, demand vast amounts of training data to achieve robust performance. Generating labeled image datasets for every possible indoor environment can be both time-consuming and cost-intensive, which is where few-shot learning becomes highly relevant.

2.2 Few-shot Learning in Construction

Few-shot learning techniques enable models to generalize from a limited number of examples [14], thereby reducing the reliance on large, labeled datasets. They encompass various approaches, including meta-learning [14] and similarity-based methods [15], and provide a promising solution by requiring only minimal data per class. In the construction domain, where collecting extensive labeled datasets can be costly and labor-intensive [16], few-shot learning helps alleviate the burdens typically associated with vision-based monitoring techniques [17].

In the context of indoor positioning, few-shot learning substantially decreases the need for exhaustive image capture and labeling in each room or space. By focusing on representative images or leveraging meta-level patterns across different tasks, these approaches maintain high accuracy even in visually similar environments—a feature particularly advantageous in high-rise residential buildings with repeated floor plans. Through the integration of 360-degree imaging and few-shot learning, it becomes possible to capture comprehensive spatial information while avoiding the data-intensive bottlenecks often encountered in deep learning methods.

2.3 Research Gap

In summary, two major challenges arise when implementing indoor positioning systems that rely primarily on visual information and image similarity [7]. One involves calibrating the camera's extrinsic parameters [11], and the other concerns assembling the large dataset required to construct the model [8]. As a potential solution, the use of 360-degree images has been proposed in prior work. Within this approach, some studies focus on calibration, while others involve subdividing images to increase the available data. However, the former still requires a feasibility assessment for practical use, and the latter necessitates additional preprocessing, which restricts direct application under few-shot conditions.

In this study, we combine the strengths of these prior methods to propose an indoor positioning technique that

functions with only a small number of images. Through feature matching, we correct the camera's external parameters, and by employing CMP-based 360-degree images, we make full use of omnidirectional visual information. As a result, accurate positioning becomes possible even with minimal data, providing a novel approach to vision-based indoor localization.

3 Research Proposal

Our proposed method is divided into two primary steps (Figure 1). The first step is a preprocessing stage performed when the query image is provided. During this stage, we align the 360-degree image and, if necessary, apply inpainting to remove the photographer or other unintended objects. This process corrects for variations in camera angle and eliminates noise that could otherwise skew comparisons, thereby ensuring an equal basis for evaluating similarity.

In the second step, we compare the corrected query image with each reference image. By applying a projection technique, we segment both the query image and the reference image into multiple directions, splitting them into six sections via cube-map projection (CMP), so that images corresponding to the same direction can be compared individually [8]. This approach addresses the distortions inherent in the equirectangular projection (ERP) format of 360-degree images, which can vary based on the camera's position inside the space. We repeat these comparisons for all reference images in the indoor environment, and the final positioning result is determined by selecting the space with the highest average similarity score. Further details on each step of the process are provided in the following subsections.

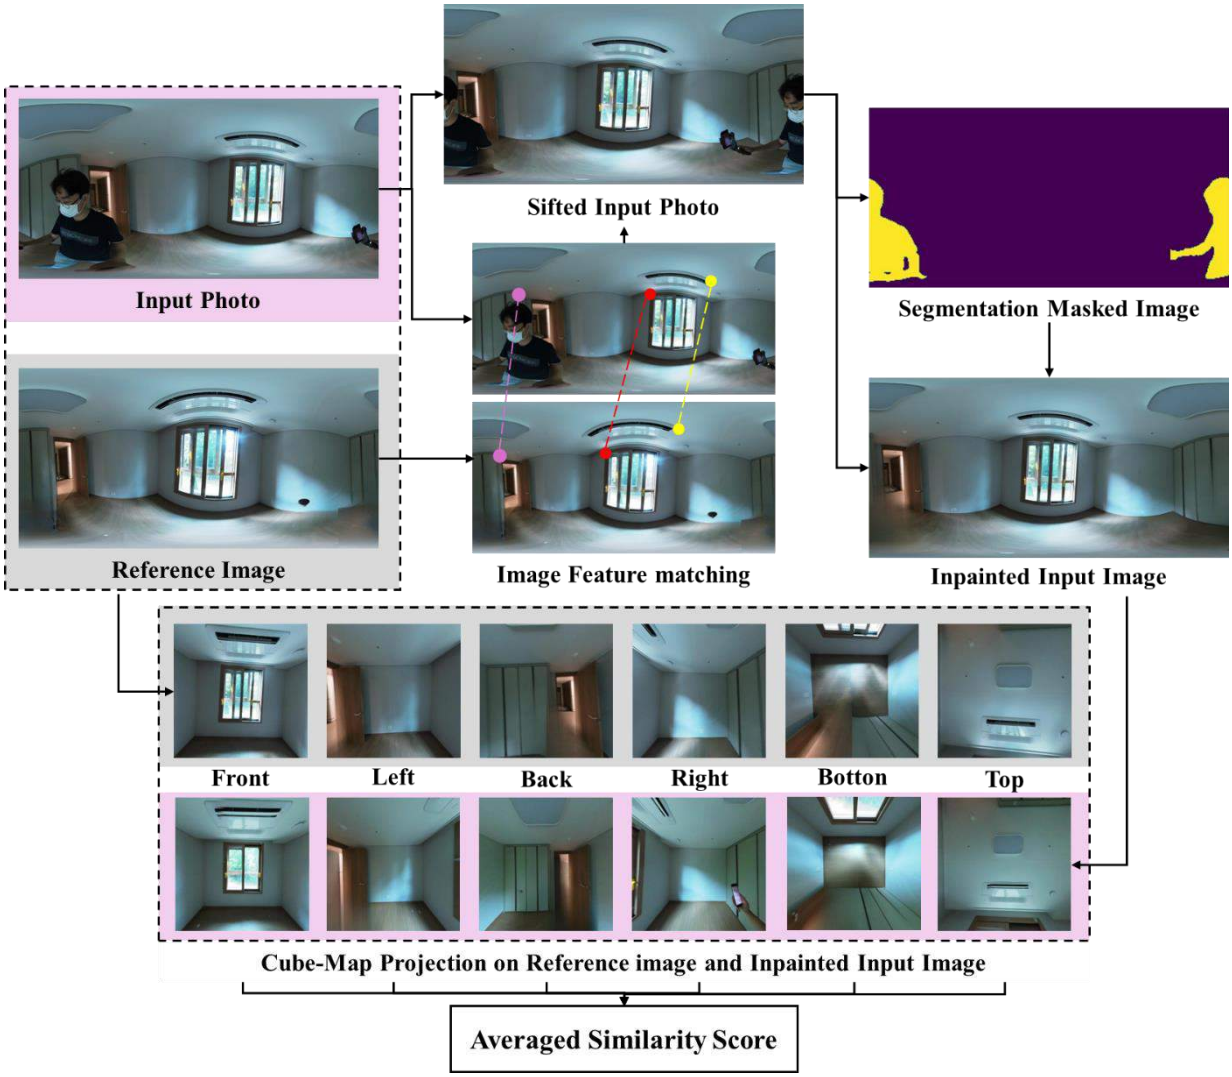

Figure 1. Overall flow of preprocessing on input image and similarity comparison with reference image

3.1 Preprocessing on Input Image

First, once the input photo is provided, serving as the query image, both the query image and the reference image undergo feature extraction using keypoint-descriptor methods. In this study, we employ an ensemble model comprising ORB [9], BRISK [18], and AKAZE [19]. [20][10]We then measure the horizontal distance between the keypoint-pairs that yield the highest match scores. This distance is used to shift the input image so that it is aligned to face the same direction as the reference image.

Next, if the image contains a human subject, it introduces noise that must be removed. We accomplish this by performing inpainting technique, which requires a segmentation mask to identify the person's location. In this process, we employ semantic segmentation to generate the mask. Specifically, we use the BEiT model [21], pre-trained on the ADE20K dataset [22], for segmentation, and the LaMa model for inpainting [23].

3.2 Similarity Comparison

After aligning the orientation of the input image and removing noisy objects, we compare the resulting image with a reference image to evaluate their similarity. In this study, we use a CMP approach for this comparison, aiming to compensate for the substantial distortions in ERP images that can occur even within the same space. In typical residential buildings, each room can be approximated as having a roughly cubic shape; therefore, once the reference image is properly adjusted, each CMP section captures a distinct wall in the room. This setup allows both the CMP-based reference image and the pre-processed input image to be compared on a wall-by-wall basis.

To quantify similarity between images, we employ a pretrained Siamese network that outputs a similarity score [24]. The final similarity score between one input photo and a reference image is the average of the scores obtained from the six CMP sections. Repeating this process for every reference image in each room, we identify the final location as the room whose reference image yields the highest average similarity.

4 Experiment & Results

4.1 Dataset Preparation and Setting for Experiment

Performance experiments on the proposed method were conducted in residential buildings. Specifically, we selected six housing units, and categorized their spaces into eight areas: ["Bathroom", "Bedroom", "Living Room", "Dress Room", "Balcony", "Utility Room", "Unit Room", "Kitchen"]. In each space, we captured 360-degree images. When a single unit contained multiple spaces of the same type (e.g., multiple bathrooms or bedrooms), we labeled them numerically to distinguish them as separate spaces. As a result, we compiled 288 images across 11 spatial categories for our experimental dataset (Table 1).

In addition, we prepared separate reference images for each room. To correct for potential distortions that could arise during the similarity-check process, these reference images were taken from the center of each room. Once converted via CMP, the resulting six images were oriented to provide frontal views of each wall in the space.

Table 1. Photo distribution of each room in the test Dataset

Balcony	**Dressroom**	**Kitchen**	**Livingroom**
18	20	30	30
Bedroom	**Bathroom**	**Unit**	**Utility**
34 / 31 / 35	24 / 21	24	21

4.2 Performance Check

In our experiments, the primary parameters requiring careful configuration were the number of features used during the feature matching step and the FoV value applied in the CMP process. In this study, we limited the number of matched features to one and fixed the FoV at 90, based on empirical findings that the performance gains from using a larger number of features were outweighed by the degradation caused by increased noise.

Furthermore, for feature matching, we employed three representative keypoint descriptors (ORB, BRISK, and AKAZE) and ensemble model. Propose ensemble model selects the best descriptor on a per-match basis by choosing the one that yields the highest match score, thereby enhancing the overall reliability of the matching process.

Based on the ensemble model, the highest performance among the tested descriptors was 72.57%, largely attributable to BRISK, which was the primary descriptor used in the ensemble (Table 2). Notably, previous studies employing similar approaches relied on AKAZE [11], suggesting that no single descriptor offers superior performance in all scenarios [10]. Instead, a composite approach like the ensemble appears to be more effective overall.

A closer examination of the data reveals varying classification performance across different rooms (Figure 2). Bedrooms 1, 2, and 3 were frequently misclassified due to their high degree of visual similarity, while spaces

with more distinctive features, such as balconies or dressing rooms, showed better performance. In contrast, although bathrooms displayed relatively favorable recall values, their precision scores dropped significantly. This was attributable to low feature-matching scores across all descriptors, which led to reduced overall similarity scores. One likely cause is the large mirror occupying one wall, which may have interfered with the feature-matching process. Future research should address this issue to further enhance system performance.

Table 2. Average accuracy according to each descriptor

Descriptor	ORB	BRISK	AKAZE	Ensemble
Accuracy	69.44%	71.53%	68.40%	72.57%

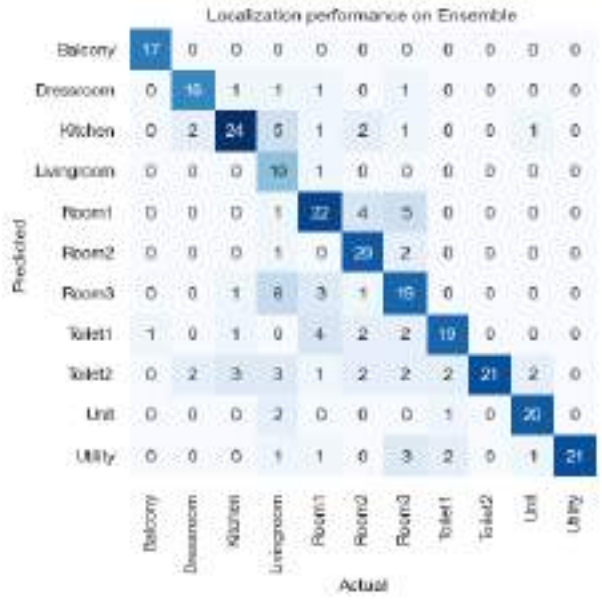

Figure 2. Confusion matrix of the ensemble model for each room

4.3 Ablation Studies

To evaluate how our proposed method, which utilizes feature matching for image alignment and CMP for image comparison, contributes to overall performance, we conducted an ablation study by selectively removing each of these components. First, (a) we measured accuracy using only the reference image and the input photo, without either feature matching or CMP, resulting in 9.13% accuracy. This is the result of the previous method based on a 360-degree image approach that relies solely on simple feature descriptors [11], excluding all the suggestions from this study. Second, (b) we performed feature matching for image alignment on the 360-degree images but used the ERP images for the comparison step, yielding 8.14% accuracy. Third, (c) we omitted the feature matching step and used only CMP, reaching 8.56% accuracy (Table 3).

Table 3. Performance changes according to application of suggestions

	(a) Without proposal	(b) Only feature matching	(c) Only CMP comparison	(d) Proposed method
Accuracy	9.13%	8.14%	8.56%	72.57%

These results are significantly lower than the 72.57% accuracy achieved by (d) our complete method. Moreover, given that the dataset contains 11 classes, the near 9–10% performance suggests results approaching random chance, thereby underscoring the limited utility of each individual component on its own. Consequently, our findings indicate that the benefits of the proposed method manifest only when feature matching and CMP are applied in tandem. Furthermore, considering that existing studies typically rely on feature matching alone [11], the considerable distortion inherent in 360-degree images can introduce major complications, supporting the necessity of our combined approach for robust indoor positioning.

5 Conclusion

This study presents a 360-degree image-based indoor positioning method that can be applied in small, repetitive indoor spaces using a single reference image. Unlike conventional images, 360-degree images provide substantially more visual information, which can alleviate the demands for a large dataset. However, to address the potential distortion and noise inherent in these images, we propose a two-step approach comprising of a preprocessing phase and a comparison phase. The method achieved an accuracy of 72.56% using only a single image per room. This represents a significant improvement compared to traditional feature-matching-based methods that are difficult to apply in practice [11], as confirmed by the ablation study. Furthermore, the performance is comparable to previous studies that required large amounts of training data [7], demonstrating that this study successfully achieved its goal of developing a practical model with minimal image input.

The primary contribution of this work lies in proposing a practical indoor positioning system that requires only one 360-degree image per room, alleviating the burden of preparing a large dataset in previous vision-based methods or the high cost of installing signal-based systems. Another key contribution of this study lies in the automated calibration approach by combining the use of

feature matching and an image similarity comparison technique. When image shifting via feature matching is integrated with CMP-based image similarity, we can achieve a level of performance suitable for practical use, even with only a single image per room. These benefits can also be extended to other studies requiring approximate location tracking, thus broadening the potential applications of our method.

Nevertheless, future research should aim to further enhance positioning accuracy, particularly in spaces like bathrooms that exhibit lower performance. Additionally, although the proposed method demands substantial computational resources and processing time, we anticipate that subsequent optimization and module simplification in future work will help mitigate these limitations.

Abstract

3D human joint estimation is essential for enabling effective human-robot interaction in construction automation, facilitating precise monitoring of worker movements to enhance safety, ergonomics, and operational efficiency. Vision-based systems utilizing multi-camera setups offer diverse perspectives to address challenges such as occlusions, projection ambiguities, and sensor noise. However, these systems depend heavily on accurate camera calibration to align views and synchronize measurements. Traditional manual calibration methods are time-consuming, labor-intensive, and prone to human error, making them unsuitable for dynamic construction sites where frequent camera repositioning is required due to shifting conditions and tasks. This study proposes a novel framework that leverages external marker detection for real-time, automated camera calibration, eliminating the need for manual intervention. This approach significantly reduces setup time, minimizes errors, and ensures reliable performance in rapidly changing environments. Furthermore, the framework integrates an Extended Kalman Filter (EKF) to fuse 2D joint locations from multiple cameras, effectively handling sensor noise and the nonlinear nature of human motion. By combining marker-based calibration with EKF-based fusion, the proposed framework delivers a robust and automated solution for 3D human joint estimation, enhancing safety, efficiency, and adaptability in construction automation applications.

Keywords – 3D Human Joint Estimation; Multi Camera System; Automated Camera Calibration; Extended Kalman Filter

1 Introduction

Construction automation has emerged as a transformative approach to improving efficiency, safety, and ergonomics on job sites. Central to this advancement is the ability to accurately recognize human activities and estimate 3D poses, enabling seamless interaction between workers and automated systems. Modern construction sites increasingly feature human-robot collaboration, where workers and autonomous machines must operate in close proximity to accomplish complex tasks. However, these environments present significant hazards, including heavy machinery, work at heights, uneven terrain, and dynamic interactions between workers and automated systems [1], [2], [3]. In such settings, precise monitoring of worker movements is essential not only for ensuring safe interactions but also for optimizing task coordination and preventing errors. By reconstructing human movements through 3D joint estimation, construction managers can identify unsafe behaviors, assess ergonomic risks, and refine workflow strategies. This capability enhances safety protocols, task efficiency, and human-robot collaboration, reducing the likelihood of injuries from improper posture, repetitive strain, or equipment misuse [4].

Various 3D joint estimation approaches leverage advanced sensing, filtering, and modeling techniques. Among these, vision-based methods are widely adopted, utilizing camera data to track joint positions in three dimensions. RGB-D and 3D cameras help overcome the dimensional limitations of 2D cameras by providing depth information [5], [6], [7]. However, such systems often struggle with resolution constraints and sensitivity to lighting variations [8], [9], [10]. Recent monocular 3D pose estimation techniques have advanced significantly by leveraging Convolutional Neural Networks (CNNs) to regress 3D joint locations from single RGB images [11]. These approaches have expanded the application of vision-based motion capture to unconstrained

environments, but real-world deployment remains challenging due to occlusion, motion blur, and variable lighting conditions, necessitating further improvements.

While monocular methods offer promising results, they often struggle with depth ambiguities. Multi-camera setups address this limitation by capturing multiple viewpoints of a subject, enabling robust triangulation of joint positions. However, such setups require accurate camera calibration to ensure proper alignment across views. Once calibrated, their performance can be enhanced using data fusion techniques such as the Kalman Filter (KF) and Extended Kalman Filter (EKF) to mitigate sensor noise and missing data, while particle filters are particularly effective in handling nonlinearities and occlusions [12], [13], [14]. Additionally, deep learning-based approaches, including Recurrent Neural Networks (RNNs), Generative Adversarial Networks (GANs), and sequence-to-sequence models, further improve motion prediction and temporal consistency in pose estimation [15], [16], [17].

Despite these advancements, significant challenges remain, particularly in dynamic and complex environments like construction. A major limitation is the reliance on accurate camera calibration, which is essential for precise depth perception and spatial alignment. Misaligned views due to improper calibration compromise depth calculations, reducing 3D estimations accuracy. Traditional calibration methods, such as the Direct Linear Transformation and two-step approaches, provide high precision in estimating intrinsic and extrinsic camera parameters. However, they are manual, time-consuming, and best suited for controlled environments, making them impractical for dynamic and unpredictable construction settings [18], [19].

To address these limitations, researchers have explored alternative approaches. Active vision-based methods leverage controlled camera movements to simplify mathematical modeling, but their dependency on precise motion control makes them challenging to implement in real-world applications. Similarly, advancements in computational techniques, such as neural networks combined with global optimization algorithms, have shown promise for automated calibration. These methods effectively model nonlinear relationships in calibration, but their reliance on large training datasets, intensive computation, and careful initialization can limit their applicability in time-sensitive or resource-constrained settings [20], [21].

While these techniques perform well in controlled environments, they encounter significant challenges in dynamic settings where frequent recalibration is required. On construction sites, cameras must be regularly repositioned to accommodate shifting tasks, occlusions, changing lighting conditions, and complex human motion patterns. Manual recalibration in such scenarios is time-consuming and inefficient, emphasizing the need for a real-time, automated calibration system that can maintain accuracy without disrupting ongoing operations.

In this study, we propose an automated calibration framework that integrates a real-time, self-updating multi-camera calibration process for 3D joint estimation. Unlike traditional methods, where camera calibration is performed separately before pose estimation, our framework simultaneously calibrates camera positions, orientations, and fields of view (FoV) while estimating 3D joint positions, enhancing both efficiency and adaptability. To achieve this, we employ an EKF-based multi-view fusion approach, where 2D joint detections from multiple cameras are integrated to generate robust 3D pose estimates, effectively reducing sensor noise and motion uncertainties. Additionally, we introduce an external marker-based calibration technique that automatically updates camera parameters throughout the estimation process, eliminating the need for manual recalibration, which is often time-consuming and prone to errors. This approach minimizes setup errors, enhances real-time adaptability, and ensures consistent calibration even in dynamic and complex applications such as construction automation.

2 Methodology

This study aims to simultaneously estimate the 3D joint positions of a human and automatically calibrate a multi-camera system. To achieve this, a state vector, X_t is defined at a given time t representing all the unknown variables to be estimated: human 3D joint positions and camera parameters (position, orientation, and FoV).

The 3D joint positions are denoted as $H_{t,j}$, where $j \in \{1, \dots n\}$, and n represents the total number of joints in the human body. Each $H_{t,j}$ specifies the global 3D coordinates of the j-th joint in a Cartesian coordinate system. The camera parameters are expressed as $C_{t,i}$, where $i \in \{1, \dots m\}$, and m denotes the total number of cameras. Each $C_{t,i}$ includes both the extrinsic parameters (3D position and orientation) and intrinsic parameters (horizontal and vertical fields of view) of the i-th camera.

The state vector, X_t is defined as:

$$X_t = \left[H_{t,1}, H_{t,2} \cdots H_{t,n}, C_{t,1}, C_{t,2} \cdots C_{t,m}\right]^T \quad (1)$$

Here, each joint position $H_{t,j}$ is a 3D vector representing the global coordinates $(x_{h,j}, y_{h,j}, z_{h,j})$ of the j-th joint:

$$H_{t,j} = [x_{h,j} \quad y_{h,j} \quad z_{h,j}]^T \quad (2)$$

Similarly, the camera parameter $C_{t,i}$ represents the 3D position $(x_{c,i}, y_{c,i}, z_{c,i})$, orientation defined by roll $\varphi_{c,i}$, pitch $\varphi_{c,i}$, yaw $\psi_{c,i}$, as well as the horizontal ($F_{h_{c,i}}$) and vertical ($F_{v_{c,i}}$) FoV:

$$C_{t,i} = \left[x_{c,i}, y_{c,i}, z_{c,i}, \varphi_{c,i}, \varphi_{c,i}, \psi_{c,i}, F_{h_{c,i}}, F_{v_{c,i}}\right]^T \quad (3)$$

This formulation serves as the foundation for simultaneously refining 3D joint positions and calibrating the multi-camera system. The proposed methodology, illustrated in Figure 1, comprises three main steps: 2D joint estimation, marker detection and alignment, and EKF-based integration. 2D joint estimation extracts pixel coordinates of human joints, while marker detection establishes a global reference frame through ArUco marker corners. These measurements feed into the EKF, which refines the state vector, X_t to estimate 3D joint positions and camera parameters, ensuring precise alignment. The following sections provide a detailed explanation of each step.

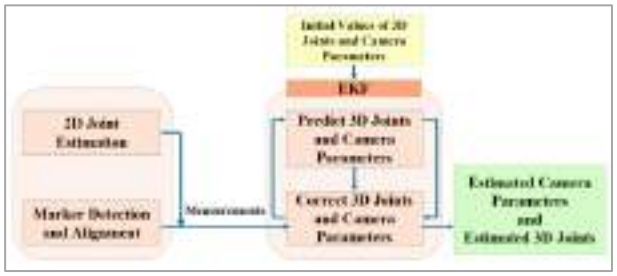

Figure 1. Overall framework

2.1 2D Joint Estimation

The performance of the 3D joint estimation largely depends on accurate 2D joint detection. This study employs MediaPipe's Pose module; a deep learning-based framework developed by Google for high-accuracy, real-time application [22]. It utilizes the lightweight BlazePose model, which features a detector-tracker architecture that reduces latency by tracking previously detected keypoints rather than re-detecting them in each frame. BlazePose outputs 33 keypoints [23]; but this research selects 15 primary keypoints, including major body joints (shoulders, elbows, wrists, hips, knees, and ankles) and key facial landmarks, while excluding keypoints that are not essential for pose estimation [2]. This selection provides a comprehensive 2D representation of the human body, as shown in Figure 2.

Before 2D joint estimation, images from all cameras are synchronized to ensure temporal alignment across views for consistent detection. Each frame is processed individually, with the model outputting pixel coordinates and a confidence score (0–1) for each keypoint. To enhance accuracy, only keypoints with confidence scores above 0.8 are retained, reducing false detections from occlusions or challenging poses. The extracted 2D joint data is structured into arrays for each camera view, enabling synchronized multi-camera processing. This serves as input for the fusion algorithm, facilitating precise 3D joint reconstruction. Leveraging MediaPipe's efficient architecture, this approach achieves low latency, making it ideal for real-time multi-view analysis.

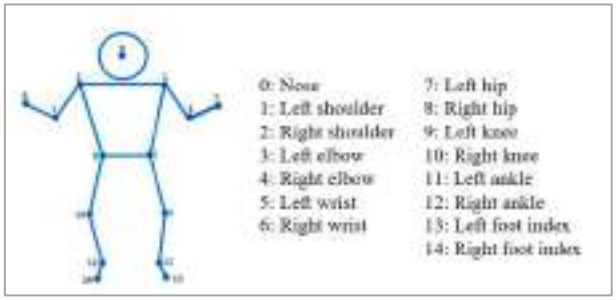

Figure 2. Defined 2D human joints

2.2 Marker Detection and Alignment

In this study, ArUco markers are chosen for their unique binary patterns, which enable easy identification and robust tracking. Unlike checkerboards or circular grids, ArUco markers are resilient to moderate lighting variations and can be reliably detected from diverse angles and distances, making them ideal for multi-camera setups [24].

For this phase, an ArUco marker with a predefined size is used as the reference for automatic camera calibration. The bottom-left corner of the marker is defined as the origin of the global coordinate system, $(0,0,0)$. Based on the marker's size, s, the 3D coordinates of the other corners are defined as $(s,0,0)$, $(0,s,0)$ and $(s,s,0)$. These fixed coordinates serve as reference points for aligning all camera views within a unified coordinate system.

The process begins with detecting the precise corner coordinates of the marker in the camera image planes. These detected coordinates serve as observed measurements for the fusion algorithm, which subsequently estimates both extrinsic and intrinsic camera parameters. The extrinsic parameters, represented by the 3×4 transformation matrix $[R|t]$, define each camera's orientation, R relative to the marker and its position, t in 3D space. Meanwhile, the intrinsic parameters such as FoV, influence how 3D points are projected onto the image plane. This simultaneous estimation ensures that all camera views are accurately aligned within a unified global coordinate system, reducing projection errors and improving multi-view consistency.

2.3 Estimation of Human Pose and Camera Parameter

EKF serves as the core algorithm for simultaneously estimating the 3D human joint positions and the intrinsic

and extrinsic parameters of the multi-camera system by integrating synchronized 2D joint detections and marker-based measurements to iteratively refine the state vector X_t (Equation (1)), which encapsulates both the human joint positions and the camera parameters.

The EKF follows a prediction-correction cycle. In the prediction phase, the system propagates the state and uncertainty forward using a process model, where each joint position evolves independently over time, modeled as:

$$x_{t+1,j} = x_{t,j} + \eta_t \tag{4}$$

where $\eta_{t,j} \sim \mathcal{N}(0, Q_t)$ represents Gaussian process noise, with Q_t as a covariance matrix capturing uncertainties for each joint and camera. The prediction step maintains a Gaussian assumption centered around the current estimate while updating the state distribution over time. Unlike methods relying on pre-known 3D joint positions or calibrated camera parameters, our approach uses the EKF framework to estimate both the joint positions and camera parameters dynamically. The EKF estimates and refines these parameters through its fusion of multi-camera observations and marker-based measurements, ensuring adaptability to dynamic environments.

In the correction phase, 2D joint detections and marker corner coordinates are incorporated to refine the state vector. The observation model predicts the expected pixel coordinates (u_e, v_e) for both joints and marker corners based on the current state estimate. Figure 3 illustrates how a point (joint or marker corner) is transformed from the world coordinate system to the camera coordinate system and finally to the pixel coordinate system.

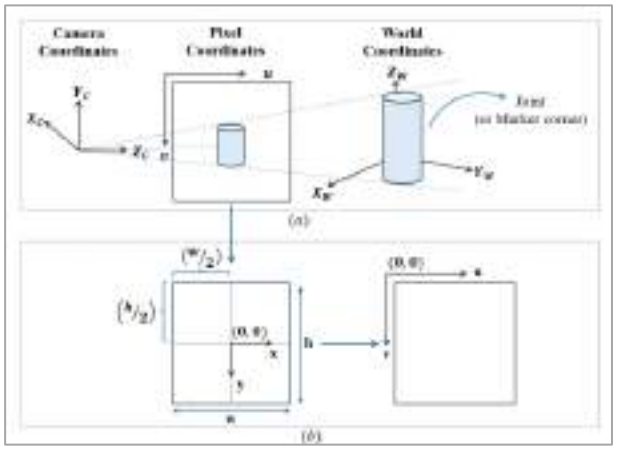

Figure 3. Imaging geometry for joint or marker corner (a) projection joint or marker onto image plane (b) joint or marker in pixel coordinates

To map global joint positions to each camera i's local frame, the EKF employs a transformation matrix T_i and a rotation matrix R_i which is defined as:

$$v_{h,j|C_i} = R_i^{-1} \cdot T_i^{-1} \cdot \mathrm{v}_{h,\mathrm{j}|\mathrm{G}} \tag{5}$$

where $\mathrm{v}_{h,\mathrm{j}|\mathrm{G}}$ and $\mathrm{v}_{h,\mathrm{j}|\mathrm{C_i}}$ represent the j-th joint location in the global frame and in the camera i's frame respectively. They are defined as:

$$\mathrm{v}_{h,\mathrm{j}|\mathrm{G}} = \left[x_{h,j}, y_{h,j}, z_{h,j}, 1\right]^T \tag{6}$$

$$v_{h,j|C_i} = \left[x_{h,cam.j}, y_{h,cam,j}, z_{h,cam,j}, 1\right]^T \tag{7}$$

Similarly, each corner of the marker is mapped to each camera i's local frame:

$$v_{m,k|C_i} = R_i^{-1} \cdot T_i^{-1} \cdot \mathrm{v}_{m,\mathrm{k}|\mathrm{G}} \tag{8}$$

where $\mathrm{v}_{m,\mathrm{k}|\mathrm{G}}$ and $\mathrm{v}_{m,\mathrm{k}|\mathrm{C_i}}$ represent the marker's k-th corner location in the global frame and in the camera i's frame respectively. They are defined as:

$$\mathrm{v}_{m,\mathrm{k}|\mathrm{G}} = \left[x_{m,k}, y_{m,k}, z_{m,k}, 1\right]^T \tag{9}$$

$$v_{m,k|C_i} = \left[x_{m,cam.k}, y_{m,cam,k}, z_{m,cam,k}, 1\right]^T \tag{10}$$

The transformation matrix T_i, where $(x_{c,i}, y_{c,i}, z_{c,i})$ represents the translation of camera i in the global coordinate system. is defined as:

$$T_i = \begin{bmatrix} 1 & 0 & 0 & x_{c,i} \\ 0 & 1 & 0 & y_{c,i} \\ 0 & 0 & 1 & z_{c.i} \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{11}$$

The rotation matrix R_i accounts for the camera's orientation, combining rotations along the $x, y,$ and z axes:

$$R_i = R_z(\theta_{c,i}) R_y(\phi_{c,i}) R_x(\psi_{c,i}) \tag{12}$$

where $\theta_{c,i}$, $\phi_{c,i}$, and $\psi_{c,i}$ are the roll, pitch, and yaw angles of camera i, respectively. These transformations map global 3D positions to the local coordinate system of each camera, resulting in the camera-frame coordinates $(x_{cam}, y_{cam}, z_{cam})$.

The transformed 3D coordinates are then projected onto the image plane to compute the expected pixel coordinates (u_e, v_e) normalized by the image width (w) and height (h) to ensure values range between 0 and 1. Using the horizontal and vertical FoV (FoV_h and FoV_v) the equations for the expected pixel coordinates are:

$$u_e = \frac{1}{2}\left(1 + \frac{x_{cam}}{z_{cam}\, tan\left(\frac{FoV_h}{2}\right)}\right) \tag{13}$$

$$v_e = \frac{1}{2}\left(1 + \frac{y_{cam}}{z_{cam}\, tan\left(\frac{FoV_v}{2}\right)}\right) \tag{14}$$

In this formulation, we use the pinhole camera model,

detailed in figure 4, where FoV inherently defines the camera's intrinsic properties seamlessly integrating with our projection model. This approach eliminates the need for focal length as a separate parameter, making the formulation more compact and efficient while maintaining accuracy in projection calculations. This formulation is applicable to both human joints and marker corners, denoted as $\left(u_{e_{h,j}}, v_{e_{h,j}}\right)$ for the j th human joint and $\left(u_{e_{m,k}}, v_{e_{m,k}}\right)$ for the k-th marker corner.

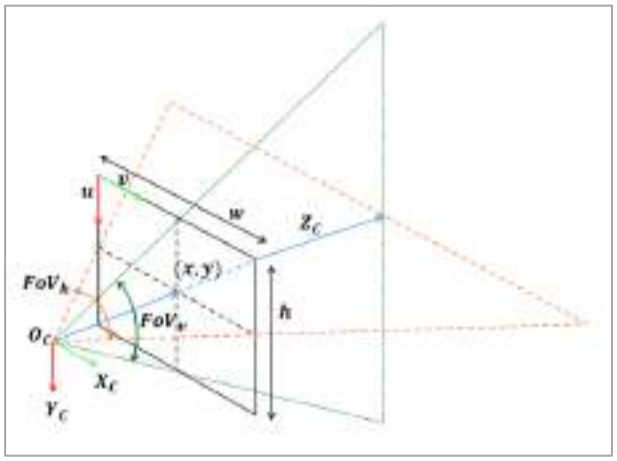

Figure 4. Expected measurements from planar projection

For n cameras, the expected measurement vector $z_{t,e}$ combines the expected 2D pixel coordinates of the detected human joints, $z_{t,e,h}$ and marker corners, $z_{t,e,m}$ from each camera i. It is defined as:

$$z_{t,e} = \left[z_{t,e,h}, z_{t,e,m}\right]^T \quad (15)$$

$$z_{t,e,h} = \left[u_{e,h,i,1}, v_{e,h,i,1}, \ldots, u_{e,h,i,n}, v_{e,h,i,n}\right]^T \quad (16)$$

$$z_{t,e,m} = \left[u_{e,m,i,1}, v_{e,m,i,1}, \ldots u_{e,m,i,k}, v_{e,m,i,k}\right]^T \quad (17)$$

Here $u_{e,h,i,j}$ and $v_{e,h,i,j}$ are the expected pixel coordinates of joint j in camera i's image plane, and $u_{e,m,i,k}$ and $v_{e,m,i,k}$ are the pixel coordinates of marker k's corners.

Once the actual measurements $z_{t,a}$, obtained directly from sensors as noisy 2D pixel coordinates of detected joints and marker corners, are available, the measurement residual,y_t is computed:

$$y_t = z_{t,a} - z_{t,e} \quad (18)$$

where $z_{t,a}$ is derived from the outputs of the 2D joint detection and marker detection algorithms steps discussed earlier in the methodology, while $z_{t,e}$ represents the expected measurements predicted by the observation model.

To incorporate this residual into the state update, the Kalman gain K_t is computed as:

$$K_t = P_t H_t^T (H_t P_t H_t^T + R_t)^{-1} \quad (19)$$

where H_t is the Jacobian of the observation model relative to the state vector, capturing the sensitivity of the measurements to changes in state. R_t is the measurement noise covariance matrix which captures the uncertainty in each camera's observation and P_t is the predicted state covariance matrix, representing uncertainty prior to incorporating the measurements.

In the measurement update step, the EKF integrates the observed measurements $z_{t,a}$. The updated state x_{t+1} is computed as:

$$x_{t+1} = x_{t+1}^- + K_t y_t \quad (20)$$

and the updated state covariance, P_{t+1} is:

$$P_{t+1} = (I - K_t H_t) P_{t+1}^- \quad (21)$$

where x_{t+1}^- and P_{t+1}^- the predicted state and covariance before the measurement update.

This EKF-based filtering algorithm effectively combines predicted and observed data, yielding precise and robust 3D joint estimations and camera parameter calibrations in dynamic, multi-camera environments.

3 Experimental Setup

To evaluate the proposed EKF-based multi-camera calibration and 3D joint estimation system, the implementation was carried out in the Webots simulation environment. Webots was chosen for its ability to replicate real-world scenarios in a controlled setting, providing access to ground truth data, enabling repetitive and reproducible experiments, and allowing systematic testing of algorithms under various configurations.

The simulation was designed to emulate a real-world multi-camera setup with four static cameras and a 5 cm ArUco marker. A pedestrian proto model simulated a human subject, with predefined joint positions replicating realistic human motion. Planar projection was utilized to simulate the 2D image planes of the cameras, enabling accurate marker and joint detections essential for subsequent calibration and estimation steps. The key parameters of the simulation environment are as follows:

- Image Resolution: 640 × 640 pixels.
- Marker Size: 5 cm (edge length).
- Camera Configuration: Planar layout with four static cameras.
- Subject: Webots pedestrian proto model.
- Number of Trials: 30.

The evaluation focused on quantifying the accuracy of the estimated 3D joint positions, camera positions,

camera orientations, and camera FoVs. The Root Mean Square (RMS) error was used as the primary metric for all evaluations:

$$RMS = \sqrt{\frac{1}{N \cdot K} \sum_{i=1}^{N} \sum_{k=1}^{K} \left\| x_{i,k}^{tr} - x_{ik}^{est} \right\|^2} \qquad (22)$$

where, N is the total number of measurements, K is the total number of cameras, $x_{i,k}^{tr}$ and x_{ik}^{est} are the true and estimated values of the quantity being evaluated. x can represent joint positions, camera positions, camera orientations, or FoVs.

By simulating a multi-camera system with realistic projections, human motion, and marker detections, the experimental setup successfully replicated the challenges of real-world environments.

4 Results

This section presents the proposed methodology's findings in the Webots simulation environment. Figure 5 illustrates the successful detection of joints in the pedestrian model and all four corners of the ArUco marker in the image planes from all four cameras. The joint detection provides 2D coordinates for estimating 3D joint positions, while marker corner detection establishes a global reference for camera calibration by defining a consistent coordinate system.

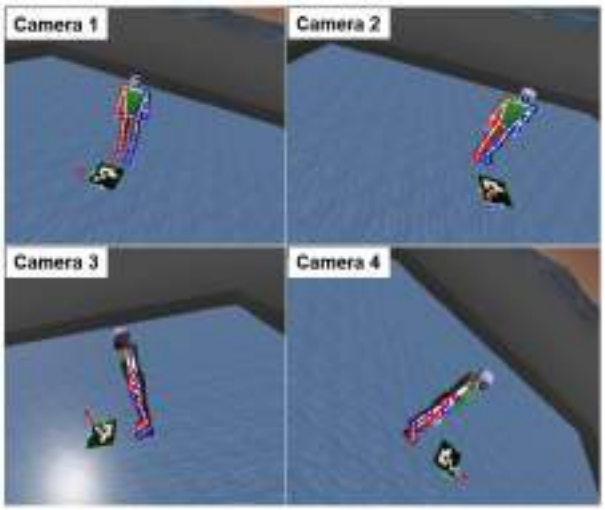

Figure 5. Detection of joints and ArUco marker corners across all camera views

The performance of the proposed methodology was evaluated by analyzing the error trends for joint positions, camera positions, camera orientations, and camera FoV. The results showed an RMS error of 0.18m for joint positions and $0.32m$ for camera positions, while the RMS errors for camera orientations and FoV were approximately 11° and 9° , respectively. Figure. 6 illustrates the error trends for joint positions, camera positions, camera orientations, and camera FoV over time. The graphs show a steady reduction in errors as the EKF iteratively refines the state estimates using multi-camera observations and marker-based measurements.

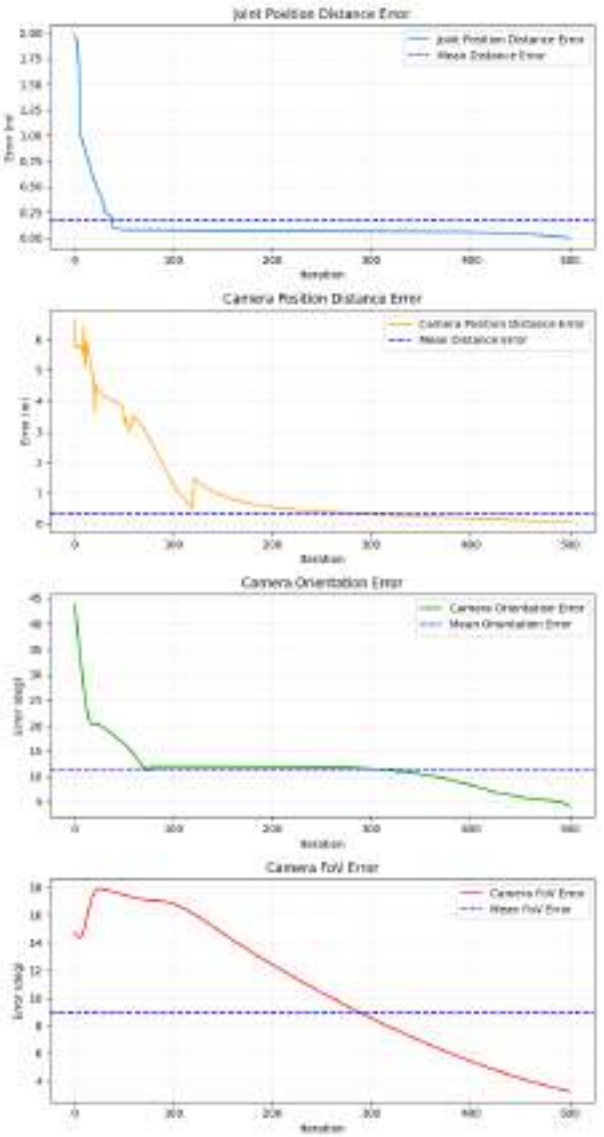

Figure 6. Error trends of joint positions and camera parameters

These RMS errors indicate that the proposed system achieved automatic camera calibration for 3D joint estimation. The consistently small deviations across trials highlight the robustness of the methodology in handling challenges such as sensor noise, nonlinearities, and multi-camera synchronization. Combined with the error trends shown in Figure 6, these findings validate the

reliability and accuracy of the framework in achieving its objectives in a controlled simulation environment.

5 Conclusion

This study proposed a novel framework for automatic camera calibration for 3D joint estimation using a multi-camera system. By integrating an EKF for multi-camera data fusion and an external marker-based calibration method, the framework eliminates the need for manual calibration. Simulations conducted in Webots demonstrated its capability to accurately estimate 3D joint positions and maintain reliable calibration with four cameras. Results showed that the automated calibration method reduced reliance on manual interventions, highlighting the framework's potential for real-world applications where rapid deployment and adaptability are critical.

Despite promising results, certain limitations present opportunities for future research. Simulations, while providing controlled and reproducible results, may not fully capture real-world complexities such as dynamic lighting, occlusions, and irregular motion patterns. Future work should validate the framework in real-world settings to assess its robustness. While our approach models intrinsics via FoV, camera parameter calibration remains a challenge, as real-world systems often require calibration of focal length, principal point, and distortion coefficients. Additionally, the reliance on external markers may pose challenges in cluttered environments where occlusions impact visibility. Optimizing marker placement, increasing marker count, or exploring marker-free calibration could enhance performance. Scalability is another concern, as real-time EKF updates and multi-camera processing demand high computational resources. Leveraging parallel processing or Edge AI acceleration could improve efficiency for real-time deployment. Lastly, while EKF performed well, exploring alternative filtering techniques could further improve accuracy or reduce computational overhead.

With these advancements, the proposed framework has the potential to evolve into a robust and adaptable tool for enhancing worker safety and efficiency in high-risk, dynamic environments. This progress would pave the way for more intelligent and scalable systems in construction automation, furthering the integration of AI and robotics in real-world applications.

Abstract -

Deterioration and maintenance are a constant part of the operational phase of a structures life cycle. Managing and analyzing a structure's history of damage and repair is essential for present operational decisions. Images are a central way of documenting the location of damages during maintenance, but often lack references to the structure. Mapping defects not only spatially, but also over time, can give inspectors a deep insight into the health of a structure. Therefore, we present *LiLoc*, a module for localizing images of inspection documentation in laser scans. Images are matched to the panoramic images of a laser scan, and matrix transformations for mapping points to laser scans are determined. Extracted matrices can be used to transform damage masks and other overlaying information. We then compare the algorithms on two bridge data sets.

Keywords -

Localization, Maintenance, Laser Scanning, Inspection, Defect Mapping

1 Introduction

The maintenance effort required for infrastructure is at an unprecedented high with many concrete structures in Europe and North America reaching the end of their life span. Among the various activities involved in infrastructure upkeep, inspections stand out as the most critical component for assessing the health and integrity of structures. This is especially true for concrete bridges, for which regular inspections throughout their lifespan are an absolute necessity for public safety.

Currently, the inspections in Germany are in most cases conducted by traversing the bridge, identifying old and new defects, documenting the bridge's current state with images and written notes, and finally summarizing the inspection results in a standardized report, consisting of text and images. The images document defects visually, and are used for referencing the defects in later inspections to enable the evaluation of defect progression. Textual information is used to further describe the defect, such as material and size. Usually, the textual information also describes the location of the defect, such as the building component identifier, and less often, road kilometer or cardinal direction. Due to a lack of detail, this recorded location is often imprecise. Finding the defect again is therefore difficult, even though it is required as a basis for the analysis of the structural condition and the defect progression. Enhancing the largely analog and inefficient inspection process through digital tools enables earlier detection of defects and defect progression, thereby providing a stronger foundation for making informed operational decisions.

One possible solution is creating a defect map, meaning a module for a Digital Twin (DT) of the structure that stores defect information and location over time. The planning and execution of maintenance measures for bridge structures benefits from the concept of DTs. Inspectors can easily locate defects with the defect map in a 3D model, while operators can efficiently analyze large amounts of data on a holistic level. Especially the comprehensive map of all defects on a structure over time improves the informational value of inspections by also giving exact spatial information. This defect map will save time during inspections and allow operators to make more informed decisions during the life cycle of a bridge. While a lot of data is available with many inspections reaching back decades, mapping defects from older or current inspections manually is however inefficient.

The major hurdle to overcome for automatically creating a defect map is transforming the data from existing databases. Since the location of defects is often only documented in inconsistent and imprecise textual descriptions, automatically placing a defect on a 3D model becomes challenging. Inspection images may contain hints to the location of a defect, but often lack context, consisting of close ups and zoomed-in pictures for a detailed documentation of defects. Thus, a way to localize images from historical databases is an essential step for the creation of a defect map.

Furthermore, a 3D model into which defects can be mapped is required. Capturing the as-built state of a structure by creating a digital model using laser scanning has been used in practice for several years. As laser scanning allows for the efficient generation of an as-built model, and images of defects are readily available, combining the two methods enables comprehensive defect mapping in conjunction with detailed visual and textual information.

Therefore, we propose an approach to map defects using one-time laser scans and images from multiple inspections through feature matching.

2 Related Works

Improving the mapping of defects is an important topic in structural health research, with a focus on accurately and automatically localizing defects in a 3D model. An often-used tool for concurrent 3D model creation and defect mapping are Unmanned Aerial Systems (UAS). For example, Lin et al. [1] use an UAS to take images of a bridge. The images are used to create a 3D model with Structure from Motion (SfM), and therefore first clustered based on GPS coordinates for to prevent mismatches due to the inherent self-similarity of bridge structures. Defects are then detected on the same images. Since the location of the latter within the 3D model is known, the detected defects can be mapped into the model easily. However, extensive flight planning is necessary to account for GPS inaccuracy. A similar approach is used by Tan et al. [2] for external building walls. Here, GPS is used to compute the UAS position, which is then used to map defects onto a Building Information Modelling (BIM) model.

Research has shown that localization with GPS can lack the accuracy required for defect mapping, especially in areas with little reception, such as underneath a bridge. Therefore, additional technology has been tested to increase localization and thereby mapping accuracy. Yoon et al. [3] utilize an UAS with LiDAR, GPS, and IMU to achieve an accuracy of 10 cm even underneath a bridge. The system is however only evaluated on flat surfaces, such as one side of a bridge column, and issues due to GPS inaccuracy are reported, such as image curving, distortion, and areas missed by the UAS. In another example, Zhao et al. [4] use an UAS with LiDAR, Ground Control Points (GCP) and Check Points (CP) to take images of a concrete dam. Next, cracks larger than 5 mm are detected and mapped with Scale-Invariant Feature Transform (SIFT) [5] and SfM. However, the authors note that the GCPs are critically necessary for reliably mapping the defects, but the setup of GCP and CP is time-intensive and therefore inefficient.

Alternative, non-GPS methods for mapping defects have been tested, mainly relying on camera data. Simultaneous localization and mapping (SLAM), specifically ORB-SLAM, is used on images taken by an UAS to localize defects underneath a longer bridge structure by Jiang et al. [6]. The images were taken from a distance of 2 m and the method results in a localization error of around 25 cm. Bartczak et al. [7] use images taken by an UAS for photogrammetric reconstruction of a 3D model by employing sequential image pairing, explicitly foregoing GPS due to inaccuracies. Defects are detected in the UAS images and thereby mapped to the resulting 3D model.

The previous literature shows the general suitability of using UAS for defect mapping. If an image is used for 3D model creation and defect detection concurrently, the defects are mapped into the resulting model automatically. However, UAS rely on GPS or other methods to localize themselves and thereby images. The previously presented studies show that these methods are still time- and/or cost-intensive, and prone to localization errors. Additionally, although the research is promising, there are further issues with the usage of UAS for defect mapping. First, UAS require a trained user for utilization, which adds further costs to the inspection process, as they cannot replace inspectors. UAS have to keep a safe distance to walls, which decreases the defect resolution in an image. In Xiao et al. [8] for example, close-up shots were taken, but could not be used for model generation successfully and were therefore discarded, leaving their data unavailable for defect detection. The detection of fine cracks with a width of 0.1 mm is required during inspections. Second, usage of UAS is highly regulated and can be restricted in environments such as the vicinity of critical infrastructure, which highway bridges are part of.

In summary, while the most common method of 3D model creation and defect mapping for bridges with UAS does have accuracy issues with regards to localization and resolution, it's not an unsuitable method, and it's apparent that it will play a major role in future inspection processes. However, due to usage restrictions and efficiency considerations, other methods of defect mapping are necessary. A simple alternative for 3D model creation are laser scans with portable scanners, which require little training and are explicitly encouraged in German inspection regulations [9]. Laser scanners usually record either panoramic or stitched images of their scanning pose to capture color information in the point cloud. While panoramic images can be taken during laser scans and are mapped to the scans point cloud, the images are not suitable for defect detection. Therefore, scans are usually not used for defect mapping.

Both laser scanning and UAS are used for as-built model creation but only consider the current state of the structure. A wealth of historical defect images exists, and new images are taken regularly during in-person inspections. Automatically mapping this defect data into a laser scan fulfills the need for a defect map. It also offers additional benefits, as the historical data is very valuable during inspections, e.g., to assess defect progression.

This historical data is not considered by any of the studies described previously, but the textual location descriptions have been considered the two following studies. Göbels and Beetz [10] localize defects via text from bridge defect inspection reports with an ontology called RELOC.

The localization is accurate to the structural component and the directions left/right/top/bottom, with the level of detail corresponding to the detail of the inspectors notes. Heise et al. [11] show the importance of the spatial location of defects in reports, and propose a linked data approach to road and bridge infrastructure data. Through mapping defect location between cross-domain systems, such as road and bridge databases with differing spatial reference systems, defect information can be referenced into other systems and historical data can be integrated. It is obvious that neither of these two works consider image data, which are not as prone to human error as text-based descriptions, or achieve an exact localization. As mentioned before, none of the other works discussed earlier consider historical data at all. Therefore, we focus on efficiently and accurately localizing current and historical defect images in present laser scans.

Since the historical data consists predominantly of individual images, image registration is a possible solution for mapping this data to the panoramic images in the laser scans. Image registration is the process of aligning two images of the same subject with different camera angles, resulting in a homography. One approach for this is key point based image matching. SIFT and adjacent methods extract comparable key points in both images, which are then used for image alignment. SIFT has previously been used for image retrieval in panoramic images, for example by Zamir and Shah [12].

In recent years, image matching using neural networks has become a dominant area of research. Neural network based key point extractors and matching methods, such as XFeat [13] and LightGlue [14] show a significant improvement in speed and accuracy over previous methods. A common research problem is image matching for panoramic images, such as street scenes or from laser scanners. Orhan and Bastanlar [15] use Convolutional Neural Networks (CNNs) to generate searchable feature sets on panoramic images by using a sliding window approach instead of rectifying multiple images. Kendall et al. [16] use a CNN for 6-DoF camera pose regression on a learned environment.

Image registration can be applied to all kinds of images. It is not limited to matching defect images with panoramic images, but can also map a historical image to a current image taken from a different angle. This is especially relevant considering UAS-image-based 3D models, into which in the future, historical defects can also be mapped.

3 LiLoc

We present *LiLoc*, a Python module for localizing images in LiDAR scans with the explicit purpose of creating a defect map for structures. The module is made up of three stages: *Image Extraction*, *Image Matching*, and *Projection*.

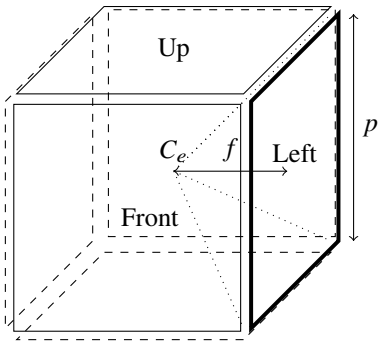

Figure 1. Cube configuration of the laser scan images. Every global camera pose C_e is associated with six images (Up, Down, Left, Right, Front, Back). f is the focal length, p is the image width.

3.1 Image Extraction

First, laser scan images and poses are extracted from a LiDAR scan. As input, we assume point clouds in the open general-purpose *E57* format [17] with multiple scan locations and RGB images. For best results, the scan locations should already be geo-referenced or registered among each other.

The images are extracted as rectified images in a cube configuration (see Figure 1). Every image is saved with an associated pose frame as a transformation matrix with translation and rotation. Pose frames are exported as JSON files with references to the associated JPEG file. We also attempt to extract camera information, such as focal length, from the *E57* file.

3.2 Image Matching

Image matching is done by first identifying visually distinct keypoints in defect and scan images. *LiLoc* supports keypoint detection using Scale-Invariant Feature Transform (SIFT), as well as XFeat [13] for finding keypoints with significant features. XFeat uses a convolutional neural network for finding features, which provides faster and more accurate keypoint detection than older methods. While SIFT produces a variable amount of keypoints, XFeat produces a maximum amount of 4096 keypoints, which are filtered by keypoint quality. All keypoints are saved per image and can be cached to disk for later reuse.

The second stage of image matching is finding keypoint matches. For image matching, we provide two matching methods: Exhaustive matching and cross matching. Exhaustive matching matches every image with every other

image, such as to find matches between all images of an inspection, or a defect instance, if one is specified. Cross matching matches every image of a set A with every image of a set B. This is useful for finding matches between laser scan images and inspection images, or between different capture dates.

Supported matching algorithms are k-Nearest-Neighbour (kNN) and LightGlue [14], a learned feature matching algorithm using deep neural networks. Both matching algorithms return a set of keypoint matches.

If the number of matches exceeds a threshold value, *LiLoc* attempts to find a homography between image pairs using OpenCV. This results in a perspective transformation matrix T. Results are written out in JSON format.

3.3 Projection

In the case of laser scan matching, we can use the match transform T to project points from the defect image onto the laser scan or a 3D model. For this, the intrinsic and extrinsic camera matrix (C_i and C_e respectively) are required for the transformation. The extrinsic camera matrix can be constructed from the position of the scanner and the direction of the scan image. The formula for the intrinsic camera matrix is as follows:

$$C_i = \begin{bmatrix} f_x & 0 & c_x \\ 0 & f_y & c_y \\ 0 & 0 & 1 \end{bmatrix} \tag{1}$$

We assume a pinhole camera model with a cube projection arrangement using square images with resolution P for width and height. Due to the cube arrangement, the focal length is equal to the half the image width/height $f_x = f_y = P/2$, resulting in a 90° field of view. Since the camera center is also the image center, it also follows $c_x = c_y = P/2$. Thus, we can simply write the intrinsic camera matrix as:

$$C_i = \begin{bmatrix} P/2 & 0 & P/2 \\ 0 & P/2 & P/2 \\ 0 & 0 & 1 \end{bmatrix} \tag{2}$$

The extrinsic matrix $C_e = (R|t)$ encodes rotation R and translation t of the camera. Combining the extrinsic and intrinsic coordinates, we can obtain a directional vector $\vec{r}$ from an image coordinate $\vec{p}$.

$$\vec{r} = C_e C_i \vec{p} \tag{3}$$

The image coordinate is equal to the image center for now, but can be expanded when the defect position in the image is given. From position t towards direction $\vec{r}$, we use a cylinder cast (analogous to a ray cast) with a radius of 10 cm to find the closest point in the laser scan. We use the median of the closest 10 points to reduce the impact of outliers. This results in a 3D position for the defect image.

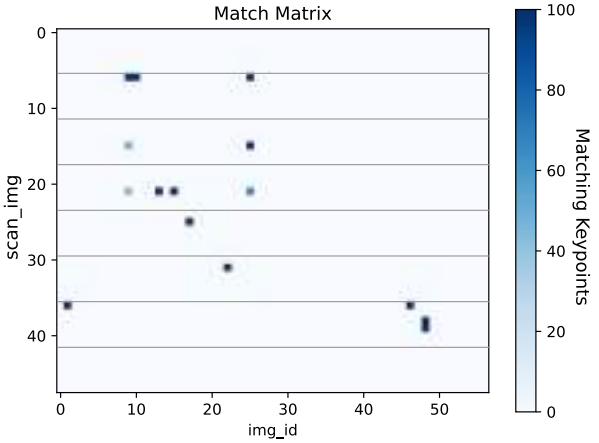

Figure 2. Match matrix of 57 defect images of to 8×6 laser scan pose images of Bridge A (scan-to-defect) using XFeat + LightGlue.

4 Case Study Results

Our approach was tested on two case studies consisting of two different highway bridges. For the lasers scans, a Leica RTC 360 was used, and photos were taken with Android and iOS smartphones.

Bridge A is a concrete bridge with a highway on-ramp. A full laser scan with 8 poses was taken, and images of concrete-based defects were collected on the same day. The individual scans were combined to a point cloud, and the point cloud was then registered to a pre-existing BIM model. For Bridge B is a 600 m pre-stressed concrete bridge. Partial laser scans were taken at five poses and 504 pictures of present defects in different camera angles were collected.

For Bridge A, we compare SIFT + kNN-Matching with XFeat + LightGlue. We only focus on XFeat + LightGlue for Bridge B.

4.1 Scan matching

For localization of the defect images in the laser scans, we attempt a match of every defect image with every scan image. For this, we extracted the scan images as described in Section 3.1. The matching threshold for all tests was set to 30 matches.

For this test we use XFeat as the keypoint extractor and LightGlue as the keypoint matcher. Bridge A with 8 scan locations (resulting in 48 rectified scan images) and 57 defect images results in 15 matches (see Figure 2). 10 images were correctly matched to at least one scan image, allowing for localization in the point cloud. Even with limited context, the matching performed well. Figure 3

Figure 3. Example of a positive match between a panoramic image (left) and a defect documentation image (middle). The defect image is projected onto the scan pose (right).

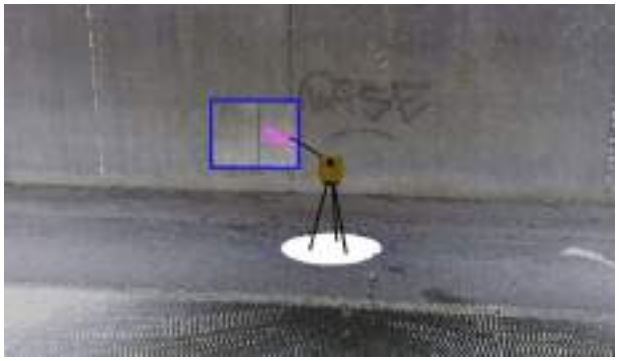

Figure 4. Projection of a defect image of graffiti on the concrete wall below Bridge A.

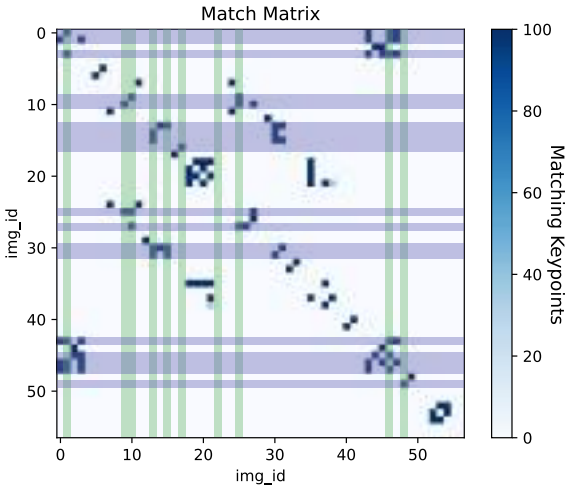

Figure 5. Match matrix of 57 defect images of Bridge A (defect-to-defect). Green lines show images that could be localized to a scan position (10 total). Blue lines include images that match to at least one localized image (18 total).

shows an example of spalling on the ceiling of the highway bridge. The detailed image of the defect was correctly matched to the scan image. Images that could not be matched to any scan image consist of extreme close-ups or of areas that the scanner did not cover. No false positives occurred in this limited data set.

We tested the projection capabilities with example images. Figure 4 shows the point cloud below the bridge. From the laser scan position, the matching defect image was projected onto the nearby wall. This links the defect to the point cloud with a 3D position.

As a baseline comparison, this data set was tested with SIFT features and kNN-matching. This resulted in 67 matches. Only four of the matches were correct (6% precision). Surprisingly, these four matches were matches that XFeat and LightGlue did not recognize. The low precision shows that classic keypoint matching methods are not suitable for finding matches in larger databases.

Bridge B with 9 scan positions (54 scan images) and 504 defect images resulted in 17 matches. We assume that the low number of matches is due to the limited scan coverage of the 600 m bridge. Again, no false positives were found. Notable is that most matches contain text written with chalk on the structure, like demarcations and measurements conducted by workers. Every matched defect image also corresponds to only one scan position, since the laser scan was limited to only significant locations with almost no overlap.

4.2 Defect matching

We used the exhaustive matching method for matching all defect images. This $n \times n$ matching allows for finding images of the same defect in the database.

Bridge A amounts to 58 matches in total (see Figure 5). Again, no false positives were found in this limited data set. Considering the scan matches from Section 4.1, we can subsequently localize overlapping and zoomed images of the same defect. 18 images are first removed to a direct scan match, and 22 images can be traced to at least one scan position in total. Some sets of images form a cluster, where 4–5 images of the same defect could be localized among each other, but could not be matched to a scan position.

For Bridge B we matched 504 images against each other. Overall, 904 matches were detected (see Figure 6). Since the image data set had up to ten pictures of the same defect from different perspectives, the matching clusters are larger than in Bridge A. Even though images were sometimes taken at extreme perspectives, the images were matched correctly (see Figure 7).

171 matches for Bridge B were manually classified as false positives (81% precision). The largest portion of false positives (120) turned out to be images with a crack

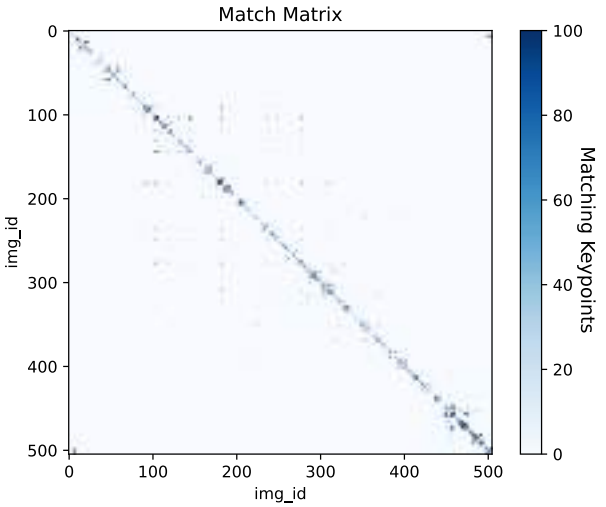

Figure 6. Match matrix of 504 defect images of Bridge B (defect-to-defect).

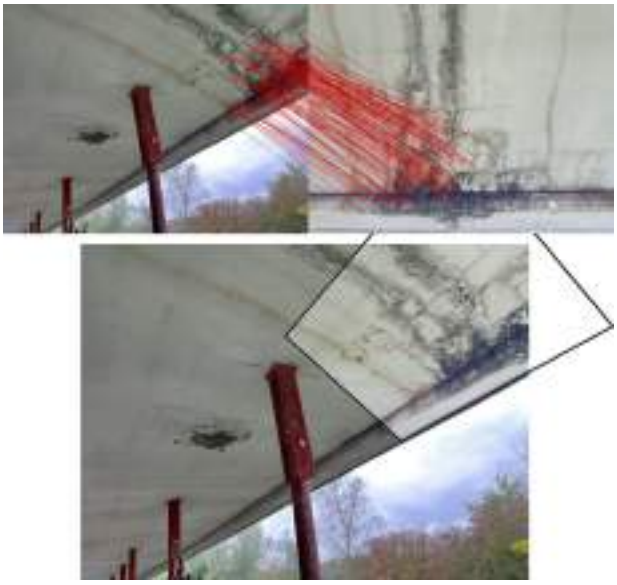

Figure 7. Example of a positive match of two images of the same defect, one with context, one with detail.

Figure 8. False positives for defect matching. Top: A crack width reference card is recognized as a match. Bottom: A similar scaffolding element is recognized as a match.

width reference card, a tool often used by inspectors to measure cracks (see Figure 8). The other false positives were mainly due to scaffolding present at the bridge, which shows a high degree of self-similarity. Increasing the keypoint match threshold to 100 reduces the number of total matches to 667 and the false positives to 47 (93% precision).

Tracing all images of Bridge B to at least one scan position allows localizing more defects. Filtering for false positives, 92 images can be traced to at least one scan position, allowing for localization in the point cloud.

4.3 Discussion

Using XFeat and LightGlue for matching shows significantly better results than using SIFT and kNN matching. SIFT and others have been developed for image stitching or live image tracking, such as SLAM, instead of recalling images taken at separate times with different cameras. While still useful in some of these situations (e. g. loop closure), matching entire databases produces too much false positives to be useful. Meanwhile, AI matching methods prove to be sensitive enough to detect significant points even in uniform concrete surfaces.

While only a small portion of defect images could be matched to scan images in our data set directly, exhaustive matching could fill some gaps. Using exhaustive matching to detect defect image clusters allowed for tracing these clusters to at least one scan image. Despite this, some images still could not be traced to a scan position. This is possibly due to incomplete laser scans or defect images that did not provide enough context for a successful localization.

False positives were mostly due to similar objects in the images, such as scaffolding or instruments. Still, some false positives are due to the self-similar nature of bridges. We have also neglected counting false negatives, as defining a false negative in terms of localization can be difficult.

5 Conclusion

We presented *LiLoc*, a tool for localizing defect images in laser scans, and tested it on two self-collected data sets. The tool supports extracting scan images from point clouds, matching images in exhaustive and cross-matching mode, and mapping defect images to a 3D coordinate. The code is documented on GitHub[1].

This tool paves the way for researchers, engineers and on-site inspectors utilizing the historical data of inspections to make maintenance easier and more comprehensible. With this image matching tool, historical data can be used in conjunction with modern digital tools. This approach can be integrated into existing inspection processes as historical data can be linked to new digital technologies. Databases can be enriched with location specific data, closing the gap between image data, laser scans, and DTs.

The results show that with AI keypoint extraction, reliable image localization is achievable. Learned features perform better on concrete structures than classic methods such as SIFT. Even difficult matches of pure concrete walls can reliably be matched based on the imperfections in the concrete. This has previously been a challenge with classic methods.

Figure 9. Example of a match between two images of the same defect, taken in 2005 and 2014 respectively.

Although the results are promising, some limitations are evident. Some objects or artifacts in the image can confuse the matching algorithm, such as measurement instruments or burnt in text on the image (such as the capture date). One option would be to detect these objects using a semantic segmentation network filter out keypoints with a mask. Lighting conditions are also a significant impact factor. In this paper, we have not compared large-scale data sets with images under different lighting conditions or camera modes (e. g. flash photography). The data set should be expanded upon for realistic applications. In this study, we have also only quantified the method's performance with data that was recorded concurrently. Figure 9 shows an example of a successful match of real historical inspection data with a time difference of nine years. Due to the difficulty of obtaining historical data sets in a large scale, this study focused on data captured without a large time difference. In future research, the data set should be expanded with more data recorded at different times and conditions. Crafting data sets that reflect these challenges is a necessary step in future work.

Future research will focus on improving the algorithms used in this paper, and adding new keypoint and matching algorithms. Both XFeat and LightGlue allow for training the network to adjust to specific conditions. Training these algorithms specifically for the materials used in the construction industry may improve precision significantly. Removing keypoints on equipment, as well as other camera artifacts such as burnt-in dates may be masked out in a pre-processing step. Other local feature extractors such as GlueStick [18] work with lines in addition to points, which may prove suitable for the built environment.

Abstract -

The accurate modeling of building facades plays a critical role in architecture, urban planning, and energy efficiency. Traditional methods of facade mapping are often labor-intensive, costly, and prone to error. Recent advancements in computer vision and sensor technology have introduced innovative approaches for capturing precise geometric data, including the use of AprilTags—fiducial markers that enable efficient facade reconstruction through digital imaging techniques. This paper explores a method that involves arranging AprilTags in a grid pattern on building surfaces, capturing multiple images of the tagged facade, and using triangulation techniques to infer the 3D geometry of the structure with high accuracy. The resulting digital models have a wide range of applications, including optimizing solar panel placement, creating detailed replicas for heritage conservation, and enhancing urban planning through improved simulations of light, shadows, and heat.

Facade Modeling; AprilTags; 3D Reconstruction; Stereo Vision; Camera Calibration; Fiducial Markers; Distance Estimation

1 Introduction

The accurate modeling of building facades has become increasingly important in various fields such as architecture, urban planning, and energy efficiency. Traditional methods of mapping and measuring facades can be time-consuming, costly, and prone to error. Recent advancements in computer vision and sensor technology have introduced new approaches for capturing detailed and precise geometric data of structures. One such method involves the use of AprilTags—fiducial [1] markers that can be placed on the facade—and digital imaging techniques [2] to estimate the real-world distances between these markers, effectively reconstructing the facade's geometry.

In this technique, AprilTags are arranged in a grid pattern on the building's surface, either manually or with the assistance of a drone. A camera then captures multiple images of the tagged facade from different angles, and, combined with information such as the camera's focal length and intrinsic parameters, these images are used to infer the relative positions of the tags. By triangulating the distances between the tags, the method can reconstruct the 3D geometry of the facade with high accuracy. This process allows for the creation of a digital model that closely represents the real-world structure, enabling applications in design, planning, and analysis.

The resulting geometric data has diverse applications beyond simple structural visualization. For example, in the field of renewable energy, the technique can be used to precisely model building surfaces for the optimal placement of solar panels. Similarly, it can assist in heritage conservation, where detailed digital replicas of historical facades can be created for restoration or archival purposes. Furthermore, this method could be applied to urban studies, enabling more accurate simulations of shadows, light exposure, and heat absorption in city planning. As building facades continue to evolve in complexity and functionality, the ability to quickly and accurately model these surfaces opens up new possibilities for both practical and theoretical applications in the built environment.

2 Problem Description and Constraints

The accurate modeling of building facades is a critical task in fields such as architecture, urban planning, and energy efficiency. However, traditional methods of mapping and measuring building facades are inherently challenging due to several factors. These methods are often time-consuming, labor-intensive, and prone to human error, especially when dealing with large or complex structures. Furthermore, the equipment required for manual measurements can be costly and may not always yield the level of precision necessary for advanced applications.

Recent advancements in computer vision and sensor technology offer an opportunity to address these challenges [3]. Specifically, the use of AprilTags—fiducial markers designed for robust detection—has emerged as a promising approach for facade modeling. These markers enable precise distance measurements and allow for the reconstruction of a facade's geometry through digital imaging.

First, the placement of AprilTags requires a systematic and controlled process, typically arranged in a grid pattern on the building's surface. This can be done manually or with the assistance of drones, but both approaches present logistical challenges, particularly for large buildings or difficult-to-access facades. Second, the accuracy of the reconstruction depends heavily on the quality and quantity of the images captured. Factors such as camera calibration, lighting conditions, and the angles from which the images are taken can significantly impact the precision of the results. Additionally, the computational process of triangulating the positions of the tags requires careful handling of camera intrinsic parameters, such as focal length, to ensure reliable 3D geometry generation.

These constraints highlight the need for a method that balances practicality and accuracy while minimizing costs and manual effort. Despite these challenges, the use of AprilTags for facade modeling represents a scalable and efficient solution that could potentially overcome the limitations of traditional techniques, enabling diverse applications in design, analysis, and planning. In short, the main problem is to determine the spacial geometry of the placed AprilTags as accurately as possible. The spacial geometry of the Apriltag grid directly gives one information about the geometry of the building facade. In this paper, we propose a pipeline, which only involves a Camera with a fixed focal length and a Python pipeline, which can be used to very accurately determine the distance to an Apriltag. This information can then be used to estimate the spacial geometry of the AprilTag grid.

3 Technical Preleminaries

In the process of reconstructing the geometry of building facades, one common challenge is the presence of noise and inaccuracies in the observed 3D data points, especially when these points are assumed to be co-planar. While techniques like AprilTag-based distance estimation offer high accuracy in reconstructing building geometry, small errors in the measurements or in the camera calibration can introduce deviations that affect the precision of the reconstructed model. In the next section, we will discuss one possible method to mitigate this issue.

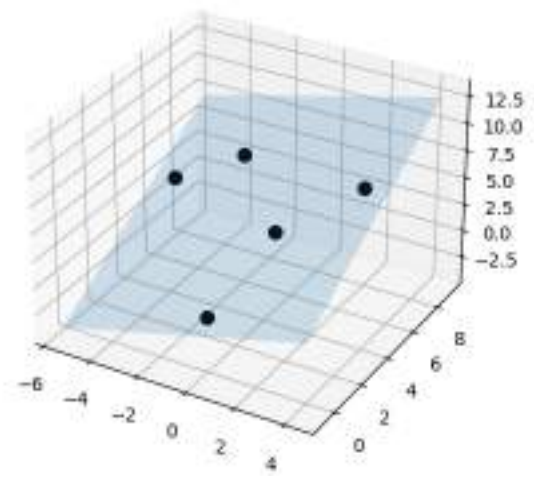

Figure 1. The Best-Fitting plane passing through 5 points

3.1 Best-Fitting Plane: The Key Improvement Strategy

A practical solution to this problem is the concept of the best-fitting plane—a mathematical approach that minimizes the error between observed data points and a plane that best represents their true position.

The best-fitting plane is typically computed using methods like least squares fitting, where the goal is to find the plane that minimizes the sum of squared distances between the observed data points and the plane itself. This method is particularly useful when dealing with 3D data points that are known a-priori to lie approximately on the same plane, such as those derived from the AprilTag markers on a building facade. By fitting a plane to these points, we can correct for small inaccuracies in their positioning, leading to a more accurate representation of the facade geometry.

In the context of our research, using a best-fitting plane can significantly enhance the quality of the 3D model by refining the locations of the AprilTags as shown in Figure 1. This correction process helps mitigate errors caused by slight misalignments or measurement noise, ensuring that the reconstructed facade closely matches the actual structure. Such improvements are particularly valuable when the facade's geometry is needed for precise applications like solar panel placement, where even minor discrepancies in the 3D model could affect performance. By leveraging the best-fitting plane approach, this method can contribute to more reliable and accurate models for various real-world applications, including energy optimization, urban planning, and architectural analysis.

3.2 Distance Estimation via Effective Focal Length

Accurate distance estimation to an AprilTag from a camera is a critical aspect of the proposed facade modeling method. This process relies on key camera parameters, including the *effective focal length* and the *pixel size* of the camera's sensor. These parameters enable the calculation of real-world distances by relating the apparent size of the AprilTag in the captured image to its known physical dimensions.

3.3 Effective Focal Length and Camera Geometry

The effective focal length (f) of a camera [4] is the distance from the lens to the sensor at which parallel rays of light converge to form a sharp image. It is typically expressed in millimeters and is a fundamental property of the camera's optics. Combined with the sensor's pixel size (p), the focal length determines the *field of view (FOV)* and directly impacts the perceived size of objects in the image.

For a camera with a focal length f and a sensor with pixel size p, the physical distance between the camera and an object, such as an AprilTag, can be determined using the principle of similar triangles. The relationship between the tag's real-world dimensions and its image size on the sensor provides the basis for this calculation.

3.4 Calculating Distance Using Image Data

When an AprilTag is captured in an image, its size in pixels (s_{pixels}) can be measured. The real-world width of the tag (W) is known a priori. Using these values, the distance to the tag (D) can be calculated using the following formula:

$$D = \frac{f \cdot W}{s_{\text{pixels}} \cdot p}$$

Here:

- f is the effective focal length of the camera (in millimeters),
- W is the real-world width of the AprilTag (in millimeters),
- s_{pixels} is the width of the AprilTag in the image (in pixels),
- p is the physical size of a single pixel on the sensor (in millimeters).

3.5 Practical Considerations

1. **Camera Calibration:** Accurate distance estimation requires precise knowledge of the camera's intrinsic parameters, including the focal length and pixel size. Camera calibration processes, such as those using checkerboard patterns, are essential for determining these values accurately.
2. **Tag Orientation and Perspective:** If the AprilTag is not perpendicular to the camera's optical axis, its apparent size in the image will be distorted. Perspective correction algorithms may be required to account for this distortion and ensure accurate measurements.
3. **Resolution and Image Quality:** The resolution of the captured image affects the precision of s_{pixels}. High-resolution images provide more accurate measurements of the tag's size, improving distance estimation accuracy.
4. **Lighting and Focus:** The clarity and visibility of the AprilTag in the image depend on proper lighting and focus. Poor lighting conditions or out-of-focus images can introduce errors in size estimation and, consequently, distance calculations.

3.6 Applications in Facade Modeling

By determining the distances to multiple AprilTags placed on a building's facade, a 3D reconstruction of the surface can be performed. The calculated distances form the basis for triangulating the relative positions of the tags, enabling the generation of a detailed geometric model of the structure. This approach, leveraging the effective focal length and pixel size, provides a robust and scalable solution for facade modeling with high accuracy.

4 The Main Pipeline

The proposed pipeline for facade modeling leverages AprilTags and digital imaging techniques to accurately reconstruct the geometry of building facades. The steps involved in the pipeline are outlined below:

4.1 Placement of AprilTags

Several AprilTags are placed in a grid-like formation on the facade like Figure 2.

This systematic arrangement ensures that the tags are evenly distributed across the surface, enabling accurate reconstruction. Care is taken to maintain consistent spacing between the tags and to cover the entire area of interest.

4.2 Image Capture

Multiple images of the tagged facade are captured from different distances. To minimize distortion and maintain accuracy, the camera angles are kept relatively shallow, avoiding overly steep perspectives that could negatively affect the results. These images serve as the input for the subsequent processing and analysis stages. For the

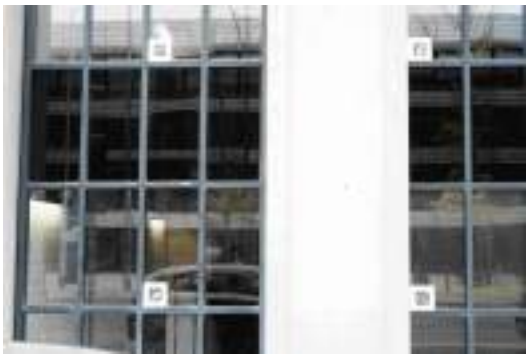

Figure 2. The setting of the AprilTags' outline

Figure 3. Contrast Adjusted Image

experiments themselves, we used the Sony Alpha 7R IV 35-mm-Vollbildkamera with 61,0 MP [5]. Based on our experiments, we found that this particular camera has an effective focal length of approximately 13257.6 (in the appropriate units).

4.3 Pre-Processing

Before detecting the AprilTags, the captured images undergo pre-processing to enhance their quality. This step includes modifying parameters such as gamma and contrast to ensure the tags are clearly visible and detectable in the images as shown in Figure 3.

These adjustments help mitigate the effects of varying lighting conditions and improve the reliability of the detection process.

4.4 AprilTag Detection

The AprilTags in the pre-processed images are detected shown in Figure 4 using the Python library `AprilTag` [6], which is available at `https://github.com/Tinker-Twins/AprilTag`. This library identifies the tags and determines their pixel dimensions (s_{pixels}) in the images. These pixel measurements are essential for calculating the real-world distances to the tags.

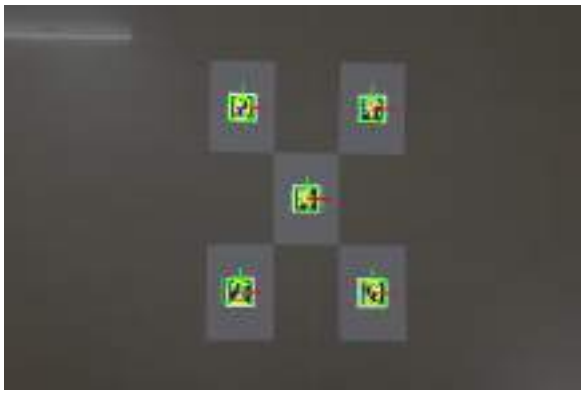

Figure 4. Detection results

4.5 Calculating the Distance Between Two AprilTags

Once the distances from the camera to individual AprilTags and their positions in the 3D space are determined, the distance between two AprilTags can be calculated by analyzing their relative spatial coordinates.

4.6 Steps for Calculation

1. **Determine the 3D Coordinates of Each AprilTag:** Using the camera as the origin of the coordinate system, the 3D position of each AprilTag (x, y, z) can be determined from the camera parameters and the pixel coordinates of the tag in the image. For a tag at distance D from the camera:

$$x = D \cdot \frac{u - u_0}{f_x}, \quad y = D \cdot \frac{v - v_0}{f_y}, \quad z = D$$

where:

- D is the distance from the camera to the AprilTag (calculated using the focal length, tag size, and pixel size),
- (u, v) are the pixel coordinates of the AprilTag in the image,
- (u_0, v_0) are the principal point coordinates (typically the center of the image),
- f_x and f_y are the focal lengths of the camera in the x- and y-axes (in pixel units).

2. **Final Correction via the Best-Fitting Plane** Since we know (approximately), that the AprilTags all lie in a Plane, we can use the best fitting plane for the 3D coordinates obtained in the previous section and project the points on this plane to obtain the corrected points (x', y', z'). Note that we used the Python library `scikit-spacial` [7] for the Best-Fitting plane compuations.

3. **Calculate the Euclidean Distance Between Two AprilTags:** Let the coordinates of the first AprilTag be (x_1, y_1, z_1) and the second AprilTag be (x_2, y_2, z_2). The distance d between the two tags is given by the Euclidean distance formula:

$$d = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2 + (z_2 - z_1)^2}$$

4.7 Practical Considerations

- **Accuracy of Coordinates:** The accuracy of the calculated coordinates depends on the precision of the distance measurements (D) and the camera's intrinsic parameters (f_x, f_y, u_0, v_0).
- **Perspective Distortion:** If the AprilTags are not aligned perpendicularly to the camera's optical axis, corrections may be required to ensure accurate coordinate estimation.
- **Tag Identification:** Each tag must be uniquely identified in the image to correctly associate its 3D position with its real-world counterpart.

By calculating the 3D positions of multiple AprilTags and using the Euclidean distance formula, the relative distances between tags can be computed with high precision. This process enables the reconstruction of the facade's geometry with reliable spatial relationships between the tags.

5 Experimental Results

Several experiments were performed on one of the TUM buildings in Arcisstrasse by considering a section of the windows as the Facade. Six AprilTags, with different tag IDs were placed on the windows as shown in Figure. In this particular experiment, AprilTags with the following IDs were used: $1, 2, 3, 1617, 18, 20, 22$. Here we describe the results of once such experiment. The results of this experiment are described in two tables. Table 1 shows the estimated distance between the tags Tag A and Tag B (A and B being the Tag IDs) for three specific cases.

On the other hand, Tables 2 and 3 show the the 3D coordinates of the Tags with ID 2 and 16. Here, the Tag 1 is the reference Tag. This means that the coordinates have been changed in such a way so that the Tag 1 becomes the origin (with coordinates $(0, 0, 0)$).

6 Conclusion and Future Developments

In this work, we presented a robust pipeline for the accurate modeling of building facades using AprilTags and digital imaging techniques. By leveraging fiducial markers arranged in a systematic grid pattern, we demonstrated how the real-world distances and relative positions of these tags can be calculated to reconstruct the 3D geometry of facades. The process incorporates critical steps such as camera calibration, pre-processing of images to enhance quality, and the use of the `AprilTag` Python library for precise tag detection. The geometric data obtained from this pipeline can be applied to a wide range of fields, including renewable energy optimization, heritage conservation, and urban planning. One more thing to note is that this pipeline does not involve complicated (and rather archaic) tools such as a Total Station. Further, this pipeline can reduce the time it takes to estimate the facade geometry in comparison to other traditional methods.

We also discussed the mathematical foundations underpinning the reconstruction process, particularly the use of the camera's effective focal length, pixel size, and image data to determine the spatial coordinates of each AprilTag. Furthermore, the ability to calculate the distances between tags using their 3D positions allows for the creation of highly accurate and detailed facade models.

Looking ahead, we plan to enhance the accuracy and scalability of our approach by incorporating stereo vision techniques [8, 9, 10, 11]. Specifically, future experiments will utilize the FUJIFILM GFX 100 II camera [12], a high-resolution imaging system, in a dual-camera setup(the other camera being the current on). By capturing synchronized images from two cameras at different perspectives, stereo vision will enable precise depth estimation and reduce potential errors caused by distortion or

steep angles. This will significantly improve the reliability of 3D reconstructions and make the method more suitable for complex facade geometries.

The integration of advanced camera systems and stereo vision techniques represents a promising direction for this work, offering increased accuracy and flexibility for facade modeling. These advancements will further expand the applicability of our approach to a broader range of architectural, engineering, and urban development challenges.

Abstract

This study presents a methodology for the automated inspection of rebar diameters and spacing in wall structures using a laser scanner. Previous studies conducted the methods in controlled laboratory environments, and primarily focused on predicting rebar diameters larger than 10 mm. However, these methods have difficulties applying to real-world construction sites which have rebars on bent, and limited scanning positions. This research was performed on an actual construction site where small-diameter rebars (10 mm) were arranged in double layers. To address the curvature presented in rebar arrangement surfaces, a new methodology was introduced; linearity was analyzed to detect the complex rebar arrangements. The spacing of the rebars was calculated by projecting the point clouds onto an axis aligned with the rebar arrangement. Rebar diameters were estimated through RANdom Sample Consensus (RANSAC) circle fitting. The results demonstrate that the proposed methodology successfully modeled distorted rebar structures presented in construction sites, enabling accurate extraction and prediction of rebar objects. This approach can replace labor-intensive manual inspections, ensuring accurate and reliable verification against design specifications.

Keywords

Laser scanner; Point cloud; Automated inspection, Rebar spacing, Rebar diameter

1 Introduction

To ensure structural safety in reinforced concrete construction, rebars must be placed precisely at the designated locations and with the appropriate sizes specified in the design drawings. The placement and size of rebars directly play a critical role in determining the load-bearing capacity of reinforced concrete [6]. Improperly arranged rebars during concrete casting can result in structural failures. Therefore, rigorous inspections of rebar placement are essential.

Traditionally, rebar placement inspections in construction sites are performed visually by inspectors who physically traverse the site, using tape measures to check spacings and sizes. As the work area expands, these inspections become increasingly time-consuming, labor-intensive, and hazardous, as inspectors must move across all rebar-equipped areas [1].

To overcome the challenges of manual inspections, numerous studies have aimed to automate the rebar inspection process. Among these approaches, laser scanners have gained significant attention for their ability to capture point cloud data of rebar arrangements and to subsequently compute rebar diameters and spacing [2]. However, previous studies have conducted experiments under laboratory conditions. These studies primarily focused on predicting rebar diameters and spacing under optimal scanning angles, with most cases involving rebar diameters larger than 10 mm. In contrast, actual construction sites feature highly complex rebar arrangements. Thus, scanning positions are often limited and conditions, which differ significantly from laboratory settings, make it challenging to accurately detect rebars on bent or irregular surfaces. Consequently, these methods are unable to recognize rebars in diverse positions or with small diameters. To address these limitations, this study focused on scanning rebars arranged at real construction sites, segmenting each rebar, and automatically predicting their diameters and spacing. Furthermore, the proposed method can be utilized in Scan-to-BIM (Building Information Modeling) workflows by enabling the automated generation of 3D as-built rebar models. This approach ultimately contributes to improving construction quality control, structural verification, and digital lifecycle management in reinforced concrete construction.

2 Literature Review

Point clouds are widely used owing to their high efficiency and accuracy [10, 11, 12, 13, 14, 15]. Previous studies have created and analyzed point clouds generated by Terrestrial Laser Scanners (TLS) to automate rebar inspection [2, 3, 4, 5, 6]. These studies typically focused

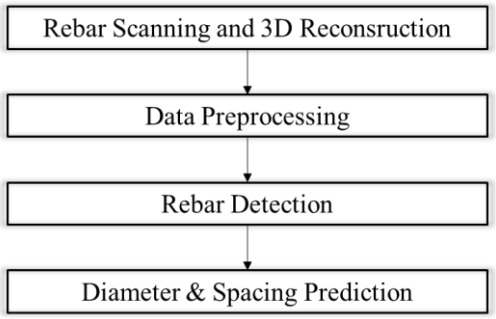
on separating vertical and horizontal rebars to estimate both the diameter of each segment and the spacing between segments. For instance, Kim et al. [2] employed RANSAC [9] to segment individual rebars and applied Density-based Modeling (DBM) to enhance the classification accuracy for rebar diameter estimation. Li et al. [17] presented a scan planning method to select the optimal scan position of laser scanner for improving the rebar inspection accuracy. However, these methods are conducted under laboratory conditions. Most of previous studies focused on predicting rebar diameters and spacing based on optimal scanning angles, primarily focusing on rebars larger than 10 mm in diameter. In real-world scenarios, rebar arrangements are far complex, and scanning positions are frequently constrained. Likewise, the environmental differences from laboratory settings pose significant challenges in accurately detecting rebars on curved of uneven surfaces.

To address these gaps, this study proposes methodology for two purposes: (1) rebar detection using laser scans in complex construction sites, and (2) diameter and spacing prediction for small-diameter rebars.

3 Methodology

3.1 Research Framework

Figure 1 illustrates the framework of this study: rebar scanning and 3D reconstruction, data preprocessing, rebar detection, and diameter and spacing prediction. During the rebar detection stage, planarity, linearity, and iterative RANSAC are utilized to remove formwork and base surfaces. Subsequently, double-layered rebar arrangements are distinguished through Otsu thresholding. For spacing prediction, projection algorithm and cubic spline interpolation are used to predict the location of vertical rebars. For diameter prediction, rebars are divided into individual instances and projected onto the surface perpendicular to the first axis of Principal Component Analysis (PCA). The diameters are then predicted using circle fitting based on the RANSAC method.



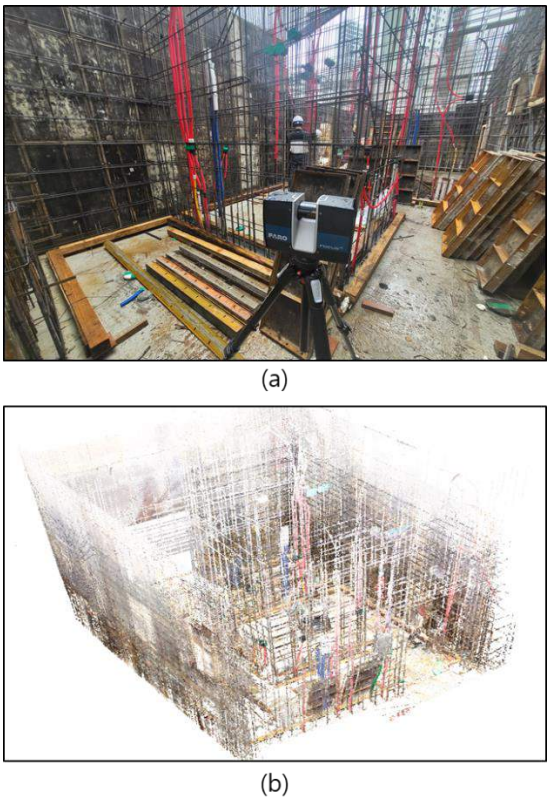


Figure 1 Research framework

3.2 Rebar Scanning and 3D Reconstruction

At an actual construction site, a wall rebar structure with 10 mm diameter rebars arranged in double layers at 300 mm intervals beside the formwork was scanned. The scanning was performed from five different positions using a FARO Focus M laser scanner. The point clouds collected from each position were subsequently combined into one unified point cloud using FARO Scene software, as shown in Figure 2.

(a)

(b)

Figure 2 (a) Scanning of wall rebar arrangement; (b) 3D point cloud reconstruction of wall rebar arrangement

3.3 Data Preprocessing

Prior to analyzing the rebars, noise was removed using the Statistical Outlier Removal (SOR) method [16]. In this process, points whose average distance to their 10 nearest neighbors exceeds twice the standard deviation threshold were considered outliers and removed.

3.4 Rebar Detection

The preprocessed point cloud contains various elements, including rebars, formwork surfaces, materials, and floor surfaces. To extract the rebar point cloud, unnecessary information must be removed. As shown in Figure 2(b), rebars exhibit an elongated linear shape in the point cloud, whereas other elements do not. To distinguish these, the linearity and planarity of the neighboring point cloud data were analyzed. For this analysis, the Radius Nearest-Neighbor Covariance (RNCC) method was applied [8]. RNCC computes the eigenvalues of the covariance matrix for points within a given radius *r*, representing the degree of data dispersion (see Equation (1)).

$$Cov = \frac{1}{N}\sum_{i=1}^{N}(p_i - \bar{p})(p_i - \bar{p})^T \quad (1)$$

In this content, N denotes the number of neighboring points within radius r, p_i is the coordinate vector of each neighboring point, and $\bar{p}$ is the centroid of the neighboring points. The first eigenvalue λ_1 represents the variance in the direction where the data is most dispersed. The second and third eigenvalues, λ_2 and λ_3, correspond to the variances in the second and third most dispersed directions, respectively.

By calculating the eigenvalues of the covariance matrix, the linearity (see Equation (2)) and planarity (see Equation (3)) of the point cloud can be evaluated. For linear data, λ_1 is large and λ_2 is small; therefore, a larger $\lambda_1 - \lambda_2$ value indicates greater linearity. For planar data, both $\lambda_1, and\ \lambda_2$ are large while $\lambda_3$is very small; thus, a larger $\lambda_2 - \lambda_3$ value indicates higher planarity.

$$L_\lambda = \frac{\lambda_1 - \lambda_2}{\lambda_1 + \lambda_2 + \lambda_3} \quad (2)$$

$$P_\lambda = \frac{\lambda_2 - \lambda_3}{\lambda_1 + \lambda_2 + \lambda_3} \quad (3)$$

Using the obtained linearity and planarity data, formwork surfaces with high planarity can be removed, while rebar point cloud data with high linearity can be segmented.

Figure 3 visually represents the distribution of linearity and planarity. As shown in Figure 3(c), the formwork appears in blue, indicating low linearity, while the rebars appear in red, indicating high linearity. In contrast, Figure 3(d) shows that the formwork has high planarity, whereas the rebars exhibit low planarity. By setting thresholds based on the distribution of linearity and planarity, filtering was applied to extract the rebar point cloud.

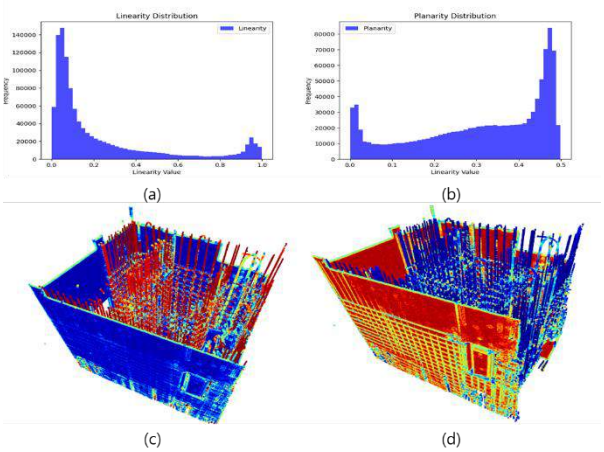

Figure 3 (a) Linearity distribution of point cloud; (b) Planarity distribution of point cloud; (c) Linearity expression of point cloud (red: high linearity, blue: low linearity); (d) Planarity expression of point cloud (red: high planarity, blue: low planarity)

A filtering threshold of 0.3 was applied to the linearity distribution, resulting in a point cloud that excludes the formwork and the floor surface, as shown in Figure 4. However, unnecessary noise still remained, such as construction materials.

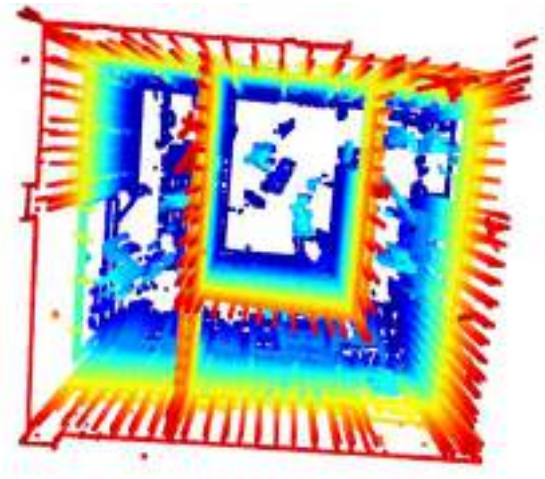

Figure 4 Filtered point cloud by linearity threshold

Such remaining noise in the point cloud needs to be removed, and the rebars arranged at various angles must be separated to calculate their spacing. To achieve this,

the RANSAC method was employed. RANSAC fits a specific model to the input data and identifies inliers that best conform to the model. Since rebar-arranged surfaces typically have a planar shape, fitting a plane model in a 3D space using RANSAC enables the extraction of the rebar-arranged surface, which is identified as inliers. By removing the extracted points and reapplying RANSAC to the remaining data, other rebar surfaces can be identified. This iterative process continues until no surface contains more than a predefined number of inliers, at which point RANSAC terminates. This method allows for the identification of all rebar surfaces while simultaneously removing noise, as illustrated in Figure 5.

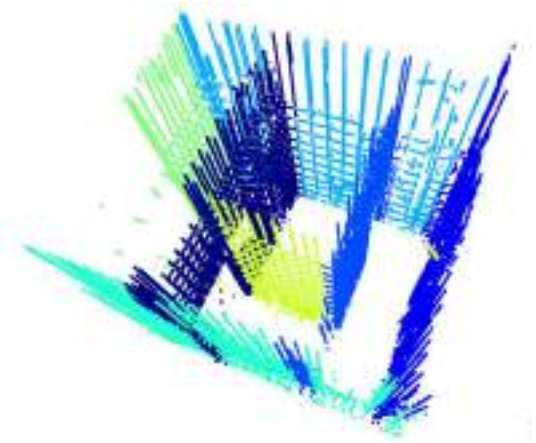

Figure 5 Iterative RANSAC of filtered point cloud

The rebar surface segments obtained through iterative RANSAC consist of rebars arranged in double layers. To further distinguish the two rebar surfaces, a plane is recalculated using RANSAC, and the point distribution by distance is analyzed, revealing two distinct peaks at different locations, as shown in Figure 6(a). To divide the data into two groups, Otsu Thresholding was applied. This method determines an optimal threshold by maximizing the between-class variance in a histogram, allowing for the separation of the double-layered rebar data (Figure 6(b)). The results are visualized in Figure 7.

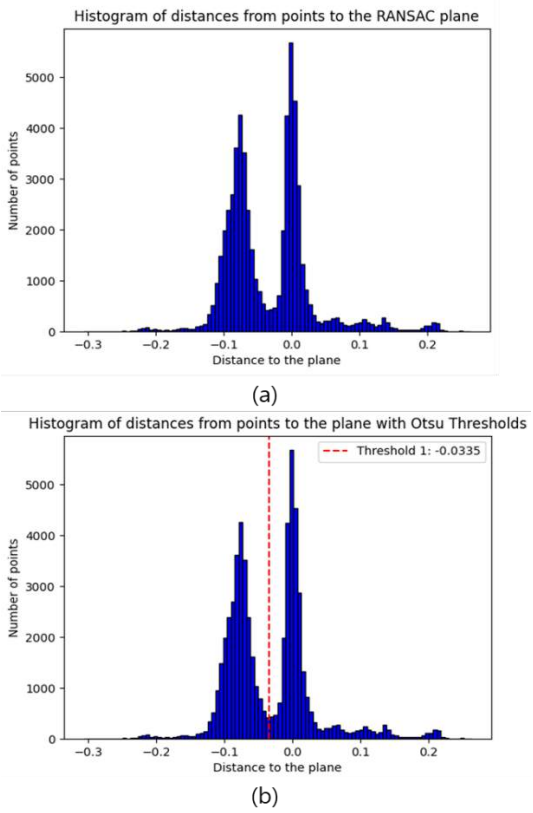

Figure 6 (a) Histogram of distances from points to the RANSAC plane; (b) Histogram of distances from points to the plane with Otsu Thresholds

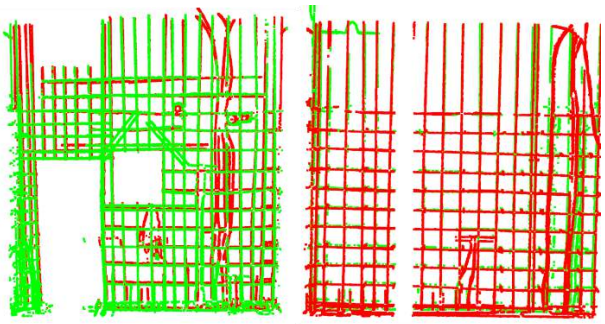

Figure 7 Visualization of double-layered rebar separation results

The study aimed to predict the rebar arrangement (i.e., spacing and diameter) of the actual double-layered rebar surfaces measured. Therefore, one-layered rebar surfaces separated in Figure 7 was used for further research.

3.5 Diameter & Spacing Prediction

Using the rebar point cloud obtained through the previous process, the rebar diameter and spacing could be estimated. In previous studies, rebar surfaces were

assumed to be perfectly planar, a feasible assumption in controlled laboratory environments. Under these conditions, RANSAC was used to separate horizontal and vertical rebars. However, as shown in Figure 8, the distance between the rebar point cloud and the RANSAC plane is visualized using color variations, with red indicating greater distances and blue representing shorter distances. This exhibits that the actual rebar surfaces in the field poses curvature rather than a perfect planar shape. This presents a limitation: in the presence of curvature, RANSAC can fit incorrect planes, leading to the spurious-plane problem [7]. This issue occurs in 3D point cloud segmentation, where the algorithm incorrectly detects planes that do not actually exist in the data. This limitation makes it difficult to apply the rebar segmentation methods proposed in previous studies to real-world construction sites. Accordingly, this study proposes a novel method for predicting the spacing of rebars that can be applied even when the rebars are bent in actual construction sites. Based on the rebar spacing data, we further suggest a methodology for estimating the rebar diameter.

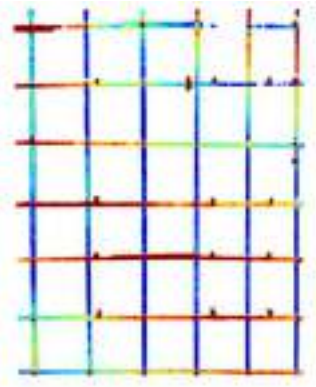

Figure 8 Visualization of distance from RANSAC plane (red: greater distance, blue: shorter distance)

3.5.1 Rebar Spacing Prediction

To estimate the spacing between rebars, the 3D points were projected onto a 1D axis aligned parallel to the rebar arrangement direction. Figure 9 shows histograms of the point distributions when the points are projected onto the horizontal and vertical axes. These histograms were normalized into curves using cubic spline interpolation, and the local maxima exceeding a specific threshold were identified, as shown in Figure 10. The locations of these local maxima on the normalized point density curve correspond to the centers of rebars aligned perpendicular to the projection axis. The spacing between horizontal and vertical rebars can thus be determined by calculating the distances between adjacent local maxima.

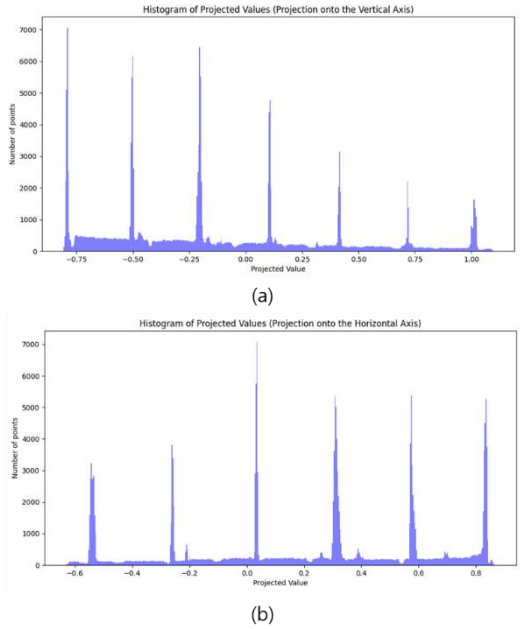

Figure 9 (a) Histogram of projected values (projection onto the vertical axis); (b) Histogram of projected values (projection onto the horizontal axis)

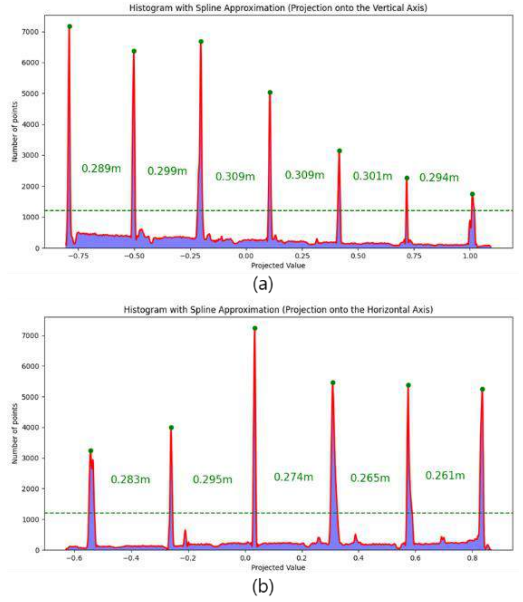

Figure 10 (a) Histogram with spline approximation and horizontal spacing prediction (projection onto the vertical axis); (b) Histogram with spline approximation and vertical spacing prediction (projection onto the horizontal axis)

The comparison between the predicted rebar spacing and the manually measured spacing is shown in Table 1.

Table 1 The comparison between the predicted rebar spacing and the manually measured spacing (mm)

		Spacing No.						Average error (mm)	Average accuracy (%)
		1	2	3	4	5	6		
Horizontal rebar spacing	Predicted	289	299	309	309	301	294		
	Measured	291	305	308	317	295	282		
	Error	2	6	1	8	6	12	6	98
Vertical rebar spacing	Predicted	283	295	274	265	261			
	Measured	284	287	282	268	252			
	Error	1	8	8	3	9		6	98

The measured spacing values refer to the manually measured spacing using a measuring tape. As shown in Table 1, the average spacing error for both horizontal and vertical rebars was 6 mm, which indicates an average error rate of 2%. This demonstrates that the proposed automated rebar spacing prediction method achieved an average accuracy of 98%.

3.5.2 Rebar Diameter Prediction

To estimate the diameter of the rebars, the cross-sectional data of each rebar was extracted. As shown in Figure 11, the segments between rebars were cropped based on the previously obtained rebar spacing information. These segments were then divided using Density-Based Spatial Clustering of Applications with Noise (DBSCAN). For each cluster, PCA was applied to calculate the first principal axis, which corresponds to the direction with the largest variance. The points were then projected onto a plane perpendicular to this principal axis. Since scanned rebars will show a circular shape in the projected points, a circle fitting algorithm could be used for diameter prediction.

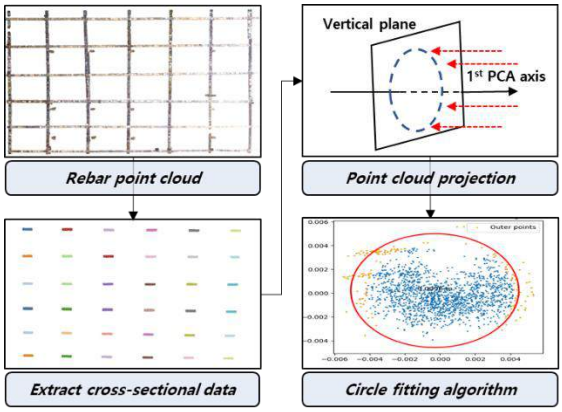

Figure 10 Processing steps for rebar diameter prediction

As the deformed rebars used at the construction site have ribs and lugs, the projected point clouds were generally distributed in circular or semi-circular shapes. However, in order to accurately estimate the diameter of each rebar segment, it is essential to use the outermost distributed points. This is because each segment contains almost no external noise, and the outermost points are likely to represent the outer surface of the rebar. Therefore, circle fitting based on outer points was applied to estimate the rebar diameters. Specifically, for each segment, a center point was determined, and RANSAC-based circle fitting was performed using the top 10% of points with the largest distances from the center. The result example is presented in Figure 12.

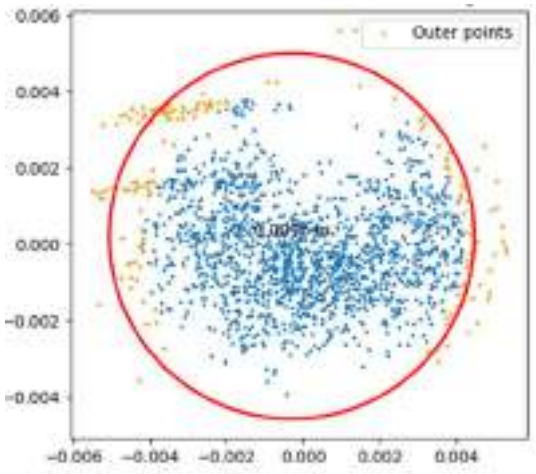

Figure 11 Segment diameter prediction example by extraction of outermost points and RANSAC circle fitting

The predicted rebar diameters were categorized into designations based on their nominal diameters, as shown in Table 2. Each segment was classified by matching its estimated diameter to the closest nominal diameter. These nominal diameters were used as the categories. The predicted diameters for each segment were classified into the nearest nominal diameter among these categories.

Table 2 Type of designation

Designation	Nominal diameter (mm)
D4	4.23
D5	5.29
D6	6.35
D8	7.94
D10	9.53
D13	12.7
D16	15.9
D19	19.1

Since each rebar was divided into multiple segments, the diameter of the rebar was determined by identifying the mode (i.e., most frequent value) of the class within the segment group. This approach helps mitigate prediction deviations caused by local noise in individual segments. It also provides a more effective basis for assessing the classification accuracy of each rebar into its correct nominal diameter, which is important for subsequent use in Scan-to-BIM applications. As shown in Figure 13, the predicted rebar diameters were 6 mm, 8 mm, 10 mm, or 13mm. At the segment level, the accuracy was 72.2%, while at the rebar level, the accuracy was 100%. In comparison, a previous study reported a segment level accuracy of 35.1% and a rebar level accuracy of 56% in estimating the 10 mm rebar diameters [2]. Therefore, the proposed method achieved significantly improved performance.

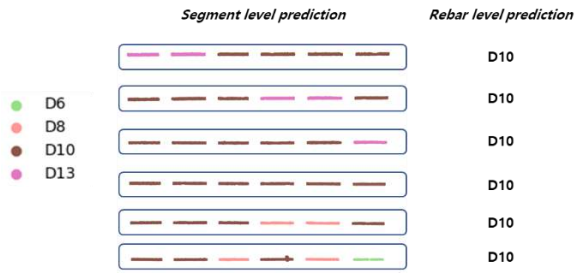

Figure 12 Rebar diameter prediction

4 Conclusion

4.1 Summary & Contribution

This study proposed a methodology for automating rebar arrangement inspection at construction sites. Unlike laboratory conditions, the research was conducted on an actual construction site where small-diameter rebars (10 mm) were arranged in double layers within a wall structure. First, a method for recognizing rebars in complex construction sites was proposed. The rebar was separated from non-rebar structural elements in the point cloud by utilizing the planar and linear characteristics of the objects. Subsequently, the rebar surfaces arranged in various directions were individually segmented using the RANSAC algorithm. A novel approach was introduced to estimate rebar diameters and spacing, even when the rebar surfaces were not perfectly planar. The accuracy of the proposed automated rebar spacing prediction was 98%, and the accuracy of rebar diameter prediction was 72.2% at the segment level and 100% at the rebar level.

Compared to thicker rebars, thinner rebars are more prone to bending or deformation. When the reinforcement surface is distorted, existing methods proposed in previous studies may no longer be applicable. Therefore, the proposed method can be particularly effective for detecting and analyzing small diameter rebars. Also, the proposed methodology can automate the complex and labor-intensive task of inspecting densely arranged rebars using laser scanners on real-world construction sites. Additionally, comparison and analysis with design specifications can ensure safe and accurate rebar arrangement inspection.

The proposed methodology can be further integrated with Scan-to-BIM technologies to support the automated generation of 3D models from scanned point cloud data. Through this process, rebar arrangement results can be accurately reflected in the digital model, enabling the classification of rebar types and the recognition of individual rebar elements within the 3D environment. Such integration allows for more precise modeling of the construction status and facilitates the identification of various components on-site.

4.2 Limitations

Since there were no rebars smaller than 10 mm in the scanned site, the current study was limited to 10 mm-diameter rebars. Further research will be conducted on sites with rebars of smaller or larger diameters.

When extracting rebar information from the point cloud using its linear or planar characteristics, information loss can occur in overlapping regions of rebars. This is due to the reduced linearity caused by distribution of adjacent points in both vertical and horizontal directions. Thus, further work will focus on constructing datasets that include rebar intersection points to enhance the applicability of the proposed method. Additionally, the method for calculating rebar spacing assumes that rebars are arranged vertically; thus, the proposed approach has limitations when rebars are placed diagonally.

Diameter and spacing estimation were performed only for a subset of the separated rebar segments, rather than for the entire dataset. This is because the current method could not effectively handle noise-included data, where other materials were not fully removed from the segmentation process. Future research will focus on addressing this issue.

Abstract

Additive manufacturing (AM) of eco-friendly materials has the potential to decarbonize the construction industry by enabling the creation of complex structures with minimal waste. Clay has been integrated into AM processes as a building material, giving rise to an emerging research field referred to as "clay printing". Defects, such as tearing and sagging, are common in clay printing and could affect the structural integrity, load-bearing capacity, and overall durability of the structures. However, limited research on defect detection in clay printing and lack of datasets restrict the development of defect detection models. This paper presents a tool – the automated defect detection (ADD) preprocessor – developed to generate a dataset for defect detection models in clay printing. The tool uses images and videos as input for preprocessing and labeling images required to build the dataset, meeting the requirements of defect detection models based on convolutional neural networks. The ADD preprocessor is implemented and validated as a proof of concept for clay printing processes. The results demonstrate the capability of the ADD preprocessor to successfully build a dataset for the deployment of defect detection models in clay printing.

Keywords –

Clay printing; additive manufacturing; defect detection; dataset; convolutional neural networks

1 Introduction

Additive Manufacturing (AM) has become a significant innovation in the construction industry due to its numerous advantages that surpass "traditional" construction methods [1]. One key aspect, compared to traditional construction methods is the ability to create complex and customized structures without additional cost or material waste [2]. The layer-by-layer construction process enables the realization of geometrically intricate designs and freeform structures that are challenging or impossible to achieve with conventional formwork or machining methods [3]. Furthermore, additive manufacturing of eco-friendly materials has the potential to decarbonize the construction industry [4].

Clay, a traditional building material, has been adapted for AM processes and has emerged as a new research field, referred to as "clay printing" [5]. Clay printing often encounters defects during printing, such as tearing and sagging, that could affect the structural integrity, load-bearing capacity, and overall durability of the structures. By exploring synergies with concrete printing, defects in clay printing may be investigated. Defects in concrete printing, including tearing (breakpoints due to low workability of the material) [6], sagging/buckling (due to deformation under self-weight) [6] and shrinkage cracking [7], can also be observed in clay printing. However, research on defect detection in clay printing remains limited, which hinders the development of defect detection models due to insufficient data.

Efforts towards automated defect detection approaches for AM processes have been reported, where most research has been focusing on fused filament fabrication (FFF) and, more recently and to a lesser extent, on concrete printing. For FFF processes, recent defect detection approaches for offline and real-time detection have been developed based on computer vision techniques, including comparing point clouds [8] and images [9] as well as on convolutional neural network (CNN) architectures [10, 11]. Similarly, approaches based on computer vision, supplemented by machine learning and deep learning, have been developed for concrete printing to detect layer deformations [12] and to assess geometries of additively manufactured structures [13]. Further approaches devised for real time defect detection in concrete printing have been developed based on detection transformers to detect and measure tearing with high accuracy [14]. Yet current defect detection approaches present several limitations. On the one hand, vision-based systems are used in real-time defect detection to monitor printing processes and detect defects, but are limited to the view point of the vision-based systems. On the other hand, defect detection models based on deep learning, such as CNN classification models, may be trained to detect and classify specific defects, where the scope and accuracy of the defect detection models are dependent of the datasets available for training [11]. Consequently, the need for datasets arises, due to the limited availability of data regarding

defects in clay printing.

In this paper, the development of a tool for automated defect detection (ADD) is presented. The tool, named "ADD preprocessor", is designed to build a dataset aiming to support defect detection models in clay printing using images and videos as input data. The image data is preprocessed and labeled to build the dataset, which meets the requirements of defect detection models based on convolutional neural networks. The ADD preprocessor is implemented and validated as a proof of concept for clay printing processes. The remainder of the paper is structured as follows. First, the methodology for deep-learning-based defect detection and the implementation of the ADD preprocessor is presented. Next, the proof of concept is described, followed by a discussion of the conclusions and potential future research.

2 Deep-learning-based defect detection model

In this section, the methodology for generating deep-learning-based defect detection models is described. The methodology is based on a previous study of the authors (described in [15]), and it is adapted for clay printing. Considering the lack of available data for clay printing, the ADD preprocessor is designed and implemented as a tool for generating datasets for defect detection models. Below, a short description of the research methodology and the implementation for the ADD preprocessor is presented.

2.1 Research methodology

The research methodology is proposed to generate a deep-learning-based defect detection model using a CNN architecture. As described in Figure 1, the creation of deep-learning-based defect detection models usually comprises two phases, the (i) data preparation phase and (ii) classification model development phase. The ADD preprocessor focuses on the data preparation phase (highlighted in orange in Figure 1) and generates a dataset D_n as an output using images and videos as input data.

In the **data preparation phase**, data is collected, preprocessed, labeled, augmented, and split. During *data collection*, *n* images of additively manufactured clay structures with and without defects are part of the dataset D_n. The images included in the dataset D_n may be collected from different sources, where the images may vary in size, color, and viewing angle. Next, during *data preprocessing*, the images are cropped, resized to a predefined size, transformed into a gray scale, and corrected for orientation to a consistent horizontal view. The gray-scale images are then *labeled* with the corresponding defect class: Tearing, sagging, buckling, and shrinkage cracking. Finally, for *data augmentation*, augmentation techniques, such as mirroring, noise, light exposure ("brightness"), rotating and random image cutouts, are applied to increase the size of the dataset D_n. Mirroring and rotating are used to improve robustness to random camera angles, while noise, cutouts, and variable exposure increase resilience to varying lighting conditions. For the next phase, dataset D_n is *split* into three sub sets, a training dataset ($D_{training}$), a validation dataset ($D_{validation}$), and a testing dataset ($D_{testing}$).

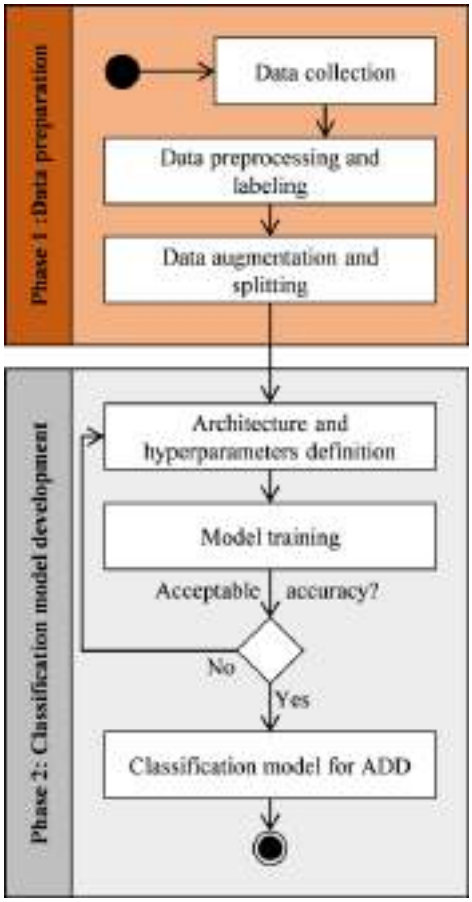

Figure 1. Methodology for generating deep-learning-based defect detection models [15]

In the **classification model development phase**, the classification model is developed in three steps, architecture definition, model training, and model testing. For *architecture definition*, the architecture of the classification model is selected and hyperparameters are defined. An architecture commonly used is the "You Only Look Once" (YOLO) architecture, which prioritizes speed, accuracy, and user-friendliness while preserving computational efficiency [14]. Upon defining the CNN architecture, the training dataset $D_{training}$ is deployed to train the CNN classification model. During

model training, the model "learns" from existing relationships between known inputs (images) and known outputs (defect classes, e.g. "sagging"). Furthermore, loss metrics are used to guide the optimization of the CNN classification model and to evaluate the error between the predictions of the model and the actual target outcomes. In general, a decreasing loss value trending toward zero indicates that the model is effectively "learning" from the training dataset. Meanwhile, and to prevent overfitting during training process, the validation dataset $D_{validation}$ is applied to fine-tune and evaluate the performance of the models during training. Upon completing training, the testing dataset $D_{testing}$ is used to test the performance of the classification model until achieving an acceptable accuracy. During *model testing*, evaluation metrics are used, including precision, recall and the mean average precision at a single intersection-over-union threshold, to test the capacity of the model aiming to avoid false positive and false negative classifications and to expresses the prediction accuracy of the model.

2.2 Implementation

Acquiring large datasets for clay printing is challenging because of to the lack of research on defects in clay printing in the context of the construction industry. Existing labeling tools are limited to only annotate images, requiring already standardized images as inputs and additional tools for data augmentation. Therefore, the ADD preprocessor aids in collecting and standardizing images stemming from various sources, as well as to labeling and augmenting the image data to generate a dataset. To satisfy the requirements for deep-learning-based defect detection models in the context of clay printing, the following requirements are considered:

- *Image size*: CNN classification models require standardized image sizes to improve accuracy and reduce complexity [12]. Images are resized, either by downscaling or upscaling, to an optimal image size that minimizes computational cost while maximizing feature resolution. To ensure efficient batch training and adequate feature resolution, an image size of 640x640 pixels is predefined as the optimal image size for this study.
- *Colorblind model*: Variations in the material color may affect the accuracy of the defect detection models [12, 14]. By using gray-scaled images, it is possible to prevent correlating material color with defect classes, as well as to increase the computational speed of the CNN model. In gray-scale images, each pixel represents a specific light intensity, ranging from black to white, with no color information.
- *Defect labeling*: Inconsistent rheological and mechanical properties of the material, dimensions of the extruded layers, and the number of stacked layers dictate the characteristics of defects, as discussed in [14]. However, details that might resemble defects may have been intentionally designed for esthetics and function, such as water protection, shading, and ventilation. Therefore, design intentions of additively manufactured structures are considered when identifying defects during the labeling process. The labeled images are accompanied by annotation files with the same name, containing the coordinates of bounding boxes that describe the location of defects and labels of the corresponding defect types.
- *Data augmentation*: Augmentation techniques are employed to increase the size of the dataset and to improve the robustness of the CNN classification models. Random camera angles are introduced to the dataset by mirroring and rotating images in the range of [-20°, 20°]. Varying lighting conditions are introduced to the dataset by adding noise to 4% of the gray-scale pixel intensity values and by adjusting brightness in the range of [-35%, 35%].

A labeling strategy is defined for the ADD preprocessor. For each defect type, a corresponding label and index number is assigned (Table 1). Defects are manually annotated with a bounding box and labeled with the corresponding index number. The annotation is then saved in a CSV file.

Table 1. Defect labeling for clay printing

Label	Index number
No defect	0
Tearing	1
Sagging	2
Buckling	3
Shrinkage cracking	4

The ADD preprocessor is implemented using Python programming language, together with a graphical user interface (GUI) for manual user inputs and processing algorithms for resizing input images, adjusting view angles, converting the images to gray scale, and augmenting the data. The GUI, as shown in Figure 2, facilitates generating datasets by importing and saving images into user-defined file directory ("source folder" and "save folder"), as well as automating the preprocessing steps with three main trigger buttons ("crop", "process", and "save").

When importing an image into the ADD preprocessor, areas of interest of the additively manufactured structures can be manually selected using the GUI and cropped with the crop button. When importing videos, a previous step is performed to capture a frame every half a second. With the process button, processing algorithms are triggered.

First, the areas of interest are centered and resized to the predefined optimal image size. Next, the viewing angle of the printed product is adjusted to ensure horizontal orientation, and the image is converted to gray-scale. Then, the generated gray-scale images are labeled with the corresponding defect class (tearing, sagging, buckling, and shrinkage cracking). Finally, the generated gray-scale images are augmented by mirroring, adding noise (randomizing 4% of the gray-scale pixel intensity values), adjusting brightness (± 35%), and rotating (± 20°) the images. With the save button, the output images and corresponding labels and annotation files are saved for the classification model development phase.

Figure 2. ADD preprocessor interface

3 Proof of concept

In this section, the ADD preprocessor functionality for generating datasets for clay printing is validated through a proof of concept. The proof of concept involves generating a dataset based on images collected from experimental tests conducted under laboratory conditions with a constant temperature of 20 °C and consistent lighting. The robotic system used for clay printing is a Potterbot SCARA v4 with a linear ram extruder and 3.5-liter extrusion tubes capable of printing highly plastic clays (Figure 3). Experimental tests for evaluating the extrudability and buildability of six clay mixtures are used to collect image data for defect detection. The clay mixtures are designed with clay contents varying between 20% and 30%, and various defects that might affect extrudability and buildability are expected during the printing process.

The images are captured with a camera with a maximum resolution of 6000x4000 pixels (Sony Alpha 6000) that is equipped with a lens with a focal length of 24-105 mm (Sony FE 24-105mm F4 G OSS) and fixed to a tripod. The focus and lens aperture are manually adjusted to ensure stable and clear image quality. Images are taken from various viewpoints, specifically highlighting defects observed during the printing process. From the images collected for validation, a total of 16 images are selected as input for the ADD preprocessor as proof of concept, from which 5 images display buckling defects, 3 images display sagging defects, 1 image displays tearing defects, and 7 images present no defects on the additively manufactured structures.

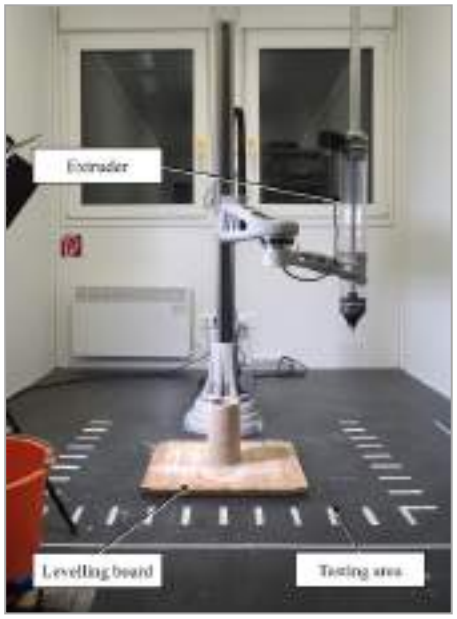

Figure 3. Robotic system for clay printing

As a result, the ADD preprocessor allows selecting areas of interest from the input images and label defects (Figure 4). The area of interests, marked exemplarily with a yellow box in Figure 4, are selected manually for cropping, focusing on the defects. Upon cropping, the defects are labeled and annotated with the corresponding defect types. As shown in Figure 4, a red bounding box annotates a sagging defect. The predefined image size of 640x640 pixels ensures adequate feature resolution to

identify defects by using the context given by the pixels in the neighborhood.

The output of the data augmentation has increased the dataset size from 16 images to 64 images, providing variability in the dataset, including various viewing angles, lighting conditions, and noise. An example of the output of data augmentation for a sagging defect is shown in Figure 5. By preprocessing the images for generating the dataset, including cropping, resizing, gray-scaling and data augmentation, the ADD preprocessor not only standardizes the dataset but also prepares it for efficient training of the CNN classification model. Owing to the data augmentation techniques employed in the ADD preprocessor, the CNN classification model can be trained to have a suitable performance under random camera angles and varying lighting conditions, while avoiding overfitting.

The dataset presents positive instances that are classifiable according to defect type (i.e. images with defects) and negative instances with no detectable defects (i.e. images without defects). By including negative instances into the dataset, the defect detection model is enabled to learn patterns to not lead to false positive predictions. Even though the proof of concept has resulted in a dataset with a relatively small size, the dataset can be enlarged by collecting more images, e.g. obtained from open-access sources and from further experimental test and printings conducted in research.

By addressing the current lack of datasets for clay printing, the ADD preprocessor enables the development of advanced defect detection models that can improve the structural quality and reliability of additively manufactured clay structures. Furthermore, the ADD preprocessor can be easily employed for concrete printing due to the synergies detected among defects in clay printing and defects in concrete printing.

4 Summary and conclusions

Automated defect detection in clay printing has been hindered due to insufficient data on defects in clay printing, driving the development and validation of the ADD preprocessor, a tool designed to generate datasets to support defect detection models in clay printing. By leveraging images and videos, the ADD preprocessor processes and labels image data to create standardized

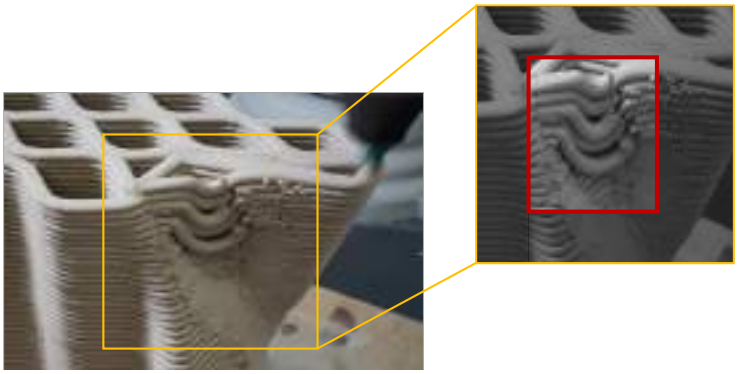

Figure 4. Identification of the area of interest (yellow box) for a “sagging” defect (red box)

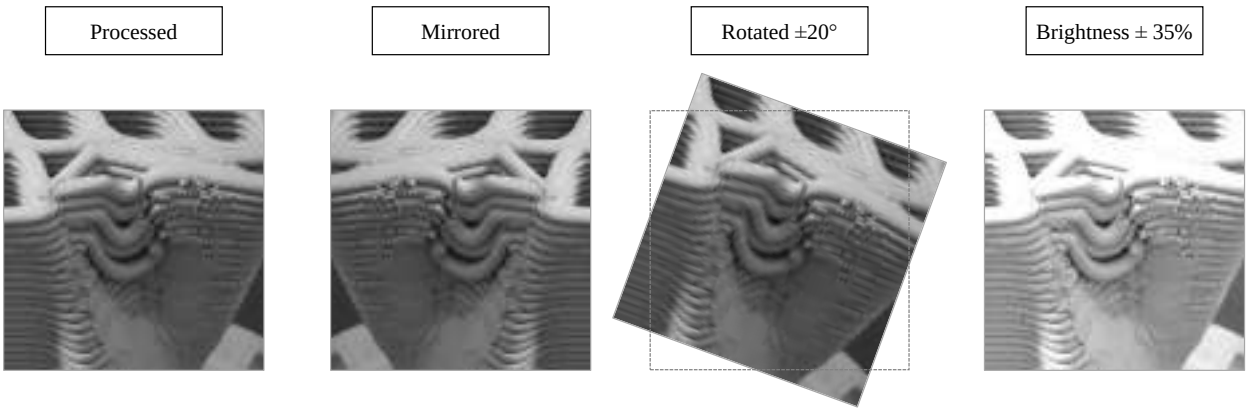

Figure 5. Outcome of the data augmentation for a “sagging” defect

datasets that meet the requirements of deep-learning-based defect detection models. The proof of concept has demonstrated the effectiveness of the ADD preprocessor in preparing positive instances that facilitate the identification and the categorization of defects (i.e., sagging, tearing, and buckling) as well as the inclusion of negative instances for more robust model training.

The ADD preprocessor possesses the ability to generate a structured dataset for defect detection in clay printing. The results showcase the potential of the ADD preprocessor to address the lack of datasets for defect detection, which has hindered the development of autonomous defect detection in clay printing. By providing a streamlined workflow for data preparation (i.e. *data preprocessing* and *data augmentation*), the ADD preprocessor supports the creation of defect detection models that are better equipped to ensure the structural integrity and quality of additively manufactured clay structures. Compared to existing labeling tools, the ADD preprocessor provides control over image standardization and data augmentation while implementing a similar labeling strategy to existing labeling tools. Yet, the manual inputs required by the ADD preprocessor, such as selecting areas of interest, could introduce subjectivity into the dataset.

To further drive the research towards automated defect detection in clay printing, future efforts could be directed towards real-time defect monitoring and towards testing the compatibility of the datasets generated by the ADD preprocessor with advanced neural network architectures, such as transformer-based models. Automated defect detection has the potential to advance the broader adoption of clay printing as a sustainable and reliable construction method.

Abstract –

Bridge inspection reports contain a wealth of crucial data on bridge components and their related structural defects. This study introduces a novel method that harnesses the power of Generative Pre-trained Transformers (GPT) for improved information extraction from bridge inspection reports. While most studies in this domain focus solely on data extraction, this study transforms inspection data into a ready-to-use format for better utilization in condition assessment and predictive modeling, enabling better-informed budget allocation and decision-making. It employs (1) a baseline GPT model (BL-GPT), which leverages OpenAI's large language models to process textual inspection data through optimized prompt engineering, and (2) a fine-tuned GPT model (FT-GPT), which enhances the baseline by incorporating domain-specific training to improve performance. These models capture and evaluate the severity levels of reinforced concrete bridge defects based on textual inspection data. The models are validated on data extracted from 2,255 inspection reports—spanning a period of five years (2018–2022)—for a set of bridges in Québec, Canada. The FT-GPT is found to significantly improve performance, stability, and reliability in detecting and standardizing the severity of different types of concrete defects in bridge decks. In specific, it achieves accuracy rates of 98.79% for rebar corrosion, 99.09% for delamination, and 98.64% for cracking, scaling, and spalling of concrete. This study demonstrates the potential integration of generative AI in asset management, an application that has yet to be realized.

1 Introduction

Bridges are a critical civil infrastructure enabling mobility, fostering social connectivity, and facilitating economic growth. However, their structural integrity is compromised by several factors, including harsh environmental conditions, freeze–thaw cycles, exposure to de-icing chemicals, deferred maintenance, increasing traffic volumes, and aging [1]. Preventive measures are essential to ensure these structures do not deteriorate to the point of compromising safety or requiring closures. Bridge deterioration is manifest in defects such as rebar corrosion, cracking, delamination, scaling, and spalling of concrete, with data on the type, location, and severity of these defects collected during bridge inspections. However, there are significant challenges concerning the effective utilization of bridge inspection data, as it is often scattered across unstructured textual formats in inspection reports [2, 3]. The extraction, structure, and characterization of this data are further complicated by the need for automated, data-driven analyses to support condition assessments, predictive modeling, and decision-making. These barriers hinder the development of reliable asset management tools, delaying preventive and corrective actions and jeopardizing bridge safety [4].

Natural Language Processing (NLP) offers a promising solution by enabling the extraction of critical information from unstructured textual data [5, 6]. Advances in Large Language Models (LLMs) and Generative Artificial Intelligence (GenAI) have further enhanced NLP's capabilities, making it increasingly effective in processing and analyzing complex technical information [7, 8]. These cutting-edge AI techniques can automate the extraction and "standardization" of bridge inspection data. In the present study, "standardization" refers to the systematic transformation of unstructured and heterogeneous bridge inspection data into a consistent, ready-to-use, machine-readable format, enabling better-

informed condition assessments, predictive modeling, and maintenance planning, ultimately improving the reliability and efficiency of bridge asset management. While numerous studies have proposed methods to extract and structure data from bridge inspection reports, e.g., [2, 9-13], a significant gap remains with respect to transforming this structured data into formats ready for direct use in condition assessment and predictive modeling.

Liu and El-Gohary [14] proposed a hybrid data fusion method combining named entity normalization and entropy-based numerical fusion to unify bridge deficiency data. Similarly, Liu and El-Gohary [15] introduced a spectral clustering-based approach to link records describing the same bridge components or deficiencies. Li et al. [10] developed a context-aware deep-learning framework using bi-directional long short-term memory and conditional random fields to extract defect-related information, although it is noteworthy that their approach requires further standardization to align the extracted data with predictive modeling requirements. Zhang et al. [13] combined rule-based methods with generation-based LLMs to structure bridge inspection data, but noted that, without standardization, the extracted information remains unsuitable for advanced analytics. The present study takes the next step by converting extracted bridge inspection data into fully standardized formats that directly support more accurate condition assessment and predictive modeling.

LLMs, which are trained on vast datasets, excel in tasks such as translation, summarization, and question-answering by capturing nuanced language patterns and long-range dependencies [16-18]. GenAI extends LLM capabilities to generate novel content across different modalities, including text, images, and videos, using generative adversarial networks and advanced transformer architectures [8, 19]. OpenAI's GPT models, including GPT-3.5 and GPT-4, among others, exemplify these capabilities. GPT-3.5, with 175 billion parameters [17], is capable of efficiently performing a wide range of tasks [20], while GPT-4, with significantly more parameters (estimated to be in the trillions), offers enhanced accuracy and versatility [8, 21]. These models have been applied across diverse domains, such as integrating ChatGPT with augmented reality for operation and maintenance guidance [7], and enabling BIM-based virtual assistants [22].

Nevertheless, the following gaps are identified: (1) *lack of standardization in inspection data*—existing studies focus on data extraction but fail to standardize it for applications such as condition assessment and predictive modeling; (2) *underutilized potential of GenAI models, such as GPTs, beyond their role as chatbots*—GenAI's capabilities in asset management remain untapped, with conventional NLP approaches struggling to handle the complexity and variability of inspection data; and (3) *need for fine-tuned domain-specific models*. In this regard, general-purpose GenAI models lack precision to interpret technical language in inspection reports, whereas fine-tuned, systematic models could significantly improve this process.

2 Objectives

This study introduces a novel method leveraging GPT to standardize inspection data for improved information extraction, enabling automated condition assessments and predictive modeling. This is achieved through the following sub-objectives: (1) developing unified guidelines for defect identification and classification to ensure consistency; (2) harnessing a baseline GPT using optimized prompt engineering for data standardization; (3) fine-tuning the baseline with a large volume of domain-specific bridge inspection data; and (4) conducting a comprehensive comparative analysis between the two models.

3 Developed Method

An overview of the method developed in the present study is depicted in Figure 1. Details of each step are provided in the following subsections.

3.1 Case Study and Data

This study focused on bridge decks and their structural elements for a set of concrete bridges in Québec that are among the oldest in Canada [23] and are managed by the Ministry of Transport and Sustainable Mobility of Québec (MTQ). The analysis was concentrated on principal deck elements (i.e., structural slab and exterior sides) [24]. Concrete defects, i.e., corrosion, cracking, delamination, scaling, and spalling, were evaluated. In this respect, two sets of data were collected: the first set consisting of inspection comments extracted from bridge inspection reports and the latter consisting of defect severity thresholds extracted from the MTQ *Structures Inspection Manual* [24].

The dataset, extracted from 2,255 inspection reports and comprising 9,430 data points, contained detailed attributes such as structure number, inspected elements, condition ratings, and inspector comments (which in turn contained detailed descriptions of the location, type, and intensity of concrete defects in different bridge deck elements). The data extraction process, illustrated in Figure 1, involved systematically retrieving and preparing the bridge inspection report data so that it could be transformed from unstructured textual data into a structured format for further analysis. The reports, typically stored across multiple sources, were automatically retrieved and prepared for data extraction. These reports then underwent automated data extraction using a rule-based approach integrating Docparser and Python via a REST API. This process involved dividing reports into manageable segments, annotating samples, creating extraction rules, and iteratively verifying and

refining the extracted data for accuracy. For further details on the data collection and extraction processes—along with examples of the unstructured inspection reports, the structure of condition data stored in these reports, and the structure of the data input/output as part of the standardization process—the interested reader may refer to the authors' previous study [12]. Data concerning defect severity thresholds (Table 1) was extracted from the aforementioned MTQ *Structures Inspection Manual* [24]. This manual categorizes severity levels from slight to severe based on standardized criteria, guiding the classification of defects. All visualizations and examples provided in this paper were translated from the original language of the collected data (i.e., French) to English.

To illustrate the developed method, the following inspection comment can be considered: "*Delamination and spalling, cracks less than 0.8 mm, moderate scaling, and rust traces and deposits*." According to Table 1, the following classifications can be made:

- *Corrosion*: rust traces are classified as severity level S_2.
- *Cracking*: cracking < 0.8 mm in width is classified as S_2.
- *Delamination*: delamination is classified as S_3.
- *Scaling*: moderate scaling is classified as S_2.
- *Spalling*: spalling is classified as S_3.

This example highlights the process of standardizing inspection comments by mapping the identified defects to their respective severity levels, ensuring systematic characterization for future utilization in condition assessment and predictive modeling, among other uses. However, applying this process to a large dataset poses significant challenges due to the variability in language styles and terminology. For example, the same given observation could be expressed differently (i.e., in different formats or phrasing) by different inspectors. As such, the models must effectively manage linguistic variability while ensuring consistent classification across the dataset.

The dataset, comprising 9,430 records, was divided as follows. A subset of 10% (947 records) was manually annotated and standardized to create the training/testing set, which was used to fine-tune the base model and evaluate model performance. This training/testing set was then further divided, with 30% (285 records) allocated to fine-tuning (focusing on refining the prompt engineering and optimizing the model's responses), and the remaining 70% (662 records) forming the testing subset for assessing the comparative performance of the models. The remaining of the dataset (90%: 8,483 records) was used as the generalization set to validate the best-performing model on a broader scale, ensuring its robustness, generalizability, and practical applicability in real-world scenarios.

3.2 Prompt Engineering

This study leveraged the power of GPT-3.5 for processing and standardizing unstructured bridge inspection data. It should be noted that this specific model was selected due to its cost-effectiveness and its having been recommended by OpenAI as the most suitable for fine-tuning, at the time of conducting the experiments in this study [25]. Prompt engineering, it should be noted, is a foundational step in guiding LLMs to produce accurate and contextually relevant responses. The design of prompts is essential when dealing with complex datasets such as bridge inspection comments. In this study, the prompt engineering process, illustrated in Figure 2(a) and Figure 2(d), integrated the following components:

- *Defect types*: defining defect categories such as corrosion, cracking, delamination, scaling, and spalling ensures that the model effectively identifies and categorizes the specific issues to be analyzed.
- *Severity levels*: standardizing defect severity levels into categories, i.e., slight, moderate, significant, and severe, enables consistent evaluation across inspection records.
- *Classification rules and thresholds*: establishing clear rules and thresholds provides a framework for consistent defect classification, ensuring the model adheres to predefined criteria.
- *Examples*: providing practical examples demonstrates how rules and thresholds are applied, enhancing the model's understanding and performance.
- *Goal definition*: specifying the purpose of the analysis (e.g., standardizing defect severity classification) makes the model's output focused on actionable insights.
- *Input and output formats*: clearly defining input and output structures ensures that the model correctly interprets raw data and generates structured, consistent outputs for downstream analysis.

These components were carefully combined to create the "*prompt base*," a foundational structure containing essential instructions and context. Inspection batch records were dynamically appended to the prompt base, creating a complete set of prompts to guide the model's analysis. This modular design, it should be noted, ensures flexibility and facilitates updates, as text files containing prompt components can be modified directly without requiring programming expertise. In this manner, the structured prompts streamline the workflow and maintain consistency.

3.3 Fine-tuning

Fine-tuning is a crucial process that customizes the LLM to enhance its performance for domain-specific tasks. In this study, the fine-tuning process was conducted using *GPT-3.5-turbo-0125*, a model optimized for such applications. The fine-tuning workflow, presented in Figure 2(b), involved the following steps:

- *Dataset preparation*: fine-tuning datasets were prepared with a training set (90%) and a validation set

(10%) to ensure effective learning and generalization; each dataset contained examples reflecting expected inputs and responses, formatted to align with the fine-tuning requirements and designed prompts.

- *Training configuration*: the model was trained (fine-tuned) using 1,399,893 tokens over three epochs, with hyperparameters such as a batch size of 1, a learning rate multiplier of 2, and a constant seed value to ensure reproducibility.
- *Performance metrics*: training and validation losses, along with training accuracy, were tracked to evaluate the model's learning and generalization capabilities.
- *Checkpoints*: intermediate checkpoints were created during training to monitor performance and prevent overfitting. These checkpoints enabled flexibility in evaluating the model at various stages of training.
- *Evaluation and iteration*: the model's outputs were evaluated against ground truth data.

Following prompt engineering and fine-tuning, the performance of both the baseline model GPT-3.5-turbo (BL-GPT) and the fine-tuned model (FT-GPT) was validated through an iterative testing process. Figure 2(c) illustrates the workflow, which involved dividing datasets into samples and batches, incorporating delays to comply with API rate limits, and analyzing performance against ground truth data. The standardized outputs were then evaluated, and the process was refined iteratively until the desired performance criteria were met.

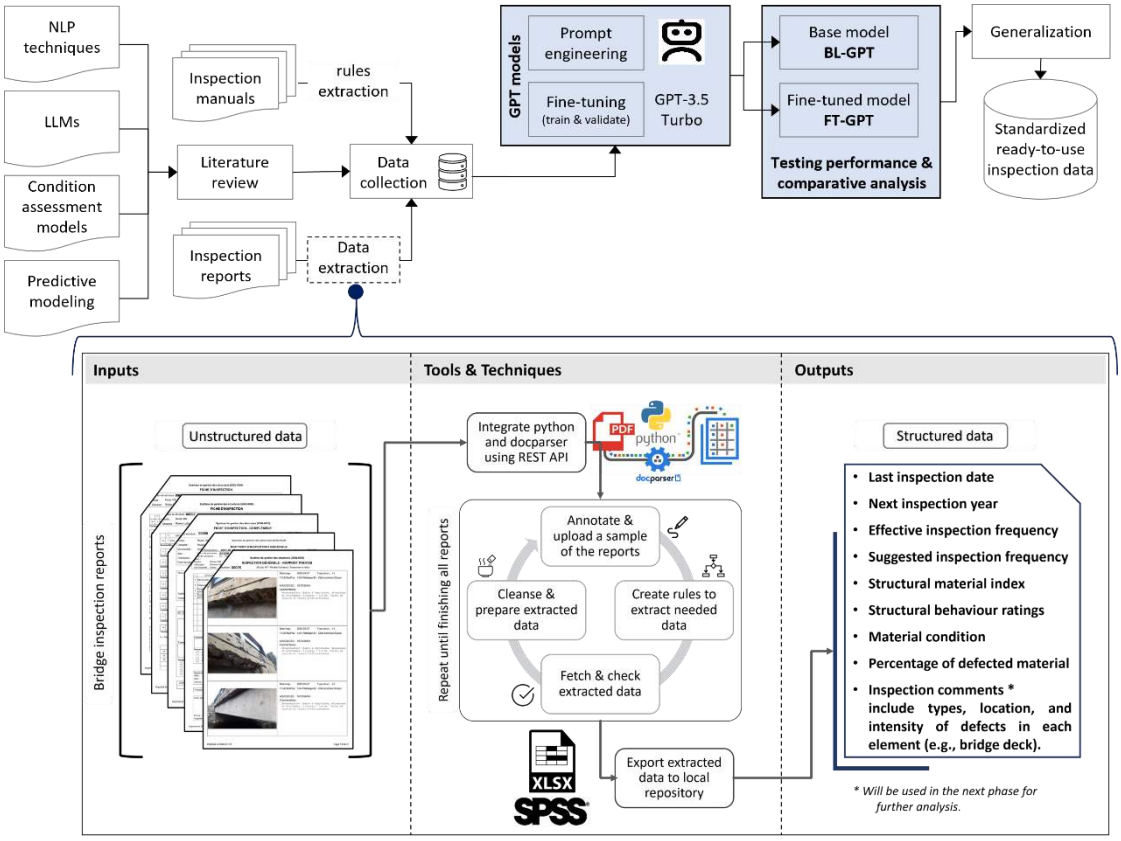

Figure 1. Overview of the developed method

Table 1. Thresholds for defect severity in bridge inspections [24]

	Severity level			
Defect	Slight (S_1)	Moderate (S_2)	Significant (S_3)	Severe (S_4)
Corrosion	Rust-free	Rusty concrete surface or reinforcement without cross-section reduction	Visible rusty reinforcement and reduced cross-section up to 30%	Very rusty reinforcement with greater than 30% reduction in cross-section
Cracking	—	< 0.8 mm	0.8–3.0 mm	> 3.0 mm
Delamination	—	—	Presence	—
Scaling	< 25 mm	25–50 mm	50–100 mm	> 100 mm
Spalling	—	—	Presence	—

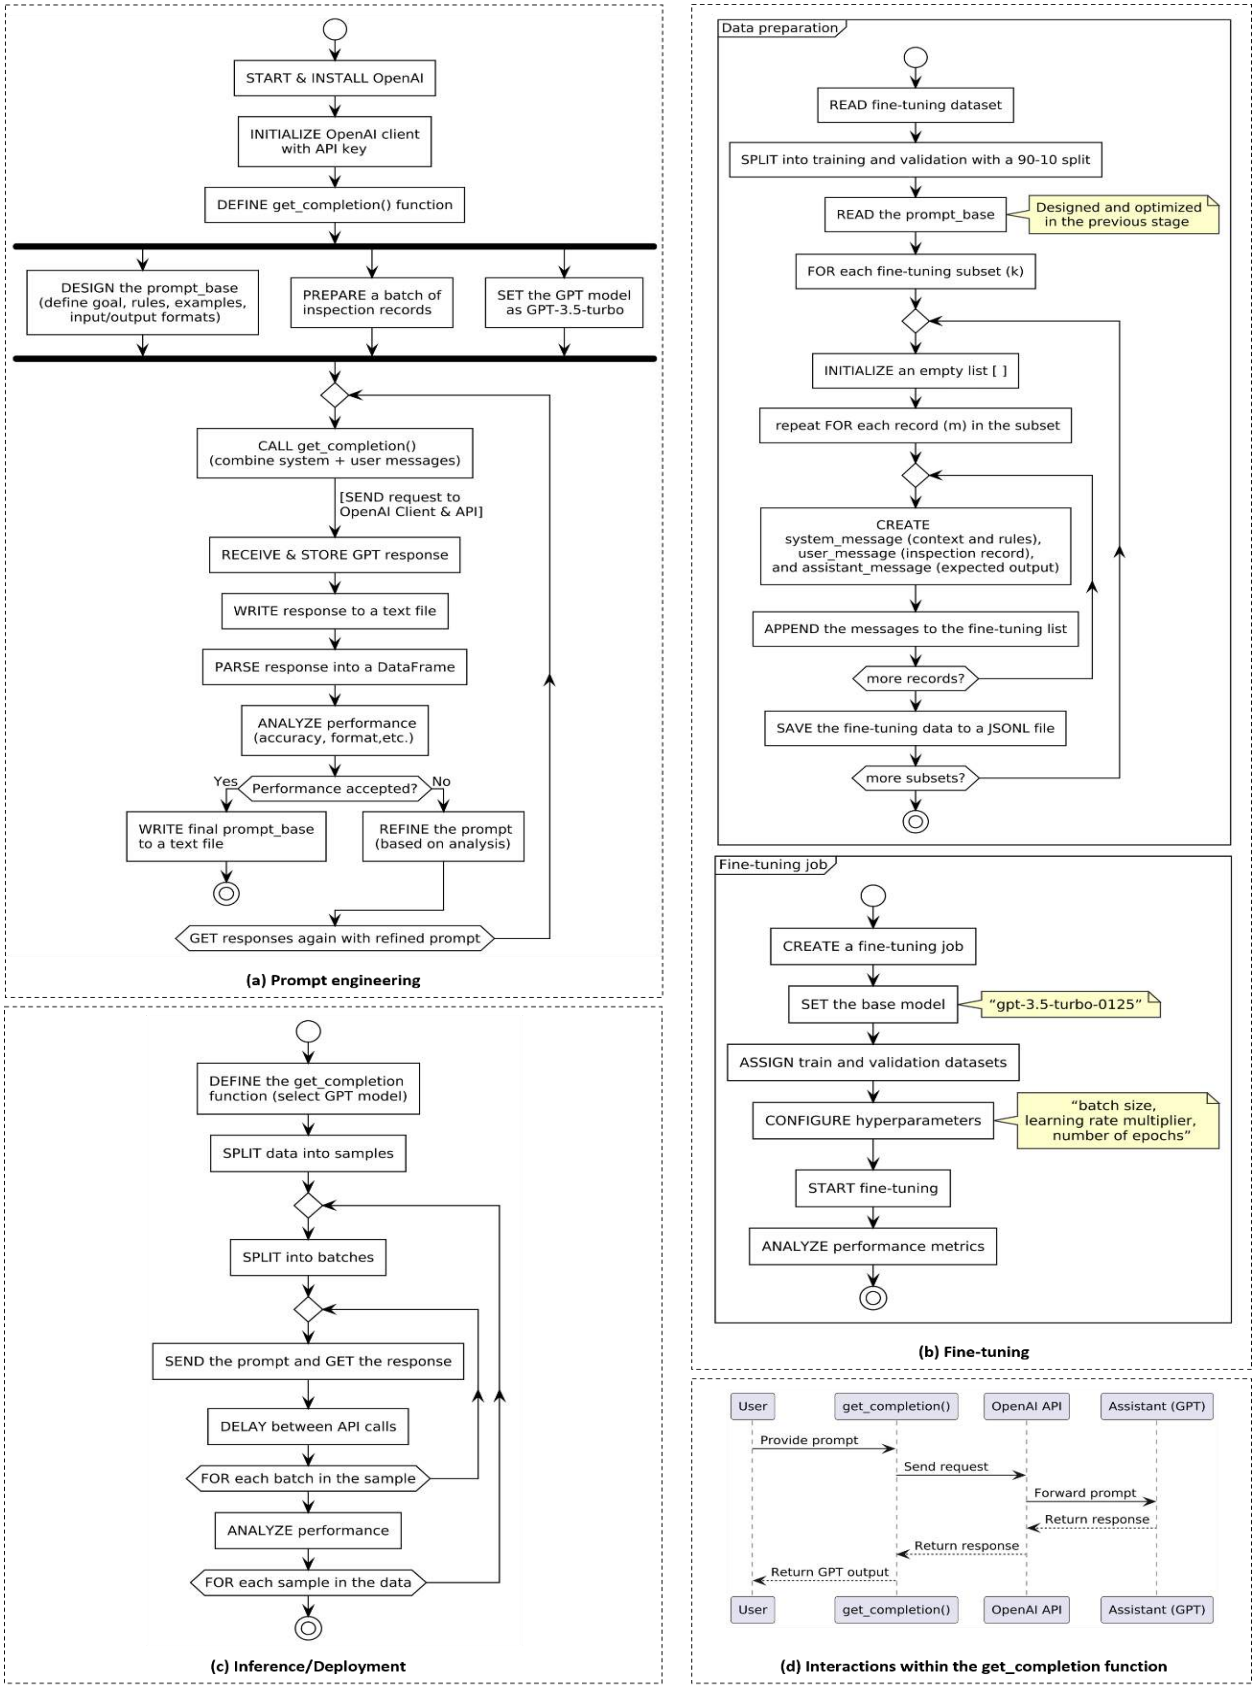

Figure 2. Workflow for GPT-based bridge data processing

4 Results and Discussion

The analysis of the 9,430 inspection records identified frequently occurring terms such as "cracking," "spalling," and "delamination." Figure 3 illustrates the structure of the input data to the BL-GPT and FT-GPT, along with the structure of the output data from the fine-tuned model. The BL-GPT and FT-GPT were tested on the 662-record test dataset, followed by a comprehensive comparative analysis of their performance in identifying and categorizing concrete bridge deck defects. The evaluation focused on accuracy, precision, recall, and F1 score across defect types, as represented by Eqs. (1) – (4), respectively, where TP, TN, FP, and FN are defined as True Positive, True Negative, False Positive, and False Negative, respectively. For the multi-class problem at hand, precision, recall, and F1 score were computed individually for each class and then aggregated using the weighted average method.

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (1)$$

$$Precision = \frac{TP}{TP + FP} \quad (2)$$

$$Recall = \frac{TP}{TP + FN} \quad (3)$$

$$F1\ score = \frac{2TP}{2TP + FP + FN} \quad (4)$$

As shown in Table 2, FT-GPT consistently outperformed BL-GPT in the detection and classification of all defect types, achieving exceptional performance and reliability. BL-GPT exhibited particularly poor performance in detecting and characterizing spalling, achieving only 61.63% accuracy and a 54.50% F1 score, substantially lower than FT-GPT's 98.64% in both metrics. The lower performance metrics of the base model is attributable to several factors:

- *Complexity of inspection comments*: Inspection comments often include multiple defect descriptions and measurements, introducing complexity and ambiguity that result in misinterpretation of context.
- *Insufficient training data and generalized knowledge*: The base model lacks exposure to a diverse and specialized dataset, limiting its ability to generalize effectively to complex inspection comments. Although it is pre-trained on extensive general-purpose data, its generalized knowledge is insufficient for the technical and domain-specific language used in bridge inspection reports. As such, without fine-tuning on domain-specific data, the model is unable to fully adapt to the terminology, phrasing, and contextual nuances unique to bridge inspection comments, resulting in less accurate and consistent standardization.
- *Stochastic nature*: Operating probabilistically with billions of parameters, the base model may produce varying outputs even with the same input, leading to inconsistencies in defect classification and severity assessment.
- *Language mismatch and translation nuances*: The process of translating between languages—in this study, the original data was in French, while the prompts and interactions with the model were designed in English—can result in the loss of subtle meanings and technical nuances.

The results of this study demonstrate that fine-tuning is as an efficient solution to overcome the limitations outlined above. By adapting the model to domain-specific data, fine-tuning enhances its ability to accurately interpret terminology, phrasing, and contextual details unique to bridge inspections. This process mitigates issues related to contextual misinterpretation, complexity, and insufficient domain knowledge. Furthermore, fine-tuning improves output reliability and stability, ensuring accurate defect classification and severity assessment. It also strengthens the model's capacity to handle multilingual inputs, maintaining the integrity of technical terms during translation and standardization. The fine-tuned model offers several advantages over conventional NLP techniques, particularly in handling complex and unstructured textual data. It reduces the need for extensive programming and manual feature crafting, allowing engineers to interact with the model and scale it to their specific tasks using their linguistic patterns. Through the use of a well-designed prompt, the model eliminates the need for complex coding expertise, making it accessible and adaptable to various practical applications.

The best-performing model, FT-GPT, was applied to the generalization dataset, which comprised 8,483 records (i.e., 90% of the overall dataset). This step involved evaluating the model's robustness, generalization capabilities, and practical applicability. The dataset was enriched (i.e., through generalization) to include standardized inspection narratives, the severities of different types of reinforced concrete bridge deck defects presented in a consistent, standardized format, and associated condition ratings for each element in these bridge decks. This data asset can be utilized in future studies on the asset management of bridges. As a proof of concept, the data has already been used in developing data-driven condition assessment models to evaluate the condition of bridge deck elements and overall deck condition based on the identified defect severities. (For further details, the interested reader may refer to the authors' previous work [12].)

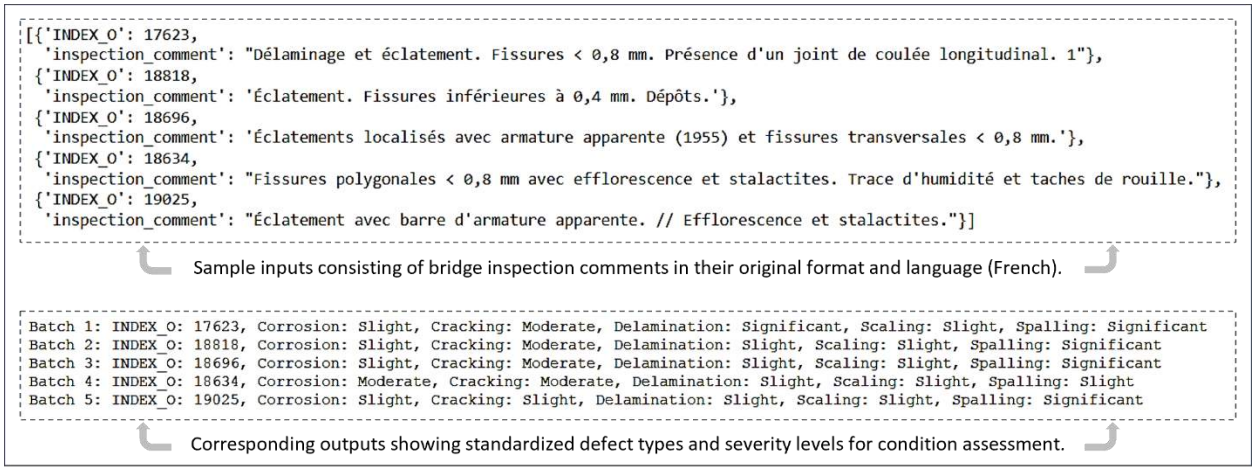

Figure 3. Structure of inputs and outputs of the fine-tuned model

Table 2. Performance comparison of BL-GPT and FT-GPT models in detecting and standardizing concrete defects

	Model	BL-GPT				FT-GPT			
	Performance	Accuracy	Precision	Recall	F1 score	Accuracy	Precision	Recall	F1 score
Defect	Corrosion	88.22%	88.43%	88.22%	87.44%	98.79%	98.99%	98.79%	98.84%
	Cracking	92.90%	94.15%	92.90%	93.35%	98.64%	98.68%	98.64%	98.58%
	Delamination	96.37%	97.41%	96.37%	96.88%	99.09%	99.10%	99.09%	99.09%
	Scaling	91.24%	88.53%	91.24%	88.37%	98.64%	98.78%	98.64%	98.64%
	Spalling	61.63%	78.09%	61.63%	54.50%	98.64%	98.64%	98.64%	98.64%

As of May, 2024, i.e., at the time of conducting the experiments for this study, the implementation cost and processing time for analyzing 100 batches of inspection comments were evaluated. The BL-GPT model incurred a total cost of ~$0.09, processing ~167,238 tokens, consisting of ~161,560 input tokens and ~5,678 output tokens, with an average processing time of approximately 7 min. In contrast, the fine-tuned GPT model had a higher total cost of ~$0.52, with ~3,449 output tokens and a slightly reduced processing time of approximately 6.5 min. This highlights that the fine-tuned model generates more concise responses while incurring a lower processing time. The fine-tuning process itself (with the number of tokens and parameters discussed in Section 3.3) incurred a total cost of ~$11.19.

5 Summary and Concluding Remarks

This study represents a significant step toward leveraging GenAI models for asset management and enhancing the utilization of bridge inspection data. The process focuses on detecting and categorizing defects in reinforced concrete bridge decks—including corrosion, cracking, delamination, scaling, and spalling—into defined severity levels. LLM-based GPT-3.5 was harnessed as a baseline model. This model was fine-tuned with domain-specific data to enhance its ability to process complex technical information from bridge inspection reports. A robust prompt engineering process was developed to effectively capture and standardize defect severity levels. The fine-tuned model demonstrated superior performance and was found to be reliable in standardizing inspection comments. The contributions of this study include (1) introducing a GPT-based method for improved information extraction from and standardizing bridge inspection data to support data-driven decision-making; (2) demonstrating the effective use of GenAI in infrastructure management; (3) fine-tuning LLMs to improve performance, stability, and reliability; (4) employing robust prompt engineering in asset management; and (5) providing a standardized dataset for utilization in future work. While this study focused on defects in concrete bridge decks, the methods are extendable to other infrastructure systems, paving the way for improved infrastructure management more broadly. It should be noted that further investigations are needed to evaluate the implementation costs associated with these models. Future research should also explore the performance of newer models, such as GPT-4o and o1, as well as open-source alternatives, such as Llama and Gemini.

Practical Considerations and Case Study for Implementing Autonomous UAV Video Collection of Construction Activities

Yusheng Huang[1], Amin Hammad[1]*

[1]Concordia University, Canada
yusheng.huang@mail.concordia.ca; amin.hammad@concordia.ca (*corresponding author)

Abstract –

Various methods have been proposed in recent years to extract valuable insights from images and videos of construction activities to improve project management. Previous studies have proposed automated video collection using camera-equipped multirotor unmanned aerial vehicles (CE-MUAVs) to enable the collection of construction videos with the ability to fit the camera's field of view (FOV) automatically to the specific areas where the activities are happening. However, multiple practical considerations should be addressed before implementing autonomous UAV video collection of construction activities to fulfill the technical, safety, and data quality requirements, while respecting the legal regulations. This paper aims to identify these considerations and to develop a workflow for implementing an effective video collection of construction activities using autonomous CE-MUAVs. A test on an actual construction site is conducted to validate the applicability of the workflow.

Keywords –
Construction activity; Video Collection; Path planning; 4D Simulation; UAV.

1 Introduction

With the emergence of advanced computer vision (CV) techniques, it is possible to automatically extract rich semantics and high-level knowledge from digital images and videos, enabling more comprehensive and efficient analysis for different construction management applications [1], including activity monitoring [2], progress monitoring [3, 4], and health and safety monitoring [5–7]. However, the complexity and high costs associated with video collection have significantly constrained the widespread adoption of these methods. Collecting high-quality videos of specific areas of interest on construction sites, where activities happen, according to the project schedule remains challenging with conventional approaches, such as stationary cameras, handheld devices, equipment-mounted cameras, and wearable systems [1].

Over the past decade, considerable attention has been paid to automated video collection using camera-equipped multirotor unmanned aerial vehicles (CE-MUAV), which provides mobility to the camera to fit its field of view (FOV) automatically to the important parts of the construction site while ensuring high efficiency and reasonable cost [8–10]. Previous studies have proposed generating collision-free UAV paths based on a BIM model to support visual inspection tasks of buildings [11, 12]. Other studies proposed methods for sampling the viewpoints to achieve full visual coverage of the structure considering the sensor (i.e., camera or laser scanner) specifications, such as FOV, focal length, and sensor size [13, 14]. Then, routing algorithms are applied to generate the optimal path through the sampled viewpoints. In addition, Ibrahim et al. [15] proposed a method of UAV path planning for progress monitoring during the construction phase considering the schedule using waypoints. However, current implementations of CE-MUAVs primarily focus on scanning static objects in outdoor and indoor environments for purposes like 3D reconstruction and inspection. On the other hand, limited research is available about collecting videos of construction activities using autonomous UAVs.

To address this research gap, the authors previously proposed a method to perform simulation-based optimization of path planning for CE-MUAVs considering multiple construction activities according to the as-planned micro-schedule [16]. This method identifies the top-ranking viewpoints (VPs) to collect high-quality videos about the construction activities in the micro-schedule with good coverage of the workspace while minimizing the distance to the workspace. In addition, the method generates optimized paths that minimize the travel duration between the top-ranking VPs while avoiding collisions. While effective in a virtual environment, this approach has yet to be tested in real-world scenarios. However, multiple practical considerations should be addressed before implementing autonomous UAV video collection of construction activities to fulfill the technical, safety, and data quality requirements, while respecting the legal regulations. This paper aims to identify these considerations and to develop a workflow for implementing an effective video collection of construction activities using autonomous

CE-MUAVs. A test on an actual construction site is conducted to validate the applicability of the workflow.

2 Simulation-Based Optimization of Path Planning for CE-MUAV

Figure 1 shows the method of simulation-based optimization of path planning for CE-MUAVs proposed in the previous work of the authors [16]. This method identifies the top-ranking viewpoints (VPs) to collect high-quality videos of construction activities based on the micro-schedule with good coverage of the workspaces, while minimizing the distance to these workspaces. In addition, the method generates an optimized path that enables the UAV to collect videos based on the identified VPs while minimizing travel time and avoiding collisions. It has been demonstrated that aerial videos captured while the UAV is hovering offer distinct advantages, as they enable the capture of finer scene details and intricacies [17]. It is assumed that the CE-MUAV will collect videos during traveling and hovering states. However, the focus is on spending more time to collect videos while hovering. There are three main modules in the simulation-based path planning: (1) Preparation of the simulation environment; (2) VPs optimization; and (3) Path planning for the UAV to minimize the travel duration.

In the *simulation environment preparation module*, the workspaces for a certain period are identified from the as-planned 4D simulation of the project. Then, the solution variables of the UAV are identified according to the selected model of the UAV. The search spaces for different workspaces are then defined considering the safety risks in the construction site, the CV requirements (e.g., range of camera, tilt angle), and the compliance with legal regulations, which will be further explained in Section 3. At last, cubic cells are generated within the workspaces for calculating the camera coverage.

In the *VPs optimization module*, the top-ranking VPs for each workspace, where the FOV of the hovering camera can provide good coverage while minimizing the distance, are identified by integrating a multi-objective genetic algorithm (MOGA) with simulation. Two objective functions are defined: maximizing coverage and minimizing the camera-to-workspace distance. For each workspace, multiple top-ranking VPs will be identified. With these VPs, the *path optimization module* solves the generalized traveling salesman problem (GTSP) to optimize the cycle path with the least travel duration to collect videos from one of the top-ranking VPs for each workspace. It is worth noting that in this paper, the Theta* algorithm is utilized to generate a more efficient collision-free path to travel between the VPs compared with the A* algorithm used in our previous paper [16]. This optimized cycle path consists of multiple waypoints, each specifying the location and pan angle of the UAV and the tilt angle of the camera. At last, the hovering duration at each VP of the optimized cycle path is defined according to the importance level of the task in different workspaces.

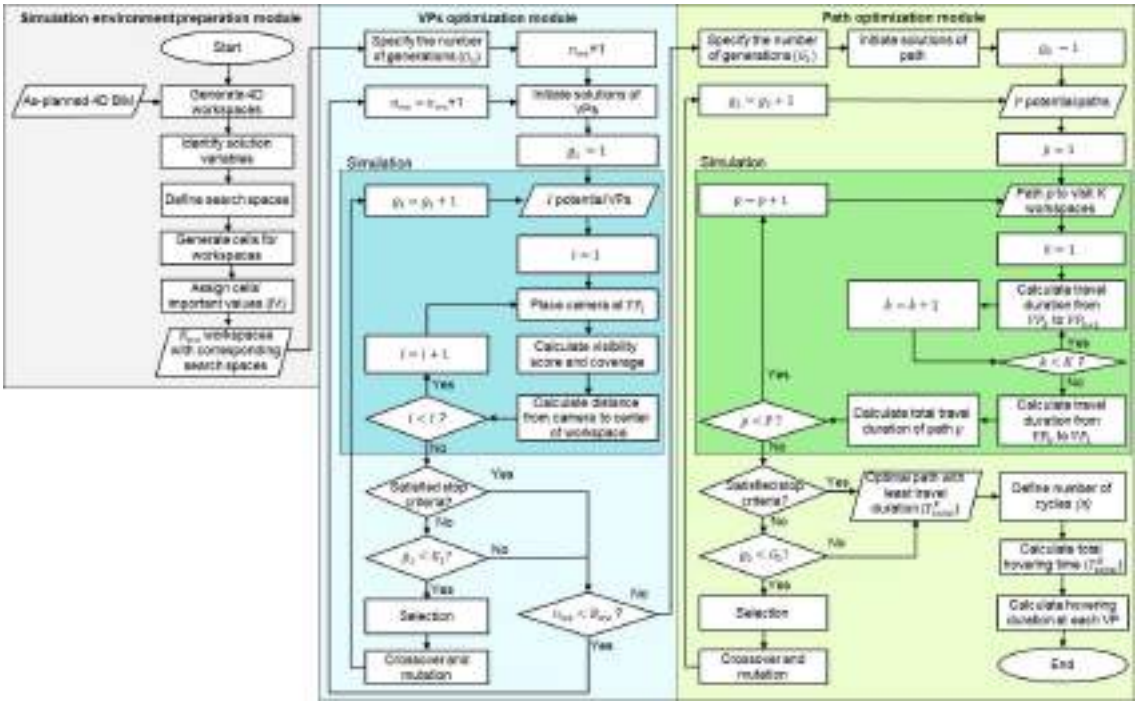

Figure 1. Simulation-Based Optimization of Path Planning for CE-MUAV

3 Practical Considerations for Implementation

Multiple practical considerations must be addressed before implementing autonomous UAV video collection of outdoor construction activities in actual projects using the optimized path generated by the proposed method in Section 2.

3.1 Technical requirements

To ensure effective implementation, several technical requirements must be addressed. Here, the technical requirements can be considered in two aspects, the hardware requirements and software requirements. The hardware requirements mainly refer to the requirements in selecting an appropriate UAV that is capable of performing the task. First, the UAV should support pre-planned flight operations and offer an application programming interface (API) to enable importing the optimized flight path from the simulation console. The UAV should also have a reliable antenna for Global Navigation Satellite System (GNSS) or alternative systems to maintain accurate flight paths. The operational range and battery life must be sufficient to complete the video collection tasks. In addition, the UAV should be equipped with a camera capable of collecting high-quality video to meet the data requirements for CV, which are explained in Section 3.4. Moreover, sufficient onboard storage for videos is essential. Automated data transmission using 5G communication to a remote console or database is highly preferable, as it enhances efficiency by eliminating manual data retrieval.

On the other hand, appropriate software tools should be selected. For example, to develop a detailed construction 4D simulation model, Naviswork [18] was used in the author's previous work [16]. This model was then imported into Unity 3D game engine [19], which has a realistic physics engine for simulating the UAV operations. In addition, converting waypoints from simulation coordinates into UAV-readable data is necessary. The implementation process involves three coordinate systems: (a) coordinate system of the construction 4D simulation, (b) coordinate system of the simulation for path planning, and (c) coordinate system for UAV navigation. Typically, models are developed in a local coordinate system specific to the software tools [20]. To incorporate the geospatial context of the coordinate system of (a) and (b), a geographic information system (GIS) can be used to show the positions in a projected coordinate system (PCS) [21]. However, UAV navigation uses a geographic coordinate system (GCS). For example, DJI UAV navigation [22] uses a geodetic coordinate system. Therefore, to navigate the UAV, it is necessary to have a tool to translate the coordinates of the waypoints of the optimized path from the PCS to GCS.

3.2 Safety requirements

The integration of UAVs in construction may encounter several safety risks [23–25], highlighting the need for careful operation planning and UAV selection to ensure safe and effective operations. The major risk is collisions with workers or objects on construction sites. During the planning phase, risk assessment should be performed to identify all potential collision risks based on the site layout. In the *simulation environment preparation module*, safety buffers should be assigned to workspaces and high-risk areas. In addition, selecting UAV models equipped with active collision avoidance can further mitigate these risks [29]. UAVs may also encounter motor malfunctions or communication loss, necessitating a detailed emergency contingency plan to address such scenarios before deployment. Moreover, the selection of a UAV model should consider risk mitigation features, such as pre-flight fault detection, automatic return-to-home functionality in case of loss of connection, and a reliable and secure communication system to prevent unauthorized access or interference to the UAV. Furthermore, UAVs may pose safety risks to workers on-site due to distractions [24]. Selecting light-weight UAV models that generate less noise can help reduce this issue.

3.3 Compliance with legal regulations

UAV deployment must comply with the legal requirements. The UAV should be properly registered in accordance with local laws and regulations. The operators must undergo training and obtain the necessary licenses or certifications before conducting operations. If the operation takes place in controlled airspace, the necessary certificates and permits must be obtained as required by regulations. In addition, detailed documentation of the operational risk assessment, precautions for risk mitigation, and an emergency contingency plan may be required by the responsible department (e.g., Transport Canada) when applying for special flight operations [26].

In *simulation environment preparation module*, zones where the project team does not have permission to operate the UAV, such as areas near surrounding buildings, should be clearly defined to prevent unauthorized intrusion. The compliance of such regulations should be verified through virtual verification after generating the optimized path and confirmed again during on-site verification before deployment.

Moreover, the selection of UAV model should take into account the ease of obtaining operational permissions. For instance, basic operations that do not require a special flight operations certificate apply to UAVs weighing less than 25 kg in Canada [27]. It is

worth noting that exceptions may apply to micro-UAVs weighing under 250 g in some countries [26], which may reduce the complex process of obtaining permission to fly. Operating a micro-UAV does not require a pilot license or certificate if the operator ensures safe operations with good practices and compliance with all applicable requirements and regulations.

Furthermore, during the operation, the UAV use must respect the privacy of workers and other individuals captured in the video. The project team should obtain consent from workers before deployment. In addition, the team is responsible for developing secure data communication and storage methods to protect the privacy of the collected data.

3.4 CV requirements

The video collection process must meet specific CV requirements to ensure the captured frames are suitable. A proper tilt angle should be maintained to clearly show the pose of workers and equipment. In addition, CV methods (either object detection or activity recognition) are usually susceptible to aerial imagery with the small size of objects and variable tilt angle of view [17, 28, 29]. Therefore, the distance from the camera to the objects should be less than a certain maximum value to avoid the low resolution of objects in the frame while maintaining the coverage of the designated workspace. This CV requirement is fulfilled through the *VPs optimization module*, as explained in Section 2. In addition, a stable FOV with minor vibration and motion blur improves the quality of CV results. It has been suggested that aerial videos captured while the UAV is hovering offer distinct advantages, as they enable the capture of finer scene details and intricacies [17]. Moreover, hovering time should be sufficient for gathering essential data from the optimal VPs.

Table 1 lists the considerations of the requirements in different processes during the implementation. It should be mentioned that these requirements are often interconnected.

4 Implementation Workflow

The proposed method for implementing optimized video collection of construction activities using CE-MUAVs based on optimized path planning is shown in Figure 2. The implementation can be divided into three phases under three different coordinate systems as mentioned in Section 3.1. In the model preparation phase, a high LOD as-planned 4D simulation is developed. Then, the as-planned 4D model is integrated with the GIS data to show the geospatial context of the project. By reviewing the 4D simulation, risk assessment is performed and requirements are identified according to the key considerations as mentioned in Section 3. Based on these requirements, the type of UAV is selected. Then, the 4D simulation model is transferred to the simulation platform for UAV path planning.

Table 1. Practical considerations during implementation

Implementation step	Technical requirements	Safety requirements	Legal regulations compliance	CV requirements
UAV model selection	-UAV and sensor specifications -Pre-planned flight function -Reliable antenna and navigation system	- Robust accident prevention functionalities - Malfunctions handling - Light-weight UAV to avoid distractions - Secure communication method	- Weight of the UAV	- UAV performance to avoid vibrations and motion blur - Camera specifications
Simulation modelling and path optimization	-Simulation tool -Tool to translate coordinates of waypoints -Operational range and battery life	-Safety buffer to avoid collision risks	-Unauthorized flight zones	-Defining reasonable search space
Pre-flight planning		-Risk assessment -Contingency plan -Precautionary measures	-Operation certificate and flight permit -Privacy protection	

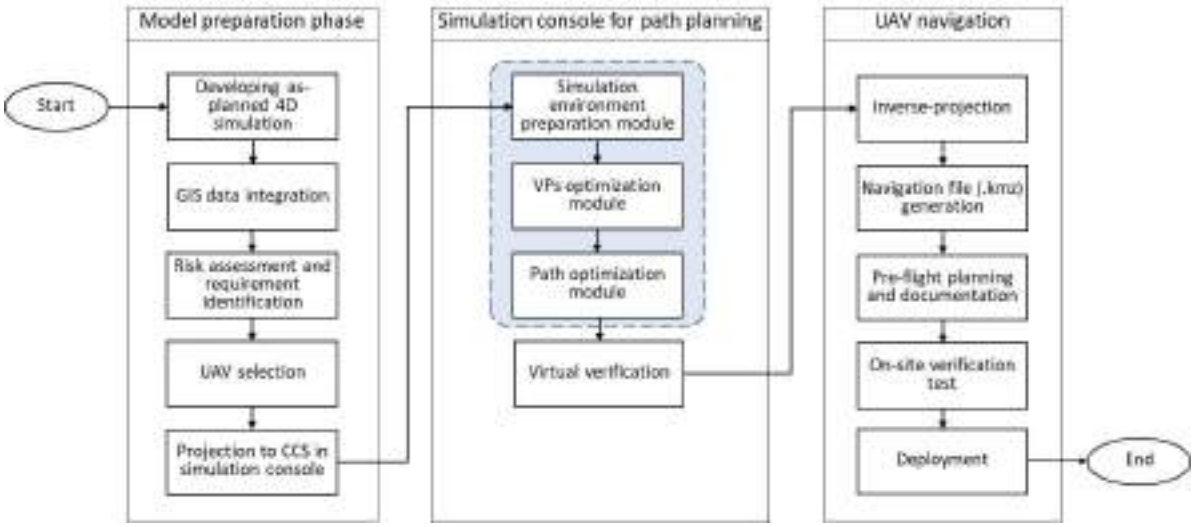

Figure 2. Implementation workflow of Autonomous UAV Video collection based on optimized path planning

Simulation-based path planning of CE-MUAVs is performed to find the optimized path for automated and effective data collection of construction activities using 4D as-planned simulation as explained in Section 2. In the *simulation environment preparation module*, the search spaces, safety buffer, and unauthorized flight zones should be defined considering the safety requirements, compliance with legal regulations, and the CV requirements as mentioned in Section 3. At the end of this phase, virtual verification is conducted to verify the efficiency and effectiveness of video collection along the optimized path. This is achieved by running a simulation in which the virtual UAV follows the same path within the virtual environment. The verification process involves reviewing the UAV's trajectory to eliminate the safety risks and analyzing the camera's FOV during hovering to ensure comprehensive coverage of the workspace.

To navigate the UAV, the waypoints of the optimized path in the simulation system are inverse-projected from PCS to the GCS as mentioned in Section 3.1. Using the waypoints in the GCS, a navigation file for the UAV is generated. One commonly used format for the navigation file is the .kmz format. Before deploying the UAV with the navigation file, pre-flight planning is carried out to outline precautionary measures and emergency contingency procedures. Once these plans are documented, an on-site verification test is conducted to ensure the UAV follows the optimized path and hovers VPs to collect videos of the expected workspaces of tasks. The on-site test should also verify that the operation is free of safety risks. In addition, it should ensure compliance with legal regulations during the deployment (e.g., preventing the collection of videos that infringe on workers' privacy). To minimize disruptions, this test should be conducted during off-peak hours, with the UAV moving slowly to allow immediate stops if any risks arise. Once verification is complete, the operation plan with the optimized path will be deployed to collect videos.

5 Case study

A field test was conducted on a construction site to validate the applicability and effectiveness of the proposed workflow. The test focused on activities carried out during a short period of a park construction project, which includes an outdoor skating rink and a pavilion. Figure 3 shows the workflow implementation in this case study.

As shown in the bird-view of the GIS integrated site layout (Figure 3(a)), the construction site is divided into two parts by a road. The left part is the main construction area, where two tasks were underway: the workspace for pouring concrete for the pavilion (WS3) and excavating and leveling the area designated for the skating rink (WS2). The right part contains a loading area used for storing the excavated soil (WS1). As shown in Figure 3(a), this construction site is surrounded by three buildings, each with a height of more than 25 meters, resulting in potential collision risks. Therefore, safety buffers are assigned to these buildings. Additionally, a safety buffer was maintained along the road, creating a danger zone with a height of 10 meters.

5.1 CE-MUAV selection and variable identification

The UAV used in this case study is the DJI Mini 4

Pro [30], which features a maximum speed of 12 m/s and a maximum ascent/descent speed of 5 m/s in "Normal Mode". Weighing 249 g with its standard battery, this UAV simplifies regulatory compliance in most North American jurisdictions as mentioned in Section 3.3, making it ideal for construction projects. Its compact and lightweight design minimizes safety risks while maintaining excellent maneuverability. Furthermore, its omnidirectional obstacle sensing system significantly reduces the risk of collisions, enhancing operational safety. The maximum flight time is 30 minutes with the standard battery.

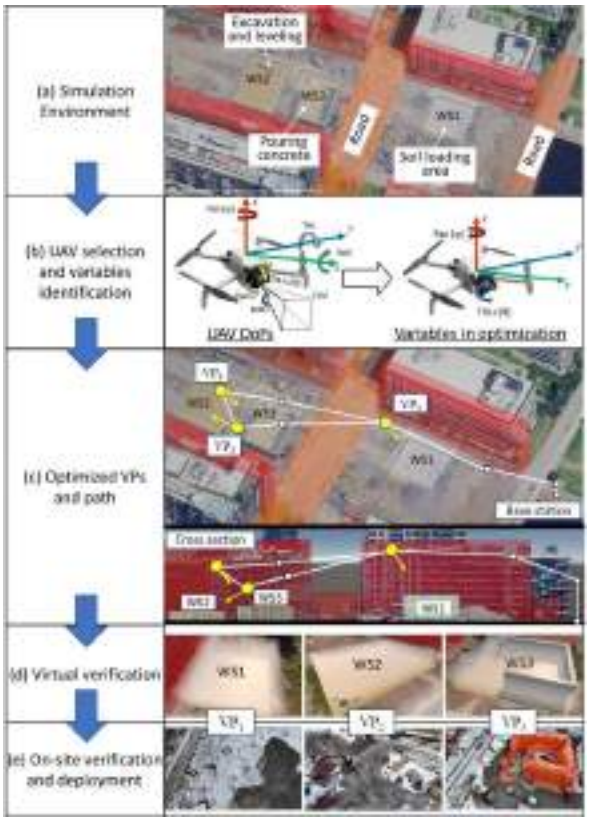

Figure 3. Workflow implementation in the case study

The UAV supports pre-planned flight operations under GNSS and provides an API [22] for importing mission files from a computer. Its camera captures 4K videos in MP4 format at up to 100 fps and offers a diagonal field of view (FOV) of 82.1° and a horizontal FOV of 74.3°, ensuring high-quality video collection for construction monitoring.

The variables for the viewpoint (VP) optimization module are defined based on this UAV model. As illustrated in Figure 3(b), the UAV provides ten degrees of freedom (DoFs). Six of these are associated with the UAV's pose (x, y, z, pan, tilt, and roll), while the camera, mounted on a 3-axis mechanical gimbal, introduces four additional DoFs (pan-c, tilt-c, roll-c, and FOV). However, the API does not allow the control of the tilt and roll angles of the UAV, as well as the pan and roll angles of the camera. In addition, the camera's FOV is fixed at its default value. Thus, the variables considered in the optimization process are the UAV's position (x, y, z), its pan angle (φ), and the tilt angle of the camera (θ).

5.2 Prototype development

A prototype system was developed using Unity3D game engine [19] to create a simulation platform for VPs optimization and path planning. As mentioned in Section 3.1, a method for translating the waypoints of the optimized path in the local coordinate of the path simulation platform to the UAV-readable waypoints under GCS is required. The 3D geospatial platform add-in for Unity named Cesium [31] is used for this purpose. The prototype system is run on a computer with i7-6800k CPU, 64 GB of random access memory (RAM), and two GTX 1070 GPUs.

5.3 Results

The results from the simulation-based path planning platform are multiple top-ranking VPs identified for each workspace. Using these top-ranking VPs, the path optimization module generates an optimized flight path as shown in Figure 3(c). The time required to travel between different waypoints is calculated. In this case study, the expected number of cycles per operation is 30, and the operation safety factor α for calculating the total operation time is set to 0.9. The traveling time between VPs (T^F_{total}), the total hovering time(T^H_{total}), and the total duration (T_{CP}) of one cycle path are calculated as shown in Table 2, using the method outlined in [16].

Table 2 Path durations with 30 expected cycles

Operation	Duration (s)
Base station → VP_1	9.55
Total cycle path (T_{CP})	53.36
- Total flight time (T^F_{total})	13.22
- VP_1→ VP_2	5.64
- VP_2→ VP_3	1.70
- VP_3→ VP_1	5.88
- Total hovering time (T^H_{total})	40.14
- Hovering at VP_1	10.04
- Hovering at VP_2	10.03
- Hovering at VP_3	20.07
VP_1→ Base station	9.55

Due to the higher level of interest associated with the task of pouring concrete, a higher importance level weight (W_{WP}) of 2 is assigned, while a weight of 1 is given to other workspaces. The distributions of the hovering durations for each VP are calculated as shown

in Table 2. Virtual verification is performed as shown in Figure 3(c) to assess the efficiency and effectiveness of video collection along the optimized path. Figure 3(d) illustrates the simulated camera views when hovering at three VPs along the optimized path.

Finally, an on-site test was conducted to validate the optimized path, as shown in Figure 3(e). The results demonstrate that the UAV successfully navigated to the designated hovering waypoints and adjusted its FOV to the intended angles, capturing videos of the areas of interest where construction activities were happening according to the schedule.

6 Conclusions and Future Work

This paper highlights the key practical considerations for implementing autonomous UAV-based video collection of outdoor construction activities. It also proposes a workflow for achieving optimized and efficient video collection using autonomous UAVs. A case study on a construction site is conducted for validation. The results of the case study demonstrate that the workflow is effective in generating an operational plan with optimized waypoints, enabling the UAV to capture videos of construction activities from areas where the main tasks are taking place.

Despite its effectiveness, several areas of the proposed workflow require further refinement. The proposed workflow focuses on collecting videos of progress-related construction activities within predefined workspaces according to the as-planned schedule. However, the location of the workspaces may change, but these changes are not reflected in the schedule. In addition, other construction activities may occur outside the predefined workspaces. Future studies will develop methods for dynamically adjusting the UAV path during the operation whenever workspace locations change or new workspaces are identified. In addition, the case study presented in this research is based on a medium-scale construction site. Given the diverse and complex nature of construction sites, further testing is needed across various scenarios to evaluate the workflow's robustness, such as indoor environments.

Abstract -

The automation of tasks in construction industries is a solution for countries experiencing a labour shortage in those industries. The task of drywall finishing in an off-site construction environment is particularly interesting for automatization because of the large amount of labour, the strain on the worker's body, the falling risk and the large quantity of dust particles. This article explores assisting workers with drywall finishing using an arm-mounted orbital sander with a collaborative robot arm placed on a mobile platform, combined with a drywall joint compound machine vision detection algorithm. Preliminary results suggest the robot can finish the same depth of material as a human worker, which is typically less than 0.19 mm.

Keywords -

Drywall Finishing; Machine Vision; Construction Robot; Collaborative robot

1 Introduction

Gypsum board, also known as gypsum drywall or plaster board, offers a cost-effective and popular [1] option to build the interior wall of modern-day construction in Canada. Unfortunately, while gypsum boards are easy to install, the seams and screws need to be covered by multiple layers of compound, also known as mud or plaster, to form a uniformly flat surface ready for paint. While drying, this compound shrinks and leave an uneven surface full of bumps and cracks. To finish the drywall, those defects need to be sanded down before applying paint. The general surface is also sanded down to make seams between boards less visible and more aesthetically pleasing.

Unfortunately, drywall finishing is quite laborious and inconvenient for workers [2]. To finish the compound, workers use power tools to remove most of the uneven cracks and bumps. Subsequently, workers use handheld tools like sanding blocks to smooth out the finer details. Sanding the compound produces a lot of irritable dust particles [2], especially when using power tools. To reach elevated walls, workers work with their arms over the shoulders for long hours, which can lead to pain and injuries [3].

Assisting workers with this task represents an opportunity for automation. Fortunately, off-site construction offers a stable environment for automatization and contributes to the reproducibility of the presented results. This paper presents the design of a sanding mobile robot capable of performing the power-assisted part of the drywall finishing task. Our key contributions are : 1) The integration of a 7-DOF collaborative manipulator arm-mounted orbital sander with an autonomous mobile platform; 2) An automatic computer vision pipeline capable of detecting and localizing sections of drywall to sand; and 3) A control scheme to perform the first pass of compound sanding on vertical walls.

This paper is structured as follows. Section 1 presents an overview of the requirements and chosen hardware for the robot. Section 2 presents the machine vision algorithm used to localize the compound joint. Section 3 presents the control strategies used to finish the drywall. Section 4 presents our measurement methodology and discusses the results.

2 Sanding robot hardware

The robot hardware has been designed in accordance with our partners' requirements, which can be summarized as follows: 1) The ability to navigate the construction plant and overcome ground obstacles such as cable covers and ground conveyor chain tracks; 2) A vertical sanding reach of 10 feet to cover the majority of their wall production output; and 3) An orbital sander compatible with vacuum dust control. Figure 1 presents the overall robot and Table 1 the major hardware components, which are described below.

The mobile base is a Clearpath's Husky[1] with the high-torque motorization option for high payload. This mobile platform let us move the robot using a wireless remote control in the off-site construction environment.

For the mobile arm, a collaborative robot is necessary to limit interaction forces, because mobile robots are not constrained to a traditionally fenced robot environment.

[1] https://clearpathrobotics.com/husky-a300-unmanned-ground-vehicle-robot/

The Fanuc CRX-20iA/L[2] has a reach of 1418 mm and a maximum payload of 20kg to manipulate the orbital sander. This arm also features internal force sensors that enables force control. An additional robot axis motor is necessary to reach 10' high walls, and an Igus linear axis of 1050 mm[3] was specified for this task.

The orbital sander mounted on the manipulator arm is a Festool PLANEX LHS-E 225 EQ[4]. The head of the orbital sander was adapted to the robot effector with a custom 3D printed part. Festool P320 ready-to-use abrasive pads for the 225 mm orbital sander are used and is the least abrasive option offered by Festool for this orbital sander.

For the vision system, the RGB-D (color + depth) Intel D435i[5] camera is common and easy to use for the design of the first prototype. After comparing multiple segmentation approaches based on other sensors, such as a Time-of-Flight camera, the combination of near-UV lights with the RGB-D camera was found to be the most efficient in maximizing the visual differences between the compound and the board's paper layer [4].

Commercially-available solutions, such as the CANVAS 1200CX[6], use similar hardware configuration. However, they usually used a sprayed compound, and our study focuses on performance with manually applied compound.

3 Perception pipeline

The perception pipeline is used to find the 3D position coordinate of the compound surface to finish in the 3D frame of the camera. The combination of a stereo depth camera with an RGB component creates a point cloud in the camera's frame with corresponding colour values for each point.

Every point in the cloud is segmented depending on whether they originate from the paper layer of the gypsum board or from the compound covering the seam of the boards and the screws head. First, near-ultraviolet spotlight helps differentiate the board and the compound because the fine layer of paper on the boards is fluorescent and emits blue light when exposed to near-UV light [4]. While the joint compound simply reflects the near UV light [4] as shown in figure 2.

To maximize this colour difference, empirical tests revealed that the red colour channel is best to differentiate the blue fluorescence from the paper layer and near-UV reflection from the compound. Thus, the compound surface corresponds to the highest value in the red channel. Then the image is equalized with a Contrast Limited Adaptive Histogram Equalization (CLAHE) and filtered with Otsu's threshold [4]. Then, a median filter is used with a kernel of 21 and a binary threshold of 250, both empirically determined. A segmentation example is shown in figure 2. Finally, the open-source computer vision algorithm minimal area rectangle from OpenCV[7] generates an oriented bounding box around the highlighted compound in the image [4].

Figure 2. Left: RGB vision. Middle: RGB vision with near-UV spotlight. Right: Segmentation result

[7]https://opencv.org/

4 Control Law

Depending on the orbital sander diameter, the 2D bounding box in the RGB image frame is segmented into smaller rectangles corresponding to the sanding passes necessary to cover the full compound surface to finish. Empirically, 2 or 3 passes are needed to cover most seams. The sequence of rectangles, from top-left to bottom-right, form a path for the orbital sender to follow. This 2D path is converted to 3D in the reference frame of the stationary robot by finding the corresponding points in the depth channel of the RGB-D camera.

The 3D path points are converted into robot's joint position with KDL inverse kinematics available with ROS's moveIT package[8] and sent to the robot with a modified version of ROS indsutrial's KAREL drivers[9]. The Fanuc's force control schedule is adjusted with a closed-loop force control of 1.1N (empirically determined) and with the parameters tuned to reduce vibration [5]. This make sure the arm applies a constant contact with a varying environment.

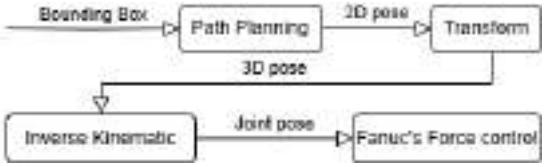

Figure 3. Block diagram of the control law

To make a good assisting robot for drywall finishing, the robot should at least remove the rougher bumps and cracks that workers would remove with similar power tools, without removing too much material so that workers may remove the finer details with handheld sanders. Also, removing too much material would leave visible traces under the paint. To leave the workers with enough material for the sanding block finish, the robot should remove slightly less material than the workers.

Three parameters determine the depth of material removed [6]: the grit of the sanding paper (Preston coefficient), the relative velocity between the compound and the orbital sander, and the pressure applied by the robot arm. Using the right equipment is key to control the first two parameters. Although the specific Preston coefficient between the compound and the sander abrasive was not examined in this study, using the finest grit abrasive reduces Preston coefficient, thus also the amount of material removed. In the same way, using the lowest orbital sander speed also reduces the amount of material removed. Reducing the commanded force in the Fanuc contouring controller would reduce the pressure, but it also reduce the performance of the algorithm to maintain contact on the compound surface.

[8] https://moveit.ai/
[9] https://wiki.ros.org/fanuc/

Although not all the sanding would be done automatically, this robot would reduce most of the workers' inconvenience with dust exposure and strain on the body, but also reduce human labour time while maintaining workers control over quality.

5 Experimental setup and results

The HandyScan 300 handheld external precision laser scanner, also known as the HandyScan SILVER[10] is used to measure the results of the finish. The difference between the scan before and the scan after the finish determines the depth of compound removed. To do so, scans are realigned using an Iterative Closest Point (ICP) algorithm with HandyScan's positioning targets to obtain the transformation between both frames of reference. Differences between point cloud positions in the Z axis serve as a basis for comparison.

The average depth in the Z-axis across the joint before and after the finishing, as shown in bottom figure 4, can help visualize the orientation of the two gypsum boards and the shape of the compound on the seam.

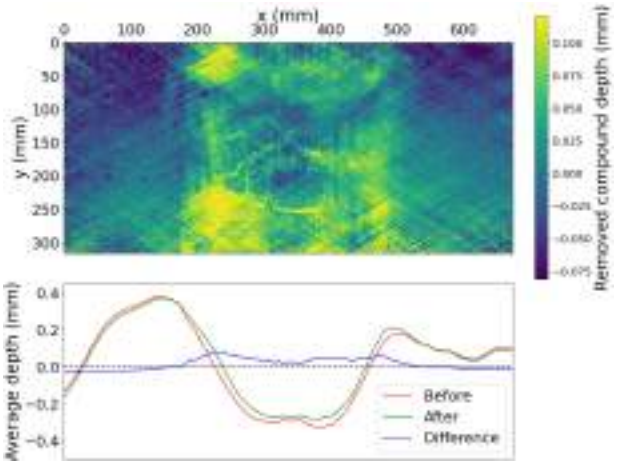

Figure 4. Top: Position difference in the camera Z axis before and after finishing. Bottom: Means position in the camera Z axis across the joint

5.1 Worker baseline

To investigate how much material is removed during workers' drywall finishing, 7 sample scans from different seams were taken before and after the complete finishing process (power tool-assisted and hand-finished). The baseline of what a typical drywall finish is the average of all depth removed plus twice the average standard deviation

[10] https://www.creaform3d.com/en/handyscan-3d-silver-series-professional-3d/technical-specifications

Table 2. Worker and robot depth removed (mm)

	Worker		Robot	
	Means	σ	Means	σ
1	0.10	0.04	0.08	0.03
2	0.11	0.07	0.09	0.06
3	0.04	0.04	0.10	0.03
4	0.04	0.04	0.14	0.05
5	0.08	0.05	0.09	0.03
6	0.13	0.08		
7	0.04	0.03		
8	0.16	0.04		
Means	0.09	0.05	0.10	0.04
Upper bound	0.19		0.18	

for each joint in Table 2. With a normal distribution, two standard deviations over the mean represent 95% of all measurements. This gives an approximate upper bound of how much material is removed from the general surface without measuring the max depth measured, which is where the large bump would skew the result.

On average, the upper bound of the worker's measured depth is 0.19 mm (average mean of 0.09 plus twice the average standard deviation of 0.05). Large bumps caused by uneven drying will have more material removed and larger cracks will have relatively less material removed.

5.2 Robot finishing

With adjusted orbital speed and commanded force, preliminary results presented in Table 2 show that the robot sanded an average amount of 0.10 mm with an average standard deviation of 0.04 mm. Thus, 95% of the robot's finish is expected to be below approximately 0.18 mm. With the upper bound of the workers estimated at 0.19 mm, it leaves enough material for the workers' finer handheld tool finish. The workers' upper bound is a useful benchmark for the robot's adjustment, but it is not a hard limit because many of the workers' and robot's individual scans had a mean and standard deviation higher than the expected workers' upper bound and they still did not damage the gypsum board. Furthermore, individual seams with a larger amount of irregular compound features, such as bumps, necessarily lead to a larger amount of material removed, even if the applied finish is the same. Thus, the proposed system performs as expected regardless of the amount of irregular compound features.

6 Conclusion

A construction robot has been tested to assist the finishing of drywall. The robot is composed of a machine vision algorithm to plan the trajectory of the robot arm, the integrated Fanuc force controller to regulate the pressure of the orbital sander on the wall, and a mobile platform to navigate autonomously inside the off-site construction environment. Preliminary results show that the robot can detect compound on gypsum boards and use the orbital sander mounted on the robot arm to do most of the drywall finishing. Compared to the workers, the robot sanded out a similar quantity of compound and left enough material to adjust the finish if necessary, without removing too much material as to irreparably damage the surface.

Future work includes confirming the repeatability of the preliminary test, introducing the robot to a production line for an assessment by the workers and investigating the automation of the mobile platform, enabling the whole system to navigate autonomously between drywall joint. We will also investigate the applicability of the approach to on-site construction settings.

Abstract -

This article documents the developments from a collaboration with the Matosinhos City Hall in Portugal. The collaboration included the development of a web platform to integrate a management software already in use by the city hall, with 3D visualization capabilities, and the development of information requirements to guide the preparation of information models to be visualized on the platform. The platform enables the visualization of 3D models developed according to the IFC (Industry Foundation Classes) schema using the IFCjs library to manipulate, investigate and visualize IFC files. In addition, the web platform enables access to and manipulation of operational data through the 3D model. The paper demonstrates how the IFC model elements are linked to the database of an existing management system. This solution addresses current operational limitations and promotes broader BIM adoption in the FM sector.

Facility Management (FM); Building Information Modelling (BIM); Interoperability; Integration; Web Platform

1 Introduction

Facility Management (FM) plays a critical role in ensuring facilities' functionality, comfort, and safety [1]. The adoption of Building Information Modelling (BIM) by facility managers to enhance operational efficiency introduces unique challenges [2]. To promote a broader implementation of BIM in FM, it is essential to advance professional knowledge of information management processes that align with ISO 19650 series guidelines and have computational resources to support such digitalization. While computerized management platforms are widely utilized, the effectiveness of these systems depends on their ability to integrate diverse data sources [3, 4]. This includes incorporating three-dimensional models to enable comprehensive and efficient management. Within this context, a collaboration between Matosinhos City Hall (CMMatosinhos) in Portugal and the University of Minho (UMinho) aimed to enhance municipal asset management by integrating BIM methodology into the Intelligent Maintenance Management Platform (IMMP) already employed by CM-Matosinhos (Infraspeak). Currentlly the IMMP provides access to a web interface that lacks the capacity for visualizing buildings and assets.

2 Development methodology and functional requirements identification

The collaboration aimed to develop a web platform that integrates CMMatosinhos's IMMP with the 3D visualization of buildings, enabling users to consult, edit, and add information about the assets. It involved defining information requirements for IFC models to be used on this platform. The requested platform's features and functions included a building selection interface, 3D visualization of buildings and assets, displaying building's and assets' identification and open requests, and enabling managers to access the IMMP page for details. Users can also submit requests for specific assets. Two main pages have been identified for the web platform: the building selection page and the interaction page, supporting two user profiles: manager and common user. Both can visualize the building in 3D, view identification information, and submit requests. Managers can also access open requests and IMMP pages. The frontend uses HTML, CSS, and JavaScript, with the IFCjs library for the interactive viewer and investigation of the IFC file. The backend is built in Python with the Flask framework. The building was modelled using Autodesk Revit 2023 and exported in the IFC4 ADD2 TC1 schema, following the information requirements developed for this research (section 3.2).

3 Implementation

To develop the proposed solution, the 'IMMP database' must be integrated into a web platform presenting the IFC model visualization. This integration necessitates the web platform to establish a correlation between specific assets within the IFC model and their equivalent within the IMMP platform. Achieving this integration depends on the

unique identification of elements across both data sources and establishing a mapping between them. For the mapping, it is essential to comprehend how the assets are identified within the IMMP database (IMMP identifiers) and how CMMatosinhos identifies them in its inventory (CMMatosinhos identifiers). The 'CMMatosinhos identifiers' were organized as part of the alphanumeric information requirements for the model (as detailed in section 3.2). These identifiers became properties associated with various elements within the model, correlating them to corresponding items in the CMMatosinhos inventory. In contrast, the 'IMMP identifiers' were not included in the IFC model but were used to establish a one-to-one mapping between the elements in the IMMP database and those in the model.

3.1 Unique identifiers

Considering the functionalities to be implemented (section 2), three types of elements are essential: *locations*, *equipment* and *requests*. *Locations* represent spatial assets that comprise the buildings and are essential to the equipment's localization. *Equipment* is any physical asset from the CMMatosinhos' inventory (vehicles, chairs, ladders, etc.). Finally, *requests* represent the solicitation for an operation action to be carried out and are always associated with the other types of elements (*equipment* or *location*).

IMMP identifier : The IMMP database contains two categories for entering elements of the type *location*: LOCATION and ELEMENT. Within the LOCATION category, *locations* are organized hierarchically (from buildings to zones and to rooms) and identified by the attribute 'local_id'. Within the second category (ELEMENT), it is possible to enter elements of two types: EQUIPMENT and LOCAL. Therefore, the *locations* classified as ELEMENT are of the type LOCAL and represent only individual rooms (i.e. an office but never a building). Regarding the elements of type *equipment*, those are entries of the ELEMENT category and EQUIPMENT type, and the 'element_id' attribute uniquely identifies each element. Therefore, the 'local_id' and 'element_id' attributes are the IMMP identifiers for *locations* and *equipment*. For the *requests* elements, those designated as 'open' are relevant for this work since they still require actions. Each open *request* is uniquely identified by the 'failure_id' attribute and includes a 'local_id' attribute that specifies the *location* associated with the *request*. Contrarily, information regarding its connection to *equipment* is accessed through the relationships of the *equipment* elements, which contain the corresponding 'failure_id' codes. The 'IMMP identifiers' established here are generated automatically by the IMMP, being a sequence of numbers (e.g. 586188) that do not correspond to the CMMatosinhos inventory.

CMMatosinhos identifier : 'CMMatosinhos identifiers' refers to the coding used by CMMatosinhos to identify its assets within its inventory. Each asset within the IMMP has a unique identifier specific to the IMMP (explained previously) but also includes the CMMatosinhos inventory code associated with one of its attributes. Of the three elements (*equipment*, *location*, and *requests*), *requests* do not have a CMMatosinhos identifier as they do not represent physical assets, being not part of CMMatosinhos' inventory. As for *locations*, the value of the 'full_code' attribute represents the codification used by CMMatosinhos to identify spaces, and it contains a unique code for each location (e.g. 009.G1.P0.048). For *equipment*, the value of the 'code' attribute is a potential unique identifier. Within the CMMatosinhos inventory, the value of this attribute relates to the type of equipment (e.g. #CAD.ESCR.0056 for an office chair). However, considering that there are cases where multiple *equipment* share the same inventory code, a combination of the 'code' attribute of the equipment and the 'full_code' attribute of the location where it is situated has been defined for identifying elements within the equipment group.

3.2 Level of information need

The information requirements developed in this work include the level of information need [5]. Given the platform features (section 2), the purpose for the model is the visualization of the building and assets, incorporating only alphanumerical information for building identificaton and integration with the IMMP. Table 1 presents the level of information need for the complete project (*IfcBuilding*), where Code represents the 'CMMatosinhos identifier'. The requirements for individual architectural elements are presented together with those within its interior.

Table 1. Level of information need for the building

Objects:	**Building**	
IFC Class:	**IfcBuilding**	
Alphanumerical information		
Attributes		
	Attribute name	Content
	LongName	Name
Properties		
Group	Property name	Content
**	Local_CMMatosinhos	Code
Legend	** CMMatosinhos_Identification	

Regarding the elements composing the building's interior, (*locations*, *equipment*, and *requests*), *requests* were excluded as their visualization is not necessary. Therefore, three main groups were established for modelling:

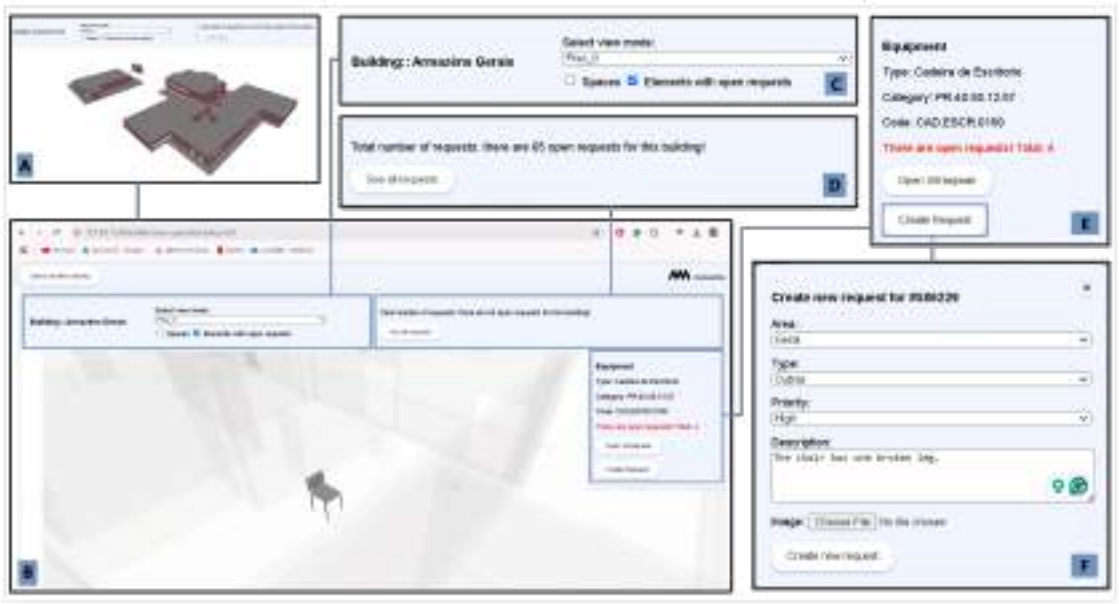

Figure 1. Web platform

architectural elements, equipment, and locations (table 2). Architectural elements serve for visualization and only require geometrical information. The alphanumerical information required for locations and equipment relates to the 'CMMatosinhos identifiers' and also some additional information for identifying and classifying the assets.

3.3 Web platform

Figure 1 shows screenshots of the web platform from the perspective of a user of the manager type. Screenshot A shows the interaction page after the model is loaded with a 3D view of the entire building. When an asset is selected, the platform appears as screenshot B. The page includes an upper section (screenshot C) with the building's identification and diverse options of visualization modes. The next section (screenshot D) warns about the presence and number of open requests. The side menu (screenshot E) displays information about the selected asset, and it appears on the user interface only when a piece of equipment or space is selected. In this menu, it is possible to visualize information identifying the asset and its number of open requests. In addition, two buttons allow the redirection to the asset's page within the IMMP and the creation of requests (screenshot F) associated with the asset. The request is registered within the IMMP platform, and the total number of open requests is updated automatically.

Figure 2 shows the information flow between the platform's frontend and backend and how the platform reacts to the manager's interactions. When a manager selects a building from a dropdown, a request retrieves the IFC file from the models' database and information from the IMMP database. Following, a 3D visualization of the building is displayed for the user, while the IFC file is investigated to retrieve the 'CMMatosinhos identifiers' of the building elements. The backend combines these 'CMMatosinhos identifiers' with 'IMMP identifiers' to map elements from both sources. This mapping allows for the identification of elements with open requests, enabling the visualization to filter and display only those elements. Additionally, the number of open requests related to the building is counted and presented to the user. Following this, users can interact with the model, view detailed asset information, access the asset's IMMP page, or create linked requests.

4 Conclusion

This work developed a BIM-based solution for FM, integrated with a previously non-BIM-supporting management platform. The outcomes of this work provide a detailed procedure for future integration processes. This collaboration demonstrates that the operational sector does not need to completely alter its management system or adopt a different management platform to implement BIM effectively. However, it does need to prepare its inventory organization to facilitate digitalization. During the collaboration, an iterative process with CMMatosinhos helped to address the limitations encountered, showing that the close participation of managers is crucial for the FM sector's digitalization.

Abstract -

The Retrieval-Augmented Generation (RAG) framework has gained attention as a fast and cost-effective method for enhancing the performance of large language models (LLMs). However, its performance remains limited in minority languages such as Korean, and this issue is exacerbated in specialized fields like construction. To address these limitations, this study proposes a dataset construction method that allows low-cost fine-tuning of embedding models originally trained on English-based data. By applying this method in the construction domain, we achieved a top-1 document retrieval accuracy of 58.65%, surpassing the performance of a commercial embedding model provided by OpenAI. We further analyzed how improvements in the embedding model influence the overall RAG pipeline and present both a dataset creation approach and an appropriate evaluation strategy for testing RAG's performance. Our findings suggest that this method can significantly enhance technical efficiency by providing a foundation for diverse language users to effectively utilize RAG in the construction domain.

Retrieval-Augmented-Generation; Embedding model; Construction; LLM; Retrieval; Fine-tuning

1 Introduction

Efforts to enhance productivity across various fields, including the construction industry, are continuously advancing. Successful examples include the application of deep learning models for optimizing schedules in large-scale construction projects [1] and detecting pavement cracks [2]. However, applying pretrained models to specialized domains such as construction requires domain adaptation through fine-tuning, which demands significant costs and resources [3, 4]. This is considered a major issue in utilizing deep learning technologies in the construction industry and is one of the challenges that must be addressed.

To mitigate this issue, many attempts have been made to adopt RAG [5]. RAG allows LLMs to generate answers by retrieving relevant information from external databases instead of relying solely on internally stored knowledge. This approach reduces the need for costly LLM fine-tuning. However, the embedding models and LLMs, which are core components of RAG, demonstrate high performance only in English or general-purpose language contexts [6, 7]. Their performance drops significantly in low-resource languages such as Korean or specialized domains like construction. Among these components, embedding models play a critical role in external database generation and retrieval. When domain adaptation is not applied, embedding models exhibit low retrieval accuracy, which negatively impacts the performance of the entire RAG pipeline, as confirmed through our experiments.

To address this challenge, we constructed a fine-tuning dataset specialized for the Korean construction domain and fine-tuned the embedding model to improve RAG performance, as shown in Figure 1. Publicly available construction standards were utilized to extract high-quality sentences, and we proposed a method to generate fine-tuning datasets using LLMs at a low cost. This approach enabled the creation of high-quality fine-tuning datasets for under $10. Using this dataset, we trained a small embedding model that outperformed OpenAI's commercial embedding model, "text-embedding-3-large" [8]. Our final approach achieved a top-1 document retrieval accuracy of 58.65%. This demonstrates that the proposed method makes LLMs and RAG more accessible and practical for low-resource construction domains.

2 Related Work

The development of LLMs has brought significant advancements across various fields [9]. However, as the size of these models increases, training costs rise substantially [10], and limitations such as hallucination remain prevalent [11]. To address these challenges, RAG has been introduced [12]. RAG enhances LLM responses by retrieving relevant information from external databases rather than relying solely on internal knowledge. This approach is particularly effective for tasks requiring domain-specific knowledge or up-to-date information [13].

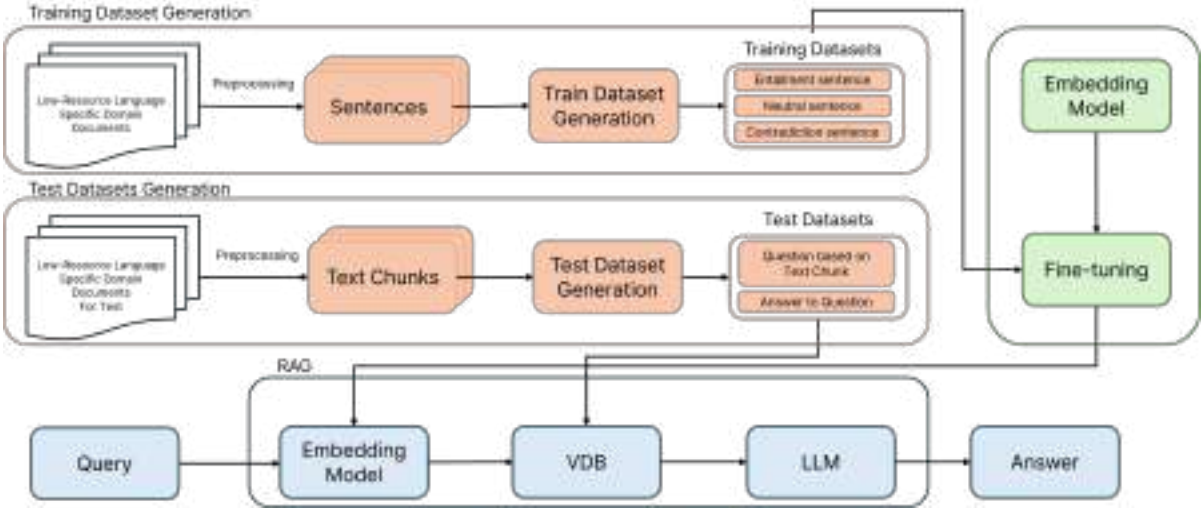

Figure 1. Workflow of embedding model fine-tuning and RAG pipeline construction. This figure illustrates the process of generating a fine-tuning dataset for the embedding model and integrating the fine-tuned model into the RAG pipeline for improved retrieval performance.

The performance of RAG heavily depends on the quality of its Retriever, which retrieves relevant external data. Dense retrieval methods, in particular, rely on embedding models to convert text into high-dimensional vectors and measure semantic similarity between queries and documents [14]. These embedding models are critical to the effectiveness of the RAG pipeline, as their ability to capture semantic meaning, contextual relationships, and syntactic nuances directly impacts retrieval accuracy. Earlier embedding techniques, such as Latent Semantic Analysis (LSA) [15] and Latent Dirichlet Allocation (LDA) [16], have been superseded by methods like Word2Vec [17] and Transformer-based architectures, including BERT [6]. Today, advanced embedding models are available as commercial APIs, such as OpenAI's high-performance models [8].

Recently, LLMs have also been applied in the construction industry. Examples include waste recognition [18], project schedule management [19], and generating captions for site images to monitor progress [20]. However, these applications remain in the early stages and primarily rely on general-purpose language processing capabilities. Discussions about embedding models tailored to construction-specific tasks are rare. To improve RAG performance in low-resource languages and specialized domains, embedding models fine-tuned on domain-specific data are essential.

Fine-tuning pre-trained models for specific tasks has become a common approach for achieving high performance in domain-specific applications [21]. In the construction domain, fine-tuning has been successfully applied to tasks such as automated compliance checking of building codes [22], pavement defect detection [23], and construction management system development [24]. However, constructing high-quality training datasets for fine-tuning in low-resource languages or niche domains is often costly, as it requires expert annotations [25].

Several methods have been proposed to address these challenges and improve the efficiency of dataset generation. One approach involves using LLMs, such as GPT-3 [26], to generate synthetic datasets automatically, which is particularly useful in low-resource language settings [27]. Another method is pseudo-labeling, where unlabeled data is annotated using pre-trained models, effectively expanding the dataset size and diversity [28]. Finally, small curated datasets have been shown to yield high performance with minimal data, as demonstrated by LIMA [29].

In this study, we propose an automatic dataset generation method using LLMs to improve RAG performance in the Korean construction domain. This approach enables the cost-effective creation of high-quality datasets while enhancing the efficiency of domain-specific embedding models.

3 Methodology

3.1 Dataset Generation

This study proposes a cost-efficient dataset generation method aimed at reducing the costs of data creation while improving the quality and applicability of the datasets to RAG systems. Figure 2 illustrates the proposed dataset generation pipeline.

To construct the training dataset, we first collected high-quality sentences written in Korean and relevant to the con-

Table 1. Training dataset structure for fine-tuning. This table presents the composition of the training dataset, where each original sentence S_1 is paired with three corresponding sentences S_2 representing Entailment, Neutral, and Contradiction relationships.

S_1	S_2 Entailment	S_2 Neutral	S_2 Contradiction
The manufacturer specializes in producing materials specified in the design documents. They evaluate production records, supply performance, and cases of product defects to select a suitable manufacturer.	They select manufacturers with a proven track record of high quality and consistently reliable deliveries.	They seek manufacturers with high production capacity, reliable supply performance, and competitive pricing.	The manufacturer only uses material types specified in the design documents, and no quality issues occur.
The concrete for the wall section is poured so that each part always maintains almost the same height.	The height is consistently maintained when pouring concrete for the wall section.	When pouring concrete for the wall section, they aim to keep the height uniform for each layer.	While pouring concrete for the wall section, some areas were made lower than others.
The allowable deviation of the target air content must be within ±1.5%.	The target air content must have an allowable deviation within ±1.5%.	The allowable deviation of the target air content should be maintained within ±1.5%.	The allowable deviation of the target air content may be ±2.0%.

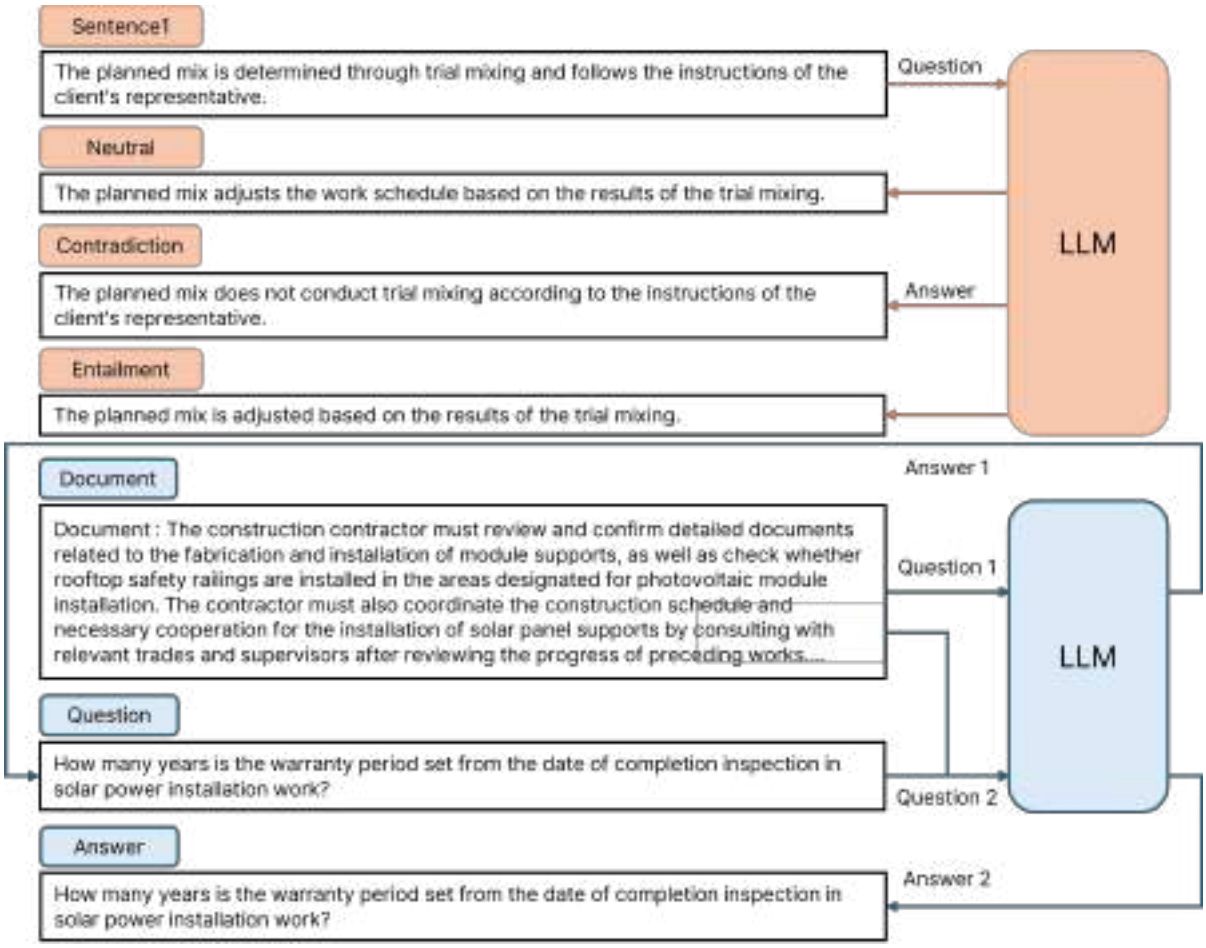

Figure 2. Process of training and test dataset generation. This figure visually represents the sequential generation of training and test datasets using an LLM. The training dataset is constructed to fine-tune the embedding model, while the test dataset is generated to evaluate retrieval performance.

struction domain. Publicly available construction specification documents were identified as appropriate sources for this purpose. Many non-English-speaking countries, including Korea, Japan, China, Vietnam, and France, maintain construction specifications in their native languages, which align well with the objectives of this study. Specifically, we extracted 8,499 sentences from the Korean Construction Specifications. Each of these sentences, referred to as S_1, was expanded into three additional sentences, S_2, representing entailment (positive), neutral, and contradiction (negative) relationships. This resulted in a total of 8,499 S_1 - S_2 pairs. The resulting dataset, named Ko Con NLI (Korea Construction Natural Language Inference), was generated using GPT-4o API with a simple data generation prompt. The entire process of generating all 8,499 pairs through the GPT-4o API incurred a total cost of less than $10.

The final datasets are summarized as follows. The training dataset consists of 8,499 S_1 - S_2 pairs, generated from Korean construction documents, with all data used for training to maximize performance. Validation was performed by observing improvements in Retriever performance based on the embedding model's vector database. Examples of the datasets are provided in Table 1.

3.2 Embedding Model Fine-tuning

To fine-tune the embedding model, this study employed Multiple Negative Ranking Loss (MNRL), which is widely recognized for its effectiveness in retrieval-based tasks.

The MNRL loss function is defined as follows:

$$J_{\text{MNRL}}(\theta) = -\frac{1}{N}\sum_{i=1}^{N}\log\frac{\exp\left(\sigma\left(f_\theta(x_i), f_\theta(y_i)\right)\right)}{\sum_{j=1}^{N}\exp\left(\sigma\left(f_\theta(x_i), f_\theta(y_j)\right)\right)} \tag{1}$$

where N is the batch size, f_θ is the sentence encoder function mapping sentences to the embedding space, and σ is a similarity function, such as cosine similarity. x_i represents the anchor sentence in the i-th pair, y_i is its corresponding positive sentence, and y_j includes all sentences in the batch, including those treated as negative samples.

MNRL optimizes retrieval performance by increasing similarity between positive pairs while minimizing similarity with negative samples, as formulated in Equation 1.

4 Experiment

4.1 Experiment Setup

This study aimed to improve the performance of RAG systems in the Korean construction domain by fine-tuning embedding models and comparing the performance of the fine-tuned models with baseline models. The dataset used for fine-tuning was the **Ko Con NLI dataset**, which was generated by extracting sentences from the Korean Construction Specifications using LLMs, as described earlier. This dataset consists of sentence pairs representing positive, neutral, and negative relationships and was specifically designed to be suitable for embedding model fine-tuning.

The baseline model selected for comparison was OpenAI's "text-embedding-3-large" model, a widely recognized embedding model known for its excellent performance across multiple languages and domains. This model is commercially available. For fine-tuning, the KLUE-RoBERTa-base model[30], pre-trained on the KLUE dataset, was used. Two experimental setups were considered:

1. Using the pre-trained KLUE-RoBERTa-base model without fine-tuning.

2. Fine-tuning the KLUE-RoBERTa-base model using MNRL.

All experiments were conducted on an NVIDIA GeForce RTX 4090 GPU using CUDA 12.2 and PyTorch. The AdamW optimizer was used with a learning rate set to 2×10^{-5}. Model performance was quantitatively measured by creating a vector database (VDB) and evaluating retrieval accuracy.

The retrieval process works by utilizing a test dataset consisting of pairs of documents and corresponding questions based on each document, ensuring that each document has a correct question. All documents are embedded to create a VDB, and when a query is given, it is embedded as well to retrieve the most similar document. Retrieval accuracy is evaluated by checking whether the retrieved document matches the correct document, and several metrics were applied to verify the accuracy of the proposed method.

4.2 Experiment Results

As shown in Table 2, the KLUE-RoBERTa-base model achieved a low Hit Rate @1 of 12.40% without fine-tuning. However, fine-tuning the model using MNRL significantly improved the Hit Rate @1 to 58.65%, demonstrating the effectiveness of the fine-tuning approach.

Notably, this result surpasses OpenAI's "text-embedding-3-large" model, which achieved a Hit Rate @1 of 52.67%, by approximately 6 percentage points, despite being a lightweight model trained on a dataset generated with less than $10 in GPT-4o API costs. This demonstrates that even in low-resource language environments, high-quality domain-specific documents can be leveraged to develop cost-effective and efficient embedding models that rival large-scale commercial models.

Table 2. Retrieval performance comparison of fine-tuned and baseline models.

Models	Learning Method	Hit Rate @1 (%)	nDCG@5	MRR@5
KLUE-RoBERTa-base	None	12.40	0.1983	0.1766
KLUE-RoBERTa-base	MNRL	58.65	0.6904	0.6621
OpenAI	None	52.67	0.6784	0.6349

The effectiveness of this approach stems from two key factors: (1) the structured dataset generation process and (2) the use of MNRL. Unlike manually curated datasets, which often include precise similarity scores or fine-grained semantic relationships between sentences, the dataset generated using GPT only provides categorical labels—such as Entailment (positive), Neutral, and Contradiction (negative)—without explicit numerical similarity scores. MNRL is well-suited for both cases, as it effectively optimizes the ranking of positive and negative samples regardless of whether explicit similarity scores are available. This characteristic makes MNRL particularly effective for training on automatically generated datasets, where manually assigned scores are not available.

This synergy between the generated dataset and MNRL loss function proved to be highly effective, enabling the fine-tuned model to achieve superior retrieval accuracy in the Korean construction domain. These findings suggest that even in specialized technical fields and low-resource languages, it is possible to construct lightweight yet high-performance embedding models using carefully curated domain data and appropriate training techniques.

The improvements in retrieval accuracy directly enhance the quality of final RAG-generated responses. Since RAG relies on retrieving relevant documents before generating answers, higher retrieval accuracy ensures that the language model is provided with more contextually relevant information. This reduces the risk of hallucinations, where the model generates inaccurate or misleading responses due to incorrect retrieval. As a result, the fine-tuned embedding model not only improves document retrieval efficiency but also significantly enhances the reliability and factual consistency of the generated responses in knowledge-intensive applications.

5 Conclusion, Limitations & Future Work

This study proposed a methodology to enhance the retrieval and answer generation performance of RAG systems in low-resource language environments, focusing on the Korean construction domain. By utilizing publicly available construction standards and LLMs, a domain-specific dataset was generated at a minimal cost of less than $10. This dataset enabled the fine-tuning of the KLUE-RoBERTa-base model, significantly improving retrieval performance. Specifically, the Hit Rate @1 of the untrained model, which was only 12.40%, increased to 58.65% after fine-tuning with MNRL. Furthermore, the fine-tuned model demonstrated approximately 6% higher retrieval performance compared to OpenAI's "text-embedding-3-large" model.

Despite its promising results, this study has several limitations, which open avenues for future research. While the study focused on improving the retrieval performance of the RAG pipeline, it did not include a demonstration of final answer generation using LLMs. Although it is widely understood that retrieval performance significantly affects final answer quality, further research is needed to explore the extent of improvement in answer generation performance. Additionally, since the LLM in the RAG pipeline was not fine-tuned, there remain many unexplored areas regarding the level of quality that can be achieved in generating answers based on retrieved documents. Without LLM fine-tuning, the study could not determine the precise impact on answer generation quality.

This study relied on publicly available construction standards to generate high-quality datasets. However, in domains where domain-specific documents are scarce or unavailable, applying this methodology may present challenges. Future research should focus on developing generalized data generation techniques that can adapt to domains lacking structured or standardized documents. Furthermore, while the study focused on the Korean construction domain, the applicability of the proposed approach to other languages and technical fields remains untested.

Beyond the Korean construction domain, the proposed approach can be extended to other low-resource languages and specialized technical fields. Many languages, such as Vietnamese, Thai, and Arabic, face similar challenges in adapting retrieval models due to the lack of high-quality domain-specific training data. Leveraging publicly available documents and generative models enables low-cost fine-tuning for these languages. Furthermore, this methodology can be applied to various technical domains, including healthcare, legal systems, and engineering, where precise retrieval and accurate knowledge synthesis are critical. Future research can investigate domain-specific optimizations and cross-lingual adaptability to improve retrieval-based applications in low-resource settings.

Future research should validate this framework's scal-

Table 3. Retrieval Accuracy Metrics

Metric	Description
Hit Rate @1	Measures whether the correct document appears as the top retrieved result.
nDCG@5	Normalized Discounted Cumulative Gain; evaluates ranking quality by considering both relevance and position in the top 5 results.
MRR@5	Mean Reciprocal Rank; calculates the inverse rank of the first correct document within the top 5 retrieved results.

ability across other low-resource languages and specialized fields, including healthcare, legal, and educational domains.

By addressing these limitations, future research can further enhance the applicability, scalability, and robustness of RAG systems in low-resource environments, ultimately expanding their utility across a broader range of domains and languages.

Abstract –

The transition from Construction 4.0 to Construction 5.0 signifies a new era of innovative and advanced practices in the construction industry. This study explores the integration of 3D Concrete Printing (3DCP) technology within the Construction 5.0 paradigm, emphasising its potential to transform conventional practices by aligning with core criteria of Construction 5.0 such as human-centricity, sustainability, resilience, and cost and environmental control. A systematic literature review was conducted to identify the key criteria of Construction 5.0 and determine the critical drivers of 3DCP across each criterion. For each criterion, ten critical drivers were identified that align 3DCP with Construction 5.0 principles. The study employs content analysis to rank and prioritise these drivers, ensuring a robust understanding of their significance, supported by a comprehensive framework for evaluating their alignment with Construction 5.0. Additionally, a conceptual implementation framework for 3DCP was developed, encompassing three phases: knowledge building, the adoption phase, and performance assessment. This framework aims to facilitate the practical application of 3DCP within the construction industry and provides a roadmap for industry and academia to integrate 3DCP into Construction 5.0 practices effectively.

Keywords –

construction 4.0, construction 5.0, 3D concrete printing, human centricity, sustainability, resilience, cost and environmental control

1 Introduction

The construction industry has undergone significant transformations over the years, with the advent of Construction Industry 4.0 marking a pivotal shift through Internet of Things (IoT), artificial intelligence (AI), Cloud Computing (CM), Big data Analytics (DBA), robots and Cyber Physical Systems (CPS), 3DCP, Augmented and Virtual Reality (AR/VR) and blockchain technology to enhance efficiency, automation, and data-driven decision-making [1]. Construction Industry 4.0 primarily focuses on the technological aspects of construction, emphasising automation, digitisation, and data-driven processes, but it often overlooks the human-centric elements of the industry. Despite the potential of these technologies to improve the design, management, operation, and decision-making of construction projects, the industry's ability to fully integrate them remains low [2].

In response, the Construction 5.0 paradigm is the next phase in industrial development that aims to combine the skills of human experts in partnership with efficient and precise machines to achieve production solutions that are resource efficient and preferred by clients [3]. Rather than replacing workers with machines, Construction 5.0 seeks to create a balance where smart technologies such as AI, robotics, 3DCP, Building Information Modelling (BIM), Digital Twin (DT) and IoT, empower workers to become more efficient and safer while fostering innovation [4]. This human-centred approach addresses the evolving demands of the industry, including sustainability, precision, and adaptability. Construction 5.0 builds on advancements from Construction 4.0, prioritising the collaboration between people and technology. It ensures that workers remain central to the process, using technology as a tool to enhance rather than replace their capabilities [3]. Construction 5.0 is neither a replacement nor an alternative to Construction 4.0 but rather an evolution and logical continuation. It centres around four interconnected core values: human-centricity, sustainability, resilience, and cost reduction & environmental control [1].

Among the various promising technologies and applications that Construction 5.0 supports to enhance production and deliver customised products one key technology is 3DCP, which has capacity to completely transform the conventional construction process [5]. The construction 3D Printing process involves using digital

models to layer materials, such as concrete or polymers, to build structures by layering them systematically [6]. The use of this technology provides numerous benefits, including decreased labour needs, lower production expenses, increased productivity due to faster construction processes, cost savings, high efficiency, eco-friendliness, reduced waste generation, and the capability to construct intricate shapes and structures [5]. Thus, 3DCP is pivotal in advancing the construction industry towards the holistic goals of Construction 5.0.

Up to date very limited research studies have investigated the alignment of 3DCP technology with Construction 5.0 goals. Max et al. [7] examined the sustainability benefits of adopting 3DCP in the construction industry, highlighting its potential for significant material savings, reduced carbon footprints compared to traditional methods, increased automation, and addressing the current shortage of skilled labour in the sector. Himanshu et al. [8] highlighted the resilience of 3DCP structures, attributing it to enhanced customisation and faster adaptation to design changes, aligning with Construction 5.0 adaptability goals. Giovanni et al [9] explored the human-centric aspects of 3DCP, demonstrating its potential to create ergonomically safer environments by reducing manual labour. Wang et al. [10] analysed the integration of cloud manufacturing and IoT in 3DCP, highlighting its role in digitalising construction to provide reliable features, enable real-time monitoring, and improve operational efficiency, aligning with Industry 5.0 focus on technology-human collaboration. The above studies collectively underline the significance of 3DCP in fulfilling the core values of Construction 5.0, including human-centricity, sustainability, resilience, and cost reduction & environmental control. They also highlight the need for an integrated assessment framework to optimise its adoption.

A key limitation in the existing body of research is the absence of structured frameworks to evaluate how effectively 3DCP aligns with the criteria of Construction 5.0. This study seeks to fill this critical gap by developing an assessment and implementing framework that systematically evaluates 3DCP technology in alignment with Construction 5.0 criteria.

2 Research Model Development

The research methodology consists of four key steps. The first step includes a literature search. A comprehensive search was conducted across the databases including Scopus, Web of Science, and Google Scholar were utilised to retrieve peer-reviewed journal articles, conference papers, and review articles published in English since 2015. Keywords including “Industry 4.0,” “3D Concrete Printing,” “Industry 5.0,” “Construction Industry,” and “digital Construction” were used to find the articles. This ensured the inclusion of up-to-date and high-quality research addressing the study objectives.

Secondly, a systematic analysis was conducted to explore the alignment of 3DCP technology with Construction 5.0 criteria. The focus was on identifying key criteria for Construction 5.0, which broadly encompass the essential elements necessary for driving innovation, sustainability, and collaboration in modern construction practices. These criteria reflect the integration of advanced technologies with human-centric approaches to create a more adaptive and resilient construction ecosystem. This analysis provided the foundational insights necessary for developing the assessment framework.

Thirdly, a content analysis of the selected literature was conducted to identify the key drivers of 3DCP technology for each of the Construction 5.0 criteria. This is essential because the criteria of Construction 5.0 are inherently abstract and require the identification of specific drivers to enable their practical evaluation. These drivers act as measurable and actionable components that link theoretical concepts to real-world applications. By categorising and highlighting these drivers, the analysis provided valuable insights into how 3DCP technology can align with and support the overarching criteria of Construction 5.0. The findings from this analysis served as an essential foundation for the development of the proposed assessment framework.

Finally, an assessment and conceptual framework for implementing 3DCP in alignment with Construction 5.0 criteria was developed, based on identified key drivers and expert opinions from construction engineering and 3DCP specialists.

2.1 Systematic Literature Review

The systematic literature review was conducted to critically examine existing research and identify the core criteria of Construction 5.0, with a particular focus on their relevance to 3DCP technology. A summary of the systematic literature review is presented in Table 1. The four core dimensions of Construction 5.0 identified through this review are:

Human Centricity (HC): This dimension focuses on prioritising human well-being in construction by combining human ingenuity and craftsmanship with the efficiency and consistency of technology [3].

Sustainability (SU): Additive manufacturing, also known as 3D printing, is a key feature of Construction 5.0, playing a significant role in enhancing the sustainability of manufacturing processes. In Construction 5.0, additive manufacturing focuses on improving customer satisfaction by integrating added value into products and services [3].

Resilience (R): The term 'resilience' refers to the need

to enhance the robustness of industrial production, enabling it to better withstand disruptions and maintain essential infrastructure during crises [1].

Cost and Environmental Efficiency (C&EE): In Construction Industry 5.0, "Cost Reduction and Environmental Control" refers to the strategic approach of minimising expenses while managing and reducing environmental impact [11].

3 Mapping 3DCP Drivers to Construction 5.0 Criteria

This section outlines how to identify and shortlist the key drivers of 3DCP to meet the criteria of Construction 5.0 criteria using a content analysis approach. A content analysis of more than 20 academic papers was conducted to identify and evaluate the key drivers enabling 3DCP to meet the core criteria of Construction 5.0: Human-Centricity, Sustainability, Resilience, and Cost Reduction & Environmental Control. A total of 10 drivers were identified for each criterion. Each driver was assigned a unique Code (C) to facilitate clear and structured representation throughout the analysis. The Frequency (F) of each driver's occurrence in the literature was calculated using Equation 1 to quantify its prominence [17]. This frequency evaluation identified the prominence of each driver based on its repetition mention in the literature, providing insight into its significance for aligning 3DCP with the principles of Construction 5.0.

$$\mathrm{F} = \sum \text{Driver Occurance in articles} \quad (1)$$

Next, the Significance (S) of each driver was assessed to quantify its relative importance based on its representation in the reviewed literature. Each driver was classified into one of three qualitative categories: High, Medium, or Low. This qualitative categorisation was determined by observing the emphasis placed on the driver across the reviewed studies. The category with the highest mentions was used to assign the driver's overall significance. To transform the qualitative significance into a quantitative measure for subsequent analysis a Quantitative Score (QS) is assigned to each driver (High as 5, Medium as 3, and Low as 1) and the highest frequency impact is selected for each driver following Rasul et al. [18].

$$Ls = \frac{QS \times F}{A \times N} \quad (2)$$

$$NLS = \frac{LS_{Individual}}{\sum LS} \quad (3)$$

$$\mathrm{CS} = CS_{previous\ driver} + CS_{Current\ driver} \quad (4)$$

The literature score (LS) is calculated as outlined in Equation 2, where A is the highest possible (qualitative) score, N is the total no of papers which were considered for the identification of the challenges, frequency shows the repetition of challenges in papers. The next step was to transform this LS into a Normalised Literature Score (NLS). Normalisation is required to ensure that the data directly related to the database is considered. Further, each data field contains only one data element, which removes redundant (unnecessary) data. It is obtained by dividing each driver individual LS by the total LS ($\sum$LS) as stated in Equation 3. After that, the Cumulative Score (CS) was then computed to provide an aggregated measure of importance. For the first driver, CS was equal to its NLS. For subsequent drivers, the CS was calculated using Equation 4. The drivers were ranked based on their LS and NLS, with the rankings providing a systematic representation of their relative importance [17]. This structured methodology ensured transparency and consistency in the identification, evaluation, and prioritisation of the key drivers for aligning 3DCP with the criteria of Construction 5.0, as presented in Table 2

Table 2. Driver's identification and ranking

Drivers / Human-Centricity Drivers	C	F	S	QS	LS	LNS	CS	Rank	Ref

4 Assessment Framework for 3DCP in Meeting the Criteria of Construction 5.0

The assessment framework for 3DCP offers a structured methodology to evaluate its alignment with the four core criteria of Construction 5.0: Human-Centricity, Sustainability, Resilience, and Cost and Environmental Control. To effectively illustrate the interconnected causal relationships among the drivers and core criteria, a causal path diagram is employed, enhancing the clarity of the framework and facilitating deeper discussions regarding the outlined causal relationships. Previous literature indicates that causal path diagrams serve as effective tools for visualizing complex processes and sequences of events. Additionally, the use of directional arrows, as suggested by Duncan (1966), elucidates the nature of influence among the various components of the framework [30]. By utilising arrows to indicate the direction of causality, the impact of each driver on its associated criterion is clearly demonstrated [31]. This approach ensures a coherent understanding of how 3DCP aligns with the core criteria of Construction 5.0 by systematically depicting the causal pathways between drivers and their associated criteria.

Human-Centricity is a fundamental pillar of Construction 5.0, and the framework addresses this through ten drivers (H1 to H10) that collectively prioritise the well-being, engagement, and empowerment of individuals involved in construction processes. Drivers such as worker fatigue reduction, enhanced precision, and user-centric design underscore the technology's ability to create safer and more inclusive construction environments. The integration of smart technologies and the reduction of human error further emphasise how 3DCP fosters a human-centred approach to construction.

The criterion of Sustainability is addressed by 10 drivers (S1 to S10) that focus on minimising environmental impact and maximising resource efficiency. Drivers such as material optimisation, waste reduction, and the use of recycled materials collectively reduce the environmental footprint of construction activities. Furthermore, the adoption of eco-friendly materials and circular economy principles aligns C3DP with global sustainability goals, ensuring long-term environmental benefits.

Resilience, another critical criterion, is supported by ten drivers (R1 to R10) that enhance the adaptability, durability, and reliability of 3D printed structures. Rapid deployment capabilities improved structural integrity, and resilience to natural disasters are key features that make 3DCP a transformative technology in dynamic and high-risk environments. These drivers collectively ensure that 3DCP contributes to robust and future-proof construction practices.

Finally, Cost and Environmental Control is comprehensively addressed through ten drivers (CE1 to CE10) that focus on reducing costs while maintaining environmental sustainability. Drivers such as reduced labour costs, faster construction timelines, and the elimination of formwork illustrate how 3DCP achieves cost efficiency. Simultaneously, the reduction of carbon emissions, noise pollution, and improvements in indoor environmental quality demonstrate its alignment with environmental control objectives. By addressing both economic and ecological efficiencies, 3DCP aligns with Construction 5.0 emphasis on sustainable and cost-effective practices.

This assessment framework, as depicted in Figure 1 provides a clear and logical structure to evaluate 3DCP technology to meet Construction 5.0 criteria. The causal path diagram serves as a critical tool for visualising these relationships, facilitating a comprehensive understanding of how 3DCP drivers influence the achievement of each criterion. This structured approach not only underscores the transformative potential of 3DCP but also serves as a basis for further research and practical implementation in advancing construction practices.

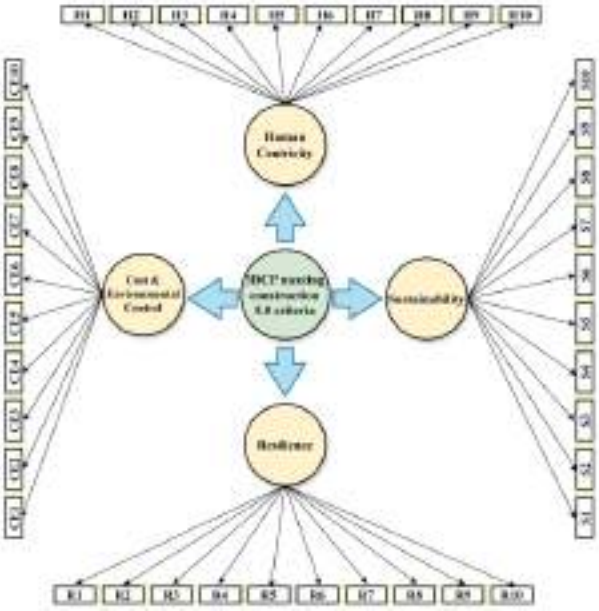

Figure 1. 3DCP assessment framework for Construction 5.0

5 Implementation Framework For 3DCP in Construction Industry

A conceptual framework for implementing a 3DCP in Construction Industry 5.0 was made using an assessment framework and expert opinions of construction engineering and 3DCP specialists, as shown in Figure 2. This conceptual framework comprised three phases: "Knowledge Building Phase", "Implementation phase", and "Evaluation Phase".

5.1 Phase 1: Knowledge Building Phase

The Knowledge Development stage emphasises the need for stakeholder awareness and capacity building through partnerships with professional organisations, academic institutions, and industry bodies. By incorporating 3DCP into training programmes, educational curriculum, and industry case studies, this stage facilitates the dissemination of reliable information and best practices.

5.2 Phase 2: Adoption Phase

The Adoption Phase operationalises the framework through decision making and implementation strategies that address critical barriers, such as high initial costs and a lack of technical expertise. Financial incentives, including subsidies, tax exemptions, and expedited approvals, are positioned as enablers for adoption, and industry stakeholders can use these mechanisms to encourage investment in 3DCP technologies.

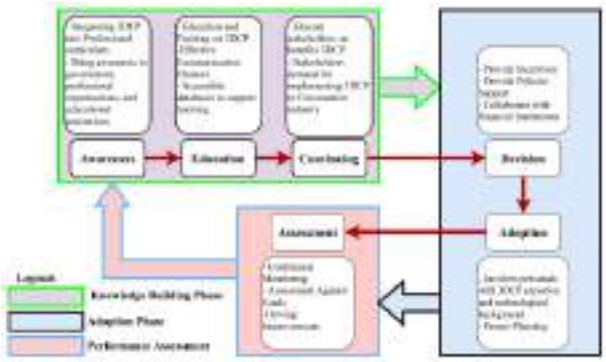

Figure 2. Implementation framework for 3DCP in the construction industry

5.3 Phase 3: Performance Assessment

The Performance Assessment stage provides a mechanism for continuous evaluation and improvement. By monitoring and assessing projects against Construction 5.0 objectives, this stage ensures compliance with human-centric, sustainable, and resilient construction goals.

This framework provides a structured, scalable, and impact-driven approach to integrating 3D concrete printing into Construction 5.0. It enables industry stakeholders to overcome barriers to adoption while delivering sustainable and efficient construction solutions. For academia, it offers a robust foundation for research, collaboration, and knowledge dissemination, advancing the discourse on next-generation construction technologies. By fostering a symbiotic relationship between research and practice, this framework has the potential to catalyse transformative advancements in the built environment, addressing global challenges in sustainability, resilience, human-centric development, and cost and environmental control.

6 Conclusion

This research highlights the transformative role of 3DCP technology in achieving the goals of Construction 5.0. By aligning with the core pillars of Construction 5.0, including human centricity, sustainability, resilience, and cost and environmental control, 3DCP has proven to be a pivotal innovation in modern construction practices. To evaluate the contribution of 3DCP to these objectives, an assessment framework was developed, systematically identifying and prioritising critical drivers across the four dimensions. This framework provided a robust mechanism to quantify the alignment of 3DCP with Construction 5.0 principles, enabling the identification of actionable insights and key performance indicators. By integrating measurable factors, such as design flexibility, material efficiency, and resilience to natural disasters, the

assessment framework establishes a foundation for benchmarking the adoption of 3DCP against Construction 5.0 goals.

In addition to the assessment framework, this research proposed a conceptual implementation framework designed to operationalise the findings and facilitate the practical application of 3DCP within the construction sector. The implementation framework is structured into three phases: knowledge building, adoption, and performance assessment. The knowledge-building phase focuses on raising awareness among stakeholders, promoting capacity development, and establishing partnerships with academic institutions and industry bodies. The adoption phase addresses challenges such as high costs and limited expertise, advocating for strategies like financial incentives and multidisciplinary collaboration. Lastly, the performance assessment phase ensures ongoing evaluation and iterative improvement, aligning implementation efforts with the objectives of Construction 5.0.

Future work will focus on integrating insights from grey literature with empirical validation through surveys and case studies to enhance the practical applicability and robustness of the proposed framework, allowing for a more comprehensive understanding of its real-world implications. These efforts will provide additional insights into the applicability of 3DCP across diverse construction scenarios, ensuring that it remains a transformative technology in the industry. Furthermore, this iterative process will facilitate continuous refinement of the framework, strengthening its role in bridging theoretical principles with practical applications.

Abstract –

Sustainability in construction practices is becoming the need of the day, and the construction sector is getting adoptive to the integration of digital tools to explore the opportunities for enhancing sustainability and circular economy applications, offering significant benefits to both industry and society. To achieve this goal, this article discusses a sustainability framework combining Digital Twin (DT), Mixed Reality (MR), and Life-Cycle Assessment (LCA) to align with circular economy principles in building construction.

A case study of a single-family house in Kelowna, BC, Canada is conducted to demonstrate the potential of this integration for comprehensive LCA of buildings. The LCA analysis of the building is performed using OneClick LCA– an LCA platform. The results of LCA account for the embodied carbon, improved material circularity, life cycle cost efficiency, etc. A DT Dashboard (DTD) of the building's circularity model is also developed, which monitors and optimizes the whole life cycle of the building. The DTD is then deployed to MR hardware – Microsoft HoloLens for enabling onsite circularity analysis of the building. This not only allows for immersive visualization of LCA data but also enhances stakeholders' collaboration and decision-making. This way the study showcases how immersive DT can potentially be a game-changer for sustainable construction and provides an industrially replicable model.

Keywords –
Mixed Reality (MR), Circular Economy (CE), Life-Cycle Assessment (LCA), Digital Twin (DT), Data Fusion.

1 Introduction

Circular Economy (CE) has become prominent in the construction industry as a way of responding to challenges of sustainability through reduced waste and resource extraction. The underlying rationale of this concept is a closed-loop use of materials, which is somewhat contrary to the traditional linear model of "take, make, dispose [1] [2]." On the one hand, it is agreed that using CE tools and practices earlier in the project can reduce the negative environmental impacts constructions can have [1]. On the other hand, it is also highlighted that adopting circular practices during the demolition phase in construction can significantly reduce waste, where most materials are currently discarded due to lack of reuse potential [3]. There are other strategies such as adaptive reuse and selective disassembly that are in line with CE principles and extend the life of building components by maximizing material recovery [4].

Furthermore, a collaboration of CE with Life-Cycle Assessment (LCA) is to be considered while designing an optimum building for sustainability in terms of reuse, recycling, and reduction of any kind of waste in the whole life cycle.

Also, advanced technologies such as Digital Twin (DT) are essential to assist in the use of these strategies, as real-time monitoring and data-driven decision-making capabilities can effectively manage resources. Digital Twin technology empowers several industries to dynamically create replicas of actual running systems. By continuously synchronizing data between the physical and digital worlds, replicas are extremely helpful for performance optimization and predicting upcoming problems [5]. The concept of Digital Twin was first proposed by Michael Grieves in 2002 and was officially named and applied by NASA in 2010 for real-time simulation and monitoring of space missions. It then

developed into a key tool for Industry 4.0 applications [6]. Digital Twin can enhance decision-making and reduce operational inefficiencies by integrating Internet of Things (IoT) sensors and Building Information Modelling (BIM) [7], and can also collect and analyze data continuously, to enable predictive maintenance, optimize the processes, and improve resource management in complex construction projects [6]. Owing to its powerful advantages, Digital Twin is playing a more and more crucial role in the construction industry.

To make digital data more accessible and interactable for stakeholders, Mixed Reality (MR) is another powerful technology to apply in construction projects. MR merges the physical world with the digital one to create an immersive environment. The users can interact with both real and virtual objects at the same time using MR technology. It has shown great potential so far in making the construction processes better by enhancing visualization and interaction with real-time data on-site [8]. MR integrates digital overlays into the physical environment, thus making communication among stakeholders easier and allowing for more intense collaboration and quicker decision-making [9]. For example, Wu et al. (2022) [10] did some research on developing MR-based systems to enhance safety by offering real-time visual warnings about potential hazards on a construction site to workers, thus reducing various accidents and improving safety protocols. In addition, MR can also enhance the construction inspection and monitoring process by allowing inspectors to visualize complex 3D models of hidden building elements and identify discrepancies between design and construction in real-time [11]. However, despite such benefits, the high cost of implementation and user acceptance are the main challenges for more widespread diffusions [9].

The integration of MR, DT, and CE technologies can be transformative in improving sustainability in construction. DT technology has increasingly been recognized as a key tool in the transition of the industry from linear to circular models, where the emphasis is on waste minimization and materials reuse for improved salvage value [12]. MR technologies introduce new ways of engaging stakeholders and building further awareness of the principles underlying CE in construction contexts [13]. The combination of MR and DT enhances real-time decision-making and visualization of the construction process, especially in tasks related to design optimization, life cycle analysis, and demolition planning. This integrated approach enables dynamic monitoring and immersive user interaction [14] [15] [16]. By embedding MR-based DT frameworks into building LCA, the construction sector can better align design and demolition phases with CE objectives, improving efficiency and sustainability throughout a building's lifecycle.

Conclusively, the main goal of this study is the development of an immersive Digital Twin Dashboard (DTD) of the circularity model of a building. This DTD helps to monitor and optimize every step of the entire life cycle of the building and contributes to sustainable construction. Then the DT is deployed into HoloLens, which is Mixed Reality (MR) hardware, for lab-scale testing. Immersive visualization and collaboration will enable stakeholders to make better decisions that improve building performance and sustainability.

2 Description of the case study

The single-family house building is located in Kelowna, British Columbia, Canada, which is designed to be a residential house, is comfortable for the family to stay in. The approximate area of this house is 4,465 square feet, having 5 bedrooms and 4 bathrooms, a spacious living area, a dining area, and a gourmet kitchen. It is situated in the Upper Mission area of Kelowna, featuring scenic views and a desirable residential environment. Kelowna has hot, dry summers and mild winters, and therefore is one of the best cities in terms of outdoor activities to enjoy throughout the year. The location and the size of the house allow the structure to be a representative example for the validation of circular economic principles in residential construction while integrating state-of-the-art technologies such as Digital Twin and Mixed Reality to optimize the life cycle performance. The detailed layout of the building is shown in **Figure 1**.

Figure 1: Plan Views of the House

This case study will go in-depth on the circularity of the building structure and the integration of LCA to analyze the environmental performances of the single-

family house. OneClick LCA, an AI-powered sustainability software platform that helps construction and manufacturing industries calculate, manage, and reduce environmental impacts through automated life-cycle assessments, environmental product declarations, and circularity evaluations [17], is used to gain important insights into the key lifecycle costs, energy efficiencies, and embodied carbon related to the building. These insights include considerations on operational energy consumption, the choice of materials, and possible end-of-life scenarios.

Generic construction materials database – the default database from OneClick LCA – is used for the LCA process [18]. The LCA for this project is conducted following ISO 14040, ISO 14044, and EN 15804 standards, and the TRACI 2.1 method is applied to align with LEED Canada requirements [19] [20]. All Global Warming Potential (GWP) values are calculated using a 100-year time horizon, as required by EN 15804, ISO 21930, and TRACI 2.1 [19] [20]. The functional unit is m^2, and the assessment is performed from cradle to grave, covering all stages from raw material extraction and manufacturing to construction, use, and end-of-life disposal, in accordance with EN 15804 and ISO 14040/44.

The following section will discuss the implementation of the principles of the circular economy in the design and how the LCA model quantifies the environmental impact.

3 Circularity of the building structure and LCA model of case-study

3.1 Introduction to Circularity and LCA

The major objective of circularity in building construction is waste and resource consumption reduction by means of design for material reuse, recycling, and adaptability during its lifetime. This also meets the wider concept of the circular economy: principles of the circular economy support the closed-loop use of materials with limited environmental impacts [1]. LCA is the structured method for assessing the environmental footprint of a building throughout its whole life cycle, from material sourcing to construction, operation, and end-of-life. The following section demonstrates how such principles can be applied in practice to a single-family house by evaluating its environmental performance based on data provided by OneClick LCA.

3.2 Circularity of the Building Structure

The building was designed with circularity principles, using materials that at the end of their life will be either reusable or recyclable. The structure is designed to allow the dismantling and reputation of materials. Materials and finishes, as evidenced shows in the results from OneClick LCA, consume 55% of the embodied carbon; therefore, its thoughtful choice is extremely important to reduce the ecological footprint. Besides, for the sake of adaptation, the building design allowed partial deconstruction with recoverable elements. This flexibility will make components reusable or recyclable both in renovations or demolishing and extend their life span by fully meeting the goals of a circular economy.

3.3 LCA Model

The life cycle assessment of the single-family house involves environmental performance at every stage from material sourcing to end-of-life. Results from OneClick LCA show that a large part of the embodied carbon in the building arises during the production and construction phases. This, therefore, calls for a greater need to employ sustainable sourcing practices and energy-efficient construction techniques. It will also have substantial energy use during the operational phase, another big contributor to its environmental footprint.

The end-of-life phase of the building is designed to maximize recovery for reuse and recycling. A design for disassembly allows the structure to recover materials such as timber, steel, and concrete with high efficiency, reducing waste and conserving virgin resources. The LCA results quantify these strategies and prove that they are effective in reducing the overall environmental impact of the building.

3.4 Integration of Circularity and LCA

Merging circularity principles into an LCA model is one of the effective ways toward sustainability. The strategies under circular design – material reuse, adaptability, and efficient construction practices – reduce the embodied carbon and operational energy demands and hence contribute to improved LCA outcomes directly. OneClick LCA data also presented economic benefits by depicting possible cost savings resulting from material waste reduction, reduced energy usage, and minimized end-of-life disposal costs [21].

This project creates a holistic framework for the evaluation and enhancement of sustainability in residential construction by linking circularity with LCA. Such synergy not only reduced the environmental impact on the building but also proved to be a replicable model to integrate these principles into future projects, balancing functionality with economic efficiency and ecological responsibility. The OneClick LCA dashboard with results is shown in **Figure 2**. It presents the value of equivalent carbon dioxide emissions per square meter ($\mathrm{kg\ CO_2e/m^2}$) for the project is 733, and this falls in the

G rating level as per Canadian standards. In addition, the result of the tool Building Circularity v2 shows that 29.59% of the building materials can be reused, recycled, or repurposed after demolition [22].

Figure 2: OneClick LCA Dashboard with Results and Benchmarking

4 Development of the immersive DT of the circularity model

The development of the immersive DT starts with the creation of the detailed 3D model (LoD 350 BIM model) using the Autodesk Revit environment. To effectively use this BIM model in the 3D game engine either the Industry Foundation Class (IFC) file or the FBX file can be imported from Revit to UNITY 3D. The only problem with using the IFC is that all the native properties of each structural element make the 3D model heavy and inefficient thus some extra manual work will be required to import all the design data of the building. Therefore, direct import using the FBX file format is preferred and recommended in such cases. Upon successful import of the BIM model to the UNITY platform, the DTD is created from scratch that works while switching to the game mode of the 3D model. The DTD workflow is based on the User Interface (UI) modules such as canvases that are used to mesh the 3D model (virtual counterpart of the DT model). These meshing elements enable the automation function of DTD and help to integrate with the physical model of the building. In the case of this research, the physical model is replicated with the online web platform (OneClick LCA) that accounts for the circularity of the building. In order to ensure the two-way communication between the DTD and OneClick LCA a C# code is embedded in the canvas of the DTD which calls upon the circularity model of the building in OneClick LCA once the game mode is switched on in the UNITY 3D.

The calculation of the circularity parameters i.e., Embodied carbon benchmark, Embodied carbon by life-cycle stage, and Embodied carbon by structure are automatically linked to the DTD directly from the OneClick LCA interface. This way the DTD performs the LCA of the building while ensuring the basic principle of circular design such as material reuse, adaptability, and efficient construction practices resultantly reducing the embodied carbon and operational energy demands while contributing to improved LCA outcomes automatically. The DTD with the LCA data is shown in **Figure 3**.

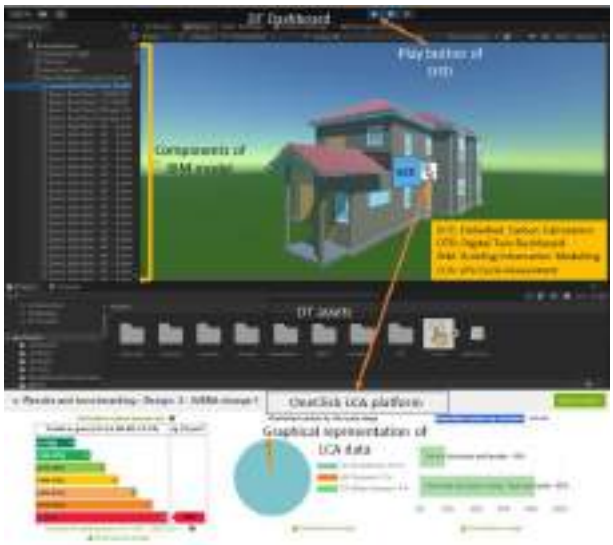

Figure 3: Digital Twin Dashboard of Integrated BIM-LCA system in 3D game engine

5 Deployment of DT to MR hardware and lab-scale testing of the DT-based circularity model

To enhance collaboration between the stakeholders and enable better visualization, the DT model, along with the LCA system, is deployed into Microsoft HoloLens – an MR hardware. This includes embedding the LCA system into the DT model, adjusting the direction and location of the model to better fit the camera, building the application in Unity, and finally deploying the application into HoloLens via Visual Studio.

For starters, the LCA system of the building is added to the DT model by attaching a button with a web link to the wall of the building, so that the user can click on the button and access the OneClick LCA webpage to see the LCA results of the building. Detailed result components will be discussed in the next section.

To deploy the app to HoloLens, the Mixed Reality Tool Kit (MRTK) is used for this project. The main camera of the Mixed Reality Play Space is adjusted to the right location to provide a better view of the building and the LCA button. It is expected that once the users open the app in HoloLens, they can see the whole building in a proper size, and can see the LCA button clearly, guiding them to click on the button to see the LCA results.

As for building the application, the Universal Windows Platform (UWP) in Unity is used for the purpose of developing and running the application on a wide range of Windows devices, including HoloLens, PCs, etc. In this way, the application can be tested not only in HoloLens but also on PCs.

The application is built on the Remote Device (Via Windows Device Portal). HoloLens is connected to the same Wi-Fi network as the PC, so the PC can be paired with HoloLens via Windows Device Portal. The application is built in Unity and then deployed to HoloLens in Visual Studio using the IP address HoloLens connected to, the username and password of the Portal. After deploying, the application can run on HoloLens.

While running the application, the users can see the entire building DT model and the LCA button attached to it. By clicking the button, that embeds the web link, the users can see a webpage jumping out, as shown in **Figure 4**. The webpage shows the LCA results, including graphs and diagrams of Embodied Carbon, Life Cycle Cost, etc.

Figure 4: Immersive DT of the building circularity system

6 Discussion

The LCA results in OneClick LCA mainly explain embodied carbon, life cycle costs, and building circularity. Following is the breakdown of each part.

6.1 Embodied Carbon Results

The analysis provides very important insights into the embodied carbon of the design. Almost all emissions lie within A1-A3 (Materials), and only a small amount lies within A4 (Transport) and C2 (Waste Transport). Those materials comprise almost the entirety of the total carbon footprint in the building project. Horizontal structures such as beams, floors, and roofs contribute the most. The results have shown strong evidence for the consideration of material alternatives in the design stage so as to reduce environmental impact.

Benchmarking also puts the performance of the design in a wider context, such as building types in Canada or the MEP benchmarks. By doing so, one gains the ability to perform a relative comparison, showing areas that are excellent or fall behind in the design. These indeed are valuable insights from where the design team can thereafter work towards making targeted improvements to meet and hopefully even better the benchmarked targets in sustainability.

6.2 Building Circularity

Circularity is important because it reduces waste, saves resources, and supports the closed-loop system for long-term sustainability [1]. The report shows that the Building Circularity is around 29.59%. This means that although there is a considerable portion of materials that can be recycled or renewed at the end of the building's life cycle, most materials may still be linear and would be disposed of in the end. To improve circularity, we changed these materials to recyclable materials, and the LCA results are shown in **Figure 5**. In this case, the Building Circularity is 100%, which means all the materials we use in this building can be reused at the end of the building's life cycle, and therefore the embodied carbon intensity is decreased from 733 kg CO_2 e/m^2 to 229 kg CO_2 e/m^2 .

Figure 5: LCA Results after Changing Materials

6.3 Life Cycle Cost Analysis

The LCC results show a detailed breakdown of the financial impacts across various building elements and life-cycle stages. Construction costs between A0 to A5 come out as the largest cost contributor. These are primarily determined by material and labor costs. The design team may reduce the initial cost through such cost-effective and sustainable methods as pre-fabrication or sourcing materials locally.

The costs of operational energy use B6 are also high, indicating that energy efficiency will be very important

for the reduction of long-term expenses. The end-of-life costs, C1 to C4, are relatively low but can be further reduced by specifying the materials and systems for reuse or recycling, thereby avoiding demolition and waste management costs.

6.4 Combined Analysis of Life-Cycle Stages and Elements

An integrated view of life cycle stages and elements gives an insightful understanding of how the costs evolve over the life of the building. The analysis will enable stakeholders to prioritize interventions based on their life-cycle stage and element-specific impact. For example, it would have immediate cost and environmental benefits if high-impact materials were focused on during the construction phase.

7 Conclusions

The integration ofDT and MR technology with the CE framework is a great improvement in the building sustainability analysis. This study has developed a novel DTD which is further deployed to MR headset and allows for immersive monitoring and optimization of the whole life cycle of the building. It enhances the efficiency of resource management and allows for the potential of collaborations between stakeholders.

The case study of the Kelowna single-family house is considered in this research. LCA of the building is performed by incorporating circularity principles – such as using reusable materials – that significantly reduce embodied carbon emission and improve building sustainability performance. After changing to more eco-friendly materials, the embodied carbon intensity decreased from 733 kg CO_2 e/m^2 to 229 kg CO_2 e/m^2, and the building circularity ratio is increased from 29.59% to 100%.

This study emphasizes the importance of embedding LCA and CE principles early in the design process to mitigate environmental impacts effectively and by integrating cutting-edge technologies such as DT and MR, this analysis process can be improved significantly.

However, there are also limitations and challenges for the integration of MR, DT, and LCA. Construction workers and project teams may need targeted training to develop the skills required to use these tools effectively, which could delay widespread implementation. Furthermore, how well these technologies perform could differ depending on project size and building type. While they may be suitable for straightforward projects, more extensive or highly complex developments could experience challenges related to data integration, system compatibility, and overall performance, which would benefit from further investigation. Future work can focus on how to implement this framework in different construction types, reducing costs and increasing user acceptance to promote wider sustainable practices. In addition, conducting a cost-benefit analysis that compares advanced tools, such as OneClick LCA software, with traditional LCA methods could provide valuable insights. This analysis would help stakeholders make more informed decisions by evaluating both the financial investment required and the potential benefits, such as improved accuracy, time savings, and enhanced sustainability outcomes.

Abstract –

The construction industry faces complex decision-making challenges that require the integration of extensive domain knowledge and data analysis. Traditional methods are inadequate to effectively address these challenges due to the dynamic nature of construction projects. In the fast-evolving landscape of construction technology, artificial intelligence (AI) plays a crucial role in enhancing decision-making and prediction processes. Therefore, the main purpose of this research is to examine how AI, particularly Large Language Models (LLMs), can be integrated in the analysis and management of emergency scenarios to improve decision-making, prediction, and optimization through knowledge-based systems. This research follows the CommonKADS method for knowledge engineering and embeds sub-symbolic and symbolic AI techniques. By integrating LLMs, this research conceptualizes and operationalizes tacit construction knowledge into structured knowledge systems. This approach has been applied in a case study analysing National Fire Protection Association (NFPA) fire incidents to test possible interactions to extract related data for the knowledge-based systems. The findings inspire future research on the scalability of AI-integrated systems across different segments of the construction industry, their potential in regulatory compliance scenarios, and the development of automated knowledge-based systems in construction industry.

Keywords –

Knowledge-based systems; Large Language Models; Fire Safety Management; Artificial Intelligence; Construction Industry

1 Introduction

The construction industry plays an important role in shaping the built environment but is facing challenges arising from the complexity and dynamic nature of its processes. These challenges are multifaceted, involving the coordination of multiple stakeholders, adapting to changing environmental conditions and complying with complex regulatory requirements especially in case of emergency management.

Traditional decision-making tools are often insufficient to meet the demands, as they struggle to proceed with large volumes of data and fail to pace up with rapid changes on construction projects. For example, Zhu et al. identifies challenges facing decision support systems in construction in the following aspects: impreciseness or uncertainty of information, dynamic and unstable situations, high volume, high velocity and high variety of the information.[1]

Algorithmic approaches to decision support show systemic limitations that push away the possibility of achieving optimal solutions for effective real time management in the era of big data. This creates a need for innovative approaches that are able to cope with result accuracy, that are computational, efficient, responsive and effective in the fast-paced world of the construction industry.

Recent developments in artificial intelligence (AI) technologies have produced significant advances to knowledge technologies, bringing renewed attention to the role of knowledge in solving complex problems. The introduction of knowledge-based systems (i.e. expert systems) in the 1980s marked a significant milestone in addressing the automation of knowledge-based problem solving. These systems used deep domain knowledge and heuristic reasoning to tackle complex, real-world problems. Their declarative nature allowed reasoning under uncertainty and provided explainable rational for their decisions [2], [3].

However, knowledge-based systems are not without limitations, such as the labor-intensive process of knowledge acquisition, scalability challenges, and an inability to provide creative, adaptive and context-specific responses[2]. Moreover, the cost of developing and maintaining such systems remains a significant barrier.

Knowledge engineering (KE) emerged to address these challenges by systematically structuring and

organizing knowledge. KE methodologies, such as CommonKADS [4], provide robust frameworks for modeling tasks, agents, and knowledge systems. These frameworks emphasize conceptualization, operationalization, and formulation, in other words, knowledge coding, which ensure the systematic transformation of domain knowledge into structured, machine-readable and reusable systems [4]. While conceptualization involves identifying and organizing domain knowledge; operationalization translates abstract concepts into actionable procedures; and formalization encodes these procedures into formal representations that can be implemented in computational rule-based systems[4], [5]. As an example, CLIPS (C-Language Integrated Production System), a rule-based tool, integrates AI outputs into operational systems by providing components like a fact-list, knowledge base, and inference engine, enabling the application of domain-specific rules as per CommonKADS methodology [6].

Despite advances, traditional KE faces obstacles in integrating tacit knowledge (informal, experiential knowledge) into structured formats. This includes the significant resources required for knowledge extraction and representation, making it labor-intensive and costly. Additionally, adapting existing models to new circumstances is challenging, as traditional methodologies often lack the flexibility needed to accommodate evolving knowledge and dynamic environments effectively. The rise of artificial intelligence (AI), in particular the emergence of Large Language Models (LLMs), offers transformative opportunities to overcome these limitations.

LLMs such as GPT-4 are adept at processing unstructured data, identifying patterns, and generating human-like responses [7], [8], thereby operationalizing tacit knowledge and transforming natural language into structured representations. These capabilities, when combined with methodologies like CommonKADS, appears as a promising approach to automate and scale KE processes, creating adaptive, dynamic systems that bridge the gap between symbolic and sub-symbolic AI.

However, LLM systems show some severe limitations, due to their black-box architecture and statistical nature of the computing, which are ill-suited to the requirements of reliability and traceability of reasoning. A reliable and explainable reasoning process is in fact required in construction decision-making, because the responsibilities assumed by the decision maker are a determining factor in the decision-making process. Hence hallucination and the lack of explainable reasoning are a barrier to the straightforward application of AI in decision-making [9], [10], [11].

The idea claimed in this paper is therefore to use AI to improve the fragility of domain models and the high cost of building the knowledge base of symbolic systems on the one hand, and to define a procedure to mitigate the hallucination and explainability problems of these systems on the other.

Building upon our previous article presented at ISARC 2024 [12], where we introduced the AI-in-the-loop model as a novel approach for the construction industry, this paper serves as a direct follow-up. While the previous one is focusing on detecting and addressing the issue of hallucinations in AI outputs, this study further explores the integration of AI, particularly LLMs, into established knowledge engineering frameworks dynamically to mitigate such hallucinations more effectively.

Technically, this study aims to structure and operationalize tacit construction knowledge into dynamic, scalable systems by following the guidelines of CommonKADS methodology. The case study is centered on National Fire Protection Association (NFPA) fire incidents because fire safety management, a critical area in construction, provides a rich testing ground for these technologies, requiring fast, responsible decision-making under uncertainty [12], [13]. The research demonstrates how knowledge modelling strategy is done by an expert manually and then how LLMs could contribute to automate or speed up some steps by replacing the manual work done by the domain expert by extracting, structuring, and categorizing the elements in a ontological framework for improved safety management decisions.

This combines structured methodologies with the adaptive capabilities of LLMs to set the foundation for future research into scalable and reliable AI-driven systems across the construction industry.

The following sections will look into the integration of Large Language Models in knowledge-based systems. Section 2 will elaborate on the essential forms of knowledge and knowledge modelling, Section 3 will explain the integration of LLMs into KE. This is followed by a case study on fire safety management in Section 4 as a practical application of LLMs into KE processes. This paper will conclude with a short discussion.

2 Knowledge Modelling

Knowledge is a multi-dimensional asset that is critical to human reasoning and decision-making. In the field of knowledge engineering (KE), it is essential to understand and benefit from forms of knowledge to develop systems that simulate expert problem solving. Knowledge is commonly classified into explicit and tacit types, as well as declarative and procedural forms, each presenting unique opportunities and challenges for formalization and utilization in computational systems [4], [14].

Explicit knowledge refers to knowledge that can be

expressed, codified, and shared, such as manuals, standards, and databases. It is relatively straightforward to capture and encode in knowledge-based systems (KBS) using tools like ontologies and knowledge graphs [5], [4]. In contrast, *tacit knowledge* is personal, context-specific, and often unspoken. This includes skills, intuitions, and experiences accumulated over time. This type of knowledge is more challenging to formalize, requiring advanced methodologies and tools for extraction and representation.

Declarative knowledge, or "know-what," captures phenomenological information and relationships, often suitable for logical reasoning and explicit modelling. *Procedural knowledge*, or "know-how," involves the steps or methods for performing tasks, making it valuable in systems that simulate decision-making processes [2], [4].

Methodologies such as CommonKADS provide structured frameworks for transforming tacit and procedural knowledge into explicit, actionable formats. This process consists of three phases: conceptualization (identifying and organizing knowledge), operationalization (structuring knowledge into workflows or rules), and formulation (formalizing it into computational representations) [4], [5].

Knowledge modelling is a cornerstone of knowledge engineering (KE), serving as the process by which knowledge is identified, structured, and formalized into models that are usable by computational systems. The strategy for knowledge modelling is essential for enabling effective decision-making, reasoning, and problem-solving in knowledge-based systems. At its core, knowledge modelling aims to bridge the gap between human expertise and computational implementation by systematically capturing and representing the subtleties of domain knowledge.

Knowledge models are abstract representations of the knowledge embedded in a domain. These models provide a structured framework to capture relationships, dependencies, and tasks, ensuring that knowledge is both understandable and applicable. The CommonKADS methodology outlines a series of models that captures the organizational, task, and agent aspects of a system, including a specialized knowledge model for domain-specific information and reasoning processes [4].

Following the CommonKADS approach, in this research, the knowledge base will be created in three stages:

1. **Conceptualization:** The initial phase involves identifying domain concepts and relationships. This stage captures both tacit and explicit knowledge through interviews, reports, and observations with domain experts. The conceptualization process prepares the ground for formal representation by structuring informal knowledge into a coherent mental model [4].
2. **Operationalization:** After conceptualization, the abstract model is translated into actionable workflows, algorithms, or rules that the system can execute. This step allows the system to mimic expert reasoning and decision-making processes by including input-output relationships, logical dependencies and procedural workflows [2], [5].
3. **Formalization:** The formalization phase is a straightforward translation of the operational knowledge arrangement into the language of the inference engine. This phase involves encoding the operationalized knowledge into formal computational languages, for example codes, or XML representations, such as ontologies, rule-based systems, or knowledge graphs. The ontological alignment can be considered as a complementary and optional phase linking the conceptualization performed with the ISO standards. This aims to enable reasoning and inference while ensuring consistency [4], [5].

However, it should be noted that one of the critical challenges in knowledge modelling is the representation and analysis of tacit knowledge. Experiential and context-specific tacit knowledge is difficult to formalize and integrate into structured systems. This requires intensive and strong expert knowledge, adaptability and serious time dedication.

3 Integrating Large Language Models into Knowledge Engineering

The integration of Large Language Models (LLMs) into knowledge engineering (KE) indicates a transformative shift in the field. LLMs, like GPT-4, are general-purpose technologies that highly useful in processing unstructured natural language, transforming it into formal, structured knowledge representations. This capability contributes one of the most challenging aspects of KE: the acquisition and formalization of tacit and unstructured knowledge. This ability allows them to formalize that tacit knowledge into explicit forms. Their ability to pre-process data complements traditional Symbolic AI, which relies on structured methods such as logical rules. While symbolic AI provides precision and explainability, LLMs contribute with adaptability and scalability.

The integration of LLMs into KE process is achieved by using the logical-linguistic capabilities of LLMs in each step of the CommonKADS protocol as a tool

available to the knowledge engineer to speed up the work and have more control over the soundness and completeness of the elicitation process. The objective of the study is therefore to qualify the various steps of KE processes in terms of the structure and quality of the input knowledge and of the output knowledge. Furthermore, for each step the knowledge engineer's interaction protocols with the LLM should be defined. This interaction, in turn, will be studied through a prompt engineering process examining diverse prompt techniques such as few-shot prompting or chain-of-thought-prompting [15].

This research contribution presents a phase of development the AI-in-the-loop approach that was presented in Durmus et al. [12], demonstrated the integration of LLMs such as GPT-4 in the development of decision support systems in fire safety planning. These developments benefit from the capabilities of AI to adaptively manage and integrate domain knowledge in dynamic building environments, thus improving operational reliability and decision accuracy.

In the following section annotated examples of the main steps will be provided. The proposed results are the outcomes of a work in progress.

4 The Use of LLMs in the Practice of Knowledge Engineering: Case Study (NFPA)

In this section, we will exemplify the proposed methodology using a case study from the NFPA Case Study: Nightclub Fires report [16]. This manual contains a series of reports of catastrophic fire events described by domain experts. These reports represent a good approximation of what an interview with a domain expert might be. The selection of the NFPA nightclub fire incidents, in particular, was based on the availability of concise and comprehensive documentation that fits well with the LLM's ability to process and analyze texts effectively in terms of text length and complexity. The discussion will be limited to one case study and to the first two phases of the KE process as they share a conceptual level of analysis. The formalization phase, which, on the contrary, involves syntactic aspects, requires specific attention and will be addressed in future works of this research.

As a case study for this research, a scenario from NFPA nightclub fire reports has been selected (Figure 1). Each step for the both phases was firstly done by an expert by manual reading and extracting, then we submitted the same fire event narrative to GPT-4 to do same task and assess its responses.

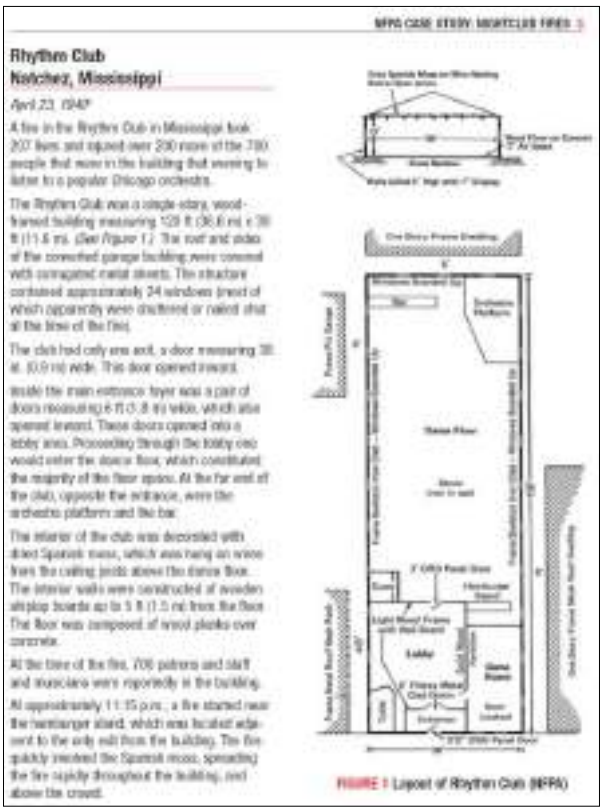

Figure 1: Selected case study from NFPA report

4.1 Conceptualization

The conceptualization phase is the foundation of knowledge engineering and focuses on understanding the domain and structuring knowledge in an informal, human-readable format. This phase increases the clarity and accessibility of domain knowledge through natural language to effectively differentiate between static and dynamic aspects of fire events. This type of structuring helps facilitate the detailed analysis of complex scenarios such as a fire emergency. The goal at this stage is to identify and categorize the critical elements of the scenario and identify key issues. In practice, as shown in the Rhythm Club fire case study, information is organized into two structured categories: context arguments (Table 1) and event arguments (Table 2). This categorization abstracts static building characteristics and dynamic aspects of the fire event and thus provides a framework for systematic analysis. Below, a detailed breakdown presents a clear comparison between the insights extracted by a human expert and GPT-4 and demonstrates the practical application and effectiveness of this approach in real-world scenarios.

a) *Context Arguments*: capture the static, descriptive aspects of the scenario, such as the building's structure, layout, and materials.

b) *Event Arguments:* describe the dynamic elements of the fire incident, including the sequence of events, fire propagation, and occupant behaviour during the emergency.

Table 1: Comparison of the context arguments extracted by human expert vs GPT-4

a) Context Arguments	
HUMAN EXPERT	**GPT-4**
	Prompt: *please extract the arguments in following groups: 1.context arguments, 2. event arguments. List the arguments in bullet points.*
The Rhythm Club was a single-story, wood-framed building measuring 120 ft (36.6 m) x 38 ft (11.6 m).	The Rhythm Club was a single-story, wood-framed building measuring 120 ft by 38 ft.
The structure contained approximately 24 windows (most of which apparently were shuttered or nailed shut at the time of the fire).	It had approximately 24 windows, most of which were shuttered or nailed shut at the time of the fire.
The club had only one exit, a door measuring 38 in. (0.9 m) wide.	There was only one exit from the club, a door measuring 38 inches wide, which opened inward.
This door opened inward.	
Inside the main entrance foyer was a pair of doors measuring 6 ft (1.8 m) wide, which also opened inward.	Inside the main entrance foyer, a pair of doors measuring 6 ft wide also opened inward, leading into a lobby area.
These doors opened into a lobby area.	
The floor was composed of wood planks over concrete.	The floor was composed of wood planks over concrete.
(the list goes on…)	*(the list goes on…)**

*In this phase of context argument extraction, domain experts extracted total 12 arguments and ChatGPT-4 extracted 10 arguments. The accuracy of these results was evaluated using the F1 scoring method [17], and the outcome was 0.90, indicating a highly successful performance.

Table 2: Comparison of the event arguments extracted by human expert vs GPT-4

b) Event Arguments	
At the time of the fire, 700 patrons and staff and musicians were reportedly in the building.	On the night of the fire, 700 patrons and staff, including musicians, were in the building.
At approximately 11:15 p.m., a fire started near the hamburger stand, which was located adjacent to the only exit from the building.	The fire started near a hamburger stand located adjacent to the only exit from the building at approximately 11:15 p.m.
The fire quickly involved the Spanish moss, spreading the fire rapidly throughout the building, and above the crowd.	The fire quickly involved the Spanish moss, spreading rapidly throughout the building and above the crowd.
Patrons in the vicinity of the entrance were able to escape.	Patrons near the entrance managed to escape, but those beyond the lobby area were trapped by the fire.
(the list goes on…)	*(the list goes on…)**

*In this phase of event argument extraction, domain experts extracted total 10 arguments and ChatGPT-4 extracted 9 arguments. The accuracy of these results was evaluated using the F1 scoring method, and the outcome was 0.94, indicating a highly successful performance.

4.2 Operationalization

The operationalization phase focuses on converting conceptual knowledge into structured elements, such as triples, to form a preliminary event ontology structure. This structure includes annotated classes, objects, and relationships in order to build a functional ontology suitable to solve problems.

This phase is conceptually complex because the expert, in order to formulate effective problem-solving strategies by means of rule sets, uses a significant amount of general domain knowledge and introduces considerations and conceptualizations that are not present in the description of the initial event.

4.2.1. Extracting Triples and Ontology Elements

By using previously extracted arguments and the 2D layout of the nightclub, triples were extracted to represent objects, relationships, and events.

Table 3: Comparison of the triples extracted by human expert vs GPT-4

HUMAN EXPERT	**GPT-4**
a) Triples From Arguments	
	Prompt: *From these arguments, please extract triples in subject predicate object form. examples: 1. (Rhythm_Club instance-of SINGLE_STORY_BUILDING) 2. (rc_windows instance-of SET) 3. (rc_exit instance-of DOOR) 4.(rc_entrance_foyer instance-of SPACE) 5. (Rhythm_Club structure wood-framed)*
(*Rhythm_Club* **instance-of** SINGLE_STORY_BUILDING)	(Rhythm_Club instance-of SINGLE_STORY_BUILDING)
(*rc_windows* **instance-of** SET)	(rc_roof_cover material corrugated_metal_sheets)
(rc_entrance_foyer **instance-of** SPACE)	(rc_walls_cover material corrugated_metal_sheets)
(rc_windows **instance-of** WINDOW)	(rc_windows instance-of SET)
(rc_windows **number-of** 24)	(rc_windows quantity 24)
(rc_windows ***status*** shuttered)	(rc_windows status shuttered)
(rc_windows ***status*** nailed-shut)	(rc_windows status nailed_shut)
(rc_exit **instance-of** DOOR)	(rc_exit instance-of DOOR)
(List goes on…)	*(List goes on…)**

*In this phase of triples extraction from the previous arguments, domain experts extracted 45 related triples and ChatGPT-4 extracted 23 triples. The accuracy of these results was evaluated using the F1 scoring method and the outcome was 0.53, indicating a satisfactory performance.

Table 4: Comparison of the triples extracted from 2D layout by human expert vs GPT-4

b) Triples From 2D Layout (Figure 1)	
	Prompt: *From the given layout, extract structured data in the form of triples (subject, predicate, object). Examples:* *1. (rc_bar adjacent rc_orchestra_platform)* *2. (rc_centre instance-of POSITION)* *3. (rc_dance_floor is-at rc_centre)*
(rc_bar **adjacent** rc_orchestra_platform)	(rc_bar adjacent rc_orchestra_platform)
(rc_centre **instance-of** POSITION)	(rc_lobby_area instance-of SPACE)
(rc_dance_floor **is-at** rc_centre)	(rc_dance_floor is-at rc_centre)
(rc_entrance **lead-to** lobby)	(rc_entrance lead-to rc_lobby_area)
(rc_coats_room is-near rc_entrance)	(rc_coat_area is-close-to rc_entrance)
(rc_metal_clad_doors instance-of DOOR)	(rc_entrance instance-of DOOR)
(rc_stove is-at dance_floor_centre)	(rc_dance_floor contains stove)
(List goes on…)	*(List goes on…)**

*In this phase of triples extraction from the 2D layout image, domain experts extracted 32 related triples and ChatGPT-4 extracted 21 triples. The accuracy of these results was evaluated using the F1 scoring method, the outcome was 0.67, indicating a satisfactory performance.

Table 5: Comparison of the objects and classes from the previously extracted triples by human expert vs GPT-4

HUMAN EXPERT	**GPT-4**
c) Objects and Classes	
	Prompt: *From the triples you extracted above, extract 1- classes and objects, 2- relationships as following example:* *1-Objects and Classes* *BUILDING TYPE: single-story-building* *COMPONENT: Windows, Door, Floor, Ceiling joists,....* *2- Relations* *above, access, adjacent, component, connect, connected-to,...*
BUILDING TYPE: single-story-building COMPONENT: Windows, Door, Floor, Ceiling joists, Interior walls, Wooden shiplap boards, Layout, Stove MATERIAL: Wood planks, Concrete, Corrugated metal sheets, Metal clad, Spanish moss STATUS: Flimsy, Dried, Trapped SPACE: Entrance, Foyer, Dance floor, Lobby, Bar, Hamburger stand, Orchestra platform, Exit, Coat area, Game room, Toilet POSITION: corner, center OCCUPANT: Patrons, Staff, Musicians	BUILDING TYPE: Single-story-building COMPONENT: Windows, Door, Floor, Ceiling joists, Stove, Lobby area doors MATERIAL: Wood planks, Concrete, Corrugated metal sheets SPACE: Dance floor, Lobby area, Entrance, Coat area, Game room, Toilet, Orchestra platform, Bar POSITION: Centre, Far end of building, Front FURNISHING: Stove (not in use), Doors (flimsy metal clad) STATUS: Not in use, Locked, Boarded up*
d) Relations	
above, access, adjacent, component, connect, connected-to, decorated, dimension, dimension-wide, hung-on, instance-of, is-a, is-at, is-close-to, is-isolated-from, is-near, is-next-to, is-opposite, layed-over, lead-to, made-of, number-of, open, part-of, status, structure	adjacent, is-at, lead-to, is-close-to, contains, located-in, located-at, number-of, dimension-wide, type, status**

*In this phase of extraction of the ontological elements from previous triples, domain experts extracted 6 classes and ChatGPT-4 extracted 7 categories. F1 score is resulted 0,87. **For the extraction of relations, domain expert listed 26 relations while GPT listed 11, this resulted as 0,59 in F1 scoring.

4.2.2. Developing System Goals

The goals of the system are derived from the Rhythm Club case study by analyzing the emergency dynamics, supported by OSHA (Occupational Safety and Health Administration) guidelines for fire safety. These goals are designed to guide the system's monitoring, planning, and action modules effectively. For example, the catastrophic consequences of a single exit, the rapid spread of fire through flammable materials, and the need for coordinated evacuation directly informed Goal 01 (monitoring safety data) and Goal 05 (leading occupants to safety). By breaking down the emergency into manageable objectives, the goals align the system's actions with real-world needs and ensure adaptive, effective responses. Goals represent strategies to minimize the impact of emergencies. Derived from case dynamics and aligned with OSHA guidelines, these rules include:

1. **Goal 01:** Continuously collect fire-safety information.
2. **Goal 02:** Collect fire-emergency information.
3. **Goal 03:** Alert rescue teams, occupants, and fire departments.
4. **Goal 04:** Mitigate fire propagation through suppression and isolation.
5. **Goal 05:** Lead occupants out of the building quickly.
6. **Goal 06:** Ensure occupant safety during evacuation.

4.2.3. Monitoring Rules to achieve defined goals

Monitoring involves tracking system states using sensor data and triggering actions based on significant changes. These rules interact with the defined goals by ensuring real-time system responsiveness. This interaction ensures that the system adapts dynamically to evolving conditions during emergencies.

The use of the LLM allows the rule-setting phase to be approached in an iterative form, in which the context is examined as a whole, and all relevant aspects are identified and examined and investigated in parallel. At this stage, it is essential to control the semantics of the language in a precise manner. A pseudo language based on triples was used for this purpose. The LLMs was asked to: "write a rule set that monitor the distribution of the fire on a fire safety management system, by asserting the triple: (fire <position> <intensity>), concerning the rhythm_club dance floor" using the whole set of triples defined so far in the conceptualization phase as the query context." LLMs was required to provide the result in: "if <conditions> the <actions> format using triples to express statements"

The LLM provided a structured outcome, tagging each rule with a statement about the issue of the rule is concerned on. The following set of issues has been identified by GPT:

1. Fire Detection at Specific Position
2. Fire Intensity Threshold
3. Fire Spreading to Opposite Spaces
4. …

…

11. Fire Alert for Boarded Windows
12. Decorative Material Hazard

A partial example of the rule set extracted by GPT follows:

1. **Fire Detection at Specific Position**
   If (fire <position> <intensity>) and (rc_dance_floor is-at <position>).
   Then (alert fire_detected_at rc_dance_floor).
2. **Fire Intensity Threshold**
   If (fire rc_dance_floor <intensity>) and (threshold exceeded_by <intensity> 5).
   Then (alert high_fire_intensity rc_dance_floor) and (dispatch fire_team to rc_dance_floor).
3. **Fire Spreading to Adjacent Spaces**
   If (fire rc_dance_floor <intensity>) and (threshold exceeded_by <intensity> 3).
4. …

…

11. **Fire Alert for Boarded Windows**
   If (fire rc_dance_floor <intensity>) and (rc_windows status boarded_up).
   Then (alert ventilation_restricted) and (alert escape_routes_blocked).
12. **Decorative Material Hazard**
   If (fire rc_dance_floor <intensity>) and (threshold exceeded_by <intensity> 2).
   Then (alert high_flammability_material rc_dried_spanish_moss).

5 Results and Discussion

The integration of GPT-4 into the knowledge engineering process revealed both its advantages and limitations. F1 scoring has applied to quantitatively assess GPT-4's performance, with experts manually extracting lists from the same texts queried to the model. These expert-curated lists as presented on the tables served as ground truth, against which GPT-4's outputs were compared. In the conceptualization phase, GPT-4 demonstrated high accuracy in extracting context and event arguments, achieving F1 scores of 0.90 and 0.94, respectively. However, its ability to identify nuanced relationships remained limited, emphasizing the importance of domain expert involvement. During operationalization, GPT-4 efficiently extracted triples and ontology elements, but its performance was moderate in capturing complex relationships, with F1 scores of 0.53 for narrative-based triples and 0.67 for layout-based triples. The tested capabilities showed a potential for automating rules development and was close in content, structure, and case specificity, which indicated alignment with what the human experts could produce. Furthermore, this reveals that GPT-4 provides contextual understanding for generating contextually logical and relevant rules from the scenarios representing complex events such as a fire emergency. Moreover, this is achieved without domain-specific, pre-trained embeddings, matching expert-made guidelines of OSHA, demonstrating strong generalization capabilities of the LLM. Despite these strengths, LLMs' reliance on probabilistic methods remain as a limitation, requiring expert oversight to address gaps; this points back AI-in-the-loop model (Durmus et al., 2024) for a hybrid human-ai collaboration for such complex tasks as fire safety management.

6 Conclusion

This study explores the integration of Large Language Models (LLMs) into the knowledge engineering (KE) process, focusing on their application on fire safety management through a hybrid approach that combines human expertise with LLM capabilities. It presents an innovative methodology for modelling both formal and tacit knowledge for decision-making purposes, demonstrating a promising and original approach to integrating structured methodologies like CommonKADS, with the adaptive and scalable potential of LLMs.

The case study on NFPA fire incidents highlighted GPT-4's potential to automate labor-intensive tasks, such as data extraction and rule generation, while complementing expert knowledge. The outcomes are twofold: first, it makes the knowledge engineering

process more scalable by providing a framework for structuring and operationalizing large volumes of tacit knowledge in a short time frame; second, it offers a tool to address and adapt to unpredictable aspects, such as emergent patterns in dynamic scenarios. While GPT-4 shows strong potential to contribute many steps of the process, its reliance on probabilistic reasoning and LLMs' lack of explainability imply it cannot yet automate the entire workflow. Expert oversight remains crucial to ensure the accountability and reliability of outputs, particularly in high-risk applications like fire safety management.

Future research should focus on automating the formalization phase and its practical applications, includes applying the methodologies and rules developed in this work using tools such as CLIPS to validate the practical implementation of LLMs into hybrid knowledge engineering systems. Expanding case studies across different construction scenarios would evaluate the scalability and generalizability of AI-integrated knowledge systems. These efforts aim to develop robust and efficient decision-support systems for complex and dynamic environments for construction industry.

Abstract -

In recent years, the construction industry has urgently needed to address labor shortages caused by an aging workforce and population decline, drawing increasing attention to automated construction technologies. In this paper, focusing on earthworks, we propose a benchmark indicator composed of two levels: an 'automated construction level', which expresses the degree of technical sophistication following the example of autonomous driving levels in automobiles, and a 'social implementation level', which represents the degree of dissemination of technology through stages from research and development to market adoption. By introducing this indicator, we aim to assess both the automation level of construction machinery operations and the extent of their widespread use.

Keywords -

Autonomous Construction; Benchmark; Earthworks

1 Introduction

The construction sector is confronting a confluence of challenges: demographic shifts have led to a dwindling, aging workforce, tight labor markets push up costs, and the complexity and scale of projects continue to increase [1]. As traditional workflows prove insufficient to meet rising demands for quality, speed, and cost-effectiveness, automation emerges as a critical enabler for enhancing productivity, improving safety, and ensuring operational continuity. Prominent initiatives, such as Japan's i-Construction2.0 [2], aim to boost productivity by integrating advanced digital technologies, automated equipment, and streamlined data exchange mechanisms, aspiring to a 30% reduction in workforce demands by 2040.

Yet merely deploying automated machines is not enough. The industry needs robust frameworks to evaluate the maturity and broader impacts of emerging technologies. An Automated Construction Level (ACL), inspired by autonomous driving classifications defined by the Society of Automotive Engineers, has been proposed to map out the progression from manual operations (Level 0) to fully autonomous site management (Level 5) [3]. However, focusing solely on technical sophistication neglects the equally important dimension of societal acceptance and diffusion. For instance, even a highly advanced technology might remain confined to experimental testbeds if it fails to address market needs, instill user trust, or integrate smoothly with existing practices.

To address this gap, we introduce a benchmark that integrates the ACL with a Social Implementation Level (SIL), inspired by Moore's Chasm Theory [4], Rogers' Diffusion of Innovations [5], and complementary concepts such as Adoption Readiness Levels and Technology Readiness Levels [6]. By defining a two-dimensional matrix, we can situate technologies in terms of both their technical automation maturity and their stage in the social adoption lifecycle. This dual perspective informs developers about the importance of standardizing core planning processes before full automation, encourages investors to calibrate risk based on market penetration rates, assists policymakers in identifying where strategic support might be most effective, and enables end-users to choose tools aligned with their operational readiness.

ARL (Adoption Readiness Level), in particular, focuses on the commercial adoption process and social risks that cannot be fully captured by technological maturity alone. While this broad scope offers a multifaceted perspective, it can make the stage of technology adoption less intuitive to grasp. Meanwhile, evaluating automation in construction requires a comprehensive approach that considers not only the automation level of the machinery itself but also the automation of construction management processes. Although TRL (Technology Readiness Level) is widely used as a general framework for assessing technological maturity, it remains challenging to comprehensively evaluate automation under the diverse conditions unique to construction sites without adopting the SAE-based concepts employed in automotive autonomous driving—namely, DDT (Dynamic Driving Task) and ODD (Operational Design Domain). By aligning our new framework with insights from ARL and TRL, we aim to capture the interplay between technical progression and societal uptake

more holistically, while remaining sufficiently tailored to the realities of the construction industry.

In the following sections, we first elaborate on the concept of Automated Construction Levels (ACL), then propose a parallel Social Implementation Level (SIL), and finally integrate both to form a two-dimensional benchmark. We illustrate this approach with references to current examples of construction automation—such as partially and fully automated machines—and discuss how the combined ACL–SIL matrix can guide various stakeholders in decision-making and policy formulation.

2 Automated Construction Level: Beyond Machine Autonomy to Systemic Intelligence

The ACL framework to date has ranged from:

- **Level 0:** Manual operation with no automation.
- **Level 1:** Operator assistance (e.g., machine guidance) that augments human control while leaving most decision-making to the operator.
- **Level 2:** Partial automation of specific machine functions (e.g., automated blade control), reducing the cognitive load and skill barrier.
- **Level 2.9:** Full automation of a single machine's essential tasks, effectively removing the need for direct operator input in core operations.
- **Level 3:** Coordinated automation across multiple machines on a single site, yet still reliant on site-specific human planning.
- **Level 4:** Automated planning and task allocation, leveraging site data and design schematics to direct multiple machines autonomously within defined operational parameters.
- **Level 5:** Full autonomy across machines and tasks, unrestricted by predefined Operational Design Domains (ODD).

We propose an additional stage: **Level 3.5**, focusing on the generalization and systematization of the construction planning process—known in Japanese practice as "dandori." While Level 3 demonstrates that automation can handle a particular site's complexity, scaling this capability to diverse conditions demands codifying planning logic into a machine-readable, standardized framework. By achieving Level 3.5, developers set the stage for more readily attainable Level 4 and 5 solutions.

Examples from the industry underscore the necessity of this intermediate level. Current site-level automation cases, such as automated dam and tunnel construction using coordinated fleets of machinery [7], rely heavily on expert planners and site managers. Without codifying these human planning heuristics, scaling up remains prohibitively expensive and complex. Level 3.5 thus represents a strategic stepping-stone: it encourages a focus on knowledge representation, standardized planning protocols, and interoperable data models.

3 Social Implementation Level: Aligning Market Penetration with Trust and Adoption

Technological capability alone does not guarantee acceptance. Innovations must navigate the chasm between early enthusiasts and the mass market. Drawing on Moore's Chasm Theory and diffusion models, we categorize social implementation into:

- **Level 1:** Laboratory-scale R&D, prototypes, and pilot projects with negligible market presence.
- **Level 2:** Limited field trials and early demonstrations, potentially with small-scale commercial pilots.
- **Level 3:** Initial commercialization with constrained market penetration, adopted by specialized or niche segments.
- **Level 4:** Approaching the "chasm", technology gains footholds in multiple segments, nearing the early market's 16% threshold. Customer testimonials and early references start to build trust.
- **Level 5:** Stable adoption exceeding approximately 20% market share, suggesting a shift from novelty-driven acceptance to widespread trust and integration into industry norms.

The precise definition of market share depends on selecting an appropriate reference population. Construction markets are heterogeneous: a technology suitable for large-scale earthworks in infrastructure projects might not translate directly to residential or specialty construction. Thus, determining the relevant "market universe" is essential. Efforts to standardize reporting—potentially through industry associations or regulatory bodies—could help normalize these metrics.

4 Integrating the Two Axes: A Two-Dimensional Benchmark

By plotting ACL on one axis and SIL on the other, we create a two-dimensional matrix (Figure 1) that situates technologies within a nuanced landscape. For instance:

- **Teleoperation (ACL 0, SIL 3):** Remote controlled machines have been proven in disaster recovery since the 1990s [8]. Although technologically simple (human-operated), their wide acceptance in niche

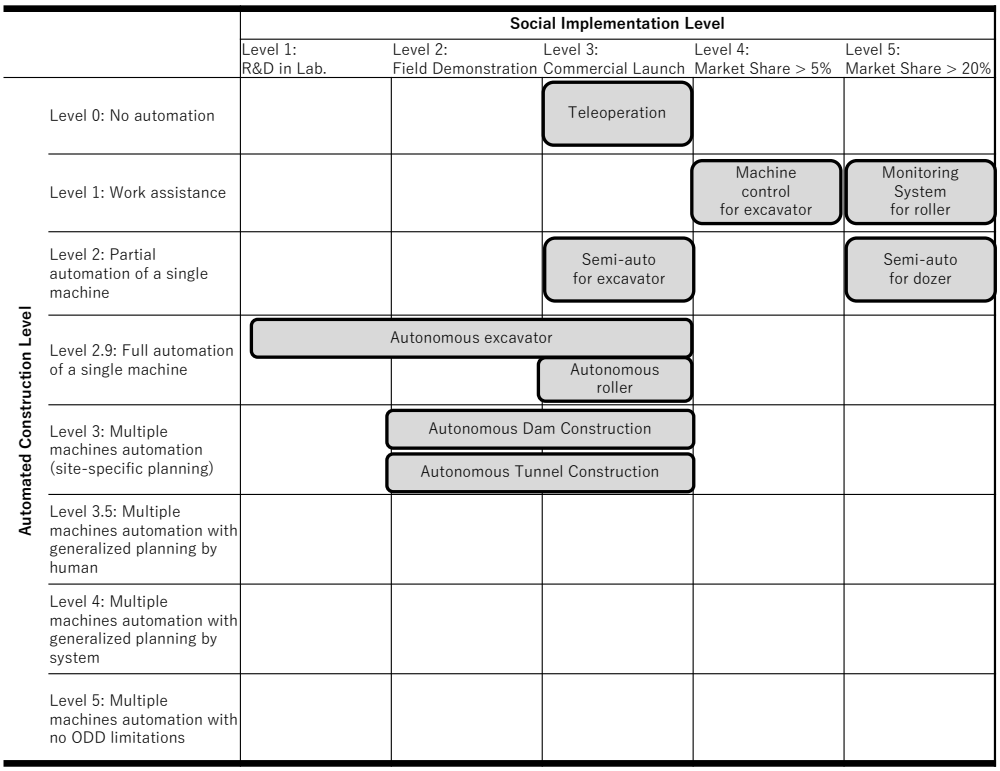

Figure 1. Evaluation of Automated Construction Technology Using Benchmark Indicators

scenarios places them around Social Implementation Level 3.

- **Machine Control System (ACL 1, SIL 4-5):** . In Japan, it is called machine guidance. Excavator machine control systems using GNSS, laser-based sensors, and 3D design data are widely available. Multiple manufacturers offer them and, in some regions, more than half of excavators can incorporate guidance features, pushing them into SIL 4 or 5.
- **Semi-auto system (ACL 2, Various SIL):** In Japan, it is called machine control. Automated blade control for bulldozers or partial autonomy in hydraulic excavators can boast significant market penetration, potentially reaching SIL 5 for certain machine categories [9].
- **Fully autonomous machine (ACL2.9, SIL 1-3):** Most fully autonomous machines remain trapped at R&D or prototype levels (SIL 1-2) [10, 11, 12, 13]. However, some autonomous excavator and roller have already been launched [14, 15].
- **Site-Level Automation (ACL 3, SIL 2-3):** Projects such as automated dam and tunnel construction [7] exemplify site-wide automation. However, these remain bespoke, heavily engineered solutions, with minimal standardization and limited replication across diverse projects.

Crucially, we find no examples at ACL 3.5, 4, or 5, nor do we see technologies in widespread, stable mainstream use at a corresponding SIL for these higher ACLs. This observation reveals a strategic opportunity: bridging the technical and social dimensions is not simply about incremental improvement, but about systemic change, collaborative data standards, and knowledge exchange.

5 Discussion and Future Directions

Our benchmark reveals that while some technologies, such as machine guidance, are well integrated and widely trusted, others, such as fully autonomous excavators or site-level systems, remain at an early stage. For researchers and developers, ACL 3.5 stands out as a priority: codifying planning processes to reduce site-specific engineering costs. Investors, meanwhile, can better calibrate risk by noting whether a technology aligns with established mainstream practices (SIL 5) or remains experimental (SIL 1–2). Since there are still few real-world cases in ACL 3 or higher, further development of these technologies should be accompanied by large-scale empirical studies and rigorous statistical analyzes to thoroughly validate and refine the proposed benchmark.

Policymakers can use these metrics to allocate resources and encourage standardization. Supporting common data protocols, testbeds, and training could streamline the transition from isolated successes to broad adoption. Prac-

titioners benefit by selecting tools that match their operational readiness and understanding whether a particular solution is proven or still exploratory.

Future refinements may involve adding sub-levels, incorporating sustainability metrics, or considering regional market nuances. Aligning this benchmark with efforts in related industries—such as automotive or mining—could further enhance its clarity and relevance. As the construction automation ecosystem evolves, continuous feedback will help refine both ACL and SIL scales, ensuring they remain practical and reflective of real-world conditions.

6 Conclusion

This paper introduced a benchmark framework that unites technical maturity (Automated Construction Level) with societal diffusion (Social Implementation Level) to provide a holistic perspective on automated construction technologies. By incorporating a novel ACL 3.5 stage that emphasizes the formalization of planning logic, and linking market penetration milestones to known thresholds of consumer acceptance, the benchmark reveals strategic development pathways and potential gaps.

In practice, this framework offers value to multiple stakeholders: researchers gain clearer R&D targets, developers appreciate the importance of systematic planning processes, investors gauge market readiness more accurately, policymakers identify priority support areas, and practitioners discern which technologies fit their current needs. Although still in a formative stage, our benchmark invites further input, adaptation, and validation. By continually refining these metrics, the construction industry can move toward more transparent, data-driven decision-making and accelerate the meaningful adoption of automation on construction sites worldwide.

BIM-Based Public Participation: Insights and Lessons Learned from a Case Study

Jonathan Matthei[1], Maximilian Friedhelm Heinrich Christ[1], Sven Mackenbach [1], Katharina Klemt-Albert[1]

[1]RWTH Aachen University, Germany
matthei@icom.rwth-aachen.de, m.christ@icom.rwth-aachen.de, mackenbach@icom.rwth-aachen.de, klemt-albert@icom.rwth-aachen.de

Abstract

Public participation is critical to the success of construction projects as it enables citizens to influence and engage in planning processes. Traditional participation methods often rely on two-dimensional technical plans, which are frequently perceived as difficult to understand, particularly by non-experts. In recent years, digital visualization techniques, especially 3D models, have emerged as promising alternatives. These approaches promise to enhance communication among stakeholders and deepen engagement by offering clearer and more comprehensible representations of construction projects.

This paper explores how public participation based on 3D BIM model data can be implemented and examines the user experiences associated with such an approach. The concept is built on a 3D BIM model-based participation platform integrated with a Common Data Environment (CDE), which serves as the source for three different model variants.

A prototype of the participation platform was tested in the context of public involvement for the redesign of a mobility space in a German city. Citizens were therefore invited to interact with the various model variants and actively participate in the process.

Findings from this initiative demonstrate that guided textual information with 3D visuals enhances citizens' comprehension of the project. Users particularly valued the 3D models for enhancing their understanding, while expressing a preference for rather realistic models, even if they are more complex. In summary, the results suggest that BIM models can significantly enhance public participation by improving comprehension and engagement, ultimately contributing to social sustainability.

Building Information Modeling (BIM), public participation, 3D visualization, e-participation, participatory planning, Scrollytelling, Common Data Environment (CDE), social sustainability

1 Introduction

Public participation plays a crucial role in the success of construction projects [1], as it enables citizens to exert influence and contribute to the decision-making processes of projects planned within their communities [2]. Inadequate integration of the public in planning processes can have significant consequences, including protests, legal disputes, and delays in project timelines. These issues often result in construction projects failing to meet budgetary and scheduling targets [3].

Understandable visualizations are considered fundamental for successful public participation [4]. According to King et al. (1989), visualizations are the only common language that all stakeholders, both technical and non-technical, can refer to [5].

Currently, primarily two-dimensional technical plans, floor plans, sections, and views are provided as supporting visualizations of the project to the public [3]. Consequently, technical drawings represent the most commonly used method for visualizing construction projects [2].

However, there is a consensus that these are generally difficult to understand, especially for stakeholders with little or no experience in interpreting maps [1; 3; 6]. Consequently, such forms of representation can be considered outdated and ineffective in the context of public participation.

With the increasing digitization in recent years, methods have increasingly been employed that promise improved communication and representation of information [2]. These novel visualization methods are often closely linked to digital participation formats, collectively referred to as e-participation measures. At the core of these measures are Information and Communication Technologies (ICT), which aim to facilitate and make the exchange between stakeholders more efficient [7].

Numerous studies can be found that examine the role of digital visualization formats and their impact on public understanding and participation.

The study by Skaaland and Pitera (2021) investigated the use of digital visualization techniques in the context of public participation in infrastructure projects in Norway. A survey was conducted among professional users in the Norwegian infrastructure sector, comparing various visualization techniques to examine their impact on public understanding. The study identified that digital visualization models led to a statistically significant increase in public understanding and engagement compared to traditional visualization models [2].

In another study by Onyimbu et al. (2018), the use of 3D visualizations in the context of digital public participation in Kenya was examined. Questionnaires were sent to planners to assess the user-friendliness of 3D visualizations. The study concluded that the use of 3D visualizations has the potential to improve both the quality and quantity of public participation. Consequently, 3D visualizations are able to promote the involvement of stakeholders and enhance their understanding of the proposed plans [1].

This finding aligns with the statement by Milosz, who further emphasizes that digital 3D models allow non-experts to have more control over what they want to see, as opposed to what planners want to show them [8].

The research project VISB+ examined the contribution of visualizations to improved communication of construction plans. Various visualization approaches were analyzed within the study, with interactive visualizations being particularly highlighted for their added value. Furthermore, the study emphasizes the potential benefits of applying Building Information Modeling (BIM) in the context of public participation [4].

BIM represents a methodology that has seen increasing adoption in the construction industry since the early 21st century. Fundamentally, this approach relies on the use of digital building models and the semantic information within these models throughout the entire lifecycle of a building [9]. Buildings are represented as three-dimensional models, with each component being detailed and digitally depicted [4].

By using BIM models, different planning variants can be visualized and made tangible in the real environment [3]. Furthermore, these models allow for the interactive integration of additional layers of information, such as noise propagation or shading effects. This could significantly simplify communication in the context of public participation and contribute to greater transparency, as well as enhance the social sustainability of construction projects [3].

Despite this potential, the VISB+ study concludes that the use and research related to the application of BIM models for public participation is still limited. In particular, there is a lack of comprehensive studies on how these models can be effectively integrated into participatory processes to foster broad acceptance and understanding among non-technical stakeholders. Therefore, further research and development efforts are necessary to explore the application of BIM in the context of public participation.

The aim of this study is to examine the use of BIM model data in the context of public participation and to collect user experiences in this regard.

The study is part of the research project BIM4People, funded by the Federal Ministry for Digital and Transport in Germany. As part of this project, a digital participation platform is being developed, which presents BIM model data and will be tested and optimized through several real-world use cases.

This study provides a comprehensive overview of the approach and findings from a case study of a BIM-based participation platform. The case study is situated in a German city with approximately 100,000 inhabitants, representing a voluntary initiative to explore innovative means of involving the public in urban development projects.

The underlying concept of BIM-based participation is detailed in the following second chapter. Additionally, the study area, the model variants, and the opportunities for public participation are described. In the third chapter, the empirical study that accompanied this case study is presented. The aim of the empirical study is to identify the user experience of participants in relation to the BIM-based participation platform. The study aims to gather insights into how digital 3D models can be effectively integrated into public participation processes to enhance transparency, foster acceptance of construction projects, and explore public perceptions of these models. This chapter includes the specific research topics as well as the corresponding findings. The final chapter of this study provides a discussion and conclusion regarding the case study of public participation based on BIM model data.

2 The concept of BIM-based public participation

At the core of BIM-based public participation are two key software products. On one hand, there is a Common Data Environment (CDE), which serves as the central information source. A CDE is used to collect, manage, and disseminate relevant information related to a specific project [10].

In the study discussed below, three model variants were developed collaboratively by the city and the planning office as part of a BIM-based planning process. These models were created using authoring software and subsequently uploaded to the CDE in Industry Foundation Classes (IFC) format. This approach facilitated a centralized storage system, enabling collaboration and data exchange among the different

stakeholders.

In this use case, the IFC model was subsequently integrated into the city model developed during the urban planning concept phase. The city model itself was also available as an IFC file.

Since a CDE is primarily designed as a planning tool for professionals, a second software product, a digital participation platform, is developed and subsequently used for a case study. This platform enables the public to view the model variants through an IFC viewer and access the associated information, allowing them to actively participate in the planning process.

In order to display the IFC models on the platform, xeokit, an IFC viewer which allows open-source 3D graphics formats to be displayed in the browser [11], was used.

The study described below incorporates a Google Maps layer into the BIM-based platform as an additional feature for spatial orientation. This integration highlights the geographical context of the project, displaying its location in relation to the existing urban structures. The familiar Google Maps interface is intended to enhance users' comprehension of the project's spatial context by offering a clear and intuitive visualization of the area in which the project is situated.

The concept of BIM-based participation, which is based on the research findings of Matthei et al. (2024) [12], is summarized in the following figure.

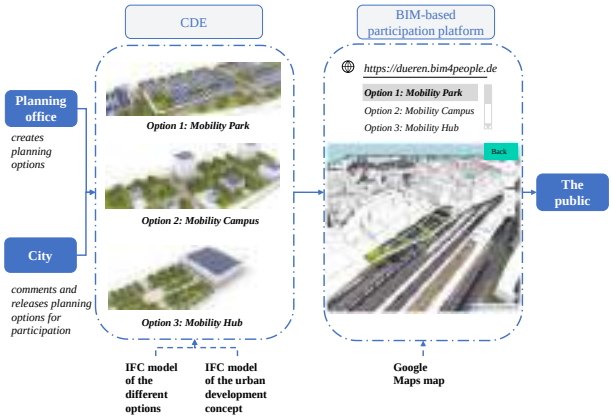

Figure 1. Concept of the BIM-based public participation

2.1 Study area

The study area for the BIM-based public participation concept is located in Düren, a city of approximately 100,000 residents, situated between Aachen and Cologne. Due to its location in a densely populated state and between two major cities, Düren has a high number of commuters. The city is also significantly impacted by the structural transformation from the coal phase-out, with job losses, weakening supply industries, and declining retail purchasing power [13].

An urban development project is planned along Düren's main train station, where a new 150,000 m² district will be created. A specific area within this project will focus on developing and evaluating innovative mobility solutions. In this area, the BIM-based public participation using three model variants is located.

2.2 Model Variants and Participation Opportunities

Three model variants were developed early in the BIM-based planning process to be assessed during the public participation phase. These are preliminary drafts, not detailed plans, aimed at gathering public input on needs and preferences. Option 1 (Mobility Park) emphasizes mobility services, open spaces, parking, green areas, and solar roofs. Option 2 (Mobility Campus) features modern parking towers with automated parking and sustainable materials. Option 3 (Mobility Hub) focuses on a compact building with integrated uses.

Each option is supplemented with brief textual descriptions on the BIM-based participation platform, providing citizens with a clearer overview of the content. The presentation of the variants is done in the format of "scrollytelling," which serves as a promising tool for conveying complex information in an understandable way [14]. In scrollytelling, participants navigate from one story point to the next by scrolling. Each story point represents specific locations or situations within the model that have been pre-selected to guide users through the respective variant in a structured manner. These story points are accompanied by explanatory texts that provide additional information about the displayed scenes, deepening the users' understanding of the content.

The model is automatically aligned with the location described in the text, establishing a strong connection between the visual content and the accompanying texts. This methodical linkage aims to enhance the understanding of the complex spatial and urban planning relationships. In addition to the guided presentation, citizens have the opportunity to freely explore the model variants. Participants can switch between views, zoom in, and rotate the 3D model, allowing for a more personalized and comprehensive impression of the planning variants. Public participation takes place by allowing citizens to view the model variants, create their own contributions, and to read contributions from other users, which they can also agree with. When submitting a contribution, users have the option to associate it with one of the three model variants and place a marker at a specific location within the model (see figure 2). This allows concerns to be linked to a precise spatial allocation, facilitating clearer understanding of the issues raised. Additionally, contributions can be categorized by topic to facilitate targeted processing of concerns by the city administration.

Figure 2. Participation opportunity on the BIM-based participation platform

3 Empirical study

3.1 Proceedings

As part of the BIM-based public participation process, 600 flyers were distributed within the study area, supplemented by announcements in local newspapers, on the city's website, and through social media channels. A QR code and a direct link to the participation platform were provided to facilitate access and encourage public engagement. The public participation period was open from October 24, 2024, to November 17, 2024.

To capture detailed user experiences, a survey was integrated directly into the BIM-based participation platform. Participants were invited to take the survey on the final page of the platform after reviewing the different model variants. Additionally, users who submitted a contribution were also prompted to complete the survey. This methodology aimed to gather a broad and representative sample by encouraging both passive and active users to participate.

The survey is divided into two sections. The first part collects demographic and socio-economic information about the participants, including gender and age. In addition, participants are asked about their relationship to the particular city, e.g. whether they are residents or commuters. The section also gathers information on their previous experiences with public participation in general.

The second part of the survey aims to gain detailed insights into the user experience of participants with the BIM-based participation platform. It focuses on experiences related to navigation and spatial orientation within the 3D models. Additionally, the usefulness of various platform functionalities is examined, including the georeferenced placement of contributions, the guided presentation of content through scrolling on the platform, and the categorization of contributions. Another key focus is on how the 3D representations help participants better understand the project and how useful the ability to compare different project variants using a 3D model is. The second part of the survey is conducted through multiple-choice questions on a 5-point Likert scale.

3.2 Findings

The following subchapter present the key findings from the conducted BIM-based public participation process. First, general observations are presented, followed by user experiences based on the insights gathered from the survey placed on the platform.

3.2.1 General findings

The BIM-based participation platform had 593 unique users, with an average visit duration of 3 minutes and 39 seconds. Of these, 364 users accessed the platform via mobile devices (61%), spending an average of 2 minutes and 12 seconds, while 229 users accessed it via desktop, spending an average of 4 minutes and 40 seconds.

Among the 593 visitors, 76 individuals were returning users, indicating that they accessed the platform multiple times. A total of 24 contributions were submitted on the platform, 16 of which included a direct link to the respective variant referenced in the comment. The first variant was linked six times, making it the most frequently referenced option. Furthermore, in three instances, contributions were linked to specific locations within the model.

An analysis of the thematic categorization of contributions revealed that in 71% of cases, the assigned topic accurately matched the content of the submission.

3.2.2 User experience

A total of 23 individuals participated in the survey aimed at identifying user experiences. Of these, 21 respondents completed at least 80% of the survey. The following section exclusively presents the findings derived from these 21 participants.

The participant background reveals that 86% had never participated in public engagement activities before. Regarding gender, 48% identified as male, 43% as female, and two participants chose not to disclose their gender. In terms of their relationship to Düren, 41% lived there, 18% worked in the city, and 27% commuted for work. The age distribution was balanced across 18-64 years, with a slight prominence in the 25–34 age group. No participants were under 18 or over 64, and one participant did not provide their age (see table 1).

Table 1 Age Distribution of Survey Participants

Age	Number
<18	0
18-24	4
25-34	5
35-44	4
45-54	3
55-64	4
>64	0
n/a	1

The evaluation of user experiences with spatial orientation and navigation in the 3D model shows that 33.33% of respondents found orientation to be "neither easy nor complicated," while 20% experienced some difficulty, and 15% found it "very easy." Regarding navigation, 38.10% rated it as "very easy," 23.81% found it "somewhat difficult," 14.29% considered it "somewhat easy," and another 14.29% viewed it as "neither easy nor difficult." One participant, aged 55–64, found navigation "very difficult." A detailed representation of these results is provided in the following figure.

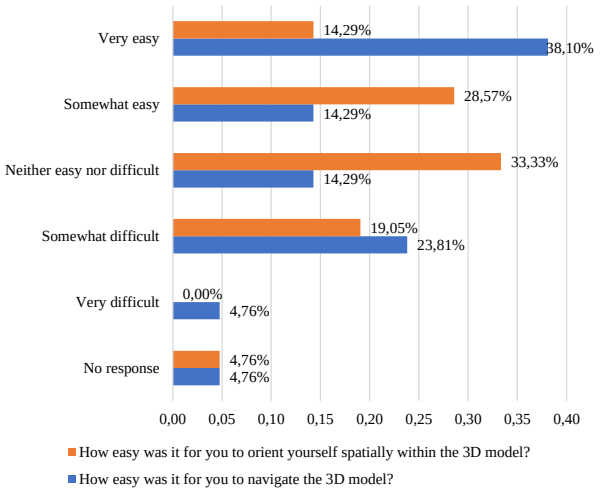

Figure 3. User experiences regarding orientation and navigation in relation to the 3D model

The investigation of functions on the BIM-based participation platform revealed that the guided presentation of information (scrollytelling) with textual and 3D model elements was seen as helpful by most participants. Over two-thirds rated it as "very helpful" (47.62%) or "somewhat helpful" (19.05%), with 14.29% neutral. The ability to assign contributions to specific locations was considered "somewhat helpful" by 35% of respondents, with an equal number providing no answer. About 15% found it "very helpful," and 10% neutral. Categorizing contributions by theme was mostly rated as "somewhat helpful" (30%) or "very helpful" (25%), while 15% were neutral and 15% found it "somewhat unhelpful".

Regarding 3D visualization, 90% of participants said it somewhat improved their understanding, with 45% rating it "very helpful" and 45% "somewhat helpful." The comparison function of different variants using the 3D model was rated positively, with 50% finding it "very helpful" and 33.33% "somewhat helpful." A detailed overview of the evaluation is shown in the following figure.

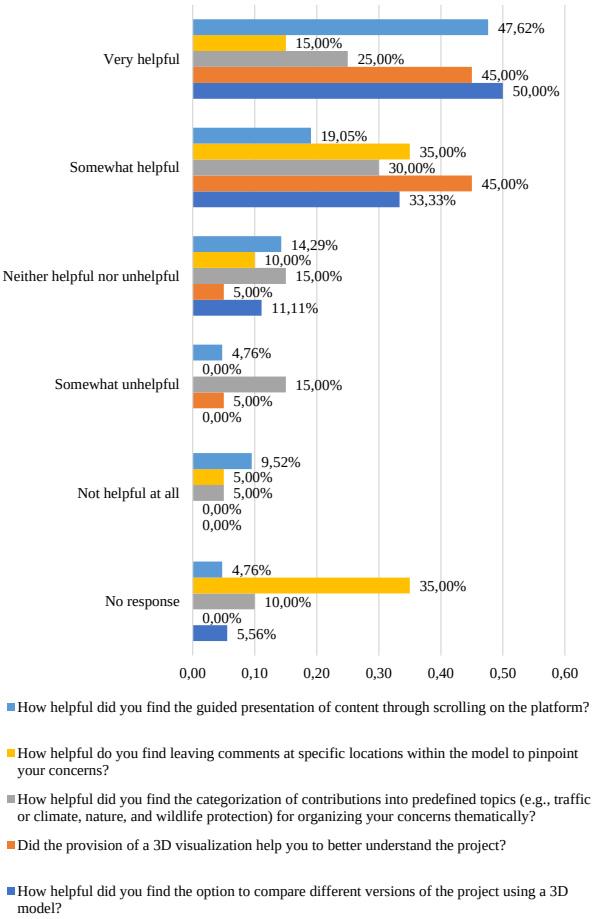

Figure 4. Usefulness of different functions

The majority of respondents preferred more realistic 3D models, even at the cost of increased complexity. About 17% favored a very realistic model, despite potential complexity, while 39% preferred a realistic model that was somewhat complex. One-third sought a balance between realism and simplicity, and only 5.56% desired a very simple, minimalistic model with little realism. No participants preferred a simple, unrealistic model. Detailed results are shown in the following figure.

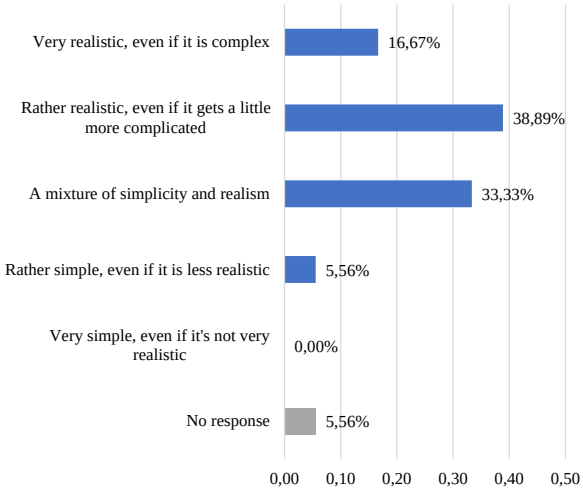

Figure 5. Respondents' 3D model detail and realism preferences

4 Discussion and Conclusion

4.1 Discussion

This case study of BIM-based public participation shows that 63% of users accessed the platform via mobile devices. However, desktop users spent more than twice as long on the platform, suggesting that while mobile devices are convenient, desktops offer a better experience for in-depth engagement, likely due to larger screens and easier navigation of complex 3D content.

Although the platform recorded a total of 593 different visitors and was available to the public for 24 days, only 24 contributions were made. This low level of participation may be due to the need to register by email when creating contributions and the mandatory public visibility of these. Low-threshold access could therefore significantly increase the willingness to participate in the future. However, the possibility of low-threshold participation harbors the risk that people will participate without having a deeper connection to the topic and without being directly affected by the measures under discussion [15]. The phenomenon of “slacktivism” or “clicktivism” can occur in this context. This term describes a form of digital participation in which people get involved through simple, often situational actions such as liking, sharing or commenting, often without deep engagement or direct personal impact [16]. The result would be a distorted participation result. Another reason for the low participation level may be due to the high information density of the platform, which could have overwhelmed users and hindered active engagement.

The active linking of contributions to the model variants was carried out for the majority of posts (16 out of 24). This indicates that the majority of users consider the option of linking their concerns directly to specific model variants to be valuable and useful. In three cases, contributions were linked to specific model locations, suggesting the function was useful to some participants.

A common problem in public participation is the lack of representation: The same, particularly committed citizens often take part, which can lead to a distorted picture of the opinions and interests of the population. Only a specific, actively engaged group participates regularly, while the majority hardly uses the opportunities for participation. As a result, the population structure often remains incompletely represented and the results of participation do not necessarily reflect the entirety of those affected [17].

The results of this study, however, present a different picture: A large majority of participants (86%) reported that they had never previously participated in a public engagement process. This high proportion of first-time participants suggests that the digital participation platform was successful in reaching individuals who would otherwise not engage in traditional participation opportunities. Additionally, the age data from the survey indicates a broad distribution of participants. The age groups between 18 and 64 years are almost evenly represented, with a slight concentration in the 25–34-year-old category. This suggests that the platform also appeals to younger adults, a group that is often underrepresented in traditional forms of public participation [18].

The balanced gender distribution and the presence of both residents and commuters among participants suggest that the platform successfully appeals to a diverse user group. These findings indicate that digital participation platforms can reach a broader and more varied audience than traditional formats.

The results regarding the analysis of user experiences of spatial orientation and navigation in the 3D model show mixed experiences. In connection with orientation in the 3D model, around a third of respondents felt that orientation in the model was neutral, which indicates that the 3D model is functional in terms of orientation, but not particularly intuitive for many. This leaves room for optimization in connection with orientation support within 3D models. If necessary, additional introductions or tutorials could help to promote orientation within 3D models for citizens.

The majority of respondents found navigation within the 3D model "very easy," suggesting that the interactive controls are well-implemented and intuitive. This may be due to the increasing accessibility of immersive technologies, familiarizing more people with 3D models [19]. However, about a quarter of participants found navigation "rather difficult," indicating potential challenges related to varying technical skills or devices.

The conclusions drawn from the analysis of the various functions of the BIM-based participation

platform show that the platform is perceived as helpful and user-friendly overall. The guided presentation of information (scrollytelling), which consists of textual and 3D model elements, was rated particularly positively. Over two thirds of participants found this function helpful, which indicates that clear and structured information transfer in conjunction with interactive visual elements promotes user understanding.

A large proportion of respondents also found it helpful to locate contributions at specific points in the model, which underlines the importance of the spatial allocation of a contribution in the context of participation. Nevertheless, there was a considerable number of participants (35%) who did not provide any information on this, which could indicate that this option was not sufficiently pointed out or that it is still considered less relevant at such an early planning stage. The categorization of contributions according to thematic categories was predominantly seen as helpful. This shows that structuring contributions thematically allows for a better overview and targeted discussion of specific aspects of a project. However, some respondents found this function less helpful, which may indicate that an even finer adjustment of the categories or additional filter options could be useful.The provision of 3D visualization was rated as helpful by almost all participants, confirming that visual representations of complex projects significantly improve understanding. In particular, the ability to compare different variants of the project in the 3D model was found to be extremely helpful by the majority of users. This shows that the visual comparison of project variants, in addition to the textual comparison, is considered valuable by users and can contribute to a better understanding of the project.

Several conclusions can be drawn from the respondents' preferences regarding the level of detail and realism of 3D models: Firstly, there is a high demand for realistic representations. The majority of respondents prefer realistic 3D models, even if this is associated with increased complexity. This indicates that a detailed and realistic visualization is perceived as more important for the understanding and acceptance of the project than a simplified representation. Furthermore, there is an acceptance of complexity for better information content. The willingness to prefer more complex models shows that users value detailed information and are prepared to accept greater complexity in favor of better understanding. This speaks in favor of using models that reproduce details as accurately as possible. Regardless of this, a need for balance can be seen among some users. Around a third of respondents prefer a balance between realism and complexity, which indicates different user needs and abilities. In addition, there is a low demand for simple models. This is reflected in the very low preference for simple or highly abstracted models.

4.2 Conclusion

Digital transformation, particularly through Building Information Modeling (BIM), is enhancing infrastructure planning and public participation. BIM enables three-dimensional representations, improving transparency and comprehensibility compared to traditional visualizations, potentially fostering more intensive citizen engagement.

As part of this study, an approach for BIM-based public participation was developed that makes it possible to present BIM model variants located in a CDE to the public using a digital participation platform. As part of a case study in the course of redesigning a mobility space in a German city, initial empirical values were collected in order to evaluate the applicability and user-friendliness of a participation platform based on 3D BIM model data.

The study aimed to understand user perceptions of the platform and identify challenges and opportunities in interacting with 3D visualizations and other features.

The BIM-based public participation process has shown that guided information transfer (scrollytelling) in conjunction with interactive visual elements can be considered helpful. Citizens consider the possibility of seeing the project in 3D and comparing variants in this way to be helpful for their understanding of the project. The option of linking contributions with different model variants was frequently used in this context.

The evaluation of navigation in the 3D model is predominantly positive, which suggests that it is generally easy to use. Orientation in the 3D model also tended to be rated positively, although some users perceived this as “rather difficult”. This indicates a need for optimization in order to improve spatial orientation when using 3D models.

The background information on the participants suggests that a digital participation platform is a suitable medium for reaching a broader and more diverse spectrum of the population than is possible in traditional formats. In this context, digital public participation represents an important step towards inclusive participation, a key element of social sustainability.

With regard to the level of detail of 3D models, this study has shown that realistic and detailed 3D models are considered more useful for public participation. However, in order to take different user needs into account, a platform that allows flexible adjustment of the level of detail - from detailed to simplified representations - could be useful.

This study has demonstrated how public participation can be facilitated using BIM model data. The results of this case study suggest that a guided presentation of information, combined with interactive 3D visualization, can significantly enhance citizens' understanding of planned projects. This structured approach appears to be effective in making complex content more accessible and comprehensible, potentially improving the quality of

public participation. However, it is important to acknowledge the relatively small number of participants who actively engaged with the platform beyond merely accessing it. While 593 users visited the site, only 23 individuals participated in the user experience survey. This raises the question of whether some users were deterred by the platform's technological aspects, particularly the 3D models, which could challenge the assumption that BIM-based visualization inherently fosters greater participation. This paradox warrants further investigation.

Future studies should expand the sample size and use detailed models for deeper insights into user experience and acceptance. Comparing 3D visualizations with 2D plans can clarify their advantages in participation, comprehension, and decision-making. Furthermore, integrating citizen feedback into BIM-based planning remains essential.

Acknowledgment

This paper was written as part of the BIM4People project, funded by Germany's Federal Ministry for Digital and Transport. The model variants were created by Carpus + Partner AG, and the BIM-based participation platform by Interactive Pioneers GmbH.

Abstract –

The post-pandemic rise in Computer-Aided Design (CAD) tool adoption has driven a shift toward accessible, cost-effective open-source and "Do-it-yourself" (DIY) CAD tools, increasingly favored by individuals, small and medium sized enterprises (SMEs), and entrepreneurs over proprietary software. Despite their growing popularity, none of the existing studies investigate the security of these open-source CAD tools, particularly when users download and install them on personal devices. This study addresses this key research gap by identifying vulnerabilities of open-source CAD tools used specifically in the Additive Manufacturing (AM) process using the Zed Attack Proxy (ZAP) scanner. A web-based security assessment of five widely used CAD tools was conducted, where 25 unique web-based vulnerabilities were identified. This study provides valuable insights for SMEs operating in the architecture, engineering, construction, and operations (AECO) industry by highlighting the potential risks associated with using open-source CAD tools. These risks include the corruption of critical information on user machines, manipulation and loss of CAD data, and unavailability of CAD tools to operate. Such issues directly impact the core principles of cyber security i.e. confidentiality (C), integrity (I), and availability (A) highlighting the critical need to address these vulnerabilities and ensure secure use of open-source CAD tools.

Keywords –

Common weakness enumeration (CWE); Cyber-attacks; AECO; CAD model; Application security testing; Web based attacks.

1 Introduction

Computer aided design (CAD) tools are essential in the additive manufacturing (AM)/Three-Dimensional (3D) printing process, serving as the primary tools for designing and verifying models across various industries. They are used to create, modify, and analyse designs, ensuring that the final product meets specific requirements. Recently, there has been an increasing use of CAD tools across various sectors or industries—whether in large organizations within industries like construction, heavy manufacturing, or aerospace, or by smaller businesses and startups looking to design on a smaller scale. CAD tools are also widely used by civil engineering students, general and sub-contractors, architects, small business owners, and freelancers working on projects or prototypes [1].

However, with the growing reliance on CAD tools, a critical question arises about their cybersecurity. Since CAD tools are among the first steps in the additive manufacturing (AM) process, it is important to assess how secure these tools are. According to [2] and [3],, the AM process can be divided into five key phases: CAD, Finite Element Analysis (FEA), slicing, printing, and assembly. While much research has been conducted on the security concerns in later stages of the AM process (such as slicing and printing), there is a significant gap in the literature when it comes to cybersecurity vulnerabilities in the CAD phase, particularly during the tool download and installation process. This study focuses on the initial phase evaluating the security of CAD tools. Each of these phases' present unique cybersecurity risks and understanding the vulnerabilities at the CAD phase is crucial for ensuring the overall security of the AM process. The risks associated with downloading and using CAD tools have not been fully explored, even though this phase is often the first line of attack. The problem lies in the insufficient research and lack of attention to cybersecurity risks, particularly during the CAD tool download and installation phase.

There are several common types of potential cybersecurity attacks that users may encounter during the usage of CAD tools. As per [4], these attack], these attacks can exploit vulnerabilities in both the software and the data it generates or handles. Some of the frequently encountered or potential threats when using CAD tools include: 1) Malware Insertion during CAD tool download; 2) Denial of Service (DoS) attacks when users brose related web pages, making them unavailable

to legitimate users; 3) Social Engineering attacks, where attackers trick users to reveal their credentials and designs; 4) Ransomware attacks targeting CAD tools, where users are locked out or their files are encrypted; 5) Vulnerabilities in the CAD tool itself, which may be exploited by attackers[5].

As mentioned in [6], open-source CAD tools open source CAD tools are often more vulnerable to cyber-attacks for several reasons which includes: 1) Visibility of source code in the public domain, allowing hackers to inspect, identify, and exploit vulnerabilities; 2) Inconsistent updates and maintenance, despite community support and upkeep; 3) Limited human resources for security management; 4) Fewer security standards compared to paid CAD tools. Despite this, the security concerns related to the initial CAD tool download phase remain under-researched, particularly in the context of open-source CAD tools. The process of a cyberattack typically follows a series of stages. It begins with reconnaissance, where attackers gather information about the target. This is followed by exploitation, where vulnerabilities are leveraged, such as phishing or malware deployment. After gaining access, the attackers may escalate privileges, steal data, or disrupt operations, while attempting to hide their presence [2].

Additionally, a recent study addressed in [3] and [7] indicates a significant increase of 63% in the number of downloads of open-source CAD tools in 2022, further highlighting the growing trend. However, this study focuses specifically on the initial phase of the CAD tool usage process—when users download the tool, as all CAD tools require a download. This paper aims to fill this gap by examining the vulnerabilities during the download and installation phase of CAD tools, which is crucial to securing the overall AM process. The following section describes the journey of a typical user who browses through the internet and visits the website of the CAD tool. It also depicts the journey of an attacker who at the same time could perform malicious activities on the internet.

2 Literature Review

In our study, we conducted a structured literature review by searching two academic databases, i.e., IEEE Xplore and Google Scholar. We used specific keywords such as CAD tools, security assessment, open-source CAD vulnerabilities, security in AM, etc., to identify relevant studies. Additionally, we applied inclusion and exclusion criteria to filter relevant papers based on their relevance to web-based security assessments of CAD tools. Upon reviewing selected papers and analyzing their abstracts, we drew inspiration from those that discuss and categorize various taxonomies of cyberattacks in the AM industry, ensuring a comprehensive understanding of the security landscape. In addition, as described above, in the interest of adhering to the page limit, not all references were included in the study**.** To understand the specific gaps in the most recent literature, it is imperative to comprehend the generic process of any user's navigation journey through typical CAD tools. In an objective to make this clear, section 2.1 outlines the overview of the user journey, section 2.2 delves into the specifics of user interaction with the CAD website, and section 2.3 details the attacker's interaction with the CAD website. Finally, section 2.4 provides a summary of the most relevant studies in the domain and identifies the specific research gaps that will be addressed in this study

2.1 Overview of the User Journey

Based on the understanding and inferences from the literature review [8], the following elements have been identified as relevant and suitable for our study (as shown in Figure 1). Where 1) user (blue icon) represents a legitimate user engaging with the website of a CAD application, and 2) attacker (black-hat icon) represents a malicious actor attempting to exploit web-based vulnerabilities for them.

2.2 User Interaction with the CAD website

First, the website exploration phase, where the user visits the CAD website, typically to explore, read, and download the CAD tool. At this phase, the website can be potentially exposed to countless potential web based cyber threats. Second, CAD tool download phase, where the user downloads the CAD application from the website. This step carries risks such as the possibility of downloading compromised or malicious software. Finally, desktop application phase, where the downloaded tool transitions into a desktop-based application. However, this phase is beyond the scope of our study and is not addressed in our analysis.

2.3 Attackers Interaction with the CAD website

The attacker can target two out of 3 phases in the user journey, i.e., the website exploration phase and the CAD tool download phase. These phases present opportunities for exploiting vulnerabilities. Figure 1 highlights several common attack vectors as mentioned by [9]: 1) DDoS (Distributed Denial-of-Service): overloads the website, making it inaccessible to legitimate users, 2) injection attacks: injects malicious code into the website or the download processes 3) phishing: tricks users into providing sensitive information or downloading harmful files, and 4) ransomware: encrypts or locks the user's data or application, demanding payment to restore access.

Figure 1: User-Attacker Interaction in CAD environment

2.4 Relevant Studies

Several existing studies emphasize the significance of cyber-attacks during different phases of the AM process. For example, in [10], [11], and [12], the authors have highlighted and discussed the taxonomy of potential cyber-attacks in the AM industry. In summary, the following five cyber-critical phases were identified: CAD, Finite Element Analysis (FEA), slicing, printing, testing, and assembly. These phases represent the primary attack vectors highlighted in the literature, providing a general overview of the current state of cybersecurity concerns in the AM industry. All three papers have identified and analyzed the attack phases; however, none of these studies specifically focus on the first attack phase, which is the CAD phase. To elaborate, study [4] examines cyber-attacks in the FEA phase, slicing phase, and printing phase, while Papers [5] and [6] primarily focus on cyber-attacks in the slicing and printing phases.

In addition to the mentioned sources, [13] and [14] emphasize the cybersecurity challenges within the AM process, particularly as it pertains to the design and simulation stages. These stages, which rely heavily on CAD tools, are crucial for ensuring the accuracy and reliability of the final product. Since CAD tools are the first point of contact in the AM process, securing them is essential for protecting the integrity of the entire workflow.

Moreover, as the AM industry continues to embrace digitalization and the integration of advanced technologies such as Artificial Intelligence (AI) and the Internet of Things (IoT), the attack surface for cyber threats expands, especially during the early stages of the design process. The evolution of these technologies brings new challenges in securing CAD tools, which, if compromised, can lead to broader risks across the entire manufacturing chain.

This paper, while drawing on these studies, emphasizes the importance of understanding and mitigating the cybersecurity risks during the CAD phase. Given the increasing reliance on digital tools in the AM industry, ensuring the security of CAD tools is paramount to maintaining the confidentiality, integrity, and availability of the data and models that are central to the manufacturing process.

3 Methodology

Figure 2 shows all the steps in the proposed methodology. This methodology outlines a nine-step process along with two decision boxes for conducting a web-based security assessment of CAD tool.

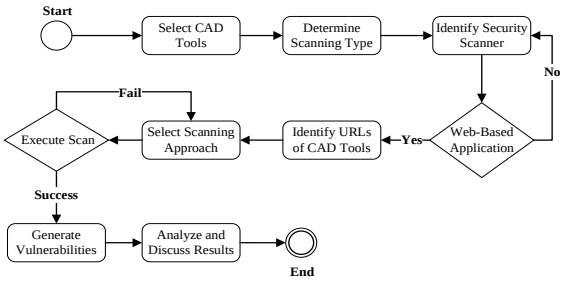

Figure 2: Overview of the proposed methodology

3.1 Select CAD Tools

The selection of appropriate CAD tools was the first step in the methodology. According to [15] and [16], CAD systems are classified based on two main criteria: 1) Licensing and 2) Type of computer application. Licensing of the CAD systems refer to their categorization based on commercial and non-commercial use. This study focuses on non-commercial use, which includes freeware and open-source tools. In contrast, commercial CAD systems fall under the closed-source category. These closed-source systems are high-performance platforms equipped with advanced features. According to the same study, the largest providers of commercial CAD systems are Autodesk, CATIA, and solid edge. The second classification is based on the type of application, which can be further divided into desktop-based, web-based, and mobile-based CAD tools. For our study, we have chosen freeware tools, and the specific type of CAD application selected is web-based**.** Therefore, selection of the right CAD tool is crucial, and it is essential to clearly identify the specific type of CAD system that this study intends to evaluate and hence of relevance in the further steps of the methodology.

3.2 Determine Scanning Type

It is crucial to understand the three main types of testing that should be conducted when an application goes live. Whether the application is intended for commercial or public use, ensuring its protection against cyberattacks is a top priority. According to [11] and [18], there are three most common types of testing namely static code analysis testing (SAST), dynamic application security testing (DAST), and interactive application security testing (IAST). For our study, we have chosen to

use Dynamic Application Security Testing (DAST). This approach is preferred as it allows for testing the application while it is running, simulating real-world cyberattacks and identifying vulnerabilities that may not be apparent during the development phase. A basic definition of each is provided in the Table 1 for easier comparison.

Table 1: Three most common scanning types

SAST	DAST	IAST
White box-based testing/ Source code-based testing	Black box testing. Conducted while the application is running	Code is analysed for security vulnerabilities while an application is running

3.3 Identify Security Scanner

Security scanners exist in various forms, each designed to identify several types of vulnerabilities, threats, and weaknesses within an environment. There are several other types of security scanners, including: 1) Network Security Scanners, in which they scan for vulnerabilities related to open ports and network configurations.2) Vulnerability Scanners, in which vulnerabilities are identified in systems or networks by comparing them against databases of common weaknesses. 3) Web Application Security Scanners: These specifically detect vulnerabilities within web applications, such as SQL injection or cross-site scripting (XSS). 4) Static Application Security Testing (SAST): These scanners analyze source code or binaries to identify security flaws before the application is run. 5) Dynamic Application Security Testing (DAST) Scanners: These scanners find vulnerabilities by testing applications during runtime, simulating real-world attacks.6) Cloud Security Scanners: These scanners identify vulnerabilities in cloud environments, such as misconfigurations or security gaps in cloud-based services.

Given that the scope of this study is focused on scanning vulnerabilities in web applications, it is important to note that, as stated in [8], web application security scanners simulate the actions of a penetration tester to thoroughly inspect and assess the target application. Among the web application security scanners used in this study, we have selected OWASP ZAP (Zed Attack Proxy), a widely recognized and popular scanner within the security community. There are two primary reasons for choosing this tool which includes: 1) Community Support and Relevance: ZAP is developed, managed, and maintained by the Open Web Application Security Project (OWASP), a prominent organization that also publishes the OWASP Top 10 list of the most critical security risks faced by web applications. According to [9], it is important to note that the OWASP Top 10 serves as a baseline for information security professionals when assessing the security posture of any web application running on the internet. 2) Customizability and Features: The ZAP scanner offers a wide range of customizable features essential for conducting a comprehensive security assessment. These include various scanning techniques, flexible reporting options, and automation capabilities, making it an ideal choice for thorough security evaluations.

3.4 Web based application

As the focus of this study is on scanning web applications, it is imperative to utilize tools and methodologies specifically designed for this purpose. The current step acts as a decision box and supports as discussed in the following sections. However, if the application under examination is not web-based, we would need to reassess our approach and move to Step 3.3, where we would identify an appropriate security scanner for non-web applications

3.5 Identify URLs of CAD Tools

Once the target application is identified, a crucial step is to determine the URLs associated with the application. This is a key step highlighted in [9], where identifying the URLs (i.e., web pages) to be scanned is considered one of the foundational tasks in conducting a security assessment. Furthermore, the paper describes the general architecture of web application security scanners, noting that the URLs serve as the primary input for the testing process. The list of the main web pages of the five open-source CAD tools that were part of our study is as follows: FreeCAD (https://www.freecad.org/),OpenScad (https://openscad.org/),Blender(https://www.blender.org/), LibreCAD (https://solvespace.com/), and Solverspace (https://librecad.org/).

3.6 Select Scanning Approach

There are two primary scanning modes: Active scanning and Passive scanning, both of which are available in the web application security scanner, OWASP ZAP. According to [20], active scanning is considered the more aggressive form of scanning, as it involves actively attacking the application to identify vulnerabilities. During this process, there is a high likelihood that the scan will be visible to the target application team, who may monitor the traffic and observe the different attacks being performed. Typically, active scanning is conducted over private web connections and can be carried out internally. In contrast, passive scanning does not modify the traffic between the scanner and the target application, nor does it execute any

malicious attacks. This mode simply observes the application's behavior without interacting with or altering the system. It is crucial to note that explicit authorization from the application owner is required to conduct active scanning, as it can potentially harm the production environment. For this study's purposes, the ZAP tool has been configured to use passive scanning, and throughout this study, only passive scanning has been performed.

3.7 Execute the Scan

Sections 3.7.1 and 3.7.2 outline the prerequisites for using the scanner, along with the appropriate environmental conditions required for its successful operation.

3.7.1 Pre-requisites for ZAP proxy 2.15.9

As mentioned in [9], there are 2 prerequisites required to install the tool: 1) Supported operating systems, i.e., Windows, Linux, and macOS. 2) Ensure that the Java Runtime Environment (JRE) is fully patched and maintained.

3.7.2 Environment setup

There are three main steps that include: 1) Cloning a Virtual Machine: The primary host machine to conduct this study was completed on Windows VM. 2) Download ZAP Proxy**:** Visit the OWASP ZAP website to download the latest version compatible with your operating system. 3) Install ZAP Proxy**:** Run the downloaded installer on the Windows VM and follow the installation prompts.

3.8 Generate Vulnerabilities

The active scanning technique performed on all five URLs was successful in identifying vulnerabilities across all five CAD tools examined. The results are displayed in Table 2. High (H), which represents critical vulnerabilities that require immediate attention; Medium (M), indicating moderate risks that should be addressed promptly; Low (L), referring to less severe issues that may not immediately impact security; and Informational (I), which are minor details that do not pose a direct threat. These levels are inherited from the scanner. Additionally, the ZAP Proxy scanner provides a breakdown of vulnerabilities based on their severity, using data from its own database. The vulnerabilities from the ZAP proxy are categorized into four levels of severity in decreasing order (as shown Table 2): High (H), Medium (M), Low (L), and Informational (I) which are inherited from the scanner.

It is important to note that OWASP ZAP utilizes its own vulnerability assessment database, meaning that the scanning algorithm and rules are defined within the ZAP scanner itself. The scanner identifies vulnerabilities based on predefined patterns. Similarly, the scanner references classifications from the Open Web Application Security Project (OWASP) and the Common Weakness Enumeration (CWE), which is maintained by MITRE.org. These are community-driven resources that catalog common software and hardware weaknesses. According to CWE.mitre.org, which is a not-for-profit organization that addresses challenges in cybersecurity, develops comprehensive cybersecurity frameworks, and provides resources to help organizations identify, defend, and respond to cyberattacks. A weakness is defined as a condition in software, firmware, hardware, or a service that, under certain conditions, could lead to vulnerabilities. These vulnerabilities were detected by the ZAP scanner, each of which is associated with a CWE ID, as explained in Section 4 and 4.1

Table 2: Breakdown of Vulnerabilities by Severity

Tool Name	H	M	L	I	Sub Total
Free Cad	1	5	2	5	13
OpenScad	0	6	4	5	15
Blender	0	2	3	5	10
LibreCad	0	3	1	3	10
SolverSpace	0	4	5	0	9

3.8.1 Risk Vs Confidence matrix

According to [9] and [10], the ZAP Proxy scanner further categorizes detected vulnerabilities using two parameters: Risk and Confidence. Risk can be defined as the potential consequences of data damage caused by a cyberattack. As noted by [21], risk is calculated in Equation 1.

$$\text{Risk} = \text{Threat} + \text{Vulnerability} \quad (1)$$

The level of Confidence is determined by the maliciousness of the Indicator of Compromise (IOC), which may include elements such as Internet Protocol (IP) addresses, email addresses, domains, URLs. The ZAP Proxy scanner provides both risk and confidence levels when listing vulnerabilities [11]. Based on this data, a heat map (as shown in Figure 4) is generated for the five CAD tools analyzed in this study. In the heat map, Confidence is represented along the X-axis, and Risk is represented along the Y-axis. The risk levels are categorized as Informational, Low, Medium, and High, in ascending order of severity. The X-axis is divided into three categories corresponding to low, medium, and high confidence levels, arranged in increasing order of confidence.

3.9 Analyze and Discuss Results

The scan was conducted independently for each of the five CAD tools. From these independent scans, a total

of 54 vulnerabilities were identified, with only 25 vulnerabilities being unique. The list of unique vulnerabilities are as follows: V1) Cross-site scripting, V2) Header not set, V3) Hidden file found, V4) Missing anti-clickjacking header, V5).htmaccess information leak, V6) Absence of anti-csrf tokens, V7) Strict-transport security header not set, V8) X-content options header missing, V9) Modern web application, V10) Re-examine cache control directives, V11) Security policy header not set, V12) User agent fuzzer, V13) User controllable HTML element (XSS), V14) Wildcard Directive, V15) style-src unsafe-inline, V16) Cross-domain misconfiguration, V17) Vulnerable JS library, V18) Cross-domain JavaScript source file inclusion, V19) Timestamp disclosure – Unix, 20) CSP: Header & Meta, V21) Information disclosure – suspicious comments, V22) Retrieved from Cache, 23) Charset Mismatch, V24) Application error disclosure, V25) Information disclosure – debug error messages. Figure 3 below displays a 5-set Venn diagram illustrating the unique vulnerabilities identified across the five CAD tools. Notably, only one vulnerability (V2) was found in all five CAD tools, while two vulnerabilities (V4 and V7) were found in four tools, and four vulnerabilities (V9, V10, V21, and V19) were found in three tools. This highlights the significant overlap among these CAD tools. In contrast, the study also identified distinct vulnerabilities unique to certain CAD tools: 8 distinct vulnerabilities for Free Cad, 4 distinct vulnerabilities for Solverspace, 3 distinct vulnerabilities for OpenScad, 1 distinct vulnerability for Blender, and none for Libre CAD. According to Figure 3, the most frequent vulnerabilities that were repeated are shown in Table 3.

The analysis of the results was conducted for the following scenarios: 1) The detected vulnerability with the highest severity, and 2) The significance of the most frequent vulnerabilities.

3.9.1 High Risk Vulnerabilities

The Free CAD tool was identified with a high-severity vulnerability classified as CWE-79, which pertains to Improper Neutralization of Input During Web Page Generation (Cross-Site Scripting). This particular vulnerability was detected exclusively within this tool. It typically arises when untrusted data is allowed to enter a web application, often via a web request. According to [12] and [13], during the process of page generation, the victim's web browser executes the injected malicious code within the context of the web server's domain, thus violating the web browser's same-origin policy. This policy is designed to prevent scripts from one domain from accessing or modifying data in another domain. According to [22], exploitation of this vulnerability could enable an attacker to perform a range of malicious activities, including, but not limited to, the theft of sensitive application data such as session cookies and other confidential information.2) Identification of Input Vectors: Understanding all potential areas where untrusted input may enter the application, such as parameters, arguments, cookies, network data, environment variables, reverse DNS lookups, query results, request headers, URL components, email data, files, filenames, databases, and external systems providing data to the application. This is a critical aspect of overall architectural design.3) Server-Side Validation: Ensuring that all input validation checks are also duplicated on the server side, providing an additional layer of protection.4) Use of Security Appliances: Implementing a Layer 7 firewall and a web application firewall (WAF) capable of detecting and mitigating attacks targeting this vulnerability [15] [16].

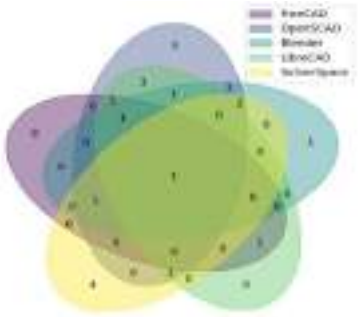

Figure 3: Vulnerability across CAD tools

Figure 4: HeatMap for FREECAD tool

Table 3: Most Frequent Vulnerabilities

Name of Vulnerability	Frequency
Header not set	5
Missing anti-clickjacking header	4
Strict transport security header not set	4
Re-examine cache control directives	3
Information disclosure – suspicious comments	3
Modern web application	3
Timestamp disclosure – Unix	3

3.9.2 Most Frequent Vulnerabilities

According to Table 3, the "Header not set" vulnerability (CWE 693) is present in all 5 CAD tools. Additionally, the "Missing anti-clickjacking header" (CWE 1021) is present in 4 CAD tools, and the "Strict Transport Security header not set" (CWE 319) is also present in 4 out of 5 CAD tools. This vulnerability represents a subset of the broader Content Security Policy (CSP) framework, which functions as an additional layer of security designed to detect and mitigate critical threats, particularly Cross-Site Scripting (XSS) and data injection attacks. By injecting CSP headers from the server, the browser becomes equipped to protect the user from malicious dynamic content that may be loaded onto the page they are currently visiting [9]. It is important to recognize that this vulnerability is also a component of XSS, and we can conclude that all five of these CAD tools are highly susceptible to Cross-Site Scripting attacks. The vulnerability related to the absence of an anti-clickjacking header has been detected across all CAD tools, except Blender [17]. Clickjacking is a type of cyberattack wherein users are deceptively manipulated into clicking on elements they did not intend to interact with. This is typically achieved by superimposing a transparent layer over legitimate content, causing the user's click to activate hidden or malicious elements controlled by the attacker [22]. One effective countermeasure against such attacks is the implementation of an anti-clickjacking header in the HTTP response. The HTTP Strict Transport Security (HSTS) vulnerability is another significant issue identified in all CAD tools, except Libre CAD. In these tools, sensitive or security-critical data is transmitted in cleartext over communication channels, making it susceptible to interception by unauthorized actors. According to [18], this compromise violates the *Confidentiality* component of the CIA triad, as anyone gaining access to the network channel can read the transmitted information. To mitigate this type of attack, it is essential to encrypt the data using robust protocols prior to transmission, ensuring SSL/TLS encryption is implemented throughout the entire session, from login to logout.

4 Conclusions and Future work

This study contributes to the web-based security evaluation of five widely used CAD tools (i.e., Free Cad, OpenScad, Blender, Libre Cad, and Solverspace) and identifies 25 unique vulnerabilities (numbered from V1 to V25) with the help of ZAP proxy scanner. The proposed methodology however is generic and applicable to examine other web-based open-source CAD tools as well. The vulnerabilities observed through the analysis in this study range in severity, from highly risky to informational, and likelihood of occurrence, from the most probable to the least probable. The most critical vulnerability, V1, was detected in the Free Cad tool and is considered a high-risk issue. That is CWE 79, which pertains to Improper Neutralization of Input During Web Page Generation, Cross-Site Scripting, common in web-based attacks.

It is crucial to address these vulnerabilities, as they compromise the tools' adherence to fundamental security principles and expose end-users to a wide range of threats, from data theft to sophisticated attacks such as clickjacking and session hijacking. These findings are particularly relevant for AECO industry professionals, who increasingly rely on CAD tools for design and collaboration, as addressing these vulnerabilities ensures the security of sensitive project data and reduces risks to increasingly prevalent digital project workflows.
Additionally, future work also seeks to draw broader, more applicable inferences about the vulnerabilities and corresponding countermeasures on specifically web-based open-source CAD tools in general, which is the focus of this study. As part of this effort, AI-driven security tools will be explored to enhance the detection, classification, and mitigation of vulnerabilities in these CAD applications.

One of the key limitations of this study is that the results were generated using the ZAP proxy scanner. Potential variations can be observed if other scanners are utilized on these CAD tools, the proposed methodology and the results observed still largely will remain applicable. That is, the authors cannot guarantee that similar results would be obtained under different conditions, such as: 1) using a different web scanner, 2) applying a different scanning method, or 3) conducting the study at a different time. Vulnerabilities may be addressed, or new ones may emerge, potentially altering the results even if the same scanner is used due to the dynamic nature of website traffic [23]. As part of an ongoing effort, the authors are working to address the identified limitations of this study. Future work aims to generate more comprehensive results that provide deeper insights into the selected CAD tools. Additionally, future work also seeks to draw broader, more applicable inferences about the vulnerabilities and corresponding counter measures on specifically web based open-source CAD tools in general which is the focus of this study.
