Abstract -

Precise segmentation of shield tunnel linings is a prerequisite for structural health monitoring and digital twin construction. However, existing methods are heavily relying on extensive annotated datasets, which are scarce in tunneling scenarios. To address this, we propose a novel zero-shot framework for the adaptive recognition and instance segmentation of tunnel linings. The proposed method starts by unfolding tunnel point cloud data to an intensity image, enabling the use of a Vision-Language Model (VLM) and a prompt-based Segment Anything Model (SAM). To enhance performance, we employ (i) an adaptive hybrid prompt generation mechanism, integrating VLM with pixel intensity priors to automatically generate bounding box and point prompts for SAM and (ii) a Stable Diffusion inpainting module to restore missing regions caused by occlusions, enabling SAM's zero-shot capability to achieve precise instance-level segmentation of tunnel linings. Experimental results in two different tunnel datasets, compared to the original baseline SAM without prompts, demonstrate the robustness of the framework, achieving a mean Intersection over Union (mIoU) of 90.58% in standard circular tunnels. This approach effectively overcomes data scarcity issues and provides an efficient, largely automated solution for intelligent tunnel maintenance.

Keywords -

Shield Tunnel; Point Cloud; Zero-Shot Segmentation; Segment Anything Model; Vision-Language Models

1 Introduction

With the acceleration and deepening of urbanization, the effective utilization of urban underground space has become a key way to address issues such as traffic congestion, population density, and resource constraints [1] . However, such facilities typically exhibit characteristics that include diverse facility types, complex environments, and extensive coverage areas. Consequently, the challenges to ensuring tunnel operational safety and quality inspection remain worthy of attention.

Currently, conventional operational maintenance is largely based on manual inspections and fragmented digital recording. This approach mainly involves maintenance personnel performing periodic assessments on-site of facility conditions, with reports compiled manually [2, 3, 4]. Moreover, the tunnel environment is characterized by poor implementation, high humidity, and hazardous conditions, making manual inspection labor-intensive and risky [5]. To address these challenges, Yi et al. [6]extract segments from point clouds to construct the corresponding three-dimensional segment models, thereby obtaining precise structural models for subsequent digital twin-based tunnel operations and maintenance. Feng et al. [7] achieve a precise segmentation of the segments to allow detailed monitoring, such as calculating the position and orientation of the lining ring and analyzing joint deformation. These techniques offer valuable information for the comprehensive management of tunnels throughout their lifecycle.

However, both constructing digital twin geometric models and monitoring deformation fundamentally require precise segmentation of structural components. Existing tunnel lining segmentation methods primarily involve direct point cloud segmentation and projection-based segmentation. However, both approaches require extensive datasets for training, imposing significant limitations in data-scarce scenarios like tunnels.

The Segment Anything Model (SAM) proposed by Meta AI [8], demonstrates unprecedented zero-shot segmentation capabilities. It can precisely segment any object within an image based on simple user prompts (e.g., points, boxes, rough boundaries). Although this model exhibits strong generalizability, its performance may vary across specific scenarios. Preliminary research has explored the application of SAM's to remote sensing image analysis, medical image segmentation, and industrial defect detection[9], achieving favorable results due to SAM's robust pre-training foundation in image segmentation.

This paper proposes a novel point cloud segmentation method for tunnel linings, leveraging SAM's zero-shot segmentation capability to achieve high-precision automated segmentation. We employ (i) Vision-Language Model (VLM) with pixel intensity prior information to automatically generate bounding boxes and point prompts, aiming to enhance SAM's segmentation capabilities. (ii) We introduce the Stable Diffusion inpainting module to complete missing image portions, thereby improving the quality of images input to SAM. The final results demonstrate that our method performs effectively.

2 Related Work

Numerous research achievements have emerged in the field of point cloud segmentation, laying a solid foundation for technological advancement. Within the domain of

tunnel point cloud segmentation, approaches primarily fall into two categories.

The first category comprises direct segmentation methods based on point clouds, exemplified by Zhou et al.[10], whose research validated the application of deep learning in point cloud segmentation. The second category involves projection-based segmentation approaches, which reduce the dimensionality of three-dimensional data to two-dimensional images for processing. This reduction in dimensionality simplifies the segmentation challenge. For example, Zhang et al. [11] utilise traditional image processing techniques for segmentation, suitable for straightforward point cloud data.

However, current deep learning-based segmentation in tunneling still faces specific limitations, primarily in relation to scarce training data. Consequently, SAM's flexible prompting mechanism has been extended to specific engineering scenarios. Jing et al. [12] proposed a segmentation framework that integrates depth map information with visual SAM features, significantly improving the accuracy of the location of the edge for engineering components. Ye et al. [13] generated template prompts centered on initial points based on lining design parameters, supplemented by coarse mask prompts using polygonal envelopes, to achieve instance segmentation in shield-tunnel construction. Xu et al. [14], focusing on the implementation of engineering automation, further optimized the efficiency of inference and the compatibility of the deployment of large visual models. Their lightweight segmentation architecture achieved a real-time balance between component segmentation and condition monitoring in construction scenarios, providing technical support for intelligent supervision of construction processes.

Existing research indicates that segmentation methods based on large visual models are progressively transitioning from general-purpose segmentation to engineering-specific segmentation. However, existing SAM-based methods mainly rely on standard prompts and do not explicitly address the challenges of missing data and structural discontinuities in tunnel inspection images. To address these limitations, This study introduces an adaptive prompt generation module and an image restoration model, offering an enhanced solution for tunnel lining segmentation and advancing progress in this field.

3 Methodology

The proposed method is shown in Figure 1, consisting of four core steps: data preprocessing, PCD image to intensity and completion, SAM integration and optimization, and reprojection. Specifically, we preprocess the raw point cloud and perform a center axis fitting. Subsequently, the dimensionality reduction is achieved through cylindrical unfolding to generate intensity images. Finally, adaptive bounding boxes and point prompts are generated using VLMs and gray-value-driven techniques, which guide the SAM to perform zero-shot segmentation.

3.1 Data Preprocessing

Raw Point Cloud Data (PCD) from shield tunnels often contains non-structural artifacts such as equipment mounts and pipelines. To ensure data quality, we employ a statistical outlier removal filter combined with manual refinement using CloudCompare to eliminate noise while preserving the tunnel geometry.

Precise axis estimation is critical for subsequent unfolding. We propose an iterative least-squares fitting algorithm. First, Principal Component Analysis (PCA) provides an initial axis L_0. In each iteration i, the tunnel is sliced into normal planes S_i at equal intervals along L_i. For each plane, the cross-section center (a_i, b_i) and radius R_i are estimated by minimizing the geometric distance:

$$E(a_i, b_i, R_i) = \sum_{j=1}^{N_i} \left(\sqrt{(x_j - a_i)^2 + (y_j - b_i)^2} - R_i \right)^2 \tag{1}$$

The optimal centers are then fitted to form an updated spatial curve L_{i+1}. This process repeats until the deviation $d(L_{i+1}, L_i)$ falls below a convergence threshold ε, yielding the final spatial axis L and radius parameters.

3.2 PCD to Intensity Image and Completion

To take advantage of 2D foundation models, the 3D tunnel surface is projected onto a 2D plane. Based on the fitted axis L, we construct a local orthogonal basis $\{\mathbf{U}, \mathbf{E}, \mathbf{N}\}$ for each point p_i. The 3D coordinates are transformed into longitudinal distance u_i and azimuth angle θ_i:

$$u_i = (p_i - \mathbf{c}) \cdot \mathbf{U}, \quad \theta_i = \text{atan2}(\delta_i \cdot \mathbf{N}, \delta_i \cdot \mathbf{E}) \tag{2}$$

where $\mathbf{c}$ is the reference center, and δ_i is the radial vector.

The unfolded point set $P' = \{(u_i, \theta_i, I_i)\}$ is then rasterized in a 2D grid. The image width W and height H are determined by the angular resolution $\Delta\theta$ and the axial resolution Δu. To handle non-uniform point density, we employ a mean aggregation strategy where the pixel value $I_{\text{final}}[y, x]$ is calculated as the average intensity of all points falling within that grid cell:

$$I_{\text{final}}[y, x] = \frac{\sum I_i}{C[y, x]} \quad \text{if } C[y, x] > 0 \tag{3}$$

However, the generated intensity image inevitably contains void regions due to scanner blind spots, equipment occlusions, or extreme sparsity in the point cloud. These discontinuities disrupt the geometric integrity of the segments and can hinder the recognition performance of SAM.

To address this, we employ a generative inpainting approach based on the Stable Diffusion model. Specifically, we first generate a binary mask that identifies the missing regions. The binary mask for missing regions is automatically generated by identifying pixels with zero intensity (or below a sparsity threshold) resulting from the unfolding process. The incomplete intensity image and the mask are then fed into the Stable Diffusion Inpainting module. Using its powerful latent generative priors, the model synthesizes realistic textures to fill the masked areas based on contextual information from valid surrounding pixels. This process effectively restores the tunnel surface, providing a complete and high-quality input for the downstream segmentation task.

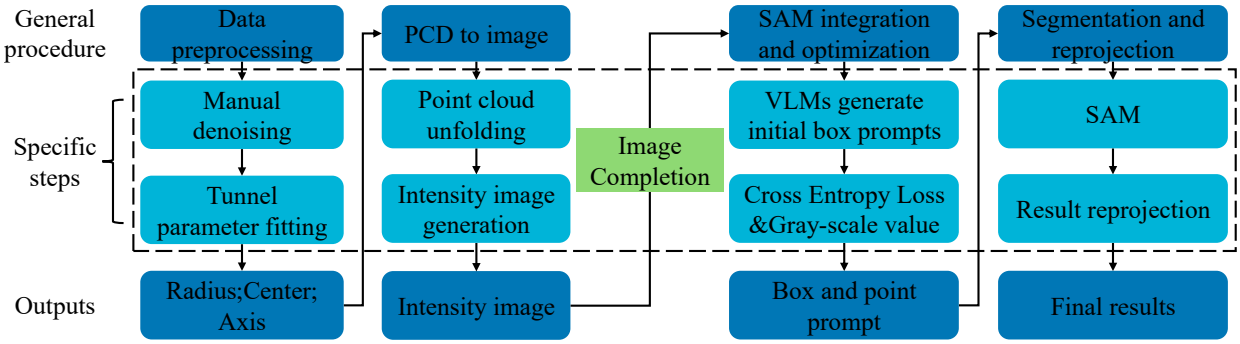

Figure 1. The framework of the proposed adaptive segmentation.

3.3 SAM integration and optimization

To enable precise zero-shot segmentation of shield tunnel segments, we propose an adaptive hybrid prompt generation module. Unlike standard SAM approaches that rely solely on generic visual foundation models, our method integrates open-vocabulary detection with domain-specific intensity priors to construct a robust prompt set:

$$P = \{V_{\text{box}}, V_{\text{point}}\} \tag{4}$$

for the SAM encoder. The specific model framework is shown in Figure 2.

3.3.1 Bounding Box Generation and Optimization

For the bounding box prompts V_{box}, we utilize the DINO-X model, which accepts the unfolded intensity image I and a text prompt T_k = "rectangles" as input. The model encodes image features $E_I(I)$ and text features $E_T(T_k)$, fusing them through a cross-modality decoder to predict initial candidate boxes. However, raw outputs often suffer from fragmentation. To address this, we introduce an optimization strategy based on cross-entropy scoring.

Specifically, we extract the classification logits from the detector head, which correspond to the cross-entropy loss used during pre-training. These logits serve as confidence scores S_{conf} for each candidate box. We first filter candidates based on a confidence threshold, and then apply an iterative merging algorithm. Boxes with high spatial overlap (IoU) are merged, prioritized by their cross-entropy scores, to form a purified set of bounding boxes V_{box}. These optimized boxes provide the coarse localization for the target segments.

3.3.2 Intensity-Driven Point Prompt Sampling

Although bounding boxes provide spatial limits, relying solely on them for segmentation often results in the background being segmented, affecting the segmentation accuracy. We formulate a heuristic sampling strategy to generate point prompts V_{point}. For each optimized bounding box, we analyze the pixel intensity distribution. Pixels falling within the background value range are sampled as negative prompts to suppress background noise. In contrast, pixels within the median intensity range of the segment are sampled as positive prompts. We randomly sample N positive points and M negative points per instance. Finally, the optimized boxes V_{box} and the intensity-driven points V_{point} are concatenated and fed into SAM to generate the final high-quality segmentation masks.

3.4 Reprojection

Upon leveraging the zero-shot capabilities of SAM to obtain high-quality 2D instance segmentation masks, the final step is to transfer these labels back to the original 3D point cloud space. This process closes the loop of our framework, allowing for the direct segmentation of the raw tunnel data.

Since our unfolding process (described in Section 3.2) maintains a deterministic mapping between the 3D points and the 2D grid pixels, the reprojection is formulated as a direct index lookup operation.

For every point p_i in the original point cloud P, we retrieve its corresponding pixel coordinates (x_i, y_i) calculated during the rasterization stage. The semantic label L_i for the 3D point p_i is then assigned based on the value of the corresponding pixel in the 2D mask:

$$L_i = \mathcal{M}_{SAM}(y_i, x_i) \tag{5}$$

By iterating through all points in P, we obtain a fully segmented 3D point cloud where each point carries an instance label consistent with the result of the 2D segmentation. This approach ensures that the precise boundaries delineated by SAM in the image domain are accurately preserved in the 3D geometric space.

4 Experiments and Results

4.1 Dataset and Setup

To evaluate the precision and robustness of the proposed method, we selected experimental data from two distinct tunnels. As shown in Figure 3, Tunnel A is a circular shield tunnel in Chongqing, while Tunnel B originates from the publicly available Seg2Tunnel T1 dataset [15], representing a horseshoe-shaped tunnel. For specific parameters, see Table 1.

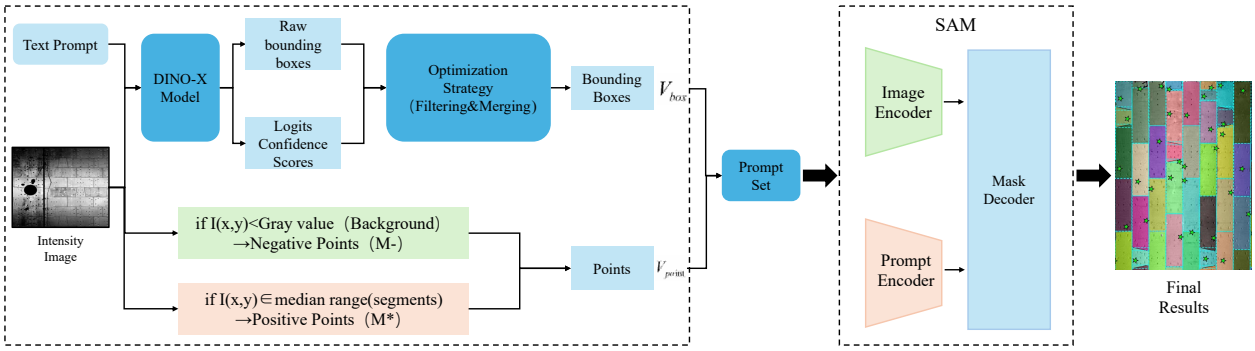

Figure 2. Optimized SAM Framework

Table 1. Key parameters of the shield tunnel datasets

Parameter	Tunnel A	Tunnel B
Design inner diameter (m)	7.5	5.5
Segments per ring	7	6
Segment width (m)	1.6	1.2
Total point count	16 million	14 million

All experiments were conducted with an NVIDIA GeForce RTX 3090 GPU (24GB VRAM). The model is implemented with the PyTorch 2.0 framework running on CUDA 11.8.

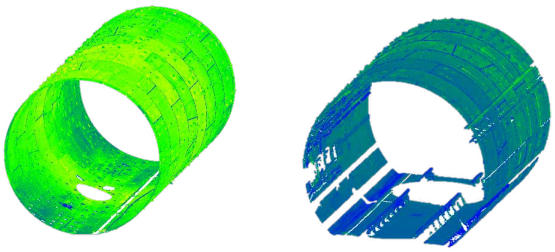

Figure 3. Overview of the experimental datasets.

4.2 Evaluation method

We offer Precision, Recall, Intersection over Union (IoU), and Mean Intersection over Union (mIoU) to quantify segmentation performance. The specific calculation formulas are as follows:

$$\text{Recall}_i = \frac{TP_i}{TP_i + FN_i} \tag{6}$$

$$\text{Precision}_i = \frac{TP_i}{TP_i + FP_i} \tag{7}$$

$$\text{IoU} = \frac{|M_{\text{GT}} \cap M_{\text{Pred}}|}{|M_{\text{GT}} \cup M_{\text{Pred}}|} \tag{8}$$

where:

- TP_i denotes the true positives (TP) for class i,
- FN_i denotes the false negatives (FN) for class i,
- FP_i denotes the false positives (FP) for class i,
- M_{GT} denotes the ground truth mask of the segment instance,
- M_{Pred} denotes the predicted mask of the segment instance.

To evaluate the overall quality of the segmentation, we calculate the average value of IoU in all annotated segment instances, i.e., mIoU:

$$\text{mIoU} = \frac{1}{N} \sum_{i=1}^{N} \text{IoU}_i \tag{9}$$

where:

- N is the total number of annotated segment instances,
- IoU_i is the IoU value of the i-th segment instance.

For instance-level evaluation, predicted instances are matched to ground-truth instances using a one-to-one IoU-based strategy. A prediction is considered a true positive if its IoU with the best-matching ground-truth instance exceeds 0.5. Otherwise, it is counted as a false positive. Precision and Recall measure instance detection performance, whereas IoU evaluates the mask quality of matched instances.

4.3 Results and Analysis

For qualitative results, as illustrated in Figure4, we select Tunnel A as an example, presenting the unfolded intensity image, the segmentation predictions of the instance at the pixel-level, and the predicted point cloud reprojected. Among these, we evaluate the original SAM as a baseline to quantify . In this baseline, we employ the official model to perform fully automatic instance segmentation on the unfolded intensity images, without using any external prompts or inpainting modules. The ground truth for Tunnel A was manually annotated using the open-source software LabelMe, with labels numbered sequentially according to the number of segments, where 0 denotes background.

Table 2 summarizes the quantitative performance of our method in two datasets.

For circular Tunnel A, the method achieves a high mIoU of 90.58, with a precision of 87.95 and a recall of 97.33. The high values for precision and recall indicate that the model effectively identified most tunnel segment instances

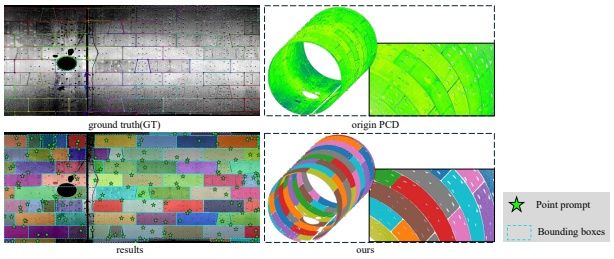

Figure 4. The segmentation results from tunnel A

(TP=73), with minimal false positives (FP=10) or false negatives (FN=2).

In contrast, performance for the horseshoe-shaped Tunnel B declined, achieving an mIoU of 75.59. While recall remained robust at 89.58, indicating the model successfully located most segments, precision dropped significantly to 75.44. This directly reflects a higher number of false positives (FP=14).

As shown in Figure5, the primary cause of this precision degradation is the extensive occlusion introduced by the equipment and cables attached to the tunnel lining. Unlike Tunnel A, these obstructions in Tunnel B result in large-scale data voids within the original point cloud.

Although our repair module mitigated this issue to some extent, the sheer size of the missing regions and the complex visual texture of the utility lines themselves posed significant challenges. Our method may misclassify missing background regions in intensity images as potential segmentation instances, thereby increasing the false positive (FP) rate. Nevertheless, recall remains robust at 89.58, demonstrating that even under severe occlusion, our method can still correctly segment a large number of tunnel segments, exhibiting significant potential for generalization.

Compared with the prompt-free SAM baseline, the proposed framework shows clear quantitative gains on both tunnels. The baseline only achieves 34.17% precision, 90.67% recall, and 80.31% mIoU on Tunnel A, and 31.48% precision, 70.83% recall, and 62.22% mIoU on Tunnel B, indicating that directly applying SAM tends to produce many spurious instances, whereas our method substantially improves precision and overall segmentation quality without sacrificing recall.

To analyze the impact of the inpainting module, Fig.6 presents a qualitative comparison of the unfolded intensity images before and after diffusion-based completion. While the inpainting process improves the visual continuity by filling missing regions, it may occasionally introduce synthetic textures that resemble structural boundaries. These pseudo-structures can mislead SAM and lead to false-positive detections, especially when large void regions must be synthesized with limited contextual information.

The proposed framework integrates three key components to achieve robust tunnel segment segmentation. The diffusion-based inpainting module improves the continuity of the unfolded intensity images by restoring missing regions caused by occlusions or sparse scanning. The box prompts generated by the vision-language model provide coarse instance localization, guiding SAM to focus on candidate segment regions. In addition, intensity-driven point

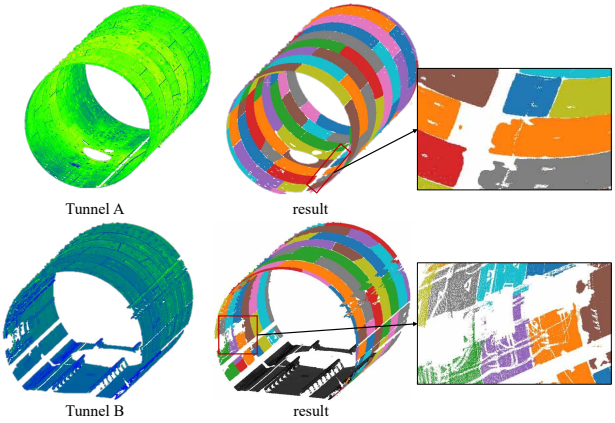

Figure 5. View of Tunnel Segmentation Results

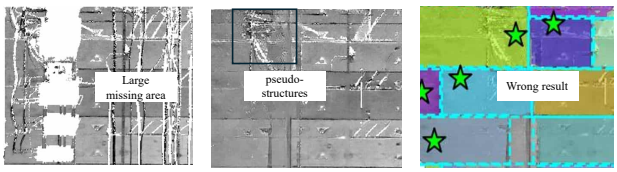

Figure 6. Error analysis of Tunnel B using the diffusion-based inpainting module.

prompts refine the segmentation boundaries by leveraging intensity variations along segment joints. These components jointly contribute to the overall segmentation performance of the framework.

Table3 presents the processing time of Tunnel A in the pipeline. It contains nine rings and containing 10 million points.

In summary, this paper proposes an automated zero-shot framework for instance-level segmentation of shield tunnel linings in 3D point clouds. Quantitative results in Table 2 show that the framework achieves high-quality instance segmentation for multi-type segments, accurately localizing most instances even under unfavorable conditions and validating its strong generalization potential.

5 Discussion

This paper constructs a complete closed-loop system. Experimental results demonstrate that this method preserves the continuity and topological consistency of segmented annular structures within circular tunnels, thereby reducing the reliance on complex three-dimensional models and extensive training datasets.

The comparison with the SAM baseline further confirms that directly applying a generic segment-everything model is insufficient in the presence of geometric distortions and severe occlusions: SAM tends to generate fragmented and spurious masks, particularly around repaired or missing regions. This approach relies entirely on pre-trained models and automated prompt-generating workflows, enabling zero-shot instance segmentation within minutes to

Table 2. Results of the Tunnel A and Tunnel B datasets

Tunnel	Method	Prec(%)	Rec(%)	mIoU(%)	TP	FP	FN
A	SAM (baseline)	34.17	90.67	80.31	68	131	7
A	**Ours**	87.95	97.33	90.58	73	10	2

meet the efficiency demands of engineering inspection and maintenance.

However, when geometric structures deviate from circularity, unfolded images may exhibit distortion, which can affect boundary recognition in SAM model. Although SAM effectively addresses boundary adaptation issues, such distortions and occlusions still diminish segmentation accuracy, particularly in tunnels with complex geometries.

However, due to the generative nature of diffusion models, the restored textures may not perfectly correspond to the true tunnel geometry. Although the inpainting process improves the visual continuity of the unfolded intensity images, it may also introduce synthetic patterns that resemble structural edges or segment boundaries. These pseudo-structures can interfere with SAM's boundary recognition and occasionally lead to false-positive detections. This phenomenon becomes particularly pronounced in tunnels with heavy equipment occlusions, where large missing regions must be synthesized with limited contextual cues. This behavior is consistent with the experimental observations in Tunnel B, where complex occlusions increase the likelihood of misclassification. Despite these limitations, the inpainting module significantly improves the overall structural continuity of the input images, contributing to more stable and reliable segmentation results in most scenarios.

This approach relies entirely on pre-trained models and automated workflows, enabling zero-shot instance segmentation within minutes to meet the efficiency demands of engineering inspection and maintenance.

6 Conclusion and Future Work

This paper addresses the typical engineering scenario of segment segmentation in shield-tunnel construction by proposing a zero-shot adaptive prompt-generation segmentation framework. By establishing a closed-loop workflow 3D - 2D - 3D, it converts unstructured tunnel point clouds into two-dimensional intensity unfolded images, effectively bridging the gap between 3D engineering data and 2D foundation models. Using a general-purpose visual model and gray values for adaptive prompt generation, it achieves high-precision segmentation (90.58% mIoU) without requiring task-specific custom training. Experimental results provide preliminary evidence of the applicability of the proposed method across different tunnel geometries and missing areas, particularly in maintaining the continuity and topological consistency of ring-shaped structures within standard circular tunnels.

These findings validate the feasibility of the proposed approach, offering a practical technical path to reduce annotation costs and improve the efficiency of model deployment. Concurrently, it establishes a foundational data set for subsequent tunnel deformation monitoring and the construction of digital twin models.

However, this method also has certain limitations. Future research should focus on two primary areas:

- Fine-tuning image restoration models: Current general models exhibit insufficient learning of texture features in intensity images, resulting in poor performance when faced with large-scale voids. Subsequent work will address this issue to achieve enhanced robustness.
- Hierarchical prompting: Explore a hierarchical approach where a primary model identifies larger structures (e.g., tunnel rings), while a secondary, fine-tuned VLM targets detailed components (e.g., structural elements), potentially using 3D bounding boxes derived directly from fitted axes as more robust prompts.

Abstract –

Reinforcing bars (rebars) are essential for resisting tensile forces and ensuring structural safety in reinforced concrete systems. However, current rebar inspection practices rely on manual and sampling-based measurements, leading to human errors and limiting inspection coverage. Although automated 3D and LiDAR-based inspection systems have been explored, their adoption rate remains low due to high cost and workflow complexity. To address these challenges, this study presents a cost-efficient vision-based inspection framework that combines high-resolution image analysis and marker-assisted geometric correction. The proposed method detects rebar and marker regions in low-resolution images, refines intersection keypoints in high resolution, performs marker-based rectification, and computes rebar spacing, diameter, and quantity from the corrected geometry. Experiments under varied distances and viewing angles demonstrated accurate and reliable performance, achieving 100% accuracy in counting vertical and horizontal rebars, mean absolute errors of 0.59 mm for diameter and 4.05 mm for spacing. These results confirm practical, low-cost automated rebar measurements for construction inspection.

Reinforcing bar; Convolutional Neural Network; Homography Transformation

1 Introduction

Quality control in the construction industry is a fundamental process for securing the structural safety of buildings. In particular, reinforcing bars (rebars) are primary load-bearing components that resist tensile forces in reinforced concrete members; therefore, improper placement of rebar can lead to serious defects such as cracking or corrosion [1,2]. Accordingly, accurate inspection of the number, diameter, spacing, and position of rebars before concrete casting is critical to ensure structural safety and construction quality [3]. However, conventional rebar inspection still depends on manual measurement and visual inspection, which are time-consuming and prone to human errors [4]. Specifically, of wall reinforcement, the bars are densely arranged and extend across a large area, which increases the amount of inspection work and makes the process highly labor-intensive. For these reasons, automation and systematization of rebar inspection processes is urgently needed to improve inspection efficiency and reliability[4].

Previous studies primarily rely on LiDAR-based 3D point cloud models to measure rebar diameter, quantity, and spacing [5–6]. Although laser-scanning-based approaches provide high accuracy, their applicability to real-time field inspection is limited due to the high equipment cost and the heavy computational burden [4,7]. As a cost-effective alternative to laser scanners, research has progressed to inspect rebars based on image processing and deep learning on RGB images [8,9]. This is mainly due to the widespread availability, low hardware cost, and ease of deployment of RGB cameras. However, these methods require an orthogonal camera angle, thereby limiting their applicability in dynamic construction environments. Photogrammetry-based 3D reconstruction has also been explored, but this approach typically requires a large number of images for a single rebar segment and involves long processing times, limiting its feasibility for on-site use [7]. Depth cameras have been frequently employed in rebar inspection studies, providing guaranteed measurement accuracy as laser scanners [1,10]. However, the accuracy of depth cameras decreases as the distance from the rebar increases and is further reduced as the camera angle deviates from the orthogonal condition to the rebar mat [5,10]. While these limitations may not be significant for small areas or short measurement ranges, they cause the

inspection process to become inefficient when applied to extensive wall reinforcement. Furthermore, the spatial complexity and tight schedules of construction sites hinder the ability to maintain a fixed camera angle.

To overcome these challenges, this study introduces a low-cost rebar placement quality inspection method based on a high-resolution DSLR (digital single-lens reflect) camera with marker-based calibration [11]. The high-resolution DSLR camera ensures the acquisition of necessary pixel density for the precise extraction of fine rebar features, even from long distances. Compared to LiDAR systems, the high-resolution DSLR camera is highly cost-effective and easy to maintain, thus securing high field applicability. Moreover, markers enable the compensation of perspective distortion through homography transformation and serve as a reference for converting pixel units into actual distances [12].

However, even with high-resolution images, extracting fine rebar features from long distances remains challenging. Traditional image processing techniques are susceptible to lighting variations, shadows, complex backgrounds, and noise, which hinder reliable detection in real-world construction environments [10]. Meanwhile, convolutional neural network (CNN)–based methods provide strong detection performance across various environments, but the computational cost increases significantly when processing high-resolution images, which limits real-time applicability [13]. Most CNN-based studies mitigate this computational burden using downsampling, but this leads to the loss of fine visual details and degrades measurement accuracy [8,9,12]. Because rebars are thin, small objects, their pixel footprint becomes extremely limited at long distances, and downsampling further reduces available information, increasing the likelihood of detection and measurement failure.

To address these limitations, the proposed method does not directly apply a CNN to the entire high-resolution image [11]. Instead, it restructures the role of CNNs by decomposing the analysis into two resolution-specific stages. At the low-resolution stage, a CNN is employed solely for global scene understanding and candidate localization, identifying rebar intersection regions and markers with minimal computational cost. These coarse predictions are not used for measurement but only to determine where high-resolution analysis is necessary. Subsequently, only the selected regions of interest are reprojected into the original high-resolution image and processed by a dedicated high-resolution network for metric-level localization. Through this resolution-aware role separation, the proposed method preserves fine geometric details required for accurate rebar measurement while avoiding the prohibitive computational cost of processing the entire image at high resolution [11].

The proposed method detects rebar intersection regions and markers from low-resolution images through a Dual-head Faster R-CNN and then processes the corresponding high-resolution patches with a modified High-Resolution Network (HRNet) to extract precise coordinates of rebar intersections. Subsequently, homography transformation is performed with the marker corner points as the reference frame to provide a perspective-corrected image and to compute the rebar count, diameter, and spacing. Through this process, the proposed method preserves detailed high-resolution information while minimizing computational cost, enabling efficient and accurate rebar inspection even at long distances and under various camera angles.

2 The Proposed Method

2.1 Overview of the Proposed Framework

This study proposes a method for the automated extraction of rebar count, diameter, and spacing in dense and extensive wall reinforcement structures using high-resolution images and fiducial markers. The overall procedure consists of four stages [11]. First, the entire input image is processed by a Dual-head Faster R-CNN to detect markers and rebar cross-section regions. For computational efficiency, the input image is scaled down to 600×400 pixels. The model is designed with a single backbone and two separate heads: one to predict markers in the form of bounding boxes and the other to predict rebar cross-section regions in the form of keypoints. This architecture enables the efficient extraction of necessary Regions of Interest (ROIs) even from noisy field images. Second, the detected rebar cross-section ROIs are projected onto the original high-resolution image, cropped to 256×256 pixels, and input into modified HRNet. Since modified HRNet maintains high-resolution representations for feature extraction, it can reliably estimate the four coordinates of the rebar corner points, even when captured from a long distance or against a complex background. Third, a Homography transformation is performed based on the marker's corner points to generate a perspective-corrected image. This transformation achieves perspective correction in non-frontal shooting environments and computes the pixel-to-real distance scale factor using the marker's known dimensions. Finally, the rebar diameter is calculated from the distances between the four corner points, while the rebar spacing is derived from the distances between centroids, defined as the intersection points of the diagonals formed by those corner points. The overview of the proposed method is shown in Figure 1.

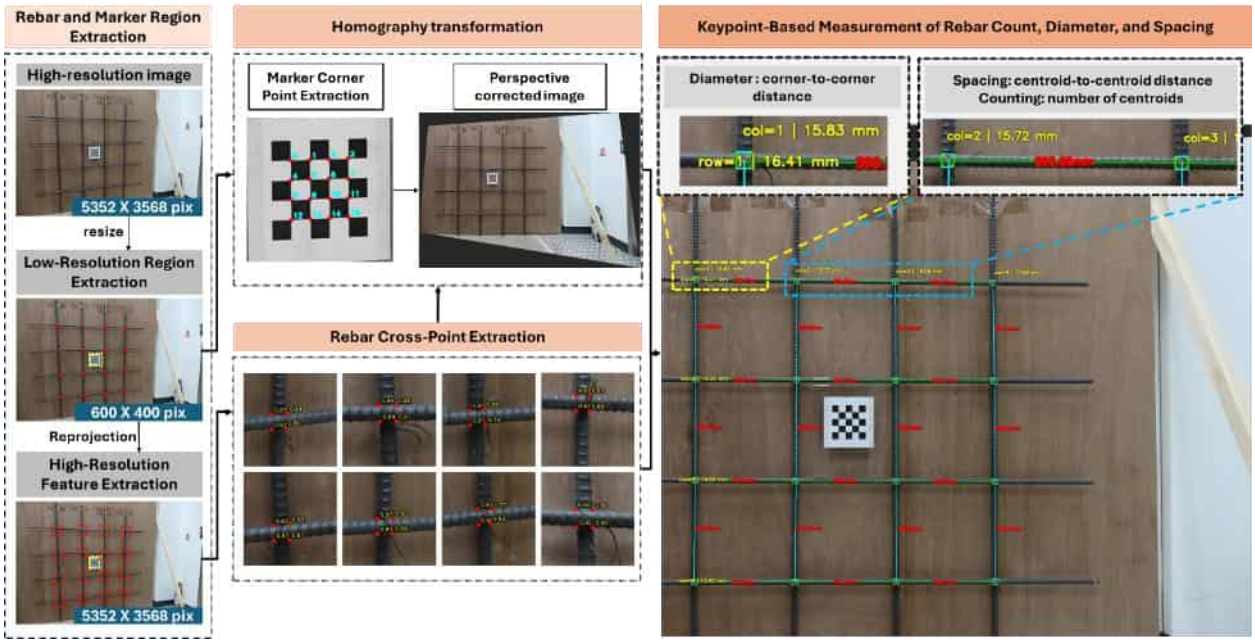

Figure 1. Overview of the proposed method

2.2 Dual-head Faster R-CNN for Rebar and Marker Detection

Since directly processing high-resolution images incurs a significant computational and memory burden, the proposed method first detects ROIs at a low-resolution stage and then performs precise keypoint extraction on the corresponding high-resolution patches. We designed a Dual-head Faster R-CNN with a single backbone and two heads to detect the ROIs from the low-resolution input image [11]. The model architecture shown in Figure 2. The Detector Head, which maintains the structure of the conventional Faster R-CNN, is designed to detect markers as bounding boxes, thereby filtering background and noise when the corner points are subsequently extracted. The Point Heatmap Head is an added component that performs convolutional operations directly on the feature maps extracted from the Feature Pyramid Network (FPN) to generate a heatmap, ensuring stable detection of the rebar keypoints. This architecture is designed to efficiently extract only the necessary ROIs even from noisy field images.

2.2.1 Experimental Settings of Dual-head Faster R-CNN

A dataset of 500 high-resolution rebar and marker images, resized to 600×400 pixels, was collected in a laboratory setting. Data augmentation (flips, blurring,

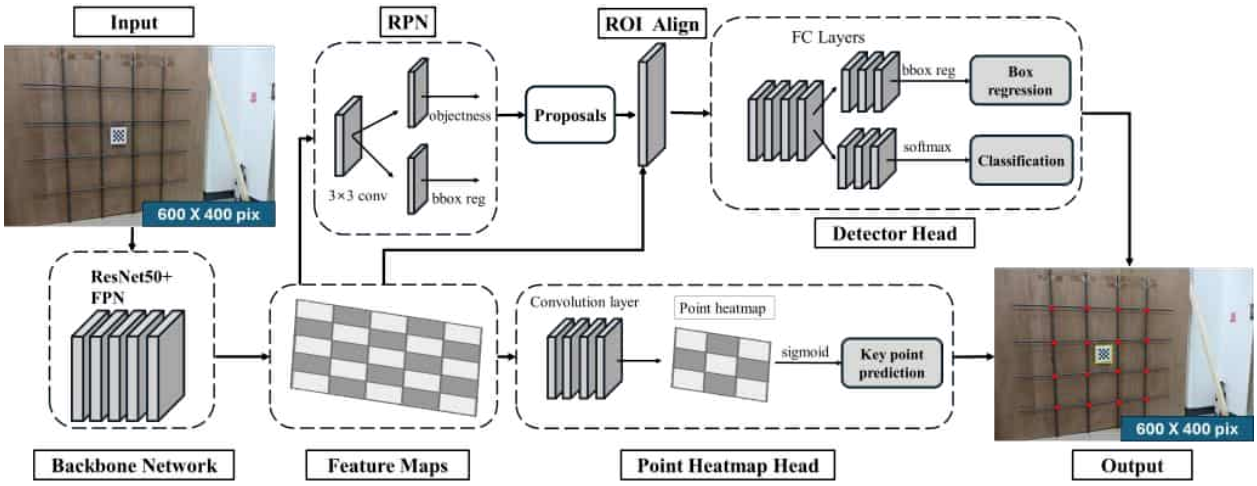

Figure 2. Architecture of the Dual-head Faster R-CNN

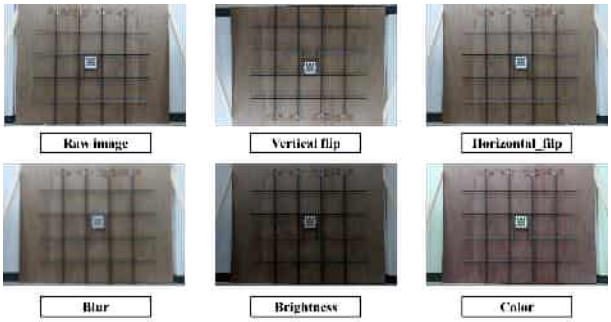

Figure 3 . Examples of data augmentation for Dual-head Faster R-CNN

brightness, color adjustments) expanded the final dataset training, 10% for validation, and 10% for testing. Examples of data augmentation are illustrated in Figure 3. Label consistency was preserved by applying identical geometric transformations to both images and annotations. The model introduced a Dual-head Faster R-CNN with a ResNet-50 FPN backbone, initialized using ImageNet pre-trained weights to leverage transfer learning for fast and stable convergence. Optimization was performed using SGD with a Cosine Annealing with Warm Restarts scheduler, a batch size of 2, and 70 epochs with early stopping. The total loss is the weighted sum of the standard Detection Loss (L_{det}) and a BCEWithLogits-based Heatmap Loss (L_{hm}), defined as:

$$L_{total} = L_{det} + w \cdot L_{hm} \quad (1)$$

Where w is the weight coefficient for the Heatmap Loss which was set to 1.8. The evaluation of bounding boxes was performed using standard metrics, including AP50, AP75, and mIoU. The evaluation of keypoint estimation was performed using the Percentage of Correct Keypoints (PCK) metric with pixel radius thresholds of 2, 5, and 8 (PCK@2, PCK@5, and PCK@8). which is computed as:

$$PCK@\rho = \frac{N_{correct}(\rho)}{N_{gt}} \quad (2)$$

$N_{\text{correct}}(\rho)$denotes the number of predicted keypoints within a pixel distance threshold ρ from the ground truth, and N_{gt} represents the total number of ground-truth keypoints.

2.3 Modified HRNet for Keypoint Extraction

Although initial rebar intersection points are detected at low resolution using a Dual-head Faster R-CNN, their direct reprojection to the high-resolution image is insufficient for precise localization due to pixel-level inaccuracies. Therefore, this study employs a high-resolution patch-based refinement approach using HRNet [11]. Accordingly, high-resolution patches of 256×256 pixels are cropped around the intersection point coordinates predicted by the dual-head Faster R-CNN, and the four corner vertices of the intersection region are precisely estimated using the modified HRNet. Figure 4 presents the architecture of the modified HRNet. To reduce computational overhead, deeper stages of the original HRNet that are unnecessary for precise keypoint estimation on small image patches are omitted. In addition, HRNet integrates a high-resolution feature stream with parallel lower-resolution branches through multi-resolution fusion. Furthermore, adopting a keypoint-based approach simplifies the model structure and reduces computational costs, as it estimates only the minimum required coordinates without predicting the entire pixel area, unlike bounding-box- or mask-based methods. Through this patch-based refinement process, high-resolution rebar features can be extracted with substantially reduced computational cost, as the network operates only on localized regions instead of processing the entire high-resolution image.

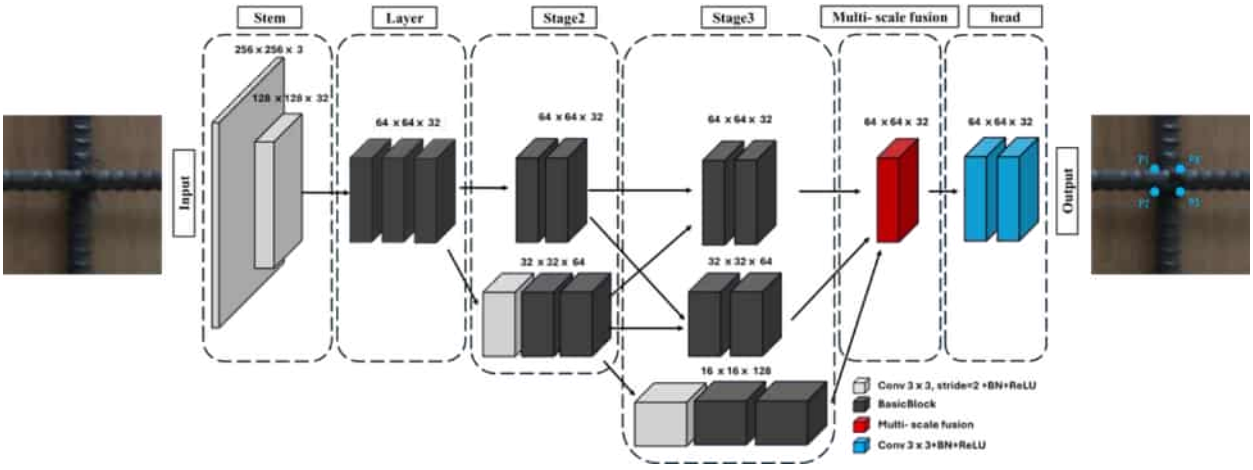

Figure 4. Architecture of the modified HRNet

2.3.1 Experimental Settings of Modified HRNet

The dataset for training modified HRNet was constructed from 880 image patches of size 256×256 pixels, cropped around the rebar intersection centers predicted by the dual-head Faster R-CNN. Extensive data augmentation was applied, including horizontal flips, rotation, blurring, and brightness and color adjustments. Examples of data augmentation are illustrated in Figure 5. The dataset was split into 80% for training, 10% for validation, and 10% for testing. Modified HRNet was trained using the AdamW optimizer, and a batch size of 5, for a maximum of 100 epochs. Early stopping was applied with a patience of 15 epochs, and no transfer learning was employed. The loss function was defined as the mean squared error (MSE) between the predicted heatmaps and the corresponding ground-truth heatmaps, computed using the batch-averaged loss to improve training stability. Keypoint estimation performance was evaluated using the PCK metric at pixel radius thresholds of 2, 5, and 8 (PCK@2, PCK@5, and PCK@8).

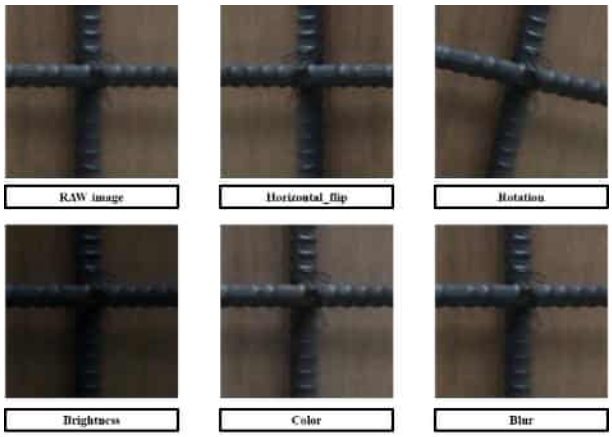

Figure 5. Examples of data augmentation for Modified HRNet

2.4 Geometric Feature Based Rebar Inspection and Quantification

2.4.1 Homography Transformation

In this study, rebar diameter and spacing were quantitatively extracted by combining high-resolution rebar intersection point coordinates with chessboard marker-based geometric correction. To ensure stable corner detection under long-distance imaging conditions, 5×5 chessboard markers with a side length of 20 mm were employed. The marker bounding boxes, detected by the Dual-head Faster R-CNN, were mapped onto the original high-resolution image, and their corner points were precisely extracted using the findChessboardCorners function of OpenCV. The detected marker corner points were matched with their

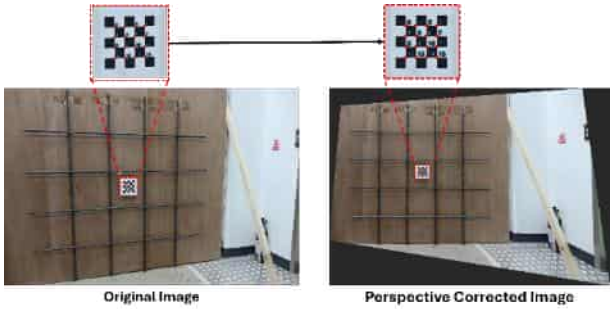

Figure 6. Perspective-corrected image using marker-based Homography Transformation

corresponding reference points defined on a marker-aligned virtual planar grid to estimate the homography matrix H. The estimated transformation was then applied to the input image as well as to the rebar corner coordinates estimated by HRNet, enabling rebar measurements to be conducted in a common, perspective-corrected system. Figure 6 illustrates an example of the perspective-corrected image generated using the marker-based homography.

2.4.2 Rebar Diameter Calculation

In this study, the rebar diameter is estimated from the distances between four corner coordinates predicted by HRNet on a perspective-corrected image obtained via marker-based homography. The pixel distances are subsequently converted to real-world units using a scale factor derived from the known geometry of the marker. To ensure consistent point ordering across samples, the top-right point in the image coordinate system is selected as the reference point ($P1$), and the remaining points are arranged in a counterclockwise order as $P2$, $P3$, and $P4$. Based on the resulting quadrilateral, opposing sides are paired and their average lengths are computed. Here, Length A corresponds to the vertical rebar direction, while Length B represents the horizontal rebar direction. Figure 7, rebar diameter estimation is performed on the perspective-corrected image by measuring the distances between HRNet-detected corner points and converting them into real-world units using the marker-based scale factor. Finally, the estimated diameters for the vertical and horizontal rebars are stored separately according to the row and column indices defined during the spacing extraction process.

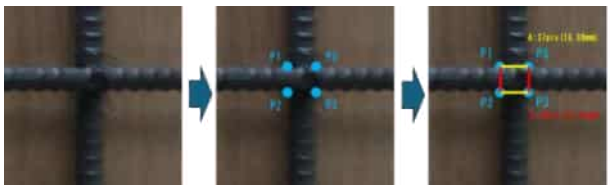

Figure 7. Rebar diameter estimation

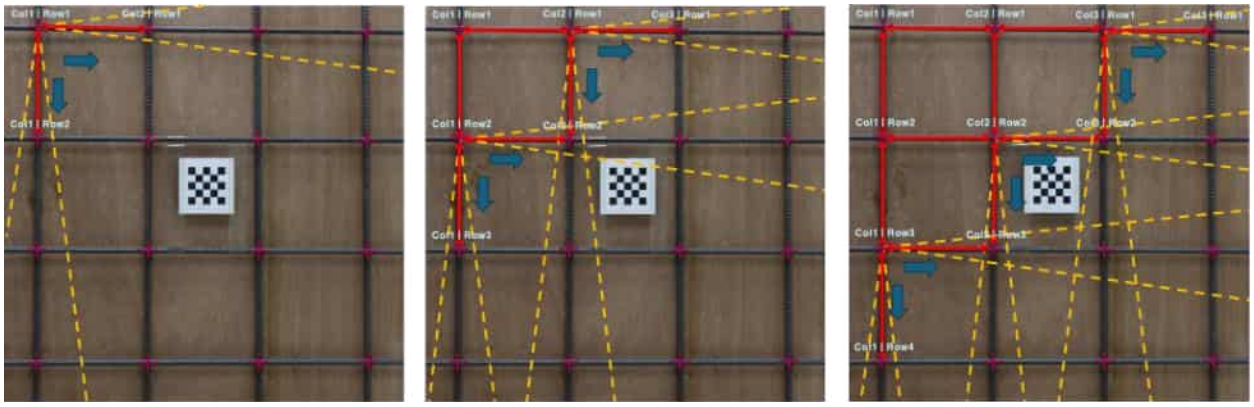

Figure 8. Grid recognition and spacing extraction based on rebar centroids

2.4.3 Calculation of Rebar Spacing and Count

In this study, the centroid of each rebar cross-section is defined as the intersection point of the diagonals $\overline{P1P3}$ and $\overline{P2P4}$ computed from the four corner coordinates estimated by HRNet. These centroids collectively form a grid-like pattern across the image, and their relative spatial arrangement is used to extract rebar spacing. To establish the grid structure, the centroid located at the top-left position in the image coordinate system is selected as the reference point. From this reference, the spacing search is sequentially expanded in the horizontal and vertical directions. An angular tolerance of 30° is applied during the search to accommodate geometric distortions caused by construction tolerances and variations in camera viewpoint. Each detected centroid is then assigned a unique column (col) and row (row) index based on its relative horizontal and vertical displacement from the reference centroid. During this indexing process, the spacing between adjacent centroids is simultaneously computed. By enforcing consistent directionality and angular tolerance, this grid-based strategy is designed to remain effective even under non-uniform rebar layouts or partially missing intersections, which are commonly encountered in real construction environments. Figure 8 illustrates the grid recognition procedure. The yellow lines indicate the 30° angular tolerance used during centroid association, while the red arrows represent the recognized spacing between adjacent centroids. The figure also visualizes the sequential assignment of row and column indices as each centroid is identified.

3 Results and Discussion

3.1 Experimental Setup

Image data were acquired using an 18-megapixel Canon EOS 100D DSLR camera, and a total of 500 images containing rebars and fiducial markers were collected in a controlled laboratory environment. The experiment was conducted in a controlled laboratory environment designed to reflect practical wall reinforcement conditions. Four D16 rebars, each 1.5 m in length, were arranged on a veneer plywood in a 3 × 3 grid pattern with a spacing of 300 mm, and fiducial markers were installed parallel to the rebars. The ground-truth rebar spacing was measured using a tape measure for quantitative comparison with the estimated results.

For image acquisition, the shooting distance was varied from 2.0 m to 4.0 m at intervals of 0.5 m to evaluate the effect of increasing distance and associated focus degradation on measurement accuracy. At each distance, more than 30 images were captured under free-view (non-frontal) perspectives. The marker-based configuration also enabled the estimation of camera extrinsic parameters, allowing the influence of viewpoint variations on image projection and measurement accuracy to be analyzed. Model performance was evaluated using the Mean Absolute Error (MAE) and the Mean Relative Error (MRE).

3.2 Detection and Refinement Model Evaluation

3.2.1 Performance of Dual-head Faster R-CNN

The Dual-head Faster R-CNN achieved optimal performance at the 68th epoch, yielding AP50 = 1.0000, AP75 = 1.0000, mIoU = 0.9633, and PCK@8/5/2 of 0.9990/0.9901/0.5315. Detailed results are summarized in Table 1.

Table 1. Evaluation metrics of Dual-head Faster R-CNN

Marker Detection		Rebar Detection	
AP50	1.0000	PCK@8	0.9992
AP75	1.0000	PCK@5	0.9901
mIoU	0.9633	PCK@2	0.5315

3.2.2 Performance of Mmodified HRNet

In the training of modified HRNet, early stopping with a patience of 15 epochs was applied and triggered at epoch 71. Evaluation on an independent test dataset yielded PCK@8/5/2 of 0.9980/0.9957/0.8930. Table 2 summarizes the prediction performance of the HRNet model.

Table 2 Evaluation metrics of modified HRNet

Evaluation index	Result
PCK@8	0.9980
PCK@5	0.9957
PCK@2	0.8930

3.3 Rebar Quantification Results

3.3.1 Rebar Counting Results

The proposed method was evaluated under varying distances (2.0–4.0 m) and viewpoints. Under all tested conditions, the numbers of both vertical and horizontal rebars were correctly estimated with 100% accuracy. These results demonstrate the robustness and practical applicability of the proposed method in real-world field environments.

3.3.2 Rebar Diameter Measurement Results

The results of rebar diameter estimation show that the MAE remained within 0.50–0.59 mm (3.1–3.7%) up to 3.5 m, increasing to 0.77 mm at 4.0 m. This trend is consistent with the reduction in effective pixel resolution as the camera-to-object distance increases, which limits localization precision. The results are summarized in Table 3.

Table 3. Rebar diameter accuracy at different distances

Distance	MAE (mm)	MRE (%)
2.0 m	0.5859	3.7045
2.5 m	0.5100	3.3702
3.0 m	0.5009	3.1310
3.5 m	0.5788	3.5556
4.0 m	0.7747	4.8427

The effect of the viewing angle on rebar spacing estimation was evaluated. The MAE increased from 0.51 mm to 0.86 mm, while the corresponding error rate rose from 3.20% to 5.40% as the viewing angle increased. This behaviour is explained by the fact that, although homography-based planar correction mitigates perspective distortion, residual errors arise at larger view angles due to the three-dimensional geometry of the rebars. A summary of the results is provided in Table 4.

Table 4. Rebar diameter accuracy at different angles

Angle	MAE (mm)	MRE (%)
0-10°	0.5127	3.2045
10-20°	0.5788	3.6178
20-30°	0.6209	3.8808
≤ 30°	0.8642	5.4012

3.3.3 Rebar Spacing Measurement Results

The results of rebar spacing estimation show that the MAE remained within 3.6–4.1 mm (1.2–1.4%) up to 3.5 m, increasing to 4.65 mm (1.55%) at 4.0 m. This trend is consistent with the reduction in effective image resolution at longer distances, which limits the precision of marker feature point localization. The quantitative results are summarized in Table 5.

Table 5. Rebar spacing accuracy at different distances

Distance	MAE (mm)	MRE (%)
2.0 m	3.9208	1.3060
2.5 m	3.6027	1.2061
3.0 m	4.0948	1.3641
3.5 m	3.9787	1.3253
4.0 m	4.6484	1.5487

The effect of the viewing angle on rebar spacing estimation was analyzed, with the MAE ranging from 3.8 mm to 4.5 mm and the corresponding error rates between 1.2% and 1.5%, showing a gradual increase as the viewing angle increased. In particular, an increase in error was observed for viewing angles exceeding 30°. This behavior is attributed to the fact that, although marker-based planar correction mitigates perspective distortion, residual errors arise at larger view angles due to the three-dimensional geometry of the rebars, which is consistent with the trends observed in diameter estimation. The results are summarized in Table 6.

Table 6. Rebar spacing accuracy at different angles

Angle	MAE (mm)	MRE (%)
0-10°	3.8600	1.2858
10-20°	4.1303	1.3759
20-30°	3.9335	1.3103
≤ 30°	4.4560	1.4843

4 Conclusion

This study presents an image-based metrology framework for efficient quality inspection of wide-area rebar placement structures, such as concrete walls. Unlike conventional inspection practices that rely on manual measurements, the proposed framework adopts a two-stage inspection pipeline integrating low-resolution

region detection and high-resolution keypoint refinement using a Faster R-CNN, HRNet, and marker-based homography transformation. To support this framework, the Faster R-CNN detector was extended with a dual-head structure to jointly detect rebars and markers. A lightweight HRNet configuration was adopted for efficient high-resolution keypoint detection.

Experimental validation under varying distances and viewpoints demonstrated robust performance. The proposed method achieved 100% accuracy in identifying both vertical and horizontal rebars under all tested distances and viewing angles. The mean absolute error was 0.59 mm (3.53%) for diameter estimation and 4.05 mm (1.35%) for spacing estimation. These results fall within the permissible tolerance for rebar diameter estimation (0.8 mm) [9] and the commonly accepted error rate for rebar spacing estimation (10%) [10]. These results fall within permissible tolerances confirming stable and practical measurement performance.

Despite these promising results, several limitations remain. First, the experiments were conducted only in a controlled laboratory setting, while real construction sites may introduce complex visual conditions such as uneven lighting, shadows, and background clutter, affecting keypoint detection robustness. Second, the proposed framework requires manual installation of markers, which may introduce additional preparation time. Third, measurement errors may increase when the viewing angle exceeds approximately 30° due to the three-dimensional geometry of rebars, requiring careful camera positioning. Fourth, measurement accuracy may degrade at longer distances due to reduced image resolution.

Future work will address these limitations. First, real construction site data will be collected to evaluate the robustness and generalizability of the proposed method under diverse environmental conditions. Second, rebar-attached markers will be developed to reduce the time and complexity of marker installation. Third, marker-based algorithms will be developed to estimate viewing angles and provide real-time guidance for proper camera positioning in field conditions. Finally, approaches to improve effective pixel resolution at long distances will be investigated to enhance measurement accuracy.

Nevertheless, the proposed approach demonstrates the potential of a low-cost, image-based solution to support practical and scalable rebar quality inspection in the construction industry.

Abstract -

Construction robotics has a significant potential to automate a wide range of construction tasks, but it requires a structured pipeline that links high-level design representations to concrete robotic actions. Robotic bricklaying is particularly well-suited to automation because it consists of repetitive, predefined steps. However, it also introduces process-planning challenges that must be resolved at the level of individual components. Fabrication Information Modeling (FIM) has been introduced as an intermediate layer between design and fabrication for construction-scale additive manufacturing. This study extends the Fabrication Information Modeling framework to enable the transformation of high-level architectural design data into detailed, machine-interpretable specifications suitable for robotic bricklaying operations. Specifically, it proposes an integrated FIM-based data and process representation that supports the systematic planning and execution of automated bricklaying tasks. The framework's utility is validated through detailed bricklaying simulations and a successful real-world application within a controlled laboratory environment.

1 Introduction

Robotics in construction is increasingly adopted to automate repetitive, rule-based tasks in domains such as masonry, welding, and structural steelwork. Through their inherent precision and reliability, robotic systems enhance both occupational safety and operational productivity in hazardous, labor-intensive construction environments [1]. Brick wall assembly, characterized by standardized operations, is a prime candidate for robotic automation [2]. However, achieving a fully automated workflow requires addressing the inherent geometric complexities of masonry [3] and establishing a digital system that bridges building design with automated construction processes [4].

Building Information Modeling (BIM) serves as the foundation, providing a semantically rich digital representation of the built asset [5, 6]. Despite the advancements in digital modeling, a significant gap persists between BIM-based design data and robotic task execution. Robots remain unable to autonomously interpret the high-level, human-centric abstractions used to define BIM entities into the precise sequences required for physical construction [7]. While BIM provides a robust geometric and semantic foundation for Industry 4.0 integration, bridging this gap requires a dedicated methodology that extends BIM data into digital manufacturing workflows, transforming static information into actionable robotic instructions [8].

Fabrication Information Modeling (FIM) acts as a BIM-based digital manufacturing framework that transforms high-level design data into detailed, robot-interpretable instructions. By establishing a cyber-physical link between digital models, processes, and the physical asset, FIM enables integration across the design, fabrication, and assembly phases [4].

This study proposes an FIM-based task-planning framework for automated robotic brick wall assembly. The framework enriches the BIM model by incorporating a fabrication information model, which adds semantic fabrication attributes at the brick level and enables robotic execution of the assembly plan. This process translates high-level entities (e.g., wall definitions) into granular data that supports masonry task planning and execution. The proposed approach was integrated into a robotic simulation framework and validated through real-world robotic bricklaying.

The remainder of this paper is organized as follows: Section 2 provides background on robotic bricklaying, fabrication information modeling in various applications, and FIM-based planning and execution, and FIM; Section 3 details the proposed methodology; Section 4 describes the system implementation in simulation and laboratory environments; Section 5 presents the results; and finally, Section 6 concludes the paper.

2 Background

Automation in construction has become a central research focus, as digital technologies and robotic systems are increasingly being investigated for their potential to enhance productivity, safety, and efficiency on construction sites[7]. Within this broader research context, robotic bricklaying remains a promising yet relatively understudied area of construction automation. It provides a valuable basis for investigating task and motion planning, execution strategies, and information requirements in automated construction workflows.

2.1 Robotic bricklaying

Several studies have explored the integration of robotics into bricklaying workflows at different levels of automation. Early methods demonstrated that human–robot collaboration, often facilitated through mobile or augmented systems, can adapt to on-site conditions, thereby enhancing placement accuracy and reducing material waste [9]. Moving beyond collaborative scenarios, the automation of cable-driven robotic systems has been studied using BIM-driven simulation frameworks that optimize robot kinematics, process physics, and site logistics, resulting in collision-free and energy-aware trajectories [10]. Higher levels of automation have been achieved in a robotic masonry context; while Zhou et al. [11] embedded viscoelastic mortar behavior into a force–position feedback controller, enabling physics-informed adjustment of trajectories, velocities, and bond thickness. Complementing these, data-centric pipelines such as the IFC-to-Robot Operating System (ROS) workflow [7] have begun to translate BIM/IFC wall models into brick-level Cartesian pick-and-place tasks and validate them in a simulation environment. Furthermore, [12] presents a multi-robot coordination system for bricklaying that optimizes robot placement, material location, and task decomposition to reduce overall construction time.

Taken together, existing studies remain project- or platform-specific and only partly address full automation of generating robot-interpretable task data from digital design entities. This leaves robotic brick-wall assembly and construction in need of a framework that can systematically handle robotic process planning down to individual brick components, while resolving discrete process-planning challenges, such as junction assembly scenarios involving T- and L-junctions of connected brick walls within a workspace and an arm robot's reachability.

2.2 Fabrication Information Modeling

Fabrication Information Modelling (FIM) is a BIM-centric digital fabrication methodology introduced to the construction sector by [4, 8]. It is designed to structure

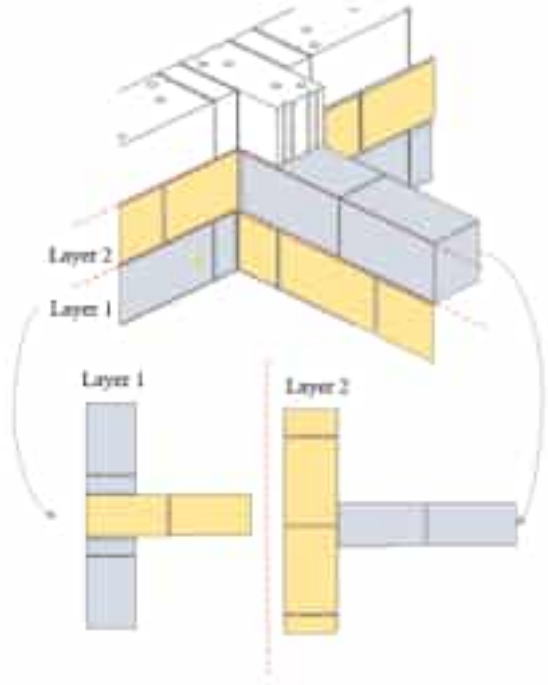

Figure 1. Illustrates the layer-by-layer changing priority wall status between walls and its relevance on the connection point brick placement adaptation [13]

and automate the data flow between high-level BIM geometry and robot-interpretable execution information. Unlike BIM, which primarily describes design intent, constructable element properties, or abstract spatial representations, FIM explicitly models how a structure will be fabricated and processed by deriving fine-grained fabrication data, toolpaths, material-deposition coordinates, sequencing, and machine-control parameters. A key step in FIM's geometry processing is component slicing, where wall or fabrication elements are processed to ordered layers that expose intermediate contours for planning and manipulation [4], enabling FIM to reference fabrication-relevant geometry at multiple levels of granularity. The framework further enables designers to interact with intermediate fabrication representations such as slice contours and path curves, forming a foundational stage for integrating feedback, optimisation, and robotic parameter control functionalities [8]. While representing fabrication and process information via slicing, the Industry Foundation Classes (IFC) schema enables aggregation, allowing multiple geometric representations to co-exist simultaneously [4]. Aggregation capability supports both automation, real-time monitoring and recalibration mechanisms such as RTDE (Real-Time Data Exchange)[14], which integrate material behaviour, nozzle pressure, movement dynamics, and environmental sensor feedback to enable closed-loop

process control during extrusion-based Additive Manufacturing [15]. The proposed framework addresses the research gap by approaching the FIM framework from a BIM-to-FIM perspective and extending FIM's established methodology and IFC-based information base for robotic bricklaying [15].

Despite these advances, robotic brick wall assembly still presents multi-scale challenges, particularly because assembly plans often lack the detailed fabrication and execution information required for robotic implementation, especially at geometrically complex conditions such as wall junctions.

2.3 FIM-based robotic execution

Recent work on construction robotics has increasingly explored methods for linking BIM-based representations with robotic task and motion planning. Initial system-oriented studies demonstrated that IFC models can be converted into robot-compatible planning environments, enabling motion planning, localization, and simulation-based task definitions [16]. Parallel graph-based approaches further showed that BIM's semantic and geometric information can be structured in machine-queryable formats to support robotic navigation and information processing [17]. While these efforts contribute important translation mechanisms, they primarily operate at the project or system level, where the focus remains on robot control, simulation environments, or data conversion pipelines, rather than component-scale fabrication. To improve component awareness, smart-component-oriented workflows segment IFC building entities into metadata-rich representations that carry individual states and robot-communication interfaces, enabling automated IFC–SDF conversion and robotic simulation execution [18]. Similarly, RDF-based middle-layer models organize BIM entities into semantic knowledge graphs that support ontology-based querying and planning of robotic tasks [19]. Although these methods improve data standardization and component-level communication, they do not yet provide a fabrication-focused structure that models building elements according to their manufacturing process to be executed in a single manufacturing process.

Overall, existing studies demonstrate multiple methodologies for establishing BIM–ROS bridges across different scales of robotic construction task planning and execution. However, current studies partly address the automation of generating robot-interpretable task data from design entities. This leaves robotic brick-wall assembly in need of a framework that can handle process planning at the individual brick component level, while resolving discrete process-planning challenges of brick walls.

To address these challenges, we developed a FIM framework that is structured as a pipeline that relies on the IFC data structure to manage and utilize fabrication data for robotic brick wall assembly. Within this pipeline, planning utilizes geometric and semantic fabrication information derived from individual wall elements, aggregating them into a structure-level FIM for the composite brick wall. Fabrication information is represented using a Labeled Property Graph (LPG) in the FIM Information Graph, which is suitable for representing IFC data structures while enabling efficient retrieval and updates of task data. The planning loop maps back the fabrication task states and geometric parameters, enabling component-level task validation, adaptation, and feedback exchange with robotic control. The framework is validated in a simulation environment, followed by robotic execution in a real-world experiment, confirming its applicability beyond digital planning.

3 Methodology

The workflow presented in this work builds on the research of M. Slepicka and A. Borrmann [15], which addressed the transformation of high-level design information into detailed, robot-interpretable data for additive manufacturing. In this context, continuous material deposition in additive manufacturing can be conceptualized as an "infinite brick," whereas the notion of a "finite brick" represents its discretized counterpart, i.e., robotic bricklaying. To support "finite brick", the FIM data structure is extended to represent individual bricks and their corresponding tasks for robotized assembly, as illustrated in Fig. 2.

Similar to 3D printing, a bricklaying fabrication model can be defined by discretizing the component into individual layers, where each layer is described by the brick placement surface (slice) – usually a plane – and the path along which the bricks are placed (toolpath). For "finite brick", the toolpath (`IfcCurve`) is additionally discretized into a list of individual points (`IfcPointOnCurve`), each representing the center of placement for a brick. For regularly shaped bricks, slices are aligned with the top surface of each brick, toolpaths follow their longitudinal centerline, and the discretized points are positioned at the center of their top surface. Thus, compared with additive manufacturing, an additional discretization step is introduced to provide discrete brick placement positions rather than a continuous toolpath.

For data storage, the IFC schema supports multiple IfcShapeRepresentations definitions per layer (cf. Section 2.2). This approach enables the systematic organization of fabrication information into multiple levels of detail, enhancing the model's adaptability and supporting efficient data retrieval. To fully describe the placement of a cuboid (brick) in three-dimensional space, both position and orientation are required. Rather than defining these

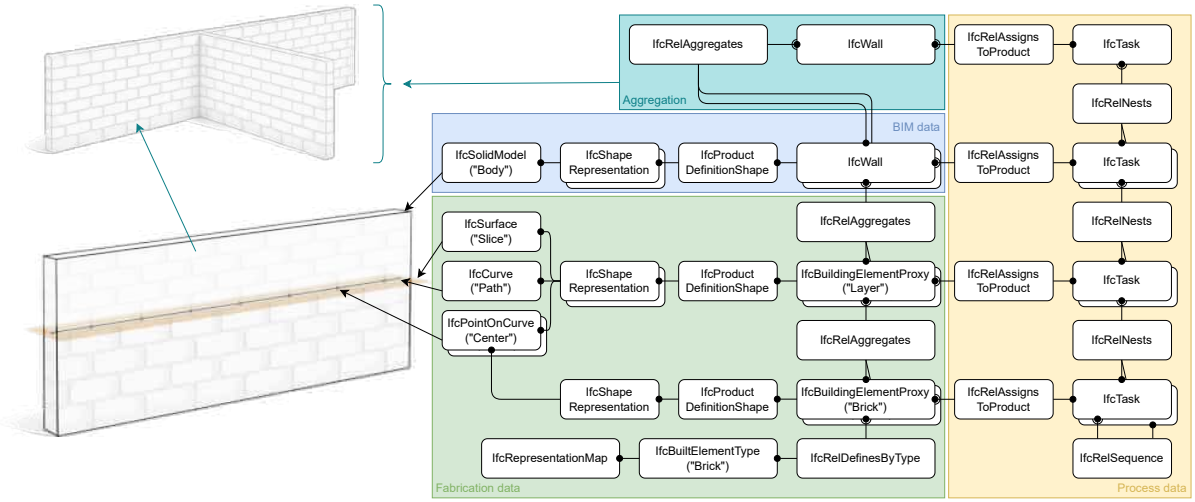

Figure 2. FIM data structure for describing brick walls composed of multiple segments. In the data structure, geometric (left), semantic (middle), and process information (right) are represented.

explicitly, they are captured parametrically through three representations for each layer: the slicing surface (slice) provides the normal orientation, the path provides the lateral orientation, and the point list provides the coordinates. At the same time, this parametric formulation establishes clear rules for discretization from volume to slice, from slice to path, and ultimately to the list of points. For each point, a semantic entity that defines the individual bricks is modeled using `IfcBuildingElementProxy`.

Overall, as defined in [15], a FIM model describes a contiguous component and its corresponding process. For brick walls, we define a contiguous component as the aggregation of wall segments for which all bricks can be placed without violating any placement condition (i.e., each brick must be fully supported). For example, a T-junction of two wall segments built with interlocking bricks at the joint can be regarded as a single contiguous wall. That means, the BIM model is subdivided into multiple FIM models, each representing one contiguous component.

For each FIM model, a new aggregated wall entity is generated that groups all BIM elements belonging to the same fabrication process (see Fig. 2, top). The adaptive planning algorithm identifies how individual wall entities are connected via the relationship `IfcRelConnectsElements` (see Ifc 4.3.2 Documentation [20, Section 5.4.3.48]). With this relationship, it is possible to define the connection type of adjacent wall segments. If the relationship is not present in the model, the adjacent wall segments are regarded as separate components.

In this study, the positional planning algorithm follows an iterative approach. After extracting the relevant BIM data, each wall segment is discretized into individual brick positions, as described in the preceding sections. Brick positions located near junctions are then modified to interlock adjacent segments in an alternating pattern, as illustrated in Fig. 1. Once all brick positions are defined, the bricklaying sequence is determined; here, a straightforward layer-by-layer strategy is adopted. More advanced sequencing algorithms could be applied in future work to optimize construction speed and minimize robot motion.

Aligned with the overall component breakdown structure (wall, wall segment, layer, and individual brick), the process can be modeled in the same hierarchical way. Although the semantic elements can implicitly suggest a task sequence, FIM describes the manufacturing process explicitly using `IfcTask`. As illustrated in Fig. 2 (right), each modeled brick is assigned an individual task representing its placement action. These tasks are organized hierarchically, with brick-level tasks nested within layer tasks, which in turn are nested within component-level tasks and higher-level groupings. In addition, individual tasks are connected through sequencing relationships (`IfcRelSequence`). These relationships can be planned and modeled in a separate planning stage to explicitly define the placement order.

To enable FIM-based robotic bricklaying in ROS, the individual placement tasks must be translated into executable robot instructions. Since each task is linked to the corresponding “Brick” IFC entity, the target pose can be retrieved directly from the FIM model; combined with the known source pose of the next brick, this allows a trajectory to be generated using a standard motion planner. To

support visualization and simulation within the ROS environment, SDF files are additionally required to represent the brick entities (cf. Section 2.3). In the FIM approach, however, SDF models are not generated through a one-to-one BIM-to-SDF conversion for every individual brick, but rather once for each brick type occurring in the model. For subsequent use, the corresponding SDF file can also be linked directly within the FIM model by means of an external reference (`IfcExternalReference`).

4 Implementation

This section presents a proof-of-concept implementation. In the implemented pipeline, BIM data is accessed using the open-source library IfcOpenShell, geometric modeling is performed with PythonOCC, and the resulting fabrication information is stored in a Neo4j graph database via Cypher queries. The implementation's validity is subsequently evaluated using a small-scale robotic setup comprising a UR10e robotic arm equipped with a Robotiq 2F-85 two-finger gripper, controlled via ROS2.

BIM-to-FIM pipeline initialization. As a starting point for the iterative pipeline, a BIM model must be provided. Using IfcOpenShell, the model is first filtered for brick walls. All brick walls that are connected via an `IfcRelConnects` relation are then grouped and aggregated. Then, for each aggregated wall, a separate FIM model is created by setting up a Neo4j database and populating it with all relevant IFC data for that wall (cf. Fig. 2, "Aggregation" and "BIM data"). As a subsequent step, the geometric information of all wall segments is derived to enable slicing operations analogous to the 3D printing methodology described in Section 2.

Segment-wise wall discretization. Using PythonOCC, the volumetric model – typically represented as a BRep or an extruded surface – is subdivided into horizontal slices, referred to as "fabrication layers", with a spacing defined by the brick height. For each layer, a centerline is computed as an alignment curve along which brick positions can be planned. These alignment curves are then discretized into a set of points representing the positions of individual bricks. The discretization is performed according to the selected brick-laying pattern, for example, the pattern shown in Fig. 1, in which every second layer is shifted by half a brick length along the centerline to create an interlocking arrangement. The spacing between adjacent brick positions is determined by the brick length plus a 1 cm clearance space. In this study, the brick dimensions were set to $12 \times 4.8 \times 3.6$ cm. In addition, bricklaying was simplified to dry stacking to focus on the pick-and-place workflow, so no additional allowance for mortar application was required. In this planning stage, the discretization is performed naively, placing only full bricks even when they exceed segment boundaries, providing a straightforward discretization of all individual wall segments.

Brick placement. In accordance with the discretization, semantic entities are instantiated for each layer and for each discretized point using the `IfcBuildingElementProxy` class. The layer entities are designated as `IfcFabricationLayer`, while the brick entities are labeled `IfcBrick`. For all instances, properties can be defined to capture the most relevant characteristics, such as identifiers or static parameters. The geometric representations created in the previous steps are attached to the semantic entities as illustrated in Fig. 2. And, to describe the individual bricks efficiently, type elements (`IfcBuiltElementType`) are instantiated for each type of brick including a representation map that defines the brick geometry.

Rule-based adaptations of brick positions and shapes. In a second iteration, all brick positions located near a segment boundary are reexamined. Two cases are distinguished: either the brick is located near a junction, indicated by an `IfcRelConnects` relationship, or it lies close to the boundary (end) of the wall segment. If the position is near the wall end, it is evaluated whether the corresponding brick extends beyond the wall's boundary representation. When this occurs and an adjustment of the brick length is required, the brick entity is reassigned to a different type entity with suitable dimensions, creating a new type entity if necessary. If the resulting brick length falls below a predefined threshold, a minimum length is enforced and the adjacent brick is shortened accordingly. This adaptation is constrained by the requirement that the modified arrangement must still satisfy the interlocking brick pattern, thereby ensuring proper interlocking across layers. For each updated brick, the position of the corresponding center point is then recomputed parametrically and updated in the model.

In the alternative case, where a brick location is close to a junction, the brick is repositioned so as to interlock with the adjacent wall segment (see Fig. 1, bottom), while the length of the neighboring brick within the same wall segment is adjusted accordingly. Simultaneously, the affected bricks in the connected wall segment are modified to accommodate the interlocking brick. As in the previous case, shape-related changes are handled through the associated type entities, whereas positional changes are reflected in the point list. Across layers, this interlocking is alternated between the involved wall segments. Within the connected wall segment, bricks that overlap with the interlocking brick are identified and trimmed as required. If a brick

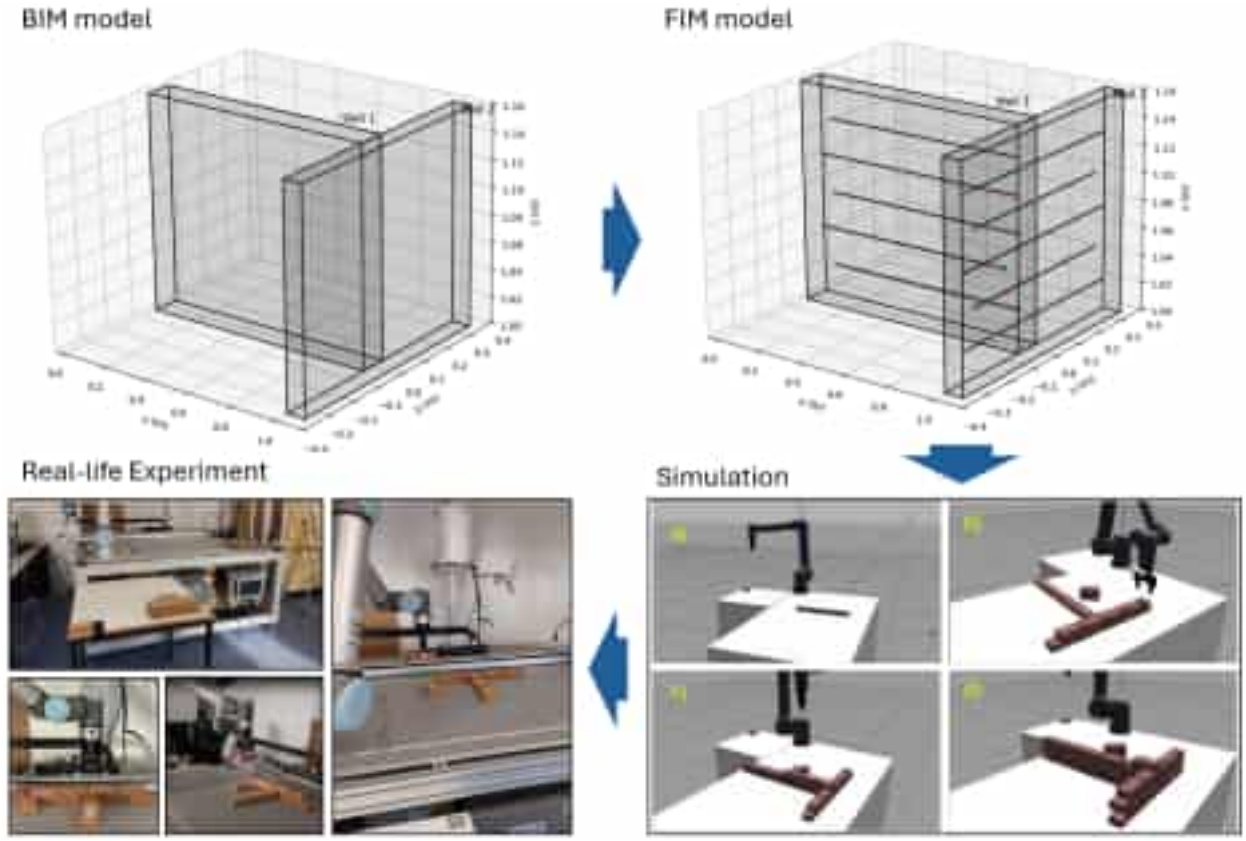

Figure 3. BIM model (top left); FIM model (top right); (a) Sequencing starts with priority wall, (b-c) Priority wall changes with layer change, (d) Successful execution in simulation (bottom right); and real-world execution using the UR10e robot (bottom left).

is split during this process, an additional discretization point and a corresponding `IfcBuildingElementProxy` are created. All resulting modifications are propagated back to the model by updating center point positions and brick dimensions accordingly.

Task planning. As an additional information layer built on top of the brick positions, the bricklaying sequence can be represented within FIM. To achieve this, each "IfcBrick" instance is associated with an `IfcTask` instance that abstractly describes the corresponding brick placement action (see Fig. 2). Consecutive placement actions are then linked using `IfcRelSequence`. In this study, sequencing is performed in a straightforward, layer-by-layer manner.

Each `IfcTask` instance represents the action of placing a single brick, includes attributes describing the task's execution state, and is linked to an `IfcTaskTime` instance that stores scheduling information. The task state can take the values *NOTSTARTED*, *STARTED*, or *COMPLETED*. The associated task time specifies the planned execution time and enables tracking of the actual execution duration.

FIM-based Robot Execution. Once the BIM-to-FIM pipeline is complete, the FIM model is ready for execution. Robot-interpretable commands are then generated sequentially for each modeled task. Each task is linked to an "IfcBrick" instance, from which the brick's position and orientation are retrieved via a simple Cypher query and transformed into a robot target pose. By additionally specifying a source position and orientation for the brick, motion paths can be generated that guide the robot to the pickup location (source pose) and from there to the drop location (target pose). Finally, gripper actions are defined to fully describe the pick-and-place action.

The streamed robotic commands consist of Tool Center Point (TCP) orientations, Cartesian movements, and gripper actions. The generated task sequences are recorded in JSON or YAML and transmitted via TCP/IP to ROS2 as granular brick action commands for execution. By streaming task data per brick instead of exporting a single static command file, the robot controller remains contin-

uously connected and synchronized with the component-level database during execution.

As an extra layer of safety, the whole process can be simulated first in a physics-based simulator, e.g., Gazebo, to detect potential issues, such as collisions or reachability problems. The simulation replicates the real robotic laboratory setup. After the simulation, the developed FIM-based fabrication can then be executed in real life using the robotic arm system.

In this study, the experiment was constrained to the reachable workspace of a single UR10e robot, with each wall discretized into a 6×6 brick grid. A T-junction case consisting of two connected walls was evaluated over 6 layers. T-junction handling resulted in 14 of 72 bricks being replanned as shown in Figure 3. After the simulation was executed without collisions, the process was successfully executed in real life using a UR10e robot arm equipped with a Robotiq 2-finger gripper 2F-85. The results of both simulation and real execution are illustrated in Fig. 3.

5 Results

The developed pipeline is responsible for the complete workflow, from geometric and semantic processing of BIM wall entities to producing the composite structure's FIM for robotic execution. Therefore, in this section, the end-to-end applicability of the developed FIM pipeline is demonstrated in the following steps: *i) Fabrication-relevant geometric and semantic information processing and mapping. ii) Deploying the adaptive planning loop. iii) Simulation execution. iv) Real-life robotic execution.*

6 Conclusion and Future Work

In this paper, a methodology for automating the robotic brick wall assembly task is presented as a BIM-to-FIM task and motion planning pipeline. The framework extends fabrication information modeling by enriching IFC-based wall geometry and semantic relationships to generate robot-interpretable process data, while leveraging this semantic information to enable rule-based adaptations to process-planning complexities, such as wall junctions. The previously introduced slicing approach is further extended to discrete Cartesian brick-placement tasks, and an adaptive planning method is proposed to maintain consistency. A streaming interface synchronizes the robot controller with FIM, ensuring that execution reflects the current fabrication state while preserving prior adaptations. The proposed approach was validated in the same simulation and real-life experiment with the UR10e setup, demonstrating that the pipeline bridges the gap between design and robotic execution in an integrated, automated workflow. However, the current evaluation should be interpreted as a proof of concept, as it was conducted in a constrained setup involving a single robot workspace, a 6*6 brick grid, and a six-layer T-junction configuration. Accordingly, the present results primarily demonstrate functional feasibility and workflow integration rather than quantitative performance in terms of execution time, planning efficiency, or geometric placement deviation.

The proposed approach demonstrates that brick-level process adaptation and junction handling can be automated directly by leveraging BIM semantics with an FIM-based planning process, while presenting the framework as a fabrication-centered, component-aware planning pipeline.

Overall, this work demonstrates that Fabrication Information Modeling can serve as a synchronized intermediate layer for robotic brick wall assembly, supporting automated sequencing and geometry-based task adaptation within a unified model. While highlighting FIM's task-agnostic and adaptable, the developed methodology opens the door to more comprehensive scenarios, such as multiple junctions and geometric complexities.

Future work will therefore extend the framework to larger and more diverse wall assemblies, including openings, corners, and multiple junction configurations, in order to assess its scalability under more realistic construction conditions. Furthermore, it will be extended by integrating process feedback mechanisms, such as sensor output and camera data, to enable continuous, process-aware, adaptive planning. In addition, future studies will incorporate quantitative evaluation metrics, including planning time, execution time, task success rate, and deviation between planned and executed brick placement. The current layer-by-layer sequencing strategy will also be extended toward optimization-based sequencing methods to improve process efficiency and reduce unnecessary robot motion.

Abstract

Scaffold inspection is critical for ensuring construction safety. However, scaffolds are typically dense, multilayered, and continuous structures, making them difficult to analyze automatically using traditional geometric methods. In this paper, a framework for automated scaffold component recognition and joint-level understanding is proposed by leveraging Vision–Language Models (VLMs) and 3D Gaussian Splatting (3DGS) to interpret complex scaffold assemblies. Domain knowledge is incorporated to decompose the structure using 3DGS, where photorealistic rendering is exploited to generate clear visualizations for semantic interpretation by pretrained VLMs. The semantic understanding of scaffold components lays a crucial foundation for future compliance-oriented analysis by enabling the precise identification and spatial reasoning of code-relevant and design-relevant scaffold components. This approach is expected to provide a reference for analyzing other continuous and complex structures in construction scenarios.

Keywords –

Scaffold; Vision-Language Model (VLM); 3D Gaussian Splatting (3DGS); Component Recognition

1 Introduction

Construction safety remains a critical concern worldwide, with falls from height consistently ranking among the leading causes of construction-related fatalities [1]. Temporary structures such as scaffolds are major contributors to these incidents, as their frequent erection and dismantling cycles significantly increase the risk of structural failure [2]. To mitigate these risks, safety regulations require that scaffolds be inspected regularly for compliance with both construction codes and design specifications throughout their lifecycle.

As shown in Figure 1, scaffold inspection tasks can be broadly categorized into two parts. The first is code compliance checking, which verifies whether key components meet regulatory requirements in terms of installation and dimensions. For example, whether base plates are properly placed, whether the vertical distance between adjacent guard rails is within the 600 mm limit, and whether toe board heights exceed the minimum of 90 mm, as mandated by standard scaffolding safety regulations [3]. The second is design compliance checking, which ensures that the scaffold has been assembled exactly as planned including checking for missing elements such as bracings, and verifying whether couplers match the design specifications.

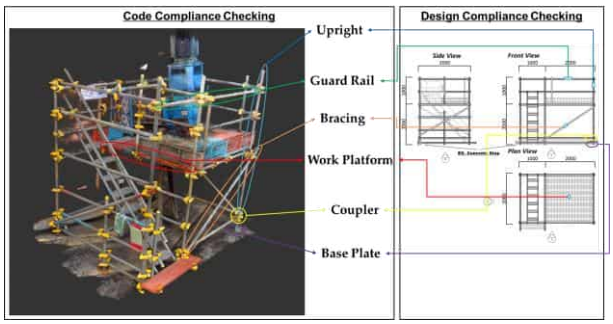

Figure 1. Conceptual workflow of scaffold component classification and compliance checking against code and design specifications. (Created by the authors based on the information provided by onsite engineers).

However, current inspection practices are still predominantly manual, relying heavily on the experience of safety managers and site supervisors. These methods are time-consuming, labor-intensive, and prone to human error, particularly in dense, multilayered scaffold systems. Although recent research has explored the use of computer vision for scaffold analysis, most existing approaches are limited to the geometric interpretation of textureless 3D point clouds [4-7]. These methods often

lack the photorealistic fidelity and semantic richness needed for detailed component recognition and are difficult to scale for complex real-world scenarios.

To address these limitations, this paper presents a framework for automated as-built scaffold understanding by integrating 3D Gaussian Splatting (3DGS) with Vision-Language Models (VLMs). Specifically, unlike sparse and textureless point clouds, 3DGS reconstructs 3D scenes with high photorealistic fidelity, preserving both accurate geometry and rich visual appearance (color, texture) to provide a high-quality foundation for downstream analysis [8-10]. Concurrently, VLMs solve the generalizability limitations of traditional deep learning methods by leveraging the photorealistic 2D renderings generated by 3DGS to perform flexible, prompt-based semantic segmentation without the need for extensive task-specific training [11-13]. This bypasses the need for extensive task-specific 3D training data and enables human-interpretable component recognition. Together, this integration serves as a robust first step toward enabling automated component recognition and compliance checking workflows.

To operationalize this integrated framework, the proposed pipeline follows a systematic workflow. Starting from site-captured point clouds and images, a photorealistic 3DGS model is constructed to represent the as-built scaffold with high visual and geometric fidelity. The structure is then decomposed into semantically meaningful subcomponents via 3DGS-based editing. Pretrained VLMs are applied to these substructures to extract and interpret semantic information, enabling fine-grained component segmentation and classification. Furthermore, critical joints can be examined in detail by adjusting viewpoints and zooming within the 3DGS model, supporting close-up inspection and providing the necessary information for compliance verification.

2 Literature Review

2.1 Scaffold Inspection

Previous research on scaffold inspection has primarily focused on two major directions. The first line of work aims to monitor scaffold deformation, which is crucial for early detection of structural instability. Two main approaches have been explored: sensor-based methods, which use strain gauges or other physical sensors to measure deformation directly [14,15], and vision-based methods, which infer deformation by analysing pixel-level changes across image sequences [16,17]. While the latter can generate heatmaps to visualize deformation trends, they often lack fine-grained, component-level information.

The second line of research focuses on semantic segmentation of scaffolds into discrete components such as uprights, guardrails, bracing, work platforms, stairs, and toe boards. These methods typically operate on 3D point cloud data, attempting to segment the scaffold into meaningful elements [4,7,18]. However, they often rely heavily on manually defined geometric rules, which are sensitive to noise and make the process unstable and difficult to generalize for large-scale scaffold inspection. While some deep learning–based methods have been proposed to improve robustness and generality, they usually require extensive annotated training data. Moreover, due to the black-box nature of deep models, it is often difficult to diagnose or fine-tune the system when performance is suboptimal in complex real-world conditions.

2.2 3D Gaussian Splatting

To remove the ambiguity of point cloud analysis–based component extraction, 3DGS provides a highly suitable solution. 3DGS is an emerging technique for real-time radiance field rendering, offering a compelling alternative to traditional mesh or point cloud based scene representations [9]. 3DGS models a scene as a collection of anisotropic 3D Gaussians, each parameterized by position, scale, orientation, color, and opacity. These Gaussians are efficiently splatted onto the image plane to generate photorealistic renderings from arbitrary viewpoints at interactive frame rates.

Recent studies have demonstrated the capability of 3DGS to capture fine surface details and complex lighting with high fidelity, which is especially valuable for detailed visual inspection in unstructured and cluttered environments. Compared to sparse and noisy point clouds, 3DGS produces a dense, view-dependent scene representation that preserves both geometric and appearance cues. This enables users to zoom into specific components, change viewpoints, and visually isolate substructures, which is essential for accurate and interpretable inspection workflows. Although 3DGS has been primarily applied in computer graphics and immersive rendering, its potential for component-level analysis in the Architecture, Engineering, and Construction (AEC) industry has not been fully explored. This paper leverages 3DGS to enhance semantic decomposition and inspection of as-built scaffold structures.

2.3 Vision-Language Model

While 3DGS enables photorealistic visualization of as-built scenes, VLMs provide potential solution to the semantic understanding of image content. VLMs have recently emerged as powerful tools for multimodal reasoning by jointly learning from both visual and textual data. These models, often pre-trained on large-scale

image text pairs, are capable of associating natural language descriptions with visual content, enabling tasks such as image captioning, visual question answering, and semantic segmentation through textual prompts. Recent advances, including CLIP [19], BLIP [20], and GPT-4V [21], have demonstrated strong generalization across domains, even with zero-shot or few-shot inputs. Such capabilities make VLMs especially promising for domains with limited labeled data or where human-like semantic understanding is needed [22-24].

In the context of construction automation, VLMs offer a new paradigm for interpreting complex scenes in a flexible and human-interpretable way. Unlike traditional vision models that require task-specific training datasets, VLMs can be prompted using natural language queries to identify or describe components, attributes, or spatial relationships. Despite their success in general vision tasks, the application of VLMs in 3D construction environments remains underexplored, and this paper aims to bridge that gap through an integration with 3DGS.

3 Methodology

This paper presents a method for as-built scaffold understanding by integrating 3DGS with VLMs, providing a foundation for downstream compliance inspection tasks. As illustrated in Figure 2, the proposed workflow consists of five main stages: (1) Mobile laser scanning is first employed to capture high-resolution point clouds and images of the as-built scaffold. (2) These multi-modal data are fused to generate a photorealistic 3DGS scene representation that preserves both geometric structure and visual appearance. (3) A 3DGS-based structure decomposition process is then applied to isolate scaffold substructures based on spatial layout. (4) Each substructure is further segmented through VLM-based semantic analysis, where pretrained VLMs interpret rendered 3DGS views to assign component-level labels (e.g., upright, bracing, guardrail). (5) Finally, a component-wise graph is constructed to encode the topological relationships among scaffold elements, enabling joint-level analysis that is relevant for code compliance and design conformance.

.

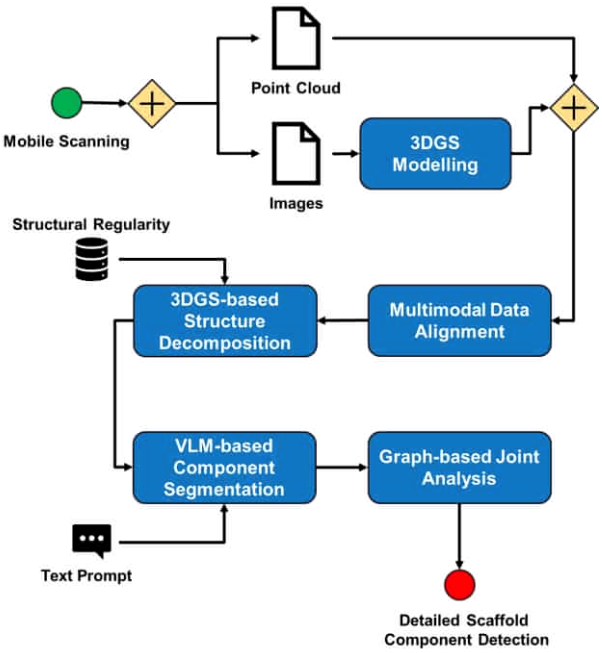

Figure 2. Pipeline for 3DGS-based, VLM-enabled understanding of as-built scaffold data.

3.1 Mobile Scanning

To capture as-built conditions of scaffold structures, a mobile scanning system was employed, as shown in Figure 3. The data acquisition platform integrates a LiDAR sensor and two high-resolution RGB cameras, enabling synchronous collection of both dense point clouds and photorealistic images. The scanning process is conducted manually by an operator walking around the scaffold with the handheld device, ensuring flexible access to complex and confined construction environments. The system adopts Fast-LIVO2 [25] as its Simultaneous Localization and Mapping (SLAM) backend, which provides robust real-time pose estimation and trajectory optimization. This allows for accurate spatial registration of the captured LiDAR frames and camera images, resulting in a globally consistent 3D representation of the scene. The acquired data serve as the foundation for 3DGS and subsequent semantic analysis in the pipeline.

Figure 3. Mobile scanning for data collection

3.2 3DGS Modelling

To obtain a high-fidelity and interpretable representation of the as-built scaffold structure, 3DGS is employed as the core modeling technique. Rather than relying on explicit mesh reconstruction or discrete point clouds, the scene was modeled as a radiance field parameterized by a set of volumetric 3D Gaussians. This representation enables photorealistic rendering from arbitrary viewpoints and provides strong support for visual inspection and downstream analysis.

The modeling process was initialized using a sparse Structure-from-Motion (SfM) reconstruction, from which camera parameters and initial 3D point distributions were estimated to guide the placement of Gaussians. An iterative optimization was then performed to refine each Gaussian's parameters including position, scale, opacity, and appearance (encoded via spherical harmonics) by minimizing a photometric loss between rendered and observed images. A visibility-aware renderer was used to simulate training views and guide updates. To ensure compactness and sufficient coverage, a density control mechanism was applied, dynamically adding or pruning Gaussians based on gradient feedback.

As shown in the left part of Figure 4, this process transforms a large set of unstructured images into a coherent 3D model that captures both photorealistic appearance and explicit spatial structure. Unlike traditional image-based methods, the resulting 3DGS model encodes geometric relationships in 3D space, allowing the scene to be interpreted as a spatially organized structure. This spatial coherence provides a robust foundation for structural decomposition, where scaffold components can be systematically separated based on their relative positions, orientations, and connectivity, enabling higher-level reasoning about component grouping and configuration in a data-driven yet interpretable manner.

3.3 Multimodal Data Alignment

Since the 3DGS reconstruction does not preserve an accurate global scale, SLAM-based point clouds were incorporated to leverage their precise geometric information. To integrate the SLAM point cloud with the 3DGS model, a registration step was performed. As the two representations exist in different coordinate frames, a two-stage alignment process was adopted. First, a coarse transformation was estimated using a three-point alignment based on corresponding anchor points identified in both datasets. The alignment was then refined using the Iterative Closest Point (ICP) algorithm to minimize geometric discrepancies. As a result, the photorealistic 3DGS model was accurately aligned with the globally referenced SLAM point cloud, as shown in Figure 4, enabling consistent spatial reasoning across subsequent processing stages.

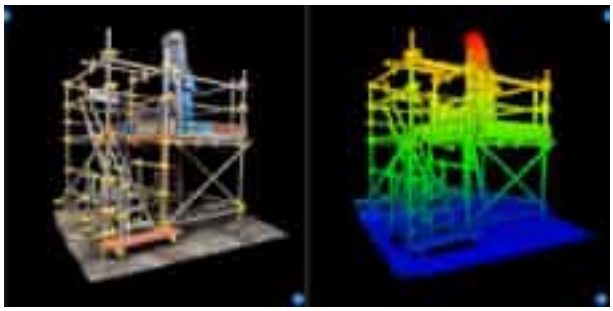

Figure 4. Geometrically aligned 3DGS (left) and point clouds (right).

3.4 3DGS-based Structure Decomposition

To simplify the analysis of complex scaffold assemblies, structure decomposition was performed directly on the 3DGS model. Based on the global coordinate system established during registration, the scaffold was segmented into meaningful substructures according to their geometric locations and spatial hierarchy. Specifically, spatial filters were applied along the X, Y, and Z axes to crop out regions corresponding to the front face, side frames, and intermediate bays. This axis-aligned cropping strategy leverages the inherent regularity of scaffold structures, which are typically aligned with global Cartesian axes. It enables clean separation of components while preserving substructure integrity, offering a simple and interpretable approach suitable for early-stage inspection workflows. By iteratively applying these geometric cropping operations, the continuous and highly layered scaffold structure was decomposed into a set of clear, modular components, each representing a distinct structural unit. As illustrated

in the left part of Figure 5, the front face has been isolated, enabling precise VLM-based analysis and component segmentation in subsequent stages.

Figure 5. 3DGS-based structure decomposition and VLM-enabled component recognition. The left image shows the cropped frontal view of the scaffold's 3DGS model; the right image illustrates the segmentation results using the text prompt "bar".

3.5 VLM-Based Component Segmentation

To achieve semantic understanding of scaffold components, a vision-language model (VLM) was employed to segment 3DGS-rendered views based on natural language prompts. Specifically, SAM3 [12] is adopted, a recent model designed for promptable concept segmentation, which supports segmentation of all instances matching a concept prompt across images and videos. SAM 3 accepts short noun phrases or image exemplars as prompts and returns corresponding segmentation masks along with object identities. Prompt-based segmentation was adopted to minimize manual labeling and avoid rigid class definitions, enabling flexible and interpretable semantic analysis. In the proposed pipeline, one rendering of the 3DGS model were generated for each substructure from calibrated camera poses, and each image was prompted with component-level concepts such as "bar", "stair", and "board". The SAM 3 model uses a DETR-based detector and a mask decoder, conditioned on both text and visual prompts, to produce high-quality masks. A presence token is used to decouple recognition and localization, improving segmentation accuracy in cluttered scenes. The segmentation results for the front side, obtained using the text prompt "bar," are presented in Figure 5.

The resulting 2D masks were projected back to the 3D space by leveraging the 2D–3D correspondences inherent in the 3DGS rendering process. Specifically, each 2D pixel in the segmentation mask was mapped to its nearest 3D point clouds by reprojecting the camera ray and using visibility-aware associations. In this way, the semantic labels predicted by the VLM were transferred to the corresponding subset of 3D point clouds, effectively labeling the scaffold model at the point level. By aggregating segmentation results across multiple views, a consistent 3D semantic segmentation was obtained as shown in the left part of Figure 6, forming the basis for subsequent component graph construction and compliance analysis.

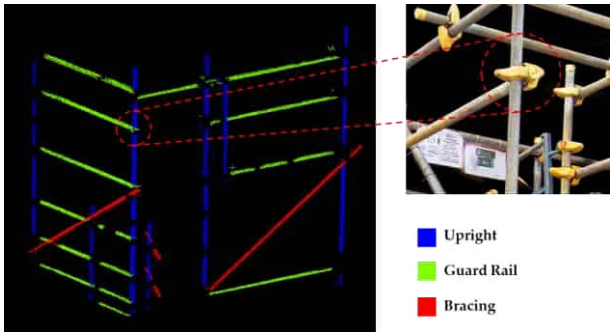

Figure 6. Scaffold component segmentation and corresponding as-built details. Left: segmented scaffold structure showing uprights (blue), guard rails (green), and bracings (red). Right: 3DGS of selected joints located at the intersection between a guard rail and an upright.

3.6 Graph-based Joint Analysis

Following instance segmentation, each scaffold component is represented as a labeled subset of 3D points corresponding to structural elements such as uprights, guard rails, and bracings. To capture the structural connectivity among these components, a spatial graph is constructed based on proximity-based interaction. Specifically, pairwise distances between segmented components are computed, and potential joints are inferred wherever two elements fall within a predefined spatial threshold. These candidate connection points serve as the edges in a component-level graph, while the scaffold members themselves define the nodes, forming a graph-based abstraction of the scaffold topology.

Once the graph is established, the precise 3D positions of joint candidates are localized using the high-fidelity 3DGS model. Since 3DGS preserves photorealistic appearance and scene geometry, rendered views of the detected joints allow for visual verification and detailed analysis of couplers and base plates. As illustrated in Figure 6, this enables the system to infer the presence of joints from geometry, providing detailed visual cues that assist in inspecting their physical condition and evaluating compliance with structural regulations. By combining geometric reasoning with appearance-based cues, this graph-based framework supports joint-level inspection in a scalable and interpretable manner. While a full-scale quantitative evaluation of the spatial graph and automated compliance checking are reserved for future work, this graph-based

abstraction serves as a crucial topological bridge. Currently, it is utilized to localize candidate joints, directly guiding the targeted detection and visual inspection of critical connection elements like couplers (as evaluated in Section 4). Thus, this joint-level understanding provides a necessary foundation for downstream analyses.

4 Experiments and Results

To evaluate the effectiveness of the proposed pipeline, experiments were conducted on real-world scaffold scenes captured via mobile laser scanning. The evaluation focused on the object detection accuracy of individual scaffold components, assessed by comparing the predicted labels to manual annotations. The tested scene serves as a representative real-world case intended to validate the feasibility of the proposed pipeline, rather than to provide a comprehensive performance benchmark. Therefore, the current findings should be considered preliminary. Broader validation across multiple sites and scaffold configurations is left for future work. Table 1 summarizes the detection performance across five key component categories (uprights, guard rails, braces, couplers, and base plates) using standard evaluation metrics: true positives (TP), false positives (FP), false negatives (FN), precision (Pre), recall (Rec), and F1-score (F1).

Table 1 Results of scaffold component detection

Component Type	TP	FP	FN	Rec.	Pre.	F1
upright	7	0	0	1.00	1.00	1.00
guard rail	11	0	0	1.00	1.00	1.00
bracing	4	0	0	1.00	1.00	1.00
coupler	28	0	2	1.00	0.93	0.96
base plate	4	0	0	1.00	1.00	1.00

A total of 56 components were annotated and used as ground truth. The results show that the proposed method achieves high precision across the evaluated categories in this specific scene, with nearly zero false negatives recorded among the 56 annotated components. Notably, the detection of couplers (achieving 28 true positives) and the joint-level visualization shown in Figure 6 (Right) serve as a validation of the graph-based joint analysis proposed in Section 3.6. By successfully localizing the intersections among linear structural elements through the spatial graph, the system was able to accurately isolate and identify the corresponding couplers. This demonstrates the practical utility of the graph-based abstraction in supporting detailed component inspection, even though a few false negatives occurred due to occlusions and limited visibility in the scanned data. While these initial results demonstrate the fundamental feasibility of the proposed 3DGS and VLM-based pipeline for component recognition, we acknowledge that this small-scale evaluation does not fully capture the complexities of diverse construction sites.

Although a direct quantitative comparison is challenging due to the absence of standardized public datasets for scaffold inspection, contrasting the proposed approach with existing literature underscores its novelty and practical feasibility. Traditional methods predominantly rely on fully supervised 3D point cloud segmentation networks (e.g., PointNet or RandLA-Net). In the broader computer vision domain, these general frameworks typically achieve mean Intersection over Union (mIoU) of around 80% on standard point cloud benchmarks [26]. Specifically for scaffolding, recent studies report mIoU scores ranging from 80% to 87% [4]. However, these approaches suffer from two major limitations: first, they are restricted to semantic segmentation and cannot provide the object-level (instance) representations essential for detailed compliance checking; second, they necessitate hundreds of manually annotated 3D frames for training. In contrast, our proposed 3DGS and VLM-based framework achieves highly competitive object-level recognition, yielding higher recall and precision on major components in our test case without requiring any task-specific 3D training data. The core novelty lies in synergizing the high-fidelity rendering of 3DGS with the zero-shot, open-vocabulary capabilities of VLMs. This paradigm fundamentally bypasses the data preparation bottleneck inherent in traditional point cloud methods, demonstrating strong potential for rapid, scalable deployment in dynamic construction environments.

Overall, the integration of 3DGS modeling and VLM-based segmentation enables high-quality detection for the tested component categories, demonstrating promising potential for automated inspection workflows.

5 Conclusion

This paper presents an automated pipeline for scaffold component recognition and joint-level understanding by integrating mobile laser scanning, 3DGS, and VLMs. Through precise 3D reconstruction and prompt-based segmentation, the system effectively identifies and labels structural elements such as uprights, guard rails, and couplers. A graph-based analysis further enables joint detection and spatial reasoning. Experimental results demonstrate high accuracy in component detection, with zero false positives and minimal false negatives.

While the current evaluation is based on a single representative scene with a limited number of components, the results confirm the initial feasibility of the approach as a proof-of-concept. However, several

critical limitations remain. The small dataset size does not sufficiently demonstrate the framework's generalizability across diverse scaffold configurations. Furthermore, the system's robustness in highly cluttered construction environments, where severe occlusions, varying lighting conditions, and dense overlapping structures are common, requires further investigation. These aspects, along with sensitivity to scan quality and prompt phrasing, will be addressed in future work through large-scale data collection and comprehensive benchmarking across multiple complex sites.

Overall, although a complete automated compliance checking system remains a subject for future work, the proposed approach successfully lays the essential foundation for such systems by providing reliable component recognition and joint-level topological understanding capabilities.

Abstract

Fire safety compliance checking is essential for BIM-based design review, yet it remains largely manual in practice, leading to substantial time costs. Although automated checking approaches (e.g., NLP-based methods) have been explored, two major challenges remain: (1) in practice, operationalization is largely limited to semantic requirements, whereas clauses involving geometric and topological structures are difficult to execute; (2) automation remains limited because NLP-based methods often require manual mapping tables due to terminology mismatch and unclear condition parsing, and the extracted rules are not sufficiently stable. To address these issues, this paper proposes the Framework of Four-Dimensional Fire Safety Knowledge–Enhanced Large Language Model (4FKE-LLM). First, this paper constructs a four-dimensional fire safety knowledge graph—Semantic, Geometric, Topological, and Scenario, which organizes and structurally represents regulations across the four dimensions to support subsequent LLM-based compliance checking. Second, this paper proposes an LLM-based two-layer compliance checking mechanism. The first layer pre-filters regulatory and model information to identify applicable regulations and relevant objects, and the second layer performs dimension-specific regulation matching and reasoning across the four categories.

Experiments on a dormitory building case study show that the 4FKE-LLM framework achieves F1 = 0.863 and Accuracy = 0.885, and outperforms the two selected baselines on this case in terms of classification performance and checkable coverage.

BIM Compliance Checking; Fire Safety Regulations; Knowledge Graph; Four-Dimensional Rule Classification; Large Language Model

1 Introduction

Fire safety inspection is of paramount importance during the BIM design process. In the event of a fire, the evacuation of personnel, smoke control, fire compartmentalization, and firefighting efforts are directly affected by the spatial and component layout of the building [1]. If issues are not detected and corrected during the design phase, the subsequent costs and risks of rework during construction and operations can be significant, impacting both project timelines and safety [2, 3]. Additionally, BIM designs must comply with fire safety regulations [4]. When a project fails to meet key regulatory clauses, designers are required to modify their plans, further delaying the construction schedule. Therefore, conducting timely and reliable fire safety compliance checks during the BIM design phase is essential [1].

Currently, there are three main approaches for fire safety compliance checking in BIM. The first method is manual inspection. Designers or reviewers examine the drawings and models, cross-referencing with checklists, applying judgment based on experience, and performing spot calculations to verify compliance [2]. While this method can address complex cases and incorporate engineering expertise, it is time-consuming, costly, and subjective, with varying results depending on the individual examiner [3]. To overcome this limitation, researchers begin using rule engines. This approach decomposes regulatory clauses into explicit conditions and thresholds, then uses geometric calculations, database queries, or scripts to automatically assess the model [4, 5]. This approach is faster and more stable, but is highly dependent on the complete accuracy of the translation of the rules into a machine-readable format and the ability of the model to contain the required parameters and relationships [6, 7]. When clauses are complex or models lack essential parameters, the rules can fail to execute, reducing the scope of checks. The

third method, based on natural language processing (NLP), attempts to automatically structure regulatory texts and align clauses with model fields for process-based checks [8, 9]. While this method reduces the need for manual clause breakdowns and organization, it still faces issues such as inconsistent terminology and unclear regulation decomposition [8]. These issues can lead to unstable clause-to-model matching, misclassification of requirements, and reduced checkable coverage in practical compliance workflows. More importantly, many fire safety clauses require spatial, component, and connectivity relationships, which are often insufficiently aligned with textual descriptions, limiting their reliability and verifiability [5-7].

In recent years, the capabilities of large language models (LLMs) have progressed rapidly. LLMs can better understand natural language clauses, normalize different expressions, and generate more coherent explanations [10]. This allows LLMs to address the shortcomings of traditional NLP in "semantic understanding" and "expressive rewriting". However, directly applying LLMs to compliance checking still leaves two key research gaps. First, LLMs can generate plausible but inaccurate conclusions and may produce inconsistent judgments across different reasoning rounds [3]. Second, fire safety compliance depends not only on semantics but also on geometric constraints, topological relationships, and attribute dependencies, such as “from where to where,” “which doors connect to which corridors,” “whether a compartment is independent,” and “whether a component’s fire resistance rating meets the requirement.” If these relations are missing from the BIM model or are not structured into usable data, the LLM may understand the text but still cannot produce stable or explainable clause-level judgments. As a result, it tends to work better on semantic clauses while struggling with geometric, topological, and scenario logic [3]. Therefore, LLMs function here not as standalone inspectors, but as supporting reasoning modules. Accordingly, this study aims to enable stable, clause-level fire safety checking by integrating these models with structured four-dimensional rules and enriched BIM data.

Thus, this paper proposes the Framework of Four-Dimensional Fire Safety Knowledge–Enhanced Large Language Model (4FKE-LLM) to solve these issues. (Figure 1). First, 4FKE-LLM constructs a four-dimensional fire safety regulation knowledge graph (Semantic, Geometric, Topological, and Scenario), which organizes and structurally represents regulations across the four dimensions to support subsequent LLM-based compliance checking. Second, 4FKE-LLM implements an LLM-based two-layer compliance checking mechanism, the first layer pre-filters regulation and model information to identify applicable regulations and relevant objects, while the second layer performs dimension-specific regulation matching and reasoning across the four dimensions. Rather than simply replacing traditional NLP modules, the key contribution of 4FKE-LLM lies in integrating a four-dimensional rule representation with a two-layer LLM checking workflow to improve classification performance and checkable coverage.

2 Methodology

Framework of Four-Dimensional Fire Safety Knowledge–Enhanced Large Language Model (4FKE-LLM)

The 4FKE-LLM Framework integrates BIM and fire safety regulation rules to provide an efficient fire safety compliance checking method (Figure 1). The overall framework comprises three main components: (1) the development of the 4D Fire Safety Knowledge Graph (steps 1-3), (2) BIM fire safety information extraction and data enrichment (steps 4-6), and (3) LLM-based reasoning using "Four-Dimensional Rule Knowledge" and "Model Data" to generate a compliance checking report (steps 7-11).

The first component is the development of the 4D Fire Safety Knowledge Graph. This process involves denoising raw regulatory texts and categorizing them into the four dimensions of semantic, geometric, topological, and scenario-based rules (step 1), enabling the LLM to better understand the structure and content of regulations. The categorized rules are then converted into a knowledge graph (step 2) and stored in a data exchange format (step 3) that is easily understood by the LLM, facilitating subsequent queries.

The second component involves BIM fire safety information enrichment and extraction. Custom parameters are added to the BIM model to enrich the key data necessary for fire safety compliance checks (step 4), which are typically missing in the original BIM model. The relevant parameters are then extracted and converted into the Industry Foundation Classes (IFC) standard (step 5), ensuring interoperability between different platforms. The enriched IFC model is then translated into a data format suitable for the LLM (step 6). This ensures that the model can read and process BIM fire safety information and provides data support for checking.

The third component is LLM-based Two-layer fire safety compliance checking. User can submit requests through a pre-configured prompt at the query interface (step 7). After ingesting the 4D Fire-Safety Knowledge Graph and the BIM data (step 8), the framework performs two-layer checking. In the first layer, the LLM applies predefined filtering rules to identify applicable clauses and select relevant BIM objects (step 9). In the second layer, it conducts rule matching and reasoning over the

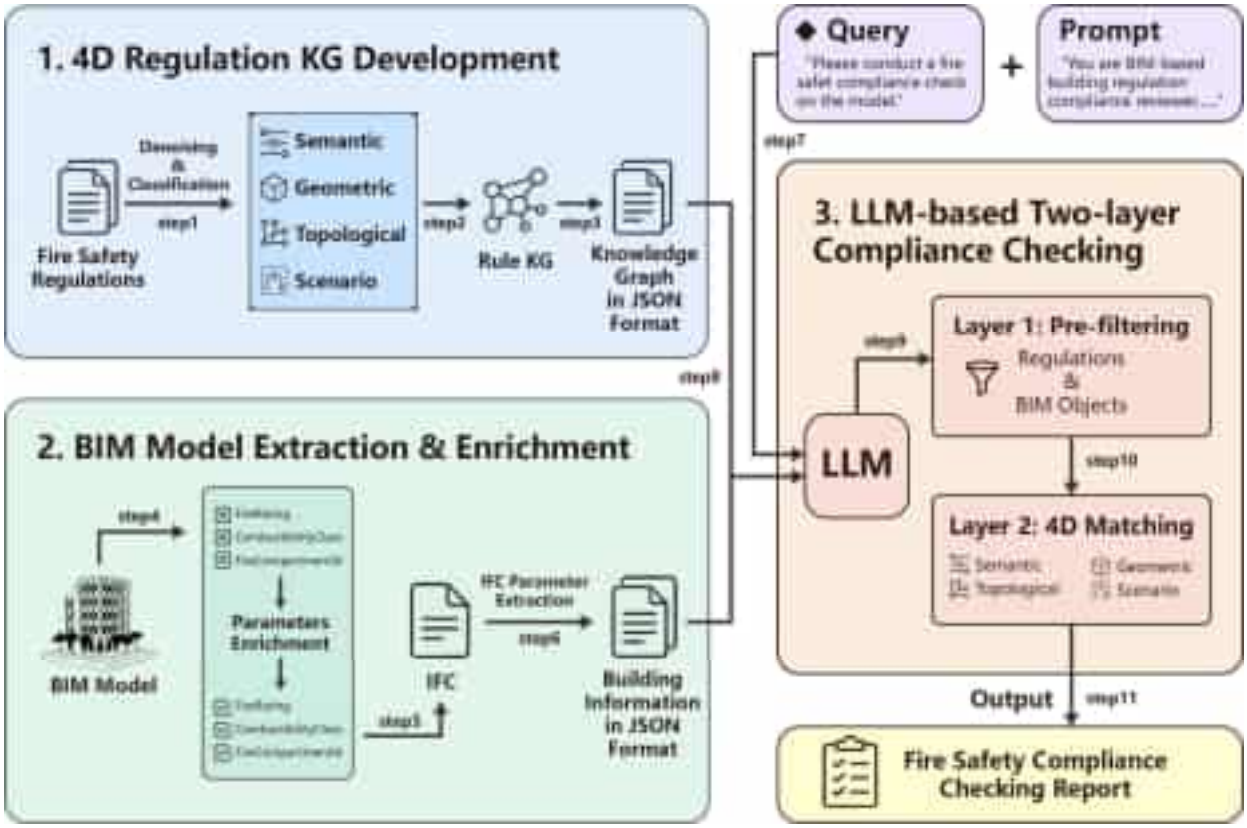

Figure 1: Framework of Four-Dimensional Fire Safety Knowledge–Enhanced Large Language Model

four-dimensional regulations using the combined knowledge graph and BIM model data to generate compliance reports (steps 10-11).

2.1 4D Rule Knowledge Graph Development

Figure 2 and Table 1 illustrate the classification of fire safety regulations into four types, each corresponding to different query designs. In this study, this four-type taxonomy is proposed as an operational representation for BIM-based fire safety compliance checking, and its broader applicability beyond the current fire regulations should be further tested in future work. The 4D Rule Knowledge Graph Development method aims to enhance the accuracy and automation of regulatory interpretation and compliance checking, reducing errors and omissions to achieve a more comprehensive and precise compliance evaluation.

Semantic Rules: Semantic regulations describe the relationships between regulations and the attributes that must be satisfied by specific components. For example, they specify the fire resistance rating required for fire doors.

$$(Regulation) - [HAS_ATTRIBUTE_REQ] -> (Component)$$

Geometric Rules: Geometric regulations focus on dimensional and distance constraints for components or spaces. These include minimum widths, maximum heights, and similar spatial metrics.

$$(Regulation) - [HAS_GEOMETRIC_REQ] -> (Component)$$

Topological Rules: Topological regulations define static relationships between components or spaces, such as connectivity, separation, or passage relations. These rules establish spatial connectivity between components using keywords such as "FROM" and "TO."

$$(Regulation) - [DEFINES] -> (TopoRule)$$

Scenario Rules: Scenario regulations define conditional logic in which a specific requirement becomes applicable only when a trigger condition is met. For instance, they specify that certain fire safety equipment must be installed when specific height requirements are met.

$$(Regulation) - [DEFINES_LOGIC] \rightarrow (Scenario)$$

Semantic rules focus on components, attributes, and constraints, mapping clauses to component nodes and abstracting fire resistance ratings and other requirements into attributes and constraint nodes. Geometric rules primarily address dimensional constraints, while topological rules define static relations among spaces or components, like connectivity and isolation. In contrast, scenario rules focus on trigger–requirement logic, following a two-phase structure with "trigger conditions" and "requirements" to manage actions based on specific scenarios, enabling automatic filtering and reasoning.

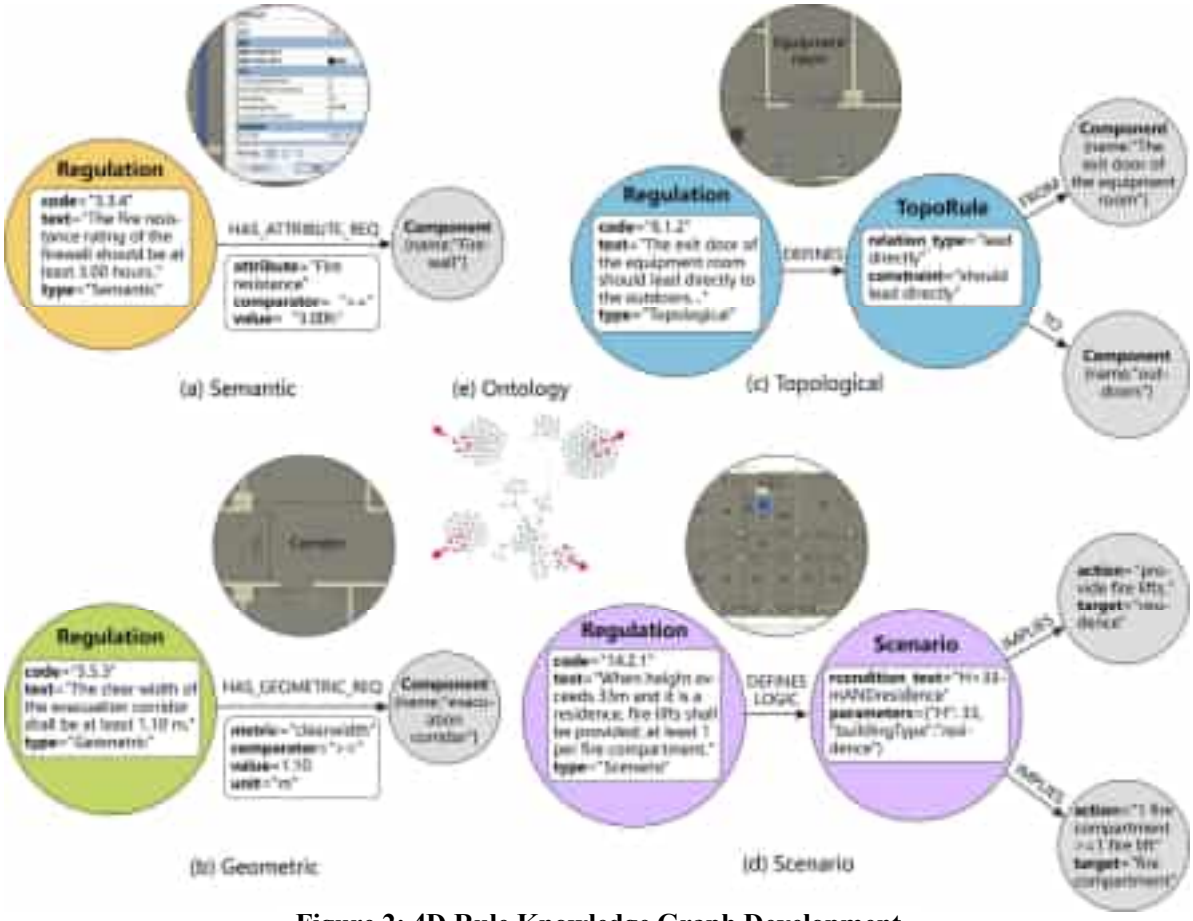

Figure 2: 4D Rule Knowledge Graph Development

Table 1
Node and Relationship Schema for the 4D Rule Knowledge Graph

Category	Node Design	Relationship Design
Semantic	Regulation: code, text, type = "Semantic". Component: name (the constrained component/object type).	**(Regulation)--[:HAS_ATTRIBUTE_REQ]→(Component)** • attribute: attribute name (e.g., fire resistance rating / combustibility) • value: required value (e.g., 2.00h / Class A / Grade A) • comparator: =, >=, <=, prohibition/permission, etc.
Geometric	Regulation: code, text, type = "Geometric". Component: name (component/space type).	**(Regulation)--[:HAS_GEOMETRIC_REQ]→(Component)** • metric: indicator (e.g., area / distance) • value: numeric value • unit: m, m², etc. • comparator: >=, <=, etc.
Topological	Regulation: code, text, type = "Topological". TopoRule: relation_type, constraint. Component: name (space/entity type).	**(Regulation)--[:DEFINES]→(TopoRule)** (the clause defines the rule) **(TopoRule)--[:FROM]→(Component_Source)** (source/endpoint) **(TopoRule)--[:TO]→(Component_Target)** (target/endpoint)
Scenario	Regulation: code, text, type = "Scenario". Scenario: condition_text, parameters. Requirement: action (required/prohibited action), target (affected object/scope).	**(Regulation)--[:DEFINES_LOGIC]→(Scenario)** (defines trigger conditions) **(Scenario)--[:IMPLIES]→(Requirement)** (requires compliance when the condition is met)

2.2 BIM Model Parameter Enrichment & Extraction

Figure 3 shows the BIM Model Parameter Enrichment and Extraction process. It adds key parameters for fire safety compliance checking, such as Fire Resistance Rating and Combustibility Class, to the BIM model so that most model elements contain information relevant to compliance checking. After parameter enrichment, the BIM model is exported in the IFC format. Fire safety attributes are bound to specific components using IFC standard property sets (Psets), enabling standardized cross-platform representation. Schedules and Mapping Tables are also exported to summarize parameters and standardize parameter mapping, naming, meaning, and units to ensure consistency across components and sources. These Mapping Tables are used for IFC/JSON field normalization and schema alignment, and they are not the manual regulation-to-model term mapping tables required by traditional rule-based compliance checking.

To ensure high-quality data input for compliance checks, this paper standardizes and denoises the data in two stages: "BIM to IFC" and "IFC to JSON." During the IFC export process, the Mapping Table is used to unify fire safety parameters' key names, meanings, and units, and essential relationships, such as those between components and rooms, are embedded directly into the data. During the conversion to JSON, the hierarchical and reference relationships in the IFC file are structured, and relevant attributes like GUIDs, component types, spatial contexts, and fire safety parameters are encapsulated in a directly accessible format, removing unrelated properties and complex geometric details. This process ensures that only the minimal necessary data required for the four types of rule checks remain in the final output.

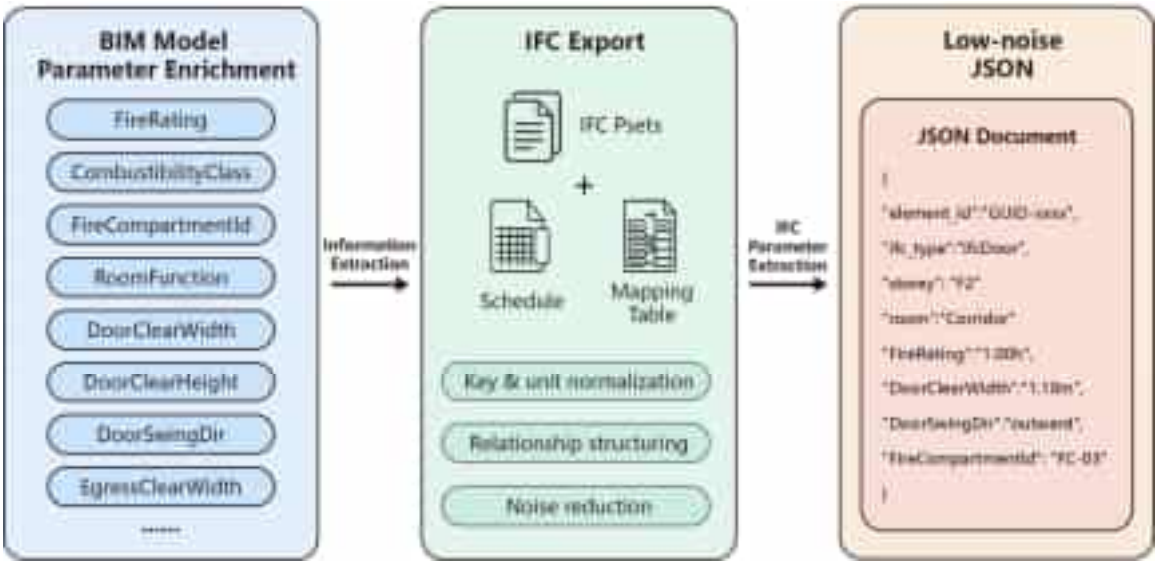
The resulting model JSON is organized by "component—attribute—spatial context" and typically includes parameters such as element ID, IFC type, spatial context (e.g., storey, room), and fire safety-related attributes (e.g., Fire Rating). This JSON file serves as input for LLM-based fire safety compliance checks. It enables direct retrieval and reference, which improves the stability and efficiency of compliance checking.

2.3 LLM-based Two-layer Compliance Checking

The third component is LLM-based Two-layer fire safety compliance checking. Users submit requests through a pre-configured prompt via the query interface, specifying the checking scope (e.g., building type, floor range, or target spaces). After the 4D Fire Safety Knowledge Graph and enriched BIM model data are provided as inputs, the framework performs two-layer checking. In Layer 1, the LLM filters applicable clauses and retrieves the relevant BIM objects. In Layer 2, it evaluates each filtered clause against the corresponding BIM evidence under the semantic, geometric, topological, or scenario category and then generates the compliance report.

3 Validation of the Framework

Figure 4 illustrates the validation process for the framework, which was conducted on a dormitory building case study. The regulations selected for testing include the "General Fire Safety Code for Buildings" GB 55037-2022 [11], the "Fire Safety Code for Interior Building Decorations" GB 50222-2017 [12], and the "Building Fire Safety Code" GB 50016-2014 (2018 edition) [13]. First, the regulatory text was denoised, and



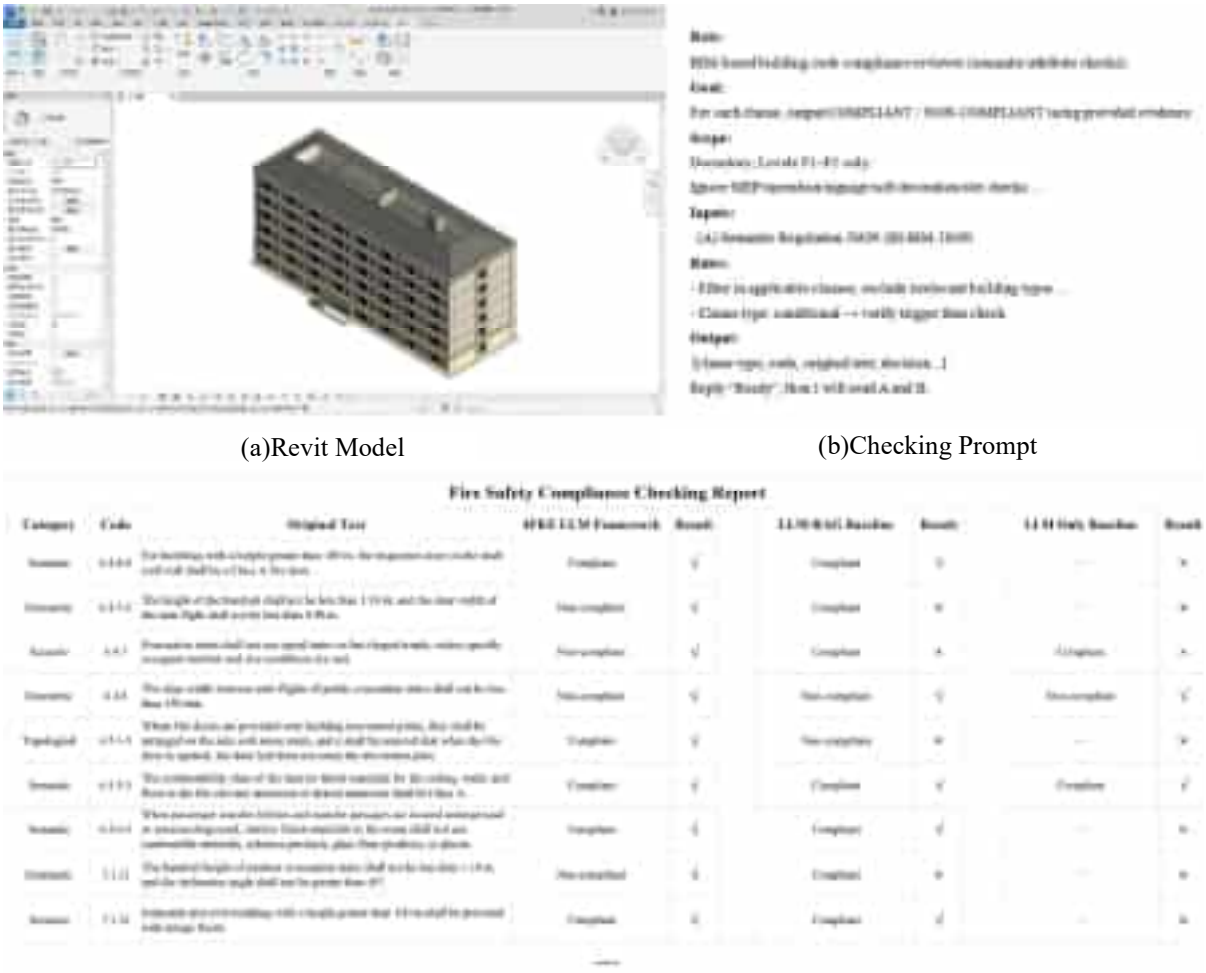


Figure 3: BIM Model Parameter Enrichment & Extraction

(a)Revit Model (b)Checking Prompt

(c)Checking Report

Figure 4: Validation of the Framework

tables were transcribed into natural language, yielding a total of 554 regulatory clauses. The rules were then classified into semantic, geometric, topological, and scenario categories and converted into Cypher queries, which were imported into Neo4j to construct the regulatory knowledge graph [14]. Structured rule data was exported as JSON for subsequent fire safety compliance checks using the LLM.

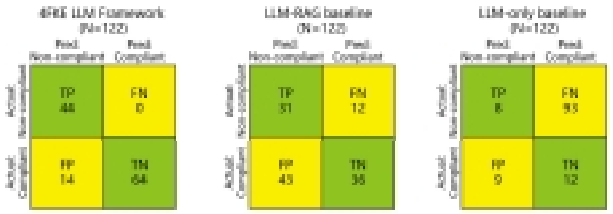
A BIM model of the dormitory building was created using Revit 2025 (Figure 4(a)), exported in IFC4 format to ensure that spatial boundary relationships and key fields were extractable. The model was then converted into structured JSON data, containing entity types, spatial hierarchies, connectivity relationships, and trigger conditions. During the compliance checking phase, the ChatGPT 5.2 Thinking model was used [15], with a pre-configured prompt (Figure 4(b)) that submitted the "4D Fire Safety Rule JSON + Model JSON" as input. This model was selected because the task requires long-context input handling and multi-step clause-level reasoning over rule JSON and model JSON. As the model is proprietary and may evolve over time, the reported results should be interpreted as a system-level evaluation under a fixed prompt setting rather than a strictly version-stable benchmark. First, the applicable clauses for the dormitory building were filtered, resulting in 122 relevant regulations. These clauses were then validated according to the four types of rules, and a compliance report was generated in Compliant/Non-compliant form (Figure 4(c)).

There are two baselines used for comparison in experiments. First, the LLM-RAG baseline takes the raw regulatory text together with the structured BIM model JSON as input. Second, the LLM-only baseline provides only the structured model JSON and asks the LLM to determine compliance without explicit rule inputs. The generated report is shown in Figure 4(c). For evaluation, each applicable clause-level decision is treated as a binary classification task, where the manually verified result is the ground truth label (Actual) and the model

output is the predicted label (Pred). We report the confusion matrix and compute Accuracy, Precision, Recall, and F1, where Precision measures the reliability of non-compliance predictions, Recall measures the coverage of true non-compliant clauses, and F1 summarizes the trade-off between them. The metrics are defined in Eqs. (1) – (4).

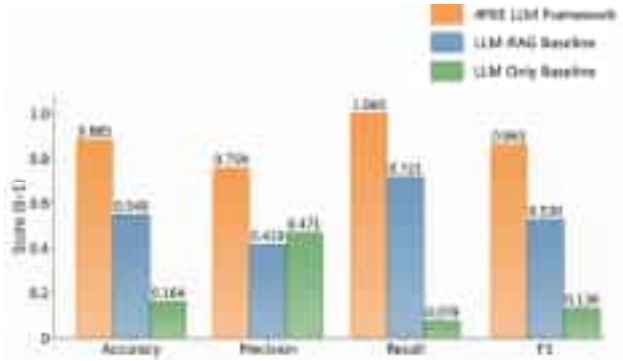
$$accuracy = \frac{TP + TN}{TP + FP + FN + TN} \quad (1)$$

$$precision = \frac{TP}{TP + FP} \quad (2)$$



$$recall = \frac{TP}{TP + FN} \quad (3)$$

$$F_1 = 2 \cdot \frac{precision \cdot recall}{precision + recall} \quad (4)$$



These four metrics are appropriate provided that the positive class is clearly defined. In this study, "Non-compliant" is treated as the positive class, so TP/FP/FN are counted with respect to non-compliance. Under this definition, Precision and Recall directly reflect the two key risks in fire-safety checking: false alarms (FP) and missed violations (FN). We choose these metrics because they capture complementary aspects of clause-level compliance checking: (1) Accuracy reports overall correctness, (2) Precision reflects the cost of false positives (unnecessary manual review or rework), (3) Recall reflects the safety-critical cost of false negatives (missed violations), and (4) F1 provides a balanced summary, avoiding misleading conclusions when class distributions are imbalanced.

Figure 5 summarizes the results (N = 122). In this context, N denotes the total number of clause-level compliance decisions evaluated, that is, the number of applicable clauses assessed across the case. The proposed Framework of Four-Dimensional Fire Safety Knowledge–Enhanced Large Language Model (4FKE-LLM) shows the best performance among the three evaluated settings, with TP = 44, TN = 64, FP = 14, FN = 0, yielding Accuracy = 0.885, Precision = 0.759, Recall = 1.000, and F1 = 0.863. This indicates zero missed violations (FN = 0) while maintaining a low false-positive rate. In contrast, the LLM-RAG baseline shows both higher false positives and false negatives (TP = 31, TN = 36, FP = 43, FN = 12), with reduced scores (Accuracy = 0.549, Precision = 0.419, Recall = 0.721, F1 = 0.530). The LLM-only baseline performs the worst, exhibiting severe missed violations (TP = 8, TN = 12, FP = 9, FN = 93; Accuracy = 0.164, Precision = 0.471, Recall = 0.079, F1 = 0.136), suggesting that providing model data alone without explicit regulatory rules does not yield stable clause-level compliance determinations.

In terms of practical expectations for safety-critical fire-safety compliance checking, this study adopts a recall-first evaluation criterion. It aims for Recall as close to 1 as possible (ideally FN = 0, or at least Recall ≥ 0.95) while keeping false positives within a manageable range (e.g., Precision ≥ 0.70 or a low FP rate), and it uses an overall target such as F1 ≥ 0.80 as a pragmatic usability threshold. This recall-first stance is consistent with prior automated fire code–compliance checking studies, which report very high precision/recall performance and, in some settings, argue that Recall is more critical than Precision [9, 16]. Under these criteria, 4FKE-LLM already falls within the expected range (Recall = 1.000, Precision ≈ 0.76, F1 ≈ 0.86), aligning with the risk preference of fire-safety review.

(b)Metrics Comparison

Figure 5: Comparison Result

4 Conclusion

This paper addresses the practical needs of BIM-based fire safety compliance checking by integrating a four-dimensional rule representation, BIM data enrichment, and a two-layer LLM checking workflow for clause-level reasoning. The Framework of Four-Dimensional Fire Safety Knowledge–Enhanced Large Language Model (4FKE-LLM) constructs regulatory knowledge graphs using a four-dimensional classification method and exports callable structured data. BIM model parameters are enriched and converted into structured data that includes attributes, spatial structures, and key relationships. In the dormitory building case study, the framework outperformed the two selected baselines, especially in recall and overall F1. These results suggest that the framework can improve clause-level fire safety compliance checking for the evaluated case. However, the current validation is limited to one

dormitory building and 122 applicable clauses, so broader testing across more building types and regulatory contexts is still needed to examine external validity. Furthermore, certain clauses still rely on finer-grained geometric calculations, and incomplete IFC exports or parameter enrichment may lead to situations that cannot be checked. Future work will focus on expanding the rule coverage and the clause template library. It will also improve IFC-based attribute mapping and the geometric/topological evidence computation modules to enhance cross-project compatibility and robustness.

Abstract –

To address the limitations of the traditional Fast Point Feature Histogram (FPFH) in heterogeneous building point cloud registration—over-reliance on geometric information, neglect of color cues, and susceptibility to lighting variations—this paper proposes a color-enhanced local feature fusion framework. First, the RGB color space is transformed to HSV, with histogram equalization applied to the Hue channel to improve illumination robustness and color discriminability. Then, normalized FPFH geometric features and PCFH color features are fused into a 44-dimensional joint vector. Experimental validation on real shopping mall indoor point clouds shows that the proposed method performs well in complex scenarios: RRE and RMSE are reduced by up to 74.9% and 74.6% under different initial poses; robust registration is achieved in asymmetric point-count scenarios where FPFH fails; and RMSE remains 27.73% lower than FPFH even with only 500 sampling points. An outdoor campus road experiment further verifies generalizability, with RRE, RTE, and RMSE reduced by 66.2%, 63.4%, and 59.8%, respectively. Overall, integrating compact color features introduces negligible computational overhead while improving registration accuracy and robustness.

Point cloud, Registration, Feature Fusion

1 Introduction

The application of point cloud technology in civil engineering has attracted widespread attention in recent years, serving as a key driver for the industry's digital transformation. Traditional surveying and mapping methods in this field are constrained by high labor costs, low efficiency, limited handling of complex scenarios, poor adaptability to dynamic environments, and time-consuming post-processing. In contrast, point cloud technology enables non-contact, high-precision capture of spatial information for engineering structures through high-density 3D data acquisition. Its advantages in efficiency, digitalization, 3D visualization, and adaptability to complex scenarios offer innovative solutions for full lifecycle management of engineering projects [1-4].

Point cloud registration, which estimates the rigid transformation (i.e., 3D rotation and translation) between source and target point clouds, is a fundamental challenge in applications such as 3D building reconstruction [5-7]. Among traditional methods, many rely on geometric feature descriptors, with the Fast Point Feature Histogram (FPFH) [8] being a common choice. By statistically analyzing angular distributions between query points and neighbors, FPFH demonstrates robustness to mild noise. However, when applied to heterogeneous building point clouds, FPFH has inherent limitations: its exclusive reliance on geometry overlooks rich color cues in RGB data. Furthermore, local geometric neighborhoods can suffer significant distortions when scanned from different viewpoints, reducing feature similarity.

As a complementary data type, color information is expected to enhance local feature discriminability. However, raw RGB values are sensitive to lighting variations, leading to suboptimal results in direct applications. For example, walls scanned on sunny days appear brighter than those captured on cloudy days, causing color discrepancies at the same physical locations [9]. Naively combining color features with FPFH fails to achieve reliable fusion; instead, targeted color enhancement is necessary to improve lighting invariance and feature distinctiveness.

To address these challenges, this paper presents a novel FPFH-based registration framework integrating color-enhanced local feature fusion. The core principle is to synergize lighting-invariant color features with geometric descriptors, leveraging their complementary strengths to improve matching accuracy and robustness for heterogeneous data. The contributions are summarized as follows:

(1) A tailored color enhancement strategy for building

point clouds: By converting RGB to HSV color space and applying histogram equalization to the Hue channel, lighting interference is mitigated, and color discriminability is enhanced.

(2) Fusion of local features by integrating color-enhanced attributes with FPFH descriptors. Through normalization and dimension balancing, both types of features effectively facilitate matching.

(3) Experimental validation on real-world point cloud datasets demonstrates superior registration accuracy and robustness compared to traditional FPFH methods.

2 Related work

Point cloud registration methods are generally classified into coarse and fine registration. Coarse registration estimates an initial transformation matrix between point clouds with significant pose differences. RANSAC [10] is a classic method that estimates the transformation by randomly sampling point pairs and evaluating their consistency. To improve robustness, 4PCS [11] selects coplanar point sets to reduce the influence of outliers, but it suffers from high computational cost on large-scale point clouds. Recently, optimal transport-based methods such as Sinkhorn algorithms [12-14] have been introduced to enhance correspondence confidence and reduce false matches. However, these methods still rely on discriminative initial features, highlighting the importance of high-quality descriptors.

For fine registration, the Iterative Closest Point (ICP) algorithm [15] and its variants [16] are widely used. These methods iteratively minimize the distance between corresponding points to achieve precise alignment, but they are highly sensitive to the initial pose. Poor initial alignment may lead to convergence to a local optimum rather than the global solution. Therefore, reliable coarse registration remains a critical prerequisite for successful point cloud registration.

Geometric feature descriptors form the foundation of point cloud registration by encoding local structural information. Early descriptors such as Shape Context [17] and Spin Images [18] laid the groundwork for 3D feature extraction but often involve high computational complexity. As an efficient variant of PFH, FPFH reduces point-pair calculations while maintaining strong geometric discriminability, making it a benchmark in geometry-based registration. Nevertheless, FPFH is sensitive to viewpoint changes and point-density variations in heterogeneous scenarios. More robust descriptors have therefore been developed. For example, SHOT [19] improves viewpoint invariance through structured neighborhood sectors but has high dimensionality, while ISS [20] detects key points based on geometric saliency but still requires auxiliary descriptors for matching.

As a complement to geometric information, color features have been increasingly used to enhance the discriminative capability of point cloud descriptors. Early studies directly incorporated RGB values to improve nearest-neighbor correspondence or pose estimation [21-24], but raw color data are highly sensitive to illumination changes, resulting in unstable matching. To improve illumination invariance, researchers have explored color space transformations—such as converting from RGB to HSV or Lab color spaces—which separate chromatic information from brightness, thereby mitigating the effects of variable lighting [25,26]. Inspired by these approaches, this work fully leverages the color information embedded in point cloud data and adopts the HSV color space, following established practices. This enables effective registration without compromising the integrity of spatial structure.

To summarize, existing registration methods face challenges in heterogeneous building environments: limited discriminability of geometric features alone, vulnerability of raw color features to illumination variations, and suboptimal performance of naive feature fusion. To address these issues, this paper proposes a color-enhanced local feature fusion framework. Compared with ColorPCR, which relies on multi-stage color–geometry fusion, and SHOT-color, which extends high-dimensional descriptors, the proposed method constructs a lightweight Hue-based color histogram and efficiently fuses it with FPFH while retaining low computational cost.

3 Methodology

3.1 Problem Statement

Given two color point clouds $\mathcal{P} = \{p_i \in \mathbb{R}^3 \mid i = 1, \dots, N\}$ with $\mathcal{P}_c = \{p_{ci} \in \mathbb{R}^3 \mid i = 1, \dots, N\}$ and $\mathcal{Q} = \{q_i \in \mathbb{R}^3 \mid i = 1, \dots, M\}$ with $\mathcal{Q}_c = \{q_{ci} \in \mathbb{R}^3 \mid i = 1, \dots, M\}$, in which, $\mathcal{P}_c$ and $\mathcal{Q}_c$ denote the color of $\mathcal{P}$ and $\mathcal{Q}$ respectively, our goal is to estimate a rigid transformation $\boldsymbol{T} = \{\boldsymbol{R}, \boldsymbol{t}\}$ which aligns the two point clouds, comprising a 3D rotation $\boldsymbol{R} \in SO(3)$ and a 3D translation $\boldsymbol{t} \in \mathbb{R}^3$. With the estimated transformation, we can align the two color point clouds. To achieve the most precise alignment, we need to solve the following optimization problem:

$$\min_{\boldsymbol{R}, \boldsymbol{t}} \sum_{(p_i^*, q_i^*) \in C^*} \|R \cdot p_i^* + t - q_i^*\|_2^2 \tag{1}$$

3.2 Overall Algorithm Design

We improve coarse registration based on FPFH by incorporating color information into the FPFH

descriptors. The resulting combined features demonstrate robust performance even in environments with limited geometric features or surface details, and show strong resilience to noise and variations in point cloud density.

The main procedure is as follows (the pipeline is illustrated in **Figure 1**.):

(1) Downsample the input source and target point clouds;

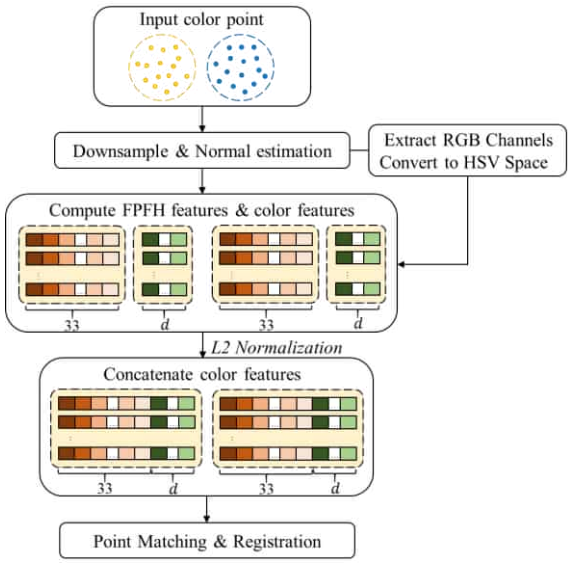
(2) Estimate surface normals for both point clouds using normal estimation methods;

(3) Compute FPFH features for each point in both point clouds;

(4) Convert the RGB values to the HSV color space and extract color descriptors using only the Hue (H) channel;

(5) Apply L2 normalization separately to the geometric (FPFH) and color descriptors, then concatenate them into a unified feature vector;

(6) Perform registration using the RANSAC algorithm.



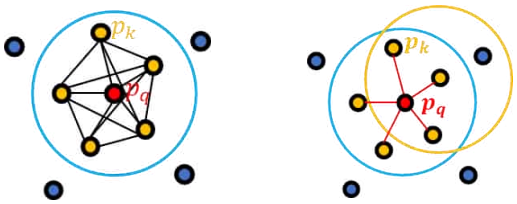


Figure 1. Pipeline of the proposed method

3.3 Computation of Fast Point Feature Histogram

The core idea of FPFH lies in first computing the Simplified Point Feature Histogram (SPFH) for each point in the k-neighborhood of the query point, and then weighting all the SPFH features via a formula to form the final FPFH feature. While FPFH reduces the computational complexity of the algorithm to O(nk), it still retains most of the discriminative properties of Point Feature Histograms (PFH). The computation process of FPFH is as follows:

(1) Only the three feature elements ($<\alpha, \phi, \theta>$) between each query point p_q and its neighborhood points are computed, which differs from PFH: while PFH calculates the feature elements for all combinations of neighborhood points, this step only computes those between the query point and its neighboring points. As shown in **Figure 2**, **Figure 2(a)** illustrates the feature computation process of PFH—i.e., the feature values for all combinations of neighborhood points (all lines in the figure, including but not limited to the lines between p_q and p_k, while **Figure 2(b)** depicts the computation scope of FPFH, which only requires calculating the feature elements between the query point p_q and its immediate neighboring points p_k (the red lines in **Figure 2(b)**). It can be seen that this design reduces the computational complexity, and this histogram is termed the Simplified Point Feature Histogram (SPFH).

(a) Spatial coverage of PFH (b) Spatial coverage of FPFH

Figure 2. The spatial coverage of FPFH and PFH

(2) A modified statistical method for k-neighborhood point pairs is proposed, comprising two components: point pairs between the query point and its k surrounding points; point pairs between each neighborhood point and its own k surrounding points. For the second component, the weight is usually set to the reciprocal of the distance, such that spatially closer neighborhood points make a greater contribution, as shown in **Eq. (2)**:

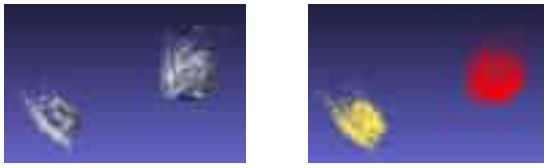
$$FPFH(p_q) = SPFH(p_q) + \frac{1}{k}\sum_{i=1}^{k}\frac{1}{w_k}\cdot SPFH(p_k) \quad (2)$$

3.4 Computation of Point Color Feature Histogram

We transform the RGB values of the point cloud data into the HSV color space and extract color features using only the Hue (H) channel. First, for each point, a d-dimensional Histogram of Hue Differences (HHD) is calculated between the query point p_q and its neighboring points p_k. Next, for each point again, the Point Color Feature Histogram (PCFH) is computed based on the HHD calculated in the first step, using **Eq. (3)-(4)**, where the weight is determined by the distance between the neighboring point and the query point.

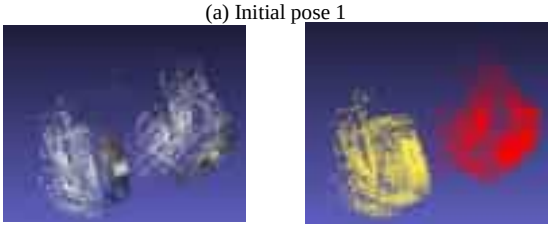
$$HHD(p_q) = Histogram(|h_q - h_k|, d) \quad (3)$$

$$PCFH(p_q) = HHD(p_q) + \frac{1}{k}\sum_{i=1}^{k}\frac{1}{w_k}\cdot HHD(p_k) \quad (4)$$



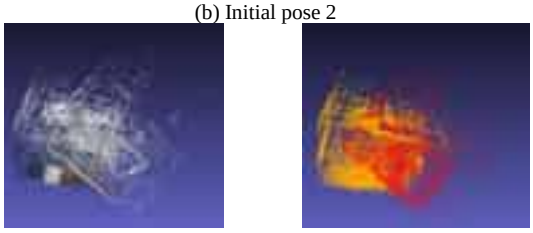
After obtaining the PCFH descriptor, we first apply L2 normalization to it, and then concatenate it with the FPFH descriptor to form a 44-dimensional feature vector (where the dimension of PCFH is fixed at 11 in subsequent experimental designs). The purpose of normalizing before concatenation is to facilitate better collaboration between the geometric and color descriptors.

4 Experiments and Results



4.1 Experiment Design

The point clouds used in this study were collected from a large shopping mall using the Leica BLK360 imaging scanner. The source and target point clouds were obtained from two scans at the same location. Since the scanner does not provide initial pose information, the ground truth transformation matrix in Eq. (5)–(7) was generated by applying an artificial transformation to the target point cloud, ensuring an exact reference. Five experiments were designed: (1) registering two 10,000-point clouds under three initial poses; (2) registering asymmetric point counts of 12,000 and 4,000 points; (3) testing reduced densities of 4,000, 2,000, 1,000, and 500 points; (4) comparing the computation time of FPFH and FPFH + PCFH; and (5) testing outdoor generalization on a campus road segment with two 10,000-point clouds.



Experiment 1: The three initial poses are detailed in Table 1. This experiment evaluated the registration accuracy of the Color-enhanced FPFH algorithm under diverse initial pose conditions. Figure 3 illustrates the downsampled point clouds and their initial relative poses, with the source cloud colored red and the target orange. The RANSAC algorithm was set to 600,000 iterations, with an inlier threshold of 0.2 m, and the results were compared with FPFH in Section 4.2.

(a) Initial pose 1

(b) Initial pose 2

(c) Initial pose 3

Figure 3. Three different initial poses in Experiment 1

Table 1 Three different initial poses in Experiment 1

	Initial pose 1	Initial pose 2	Initial pose 3
Roll/°	55.08	60.63	33.68
Pitch/°	-9.61	-84.00	41.03
Yaw/°	-55.52	97.76	17.52
X-axis translation distance/m	-20.097	8.376	-3.523
Y-axis translation distance/m	20.474	-7.014	-0.243
Z-axis translation distance/m	24.060	8.380	1.931

Experiment 2: The source and target point clouds were downsampled to 12,000 and 4,000 points, respectively, to amplify point-count discrepancy and reduce the proportion of feature-similar points. The initial pose is shown in Figure 4 and Table 2. The RANSAC settings were the same as in Experiment 1, and the results were compared with FPFH in Section 4.2.

In this paper, normal estimation employs a hybrid neighborhood search strategy, with a search radius of 2 meters and a maximum of 30 nearest neighbors. Similarly, the FPFH feature extraction algorithm utilizes a hybrid search strategy, setting the FPFH search radius to 5 meters and the maximum number of neighbors to 100.

The custom PCFH descriptor (dimension = 11) is constructed based on the Hue (H) channel. Its neighborhood search adopts a spherical neighborhood with a radius of 2.0 m (skipping points with fewer than 3 neighbors). The Hue difference calculation accounts for the 360° cyclic nature of the H channel by taking the minimum angular difference (0–180°) and normalizing it to the [0,1] range. Histogram binning uses 11 equal-width bins covering the full [0,1] range.

During feature matching, the nearest neighbor in the target point cloud is first identified for each source point in the concatenated 44-dimensional feature space. Mutual nearest neighbor filtering retains bidirectional correspondences, and incorrect matches are further filtered using edge length verification (threshold 0.9) and a correspondence distance threshold of 0.2 m. The valid correspondences are then used for RANSAC, configured with 600,000 iterations, confidence of 0.999, three sample points, and the same 0.2 m distance threshold.

4.2 Discussion

To further quantify the registration results, the Relative Rotation Error (RRE), Relative Translation Error (RTE), and Root Mean Square Error (RMSE) for different algorithms were calculated. The formulas for RRE, RTE and RMSE are as follows:

$$RRE = \arccos\left(\frac{tr(R_{gt}^{T}R_{est}) - 1}{2}\right) \times \frac{180}{\pi} \quad (5)$$

$$RTE = \left\| t_{gt} - t_{est} \right\|_2 \quad (6)$$

$$RMSE = \sqrt{\frac{1}{N}\sum \left\| (T_{gt} \cdot P) - (T_{est} \cdot P) \right\|_2^2} \qquad (7)$$

where R_{gt} and t_{gt} denote the ground truth rotation and translation, respectively; R_{est} and t_{est} denote the estimated rotation and translation; T_{gt} denote the ground truth transformation matrix; T_{est} denotes the estimated transformation matrix, and P denotes the source point cloud.

Under controlled conditions where all other experimental parameters were fixed, Tables 5-9 summarize the registration results. As shown in Table 5, under different initial poses, the Color-enhanced FPFH-based algorithm consistently outperformed standard FPFH. The most significant improvement occurred under Initial Pose 2, where RRE, RTE, and RMSE improved by 74.9%, 67.4%, and 74.6%, respectively. Although the RTE under Initial Pose 1 slightly increased from 0.0638 m to 0.104 m, this value remains within the 0.2 m RANSAC correspondence threshold and does not compromise overall stability. In Experiment 2 (Table 6), standard FPFH essentially failed under significantly different point counts, while the proposed method achieved low errors of 2.100° (RRE), 0.048 m (RTE), and 0.2 m (RMSE), indicating better matching robustness under asymmetric density. In Experiment 3 (Table 7), the proposed method maintained high accuracy at 4,000, 2,000, and 1,000 points, and even with only 500 points still improved RRE, RTE, and RMSE by 26.2%, 30.82%, and 27.73%, respectively. Table 8 shows that adding the 11-dimensional color feature causes almost no increase in computation time. Table 9 further demonstrates outdoor generalization, with RRE, RTE, and RMSE reduced by 66.2%, 63.4%, and 59.8%, respectively.

5 Conclusions

This paper proposes a color-enhanced local feature fusion framework to address the limitations of FPFH-based registration in heterogeneous building point clouds, including over-reliance on geometry, neglect of color cues, and sensitivity to lighting interference. The method transforms RGB to HSV, applies histogram equalization to the Hue channel, and fuses normalized FPFH and PCFH into a 44-dimensional joint descriptor. Experiments on real shopping mall point clouds demonstrate strong performance under different initial poses, asymmetric point counts, and sparse sampling: RRE and RMSE are reduced by up to 74.9% and 74.6%; robust registration is achieved when FPFH fails under asymmetric point counts; and at 500 points, RMSE remains 27.73% lower than FPFH. The computation-time comparison shows negligible additional overhead, and the outdoor experiment confirms promising generalization ability.

Despite the promising results, this study has limitations. The impact of PCFH dimensionality on registration performance has not been fully explored; the value of 11 was chosen following the common bin setting of PFH and FPFH. Future work will optimize the color feature dimensionality and weighting strategy through sensitivity analysis or adaptive learning. Moreover, this study only uses the Hue channel, while the influence of Saturation and Value channels should be investigated in more complex scenarios.

Abstract –
With advancements in large language models (LLMs), there has been growing attention to automatic construction specification reviews, enabling faster and more standardized assessments. However, general-purpose LLMs' effectiveness has been bounded when applied to construction contexts, because they lack necessary domain-specific vocabulary and knowledge. Therefore, we propose a domain-specialization LLM pretraining method to leverage construction terms and knowledge and quantitatively evaluate its efficacy in two specification review tasks. To this end, we generate two construction-specific corpora, i.e., close-domain and in-domain, and investigate their hybrid effects on LLM performance at varying scales. Results reveal that construction-specific contextualization led to a significant improvement, with a 6.9% increase in accuracy for extractive question answering and an 8.0% enhancement in information retrieval accuracy. We also observe that augmenting in-domain corpus with close-domain data, can achieve performance comparable to models trained with extremely large in-domain data. These will facilitate the adoption of LLMs in construction and support specification reviews.

Keywords –
Large language model; Domain-specific; Pretraining; Construction specification

1 Introduction

Construction specification review is a critical process in the construction industry, focused on ensuring that project specifications align with required standards, project goals, and regulatory compliance [1]. Specifications are detailed documents that outline project requirements, including material quality, design standards, construction methods, and safety protocols. However, manual review of such extensive documents is time-consuming and resource-intensive, leading researchers to explore automated methods using natural language processing (NLP) technologies [2,3]. Previous studies have primarily focused on two types of NLP tasks in specification reviews: (i) Contextual understanding of provisions: Its application involves interpreting and classifying regulatory provisions based on their semantic contents, such as identifying risky contractual terms [4] or categorizing provisions into classes such as technical requirements, financial regulations, and material standards [5]. This is also foundational for tasks like extractive question answering (QA) from provisions, which requires precise extraction of textual span according to user intent; and (ii) Information retrieval for specific details: Its application focuses on recognizing and extracting critical entities including subjects, requirements, actions, and standards through rule-based NLP algorithms and deep learning techniques [2,6].

Recently, large language models (LLMs), such as Bidirectional Encoder Representations from Transformers (BERT) and Generative Pre-trained Transformer (GPT), have become prominent in NLP applications due to their ability to capture rich contextual information [7]. For instance, Ahmadi et al. [8] leveraged existing LLMs like Gemini and ChatGPT to classify construction accident reports into categories including injury cause, root cause, affected body part, severity, and accident type, demonstrating the promising potential of general-purpose LLMs. Although LLMs perform well in everyday language tasks, adapting them to a specific domain, particularly construction documents with many technical terminologies, presents significant challenges. In particular, LLMs pretrained on generic corpora often struggle with domain-specific vocabulary, contextual nuances, and technical language characteristic [9]. Consequently, these models lack the precise understanding required for accurately interpreting construction specifications, demonstrating the need for target domain adaptation.

Some researchers have recognized this challenge and addressed it by employing domain-adapted LLMs, such as BERT variants pretrained on domain-contextualized corpora. In this regard, two types of corpora have

typically been used: (i) in-domain corpus, which is narrowly focused on a specific target domain (i.e., a particular type of documents) and incorporate specialized language and contextual terminology; and (ii) close-domain corpus, which encompasses a wide spectrum of construction documents, capturing diverse linguistic patterns and terminology relevant to the field. For instance, Zheng et al. utilized both close-domain and in-domain Chinese corpora and validated their individual benefits as well as the combined effects of mixing two corpora on NLP-based construction document analysis. Zhong and Goodfellow [11] also introduced pretrained language models specifically designed for construction management systems, by leveraging in-domain corpora with and without sentence concentration. While these studies indicate that domain-specific pretraining enhances LLM performance in NLP tasks, several knowledge gaps remain to be addressed. First, there is limited quantitative analysis on the effects of domain-specific knowledge on LLM performance in construction specification reviews. Although untrainable models like ChatGPT demonstrate strong capabilities, a comprehensive evaluation of domain-specific adaptation on small-scale trainable models can inform their effective utilizations in construction. This trial will also help address the scarcity of labeled domain-specific data that limits supervised methods, as pretraining on unlabeled domain data offers a promising approach to reduce dependence on extensive labeled datasets [12]. Second, although previous studies theoretically identify the advantages of incorporating domain knowledge including technical vocabulary and language patterns into LLMs, few studies have investigated how varying quantities of close-domain and in-domain corpora impact model's performance. Specifically, it remains unclear how much data can motivate the model's capability in contextual understanding. Moreover, emphasis has largely been placed on in-domain corpus due to its direct relevance to target documents. However, when the available in-domain corpus is limited, its impact on model adaptation becomes marginal, making it necessary to consider supplementary close-domain data. However, the hybrid effects of combining close-domain and in-domain corpora are rarely examined, leaving unanswered questions about the optimal quantity of these corpora for efficient domain adaptation in LLM pretraining.

Therefore, we propose a LLM pretraining method to combine close-domain and in-domain corpora and specialize LLMs to the construction field. We then fine-tune and validate LLMs in two construction specification review tasks, extractive QA and information retrieval. Particularly, we evaluate the effectiveness of domain corpora on LLM performance and investigate their impacts at varying sizes. Our findings will facilitate the domain adaptation of LLMs and offer insights on optimizing training efficacy with varying domain corpora sizes.

2 Research Method

This study followed a three-stage method comprising corpus generation, LLM pretraining, and task-specific finetuning (Figure 1). First, we collected various types of publicly accessible construction documents and generated close-domain and in-domain corpora. Subsequently, we utilized masked language modeling (MLM) for LLM pretraining. Lastly, the pretrained LLMs were fine-tuned for two construction specification review tasks: extractive QA for provisions and information retrieval from provisions. More details are provided in the following subsections.

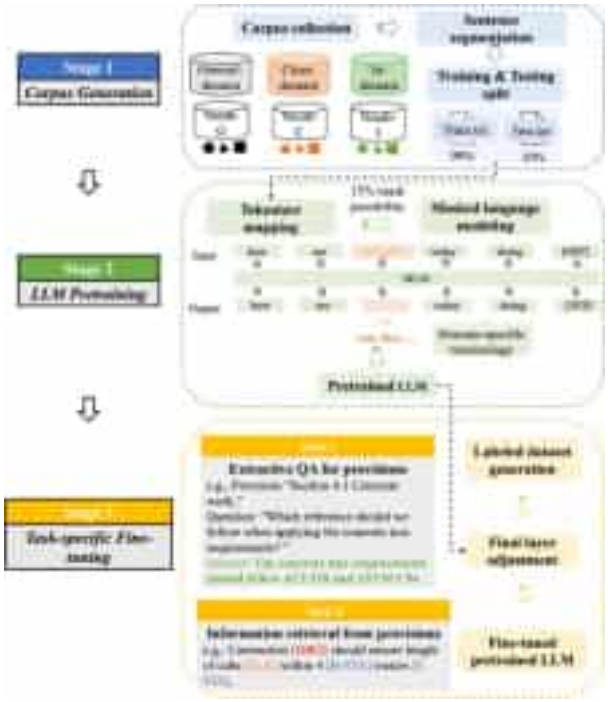

Figure 1. Overall pipeline for pretraining a construction-specific large language model

2.1 Stage 1: Corpus Generation

In Stage 1, we generated comprehensive corpora encompassing various types of documents in the construction domain, categorized into two distinct types: (i) Close-domain documents, which include a range of construction-related documents such as contracts, regulatory laws, and management guidelines; and (ii) In-domain documents, which are specific to a single document type that closely aligns with a particularly type of document (i.e., construction specifications in this study). To construct these corpora, we initially collected construction documents publicized in two different

formats. The first format consisted of Portable Document Format files, which were converted into machine-readable texts using Optical Character Recognition tools. The second format included web-based documents, for which we employed web scraping techniques to extract and consolidate textual information. Ultimately, we gathered 752 close-domain documents comprising contracts, law regulations, and management guidelines. Additionally, we obtained 56 in-domain construction specification documents from four countries, United States, United Kingdom, Canada, and Australia, covering a total of 56 distinct states and regions. Following conversions of texts for these documents, we adopted data cleaning techniques including removing extraneous characters and irrelevant formatting. We then applied text preprocessing techniques to both corpora, including sentence segmentation and training-testing splitting. Sentence segmentation enables the model to process structured linguistic units, which is critical for enhancing model understanding for complex contents. Detailed statistical information of two corpora is illustrated in Table 1. Finally, we allocated 90% of each corpus for training and 10% for testing [13]. This split ensures that the model is evaluated on a representative portion of the data while maintaining sufficient training data to capture domain-specific patterns and vocabulary.

Table 1. Statistical information of domain corpora

	Numbers of sentences	Numbers of tokens
Close-domain	1,028,086	23.6 million
In-domain	1,097,925	22.4 million

2.2 Stage 2: LLM Pretraining

After generating close-domain and in-domain corpora, we proceeded to the pretraining phase. Each sentence was initially tokenized to its numeric values that can be processed by computer programming language [10]. We then utilized MLM by randomly masking a certain percentage of input tokens within sentences, requiring the model to predict these obscured tokens. In this process, the final hidden vectors corresponding to the masked tokens were passed through an output softmax layer over the vocabulary. According to BERT implementation [13], 15% of all WordPiece tokens were randomly selected and replaced with the [MASK] token in each sequence, prompting the model to predict these tokens by learning contextual representations from neighboring words. This random selection process was managed by our data collator, which ensures 15% of token positions are designated for prediction. The cross-entropy loss function was finally computed by the average prediction error over all masked tokens in a sequence L following Eq.1 [14]:

$$Loss = -\frac{1}{|M|}\sum_{i \in M} logP(x_i|h_i^L) \quad (1).$$

where $|M|$ represents the total number of masked tokens. For each masked position i, x_i represents the original token and h_i^L is the corresponding output representation from the final layer of the model.

Notably, MLM serves as a self-supervised pretraining process, eliminating demands for additional manual labeling. Upon completion of pretraining on construction-specific corpora, this pretrained LLM acquires contextual domain knowledge, enhancing its performance in following downstream NLP tasks.

2.3 Stage 3: Task-specific Fine-tuning

Building on the pretrained LLM developed in Stage 2, we fine-tuned the final output layer by applying task-appropriate loss functions tailored for construction specification review tasks. We particularly focused on two primary tasks: extractive QA from provisions and information retrieval. With respect to the first task, we concentrated on the model's ability to identify and extract the precise span of text within a provision that answers a given question. To achieve this, we adapted the final output layer of the pretrained encoder by adding two classification heads $[Answer_s, Answer_e]$ to predict the start and end positions of the answer span within the input token sequence. During pretraining, the input consisted of a concatenated $[Provision, Question]$ pair, and the model was supervised using a span-based objective function—specifically, the cross-entropy losses for the start and end positions. This formulation enabled the model to learn fine-grained semantic alignment between the question and the contextual tokens of the provision, facilitating accurate answer localization. Meanwhile, information retrieval task refers to extract core elements from extensive documents based on their important semantic contents, which is a classical classification problem [6]. For this purpose, we appended a new classification layer $[CLS]$ to assign class labels (e.g., organization, action, element, standard, and reference) to each token based on a labeled information retrieval dataset, enabling the model to accurately categorize information of construction specifications.

3 Experiments and Results

As illustrated in Figure 2, we conducted two experiments to investigate the effects of domain-specific corpora on LLM performances (Experiment #1); and to analyze the hybrid effects of close-domain and in-domain corpora at varying sizes (Experiment #2). In both experiments, we adopted BERT as our foundational LLM due to its well-established capability in contextual understanding, which is particularly suitable for

specification review. Furthermore, it supports computationally efficient pretraining compared with larger-scale open-source LLMs, assisting practical experimentation [9]. It was then fine-tuned for two downstream tasks, extractive QA for provisions and retrieving information from provisions.

Figure 2. Experimental setups

Prior to task-specific fine-tuning, we conducted domain-adaptive pretraining to better align the LM with the semantic and syntactic characteristics of construction documents. The pretraining was carried out with the following parameters informed by [13]: a batch size of 32, a learning rate of 5×10^{-5}, a maximum sequence length of 512, and a total of 5,000 training steps. All pretraining was performed on NVIDIA A100 GPU. The evolution of both training and testing losses is demonstrated in Figure 3. It was observed that both losses converged and stabilized at around 5,000 training steps, indicating that the model reached convergence. To further validate the success and robustness of pretraining, we evaluated the model on a masked word prediction task using sentences from construction specifications. In this setting, 15% of tokens were randomly masked, and the model was tasked with recovering the original tokens. The masked token prediction accuracy reached 93.2%, demonstrating the model's strong capacity to learn and generalize over the domain terminology.

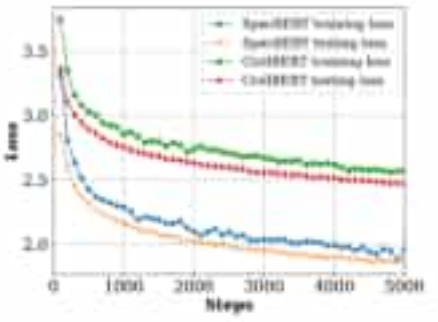

Figure 3. Losses for domain-specific pretraining

With respect to fine-tuning for experiment, we initially built fine-tuning task-specific training and test datasets as follows. To prepare the extractive QA dataset, we initially employed GPT-4o with prompt engineering to produce initial QA pairs from 201 construction provisions, as introduced in [15]. The generation process simulated real-world domain experts engaged in reviewing construction specifications, covering five question types: responsibility identification, procedure specification, numerical constraint, material standard, and regulatory references [6]. These automatically generated pairs then underwent a manual structural and semantic verification. Structurally, we ensured each pair complied with the Stanford Question Answering Dataset format—answers had to be explicitly found in the provision, with correct span indices [16]. Semantically, we first removed redundant questions that queried the same information. Second, inaccurate or contextually irrelevant questions were corrected or excluded. Third, to increase reasoning complexity, a subset of questions was reformulated. For instance, a basic question like "What curing compound is required for the concrete pouring?" was rewritten as "Which curing compound specified for concrete pouring should also satisfy water retention standard?". After this manual refinement, a total of 855 high-quality extractive QA pairs were obtained and subsequently reviewed by domain experts to ensure its quality. This dataset was divided into a training dataset (684 pairs) and testing dataset (171 pairs) with an 8:2 ratio. Using the dataset, we trained and tested models with two quantitative metrics: F1-score and Sentence-BERT (S-BERT). Specifically, F1-score provides a strict measure of token-level correspondence by balancing precision and recall, thus assessing how closely the predicted answer matches the ground truth. However, such span-based metrics penalize semantically correct answers but differ in wording. To this end, S-BERT is employed to evaluate semantic overlap by computing the cosine similarity between sentence-level embeddings of the predicted and reference answers. Collectively, these two metrics reflect both the surface-level accuracy and semantic relevance.

For the other fine-tuning task, retrieving information from provisions, a total of 1,250 provisions were extracted from the identical specifications used in the former task. These provisions were then categorized into five classes according to [6] to extract specification review information: Organization, Action, Element, Standard, and Reference. Each token was manually labeled as one entity using the open-source annotation tool Label Studio, with contiguous tokens assigned consistent labels and explicit boundaries defined to prevent overlap between entity types. In total, 15,969 tokens were annotated with corresponding semantic entity labels. This dataset was then divided into a training

dataset (1,000 provisions) and testing dataset (250 provisions) with an 8:2 ratio. To assess the model's performance, two evaluation metrics, F1-score and accuracy, were utilized. Specifically, F1-score integrates both precision and recall and requires a predicted entity match the gold standard in both its semantic label and boundary to be counted as correct. In contrast, accuracy measures performance at the token level by calculating the proportion of tokens assigned the correct label, including non-entity ("O") tokens. More detailed settings and results of each experiment are provided in the following subsections.

3.1 Experiment #1: Effects of Domain-specific Corpora on LLM

In Experiment #1, we compared the performance of four types of LLMs in construction specification review tasks: (i) an untrainable LLM like GPT-4o; (ii) BERT, which is a general-purpose LLM pretrained on a broad corpus; (iii) CivilBERT, a model pretrained on a close-domain corpus of 20 million tokens; and (iv) SpecBERT, a model pretrained on an in-domain corpus of 20 million tokens. Baseline models were determined as untrainable and pretrained LLMs from general corpus (i and ii).

3.1.1 Downstream task #1 results: Extractive QA for provisions

As illustrated in Table 2, general-purpose LLMs, such as GPT-4o, exhibited relatively lower performance. Specifically, GPT-4o achieved an F1-score of 74.0% and an S-BERT of 79.1% on the extractive QA. The BERT model, pretrained on a broad general corpus and fine-tuned on the extractive QA dataset, showed a modest improvement of 6.4% in F1-score and 4.0% in S-BERT, reaching final scores of 78.8% and 82.3% respectively. It was noteworthy that LLMs pretrained with domain-specific data, however, displayed significantly enhanced performance. CivilBERT attained an F1-score of 80.1% and an S-BERT of 86.4%, surpassing BERT by 1.4% in F1-score and 4.1% in S-BERT. Moreover, SpecBERT delivered the highest performance, with an F1-score of 82.4% and S-BERT of 89.2%, representing increases of 3.7% and 6.9% over BERT in two metrics. Overall, these results indicated that with domain-specific pretraining, smaller-scale LMs could surpass out-of-the-box commercial LLMs on specialized extractive QA tasks.

Table 2. Comparisons of LLM performances on extractive QA dataset

	F1-score	S-BERT
GPT-4o	74.0%	79.1%
BERT	78.7%	82.3%
CivilBERT	80.1%	86.4%
SpecBERT	**82.4%**	**89.2%**

Figure 4 presents a representative example of qualitative behaviors of baselines and domain-specific LLMs. Specifically, GPT-4o tended to prioritize completeness in answering the question by extracting all information related to the question and adding additional descriptions inferred from the contents. While this resulted in comprehensive responses, it often introduced unnecessary elaboration beyond the exact answer span. In contrast, BERT fine-tuned on the dataset adhered strictly to the question and focus on retrieving spans that appear directly relevant. However, due to the lack of pre-existing semantic understanding of the entire provision, BERT often extracted multiple loosely related segments. CivilBERT and SpecBERT, on the other hand, demonstrated stronger contextual comprehension. Both models exhibited a better grasp of how to localize and extract answer spans based on the semantic alignment between the question and the provision. This reflected their enhanced capacity for domain-aware understanding and more accurate extractive reasoning.

Figure 4. Qualitative behaviors of baselines and domain-specific LLMs for extractive QA pair

3.1.2 Downstream task #2 results: Information retrieval from provisions

Table 3 presented comparative results across three corpus types for the information retrieval dataset. General-purpose LLMs demonstrated relatively lower performance, with GPT-4o achieved F1-score at 53.9% and accuracy at 54.6%. BERT displayed substantial

improvement, with an F1-score of 71.7% and accuracy of 84.1%. Domain-specific pretraining further enhanced performance. CivilBERT outperformed BERT with an F1-score of 76.3% and accuracy of 87.7%, representing increases of 6.4% and 4.3% in two metrics, respectively. The best performance was observed in SpecBERT, which achieved an F1-score of 77.4% and accuracy of 88.9%, surpassing BERT by 8.0% in F1-score and 5.7% in accuracy compared to BERT.

Table 3. Comparisons of LLM performances on information retrieval dataset

	F1-score	Accuracy
GPT-4o	53.9%	54.6%
BERT	71.7%	84.1%
CivilBERT	76.3%	87.7%
SpecBERT	**77.4%**	**88.9%**

As illustrated in Figure 5, GPT-4o demonstrated limited capability to accurately classify domain-specific terms due to the lack of prior construction-specific knowledge in its general-purpose pretraining. To be specific, it failed to recognize specialized terminology such as "geotechnical fill materials," instead generalizing to broader terms like "materials." Additionally, its interpretation of standards and references tended to be ambiguous, frequently resulting in overlapping or misclassified outputs. In contrast, the fine-tuned BERT model showed improved performance, demonstrating the capability to distinguish between standards and references, while also preserving the integrity of domain-specific terminology. CivilBERT further enhanced this performance, though it struggled with certain terms, for instance, simplifying "resident engineer" to "engineer," and missed critical references, especially those pertaining to project-specific or organization-defined specifications beyond national standards. Notably, SpecBERT achieved the best overall performance. Benefiting from domain-specific pretraining, it was capable of extracting a more comprehensive set of relevant terms and correctly categorizing them semantically.

Overall, these results highlighted that domain-specific pretraining, particularly with in-domain corpora (e.g., SpecBERT), substantially enhanced performance of LLMs in both contextual comprehension and information retrieval. By integrating construction-specific technical terminologies, the model's ability to capture contextual contents and extract semantic elements was markedly strengthened, addressing unique linguistic complexities of the construction domain. This domain-aware capability proves especially valuable across a range of practical construction management applications [8,11]. Specifically, it facilitates information retrieval for decision support, allowing site engineers and project managers to quickly locate technical requirements—such as materials, construction methods, and tolerances—during on-site execution. Through aligning the model's linguistic capacity with the operational realities of construction workflows, domain-specific pretraining contributes to a more intelligent, efficient, and trustworthy document processing pipeline**,** supporting both high-level regulatory reviews and real-time field-level implementation.

Figure 5. Qualitative behaviors of baselines and domain-specific LLMs for information retrieval

3.2 Experiment #2: Hybrid Effects of Close-domain and In-domain Corpora on LLM

Experiment #2 examined the effects of varying corpus quantities by evaluating different proportions $x\%$ ($x \in \{10, 20, 30, 40, 50, 100\}$) of corpus data from single domains (close-domain or in-domain) and mixed domains in finetuning tasks. A maximum of 20 million tokens from each corpus was defined as the full-scale setting. Accordingly, 2 million tokens of in-domain data produced a 10%-SpecBERT, while mixture of 2 million tokens from each domain (total 4 million tokens) yielded a 10%+10%-MixBERT. Baseline models were established as LLMs pretrained on single-domain data with the same corpus size as the mixed-domain LLMs.

3.2.1 Downstream task #1 results: Extractive QA for provisions

Figure 6 demonstrated model performance varying with corpora quantity in extractive QA for provisions. It was found that incorporating 10% close-domain data (2 million) or 10% in-domain data (2 million) led to a slight increase in S-BERT to 82.6% and 83.1%, respectively, surpassing the baseline (82.3%). As the corpus size ranged from 2 million to 20 million tokens, models pretrained exclusively on in-domain data improved from 83.1% to 89.2% while those pretrained on a mixture of close-domain and in-domain data increased from 83.8% to 88.1%. In contrast, models pretrained totally in close-domain corpus exhibited the lowest performance. These findings indicated the substantial advantages of maximizing in-domain data for contextual comprehension. Meanwhile, when in-domain data was limited, augmenting the in-domain corpus with close-domain data during pretraining really enhanced model performance. For instance, a model pretrained on mixture of 4 million tokens of in-domain data and 4 million tokens of close-domain data attained a S-BERT of 85.9%, outperforming the 84.7% S-BERT of a model pretrained exclusively on 4 million tokens of in-domain data.

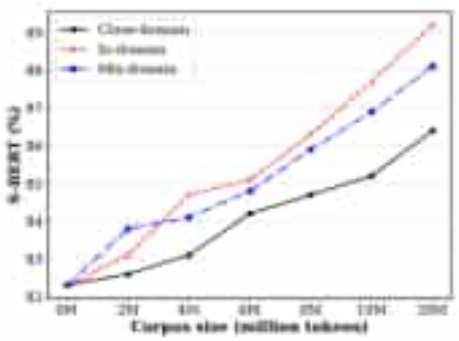

Figure 6. Model performance varying with corpora quantity in extractive QA

3.2.2 Downstream task #2 results: Information retrieval from provisions

Figure 7 illustrated how model performance varies with corpus size across three domains in information retrieval. Initial results showed that with a limited corpus of 2 million tokens (10%), models pretrained on close-domain and in-domain data achieved F1-scores of 71.1% and 71.4%, respectively, both slightly below the F1-score of 71.7% for the model without domain corpus. However, a hybrid approach combining 5% close-domain and 5% in-domain data yielded a notable improvement with an F1-score of 73.3%, a 1.9% increase over model pretrained from 10% in-domain data. This improvement suggested that the hybrid strategy effectively mitigated the overfitting risk associated with small amounts of either close-domain or in-domain data alone. As corpus size increased from 4 million to 20 million tokens, models pretrained on hybrid corpora exhibited a consistent upward trend in F1-scores, ranging from 73.5% to 76.8%. These performances were comparable to those of models pretrained exclusively on in-domain data from 73.9% to 77.4%, much higher than models pretrained using only the close-domain corpus.

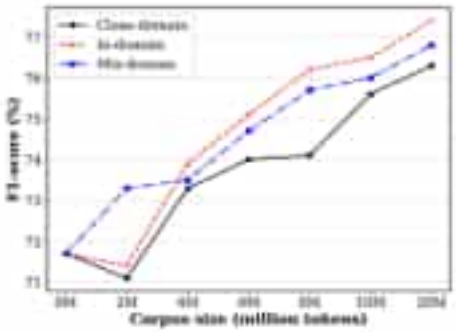

Figure 7. Model performance varying with corpora quantity in information retrieval

4 Conclusion

In this study, we proposed a three-stage LLM pretraining method to integrate domain-specific terminologies, enhancing its generalization and performances in construction specification review tasks. First, we constructed both close-domain and in-domain corpora to capture relevant construction-specific vocabulary and contexts. We then applied MLM for pretraining on these different types of corpora. Finally, we fine-tuned these pretrained models for two specification review tasks: extractive QA for provisions and information retrieval from provisions. To validate the effectiveness, we conducted two experiments. In Experiment 1, SpecBERT, our in-domain pretrained LLM, achieved the highest and at 82.4% and 89.2% in F1-score and S-BERT, surpassing the fine-tuned BERT model by 3.7% and 6.9% respectively, Additionally, SpecBERT demonstrated superior results in information retrieval from provisions, achieving a 77.4% F1-score and 88.9% accuracy, outperforming the state-of-the-art BERT model by 7.9% and 5.7%, respectively. Experiment #2 evaluated varying quantities and hybrid effects of close-domain and in-domain corpora. Results demonstrated that increasing quantity of domain corpora benefits the performance of LLMs in downstream tasks. When the size of in-domain corpus is limited, it is advisable to incorporate additional close-domain corpus data. Notably, a hybrid approach, mixture of close-domain and in-domain corpora, can yield performance levels comparable to models trained on sufficient quantities of in-domain data alone. In overall, this study

offered a practical approach to develop domain-aware pretrained LLMs adaptable to various construction specification review tasks under varying quantity.

Despite the promising potential of the work, there still exist two limitations. First, the size of the fine-tuning dataset was relatively limited. Increasing the volume and diversity of the dataset could further enhance model performance and robustness. Second, the pretraining corpus was English-centric, which may limit the model's generalizability to specifications in other languages. Future work will extend the approach to multilingual settings through cross-lingual pretraining and adaptation.

Abstract –

The construction of operating rooms involves multiple coordinated procedures. In practice, time and cost estimation are often uncertain. Additionally, project control still relies heavily on the manual interpretation of 2D drawings, resulting in inconsistencies between the design intent and on-site execution. There is one other thing that is important for the operating room. Operating rooms impose stringent requirements on illuminance and uniformity of illuminance to support long-duration surgical tasks. Inadequate lighting distribution can lead to increased visual fatigue and introduce shadows that negatively impact task performance. Therefore, this study integrates illuminance and uniformity simulation into the design workflow, allowing for the immediate evaluation of lighting performance after each layout configuration and the adjustment of lighting performance at an early stage. To address the above issues, this paper proposes a Multi-Dimension Simulation Framework based on the Omniverse platform. The proposed workflow can automatically generate the operating room interior framework (e.g., metal studs and antibacterial panels) from CAD floor plans, thereby reducing modeling time and supporting on-site installation processes. The system then placed the ceiling grid using a modular, center-out strategy, and the related attributes were recorded for subsequent quantity takeoff. At the same time, the user can place modular cabinet components, and then the system detects openings and boundaries, generating the bracing and support studs for enhancing stability. Finally, the component of the model will bind the schedule and cost data for 4D/5D simulation. Therefore, the results of this research can raise the effectiveness and efficiency of the operating room construction and project management.

1 Introduction

As a specialized interior environment defined by high sterility and process-intensive operations, the operating room demands strict adherence to specific protocols in design and construction. Guided by cleanroom design manuals, walls and ceilings must employ a modular, seamless construction integrated with a metal stud system; corners require rounded profiles to prevent dust accumulation, while openings necessitate reinforcement and edge sealing to ensure compliance with ISO Class 5–7 cleanliness standards [1]. However, current practices predominantly rely on manual interpretation of 2D schematics for modeling. This often results in inconsistent stud modularity, edge detailing, and opening-reinforcement execution, making it difficult to translate design requirements into computable parameters—such as module size and spacing, minimum clear distances, and corner radii—that serve as inputs for subsequent geometry generation and verification.

In the domain of automated configuration and digital workflows, academic research has made significant progress in recent years. Lee et al. [2] utilized Building Information Modeling (BIM) technologies to establish a template matching protocol, proposing a methodology wherein model geometry is deconstructed to allocate standard components based on rules and priorities, while defining non-configurable zones. This approach effectively illustrates the implementation path of transforming "regulation to rule to geometry." Addressing integration and collaboration across diverse data sources, Abbasianfar [3] posited that distributed construction simulation—encompassing IoT, imagery, and numerical models—relies critically on interoperability and consistency. Visualization platforms anchored by Universal Scene Description (USD) and NVIDIA Omniverse were identified as effective tools for preserving data integrity and supporting visual synchronization. Regarding the practical integration of 4D/5D dimensions, Inzerillo et al. [4] used a railway station project to demonstrate the interfacing of Revit

(3D/Quantity Take-off) with Navisworks (4D scheduling) and supplementary plugins (ArchVISION/PriMus) for cost linkage. This integration achieved real-time updates of quantities and costs in response to model changes, thereby establishing a unified management system for both schedule and expenditure.

In the domain of lighting simulation, the research focus has shifted from solely managing energy consumption to prioritizing human-centric visual comfort and optimizing illuminance distribution. Since Kennedy and Eberhart [5] introduced Particle Swarm Optimization (PSO), which employs swarm intelligence to determine global optima, this methodology has become a cornerstone of lighting control systems. Subsequently, Madias et al. [6] integrated multi-objective evolutionary algorithms into interior lighting control, demonstrating that compliance with the EN 12464-1 standard could align with the dual objectives of average illuminance and uniformity, effectively enhancing energy efficiency. Wagiman et al. [7] advanced this research by employing Multi-Objective Particle Swarm Optimization (MOPSO) alongside the Illuminance Uniformity Deviation Index (IUDI); by simultaneously minimizing power consumption and non-uniformity, their simulations achieved compliance with standards requiring a uniformity of ≥ 0.6 and an average illuminance of 500 lx. From an engineering practice perspective, Wati [8] highlighted that the Lumen Method (also known as the Zonal Cavity Method) retains a distinct efficiency advantage, enabling the rapid estimation of average illuminance and luminaire requirements, which serve as a reference for electrical configuration. In the context of operating rooms, where zoned lighting and scenario transitions (e.g., preparation, surgery, sanitation) are operational necessities, illuminance simulation must occur concurrently with geometric configuration. Only through this synchronization can the stringent requirements for shadowless illumination, uniformity, and maintenance accessibility be fully met.

In light of the foregoing analysis, three critical challenges persist within contemporary practice that demand immediate resolution. First, operating room renovation regulations remain unsystematically parameterized, rendering them unable to directly drive automated generation and verification mechanisms. Second, the integration of geometric modeling with 4D/5D data relies predominantly on manual linkage, resulting in Information not synchronized and inadequate version consistency. Third, illuminance simulation is typically introduced only in the latter stages of design, which prevents the establishment of a closed feedback loop with stud and panel configurations. To address these impediments, this study establishes an automated interior renovation workflow anchored by Universal Scene Description (USD). By implementing a rule engine using Python and Omniverse, the system translates construction principles into geometric constraints and processes. The system will generate the operating room model based on these rules. The scene utilizes the USD format to preserve readability and modification advantages, reserving metadata fields for 4D/5D integration to link scheduling and cost data simultaneously. Concurrently, the system synthesizes generated geometry for real-time assessment of illuminance and uniformity, thereby realizing a holistic workflow that unifies design, construction, and performance simulation.

2 System Framework

This study uses an operating room as the case study and targets renovation projects characterized by complex interfaces and frequent design changes. It establishes a Multi-Dimension Simulation Framework that integrates Python automation scripts with Universal Scene Description (USD). As shown in Fig. 1, the framework follows a data-driven approach and organizes the workflow into three sequential stages:

1. Drawing parsing input layer: reads 2D vector drawings, parses entities, and extracts geometric feature data.
2. Rule-based automation core: parameterizes the extracted geometry and converts it into USD assets according to predefined construction logic (e.g., opening reinforcement and light-gauge partition framing layout).
3. Simulation application layer: imports the generated model into NVIDIA Omniverse to support integrated simulations of construction sequencing and environmental performance.

Figure 1. System framework for this research.

2.1 System design

The system design is shown in Fig. 2. The workflow is implemented by two main classes, Interactor and USDScene, and three supporting components: OmniKit_Context, JSON_Data_Source, and pxr.Usd.Stage. Interactor is responsible for UI interaction and state management. It queries OmniKit_Context (e.g., get_context() and get_selection()) to access the Omniverse editor context and user selections. It also reads the initial layout inputs from JSON_Data_Source (parsed_data.json) and stores them as baseline data

(baseline_data). During editing, Interactor records user actions in a command list (cabinet_tasks) and derives the current logical state (tubes) by overlaying these commands on the baseline data, without directly editing USD geometry.

When the logical state is updated, Interactor instantiates USDScene and triggers a rebuild (Fig. 2, "Instantiates & Triggers Rebuild"). USDScene performs full-scene regeneration and writes geometry to pxr.Usd.Stage (Fig. 2, "Generates/Writes Geometry"), including floor/grid construction from wall segments (wall_segments), column placement from structural-chain data (cols_by_chain), panel and opening generation, and detailing operations such as corner correction, C-channel reinforcement, and ceiling-keel placement (create_ceiling_keels). The stage is then saved as USD-compliant outputs. In addition, Interactor reads/monitors pxr.Usd.Stage changes via a Tf.Notice listener (Fig. 2, "Reads/Monitors") to synchronize stage updates with the internal command flow.

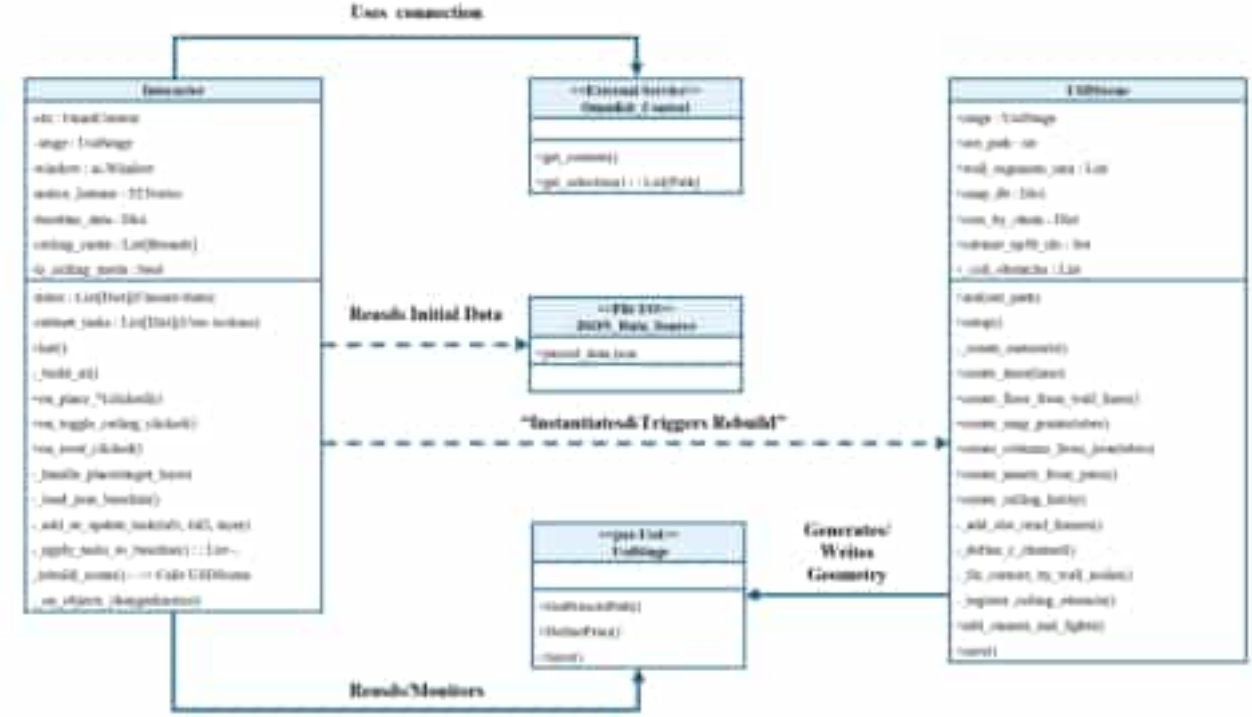

Figure 2. Schematic of the System Design.

3 Operating Room 3D Model Generation

This section outlines the comprehensive workflow for automatically generating a 3D operating room model from 2D drawings. The system divides the process into four stages. First, it parses the raw CAD data to obtain spatial coordinates. Next, it generates building components according to procedural construction rules. And then, it outputs a USD model that includes engineering information. Finally, the user can place modular cabinet components for time and cost simulation.

3.1 Layout Data Extraction

This study establishes a standardized preprocessing workflow that converts AutoCAD drawings into computable data. The program will filter out non-geometry data, such as dimensions, text, and hatches, to reduce noise, and then export only the geometry of walls and columns. The extracted coordinates of lines and points are written into the basic data as the geometric basis for subsequent automated generation and validation. The CAD drawing of the operating room layout is shown in Fig. 3.

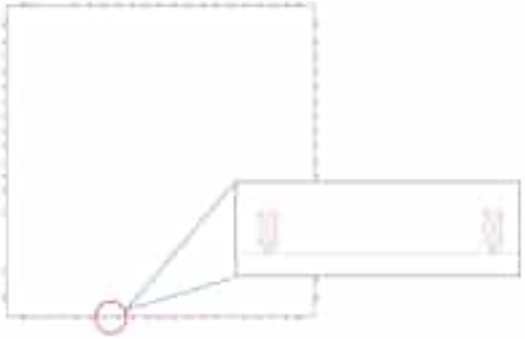

Figure 3. The CAD drawing of the operating room layout.

3.2 3D Model of Operating Room

The automated workflow in this study outputs not only 3D geometry but also a set of semantic OpenUSD assets. The resulting 3D model of the operating room is shown in Fig. 4. The assets are stored in USDA format, which features an open data structure that allows for direct access and attribute comparison, thereby improving modification and version control during the development stage. During component generation, the system writes the required metadata so that the geometry can be used as "smart objects" for engineering management. Examples include:

- Classification and model ID: bim:model (e.g., CeilKeel-3x6, Panel-<len>).
- Dimensional information: bim:length_mm, grid width, and related fields for 5D quantity takeoff.
- Construction sequence: sim:order for 4D animation and progress mapping.

Figure 4. The results of the operating room 3D model.

To ensure consistency across tools, the scene utilizes a unified upaxis and unit definition. After importing the assets into NVIDIA Omniverse, 4D/5D binding and illuminance analysis can be performed directly without additional coordinate or unit adjustments. Overall, the USDA maintains a clear linkage among "geometry–attributes–process." This supports rule verification and change detection, and provides a stable data structure for schedule- and cost-related computations.

As shown in Table 1, this research uses the general surgery operating room as a comparison with manual modeling. The proposed system not only generates the operating room geometry but also writes the required attributes and processes the data simultaneously. This allows the generated model to be directly used for later 4D scheduling, 5D cost calculation, and illuminance simulation. In contrast, manual modeling usually focuses on geometry reconstruction, while the data needed for later simulations must be added, organized, or transferred to other platforms afterward.

Table 1. Comparison between manual modeling and system-generated modeling

Item	Manual modeling	System-generated modeling
Modeling time	1 hr 6 min	1 min
Geometry	Antibacterial panels, floor, ceiling, and equipment	Antibacterial panels, floor, ceiling, equipment, peripheral framing, and equipment reinforcement structures
Data	Additional organization or manual input required	Written automatically during generation
4D / 5D / illuminance simulation	Cross-platform integration required	Can be directly continued within the proposed system

3.3 Implementation for Rule-based Engine

This study implements a rule-based engine for modeling of operating room construction, covering four functions: geometry generation, interactive reinforcement, 4D/5D simulation, and illuminance verification. To support review and implementation, Table 2 summarizes each rule set by its trigger conditions, processing steps, and output attributes.

3.4 Modular Cabinet Components Placement

The user interface and interactive mechanism for placing and reinforcing modular cabinet components are illustrated in Fig. 5. The cabinet instances used for placement are created in Revit and exported as Revit family files (RFA), and are also converted into USD assets for interaction in the scene. When the user places a cabinet asset, the system evaluates its geometric relationship to openings and boundaries and generates the corresponding reinforcement components with associated attributes for sequence simulation and cost/schedule linkage.

Table 2. Mapping of system generation rules.

Rule Category	Trigger Condition	Algorithmic Action	Generated Components	Key Attribute
Framing Generation	Closed boundary provided	Place studs and panels along the path using modular spacing; generate edge trims at boundaries.	C-Studs, Antibacterial Panels, Edge Trims	bim:model、bim:length_mm
Ceiling Grid Generation	Geometric center defined	Expand ceiling grids outward from the center, splitting at intersections and trimming at boundaries.	Ceiling Grids, Ceiling Panels	bim:model、bim:length_mm
Interactive Reinforcement	Equipment Placement	Analyze topological relations, generate opening frames, horizontal supports, and corner stiffeners, and densify studs as required.	Opening Frames, Horizontal Supports, Corner Stiffeners, Densified Studs	bim:model、bim:length_mm
4D Simulation	Visibility Activation	Toggle visibility sequentially to reconstruct the assembly order.	Step-by-step Visualization	sim:order
5D Cost Estimation	User Initiation	Convert length to modules and cost in real time; remove duplicates by selecting the longest overlapping path segment.	Itemized / Total Cost	bim:length_mm
Illuminance & Uniformity	Manual Simulation Trigger	Run illuminance mapping and uniformity checks based on the generated scene.	Illuminance Map, Uniformity Verification Map	-

Figure 5. User interface and interactive mechanism for placing and reinforcing modular cabinet components.

4 4D/5D Data Binding and Visualization

This study proposes an integrated strategy that packages geometric models, construction schedules, and cost data into a single scene description file, thereby reducing information fragmentation in conventional BIM workflows. The system uses the USD file as the computational core, where required attributes are stored in an embedded data structure within the scene. Accordingly, 4D and 5D computations are driven by reading the schema attributes attached to each component, rather than querying a separate data store.

In terms of data structure, the system uses the

component model identifier (bim:model) and geometric dimensions (e.g., bim:length_mm) as the basis for quantity measurement, and uses the sequence attribute (sim:order) to label the construction order. After parsing these attributes, both 4D reconstruction and 5D cost estimation can be performed simultaneously, as shown in Fig. 6. Each 4D event—defined as a component switching from hidden to visible and treated as "completed"—also serves as the trigger point for 5D costing. Because progress milestones and cost calculations share the same component ID and attributes, the system can accumulate costs along the timeline with synchronized data updates.

First, the 4D schedule reconstruction applies a "sequential reveal" strategy. At the start of the simulation, the entire scene is hidden, and component visibility is then switched on in batches according to sim:order to reproduce the assembly sequence and serve as the basis for computing the progress timeline. Second, 5D cost estimation is performed concurrently during the 4D animation. For components that have been revealed, the system performs real-time quantity takeoff and applies unit prices, enabling a "cost-on-completion" workflow：

1. Linear components (e.g., ceiling grids and C-channels): Quantities are accumulated using length attributes and then converted into the number of standard modules as the budgeting basis.
2. Wall panel deduplication: For the same wall-path segment, only the largest Panel-<len> is used as the calculation value to avoid duplicate counting caused by overlaps.
3. Unit-based modules (e.g., ceiling panels): The number of pieces is derived from width attributes and predefined modular rules.

These rules ensure consistency in geometry, scheduling, and cost computations within a single USD scene, facilitating tracking and comparison.

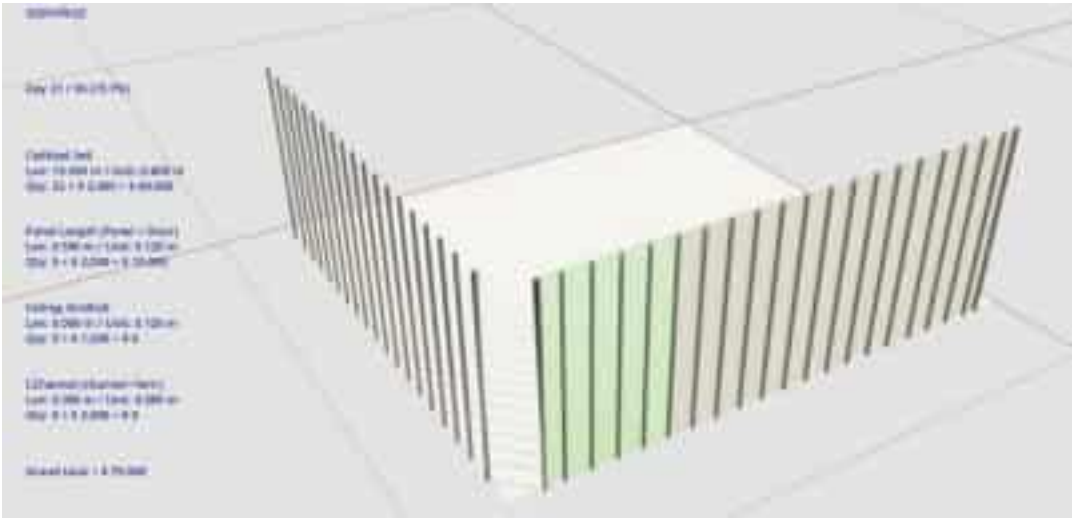

Figure 6. The Interface for 5D Process Simulation and Real-Time Cost Analysis.

5 Illuminance and Uniformity Simulation

This study undertakes a comprehensive evaluation of operating room lighting in strict compliance with the EN 12464-1 standard. Addressing the specific illuminance requirements for medical environments, the benchmark for recovery rooms is set at 500 lx, and general operating room illumination at 1000 lx. Conversely, the surgical cavity mandates an intensity ranging from 10,000 to 100,000 lx, as outlined in Table 3. Regarding the assessment of uniformity, computations are executed utilizing Equation (1):

$$U_0 = \frac{E_{min}}{E_{avg}}$$

Where U_0 denotes the uniformity of illuminance; E_{min} represents the minimum illuminance within the evaluation zone; and E_{avg} signifies the mean illuminance of the respective region. In accordance with established standards, the scope of evaluation is delineated into the task area and the immediate surrounding area:

- Task Area: Defined as the primary locus where visual tasks are executed (exemplified by the operative surface of the surgical table).
- Immediate Surrounding Area: Defined as a band-shaped zone that surrounds the task area and lies within the field of view. According to the relevant requirements, its width shall be at least 0.5 m. As illustrated in Fig. 7, the red box indicates the primary surgical task area, and the blue box represents the area expanded outward by 0.5 m. The system uses this defined range for grid discretization and uniformity verification.

In instances where the requisite illuminance upon the working plane equals or exceeds 750 lx—with this study stipulating a general operating room illuminance of 1000 lx—the objective uniformity is mandated as follows: ≥ 0.7 for the task area and ≥ 0.5 for the immediate surrounding area, as delineated in Table 4.

In the implementation, the system integrates geometric configuration with optical simulation. After the user places objects about surgical equipment, luminaires, and the surgical table in the scene, the system enables NVIDIA Omniverse Illuminance Arbitrary Output Variables (AOVs) to perform ray tracing and outputs a high-dynamic-range EXR image. At the moment the surgical table is placed, the system simultaneously detects its bounding box and defines it as the task area. The immediate surrounding area is then automatically generated by extending the task area outward by 0.5 m in accordance with EN 12464-1. The EXR data are subsequently read by a Python program developed in this study, which performs grid discretization and numerical sampling within these predefined regions for illuminance and uniformity verification. As shown in Fig. 8, a false-color map is first used to present the illuminance distribution, where red/orange indicates high illuminance, yellow/green indicates medium levels, and blue indicates low illuminance; the corresponding lx values are mapped to the color bar below, allowing designers to quickly identify hotspots and dark zones. As shown in Fig. 9, the system further performs a quantitative grid-based verification for the task area by computing illuminance values at each sampling point and checking whether the uniformity index U_0 meets the target criteria.

Table 3. Design Illuminance Specifications for Medical Environments [10].

Type of interior, task or activity	$\bar{E}_m$	Remarks
Pre-op and recovery rooms	500	
Operating theatre	1000	
Operating cavity	-	$\bar{E}_m$:10,000 to 100,000 lx

Table 4. The Relationship of Illuminance and Uniformity between the Task Area and the Immediate Surrounding Area [10].

Task illuminance (lx)	Illuminance of immediate surrounding areas (lx)	Uniformity: Task area (U_0)	Uniformity: Immediate surrounding area (U_0)
≥ 750	500	≥ 0.7	≥ 0.5

Figure 7. Schematic definition of the uniformity evaluation regions.

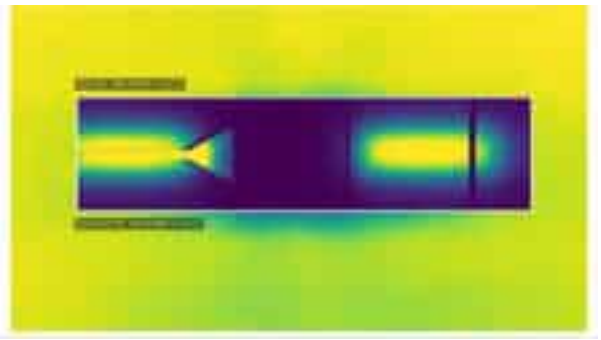

Figure 9. Analytical Diagram Verifying Illuminance Uniformity within the Task and Immediate Surrounding Areas.

6 Conclusions and Future Work

This study uses operating-room renovation as the validation scenario and develops a Multi-Dimension Simulation Framework. The framework separates computational logic from geometric data, providing a workflow from drawing parsing to multidimensional simulation. The main contributions are summarized as follows:

1. 3D Modeling: The system generates structure framing that includes metal studs and ceiling grids automatically. When the user places the cabinet components, the system updates the opening–boundary relationships and generates the required bracing and support studs. This can reduce the time and cost of 3D modeling.

2. 4D Simulation: The installation sequence is replayed by reading sequence attributes embedded in each component. This enables pre-construction checks of task precedence and supports early detection of process conflicts.
3. 5D Cost: 3D Model components are linked to a unit-price table. When wall or ceiling configurations change, quantities and total costs for panels and framing are recalculated and updated to reflect the current design state, allowing budget impact assessment without manual takeoff.
4. Illuminance and uniformity verification: Illuminance images (EXR) are generated via ray tracing. The system will calculate the average illuminance and uniformity on the operating table and verify compliance against EN 12464-1, enabling early verification during the design phase.

In summary, the results indicate that using USD as a unified data storage can integrate geometry, time, cost, and physical performance data within a single workflow, thereby reducing data discontinuities across heterogeneous tools. Future work will extend the framework to computational fluid dynamics (CFD) and human-factor evaluations, including airflow simulation for operating room ventilation, to support quantitative decision-making in healthcare space planning.

Abstract -

Full-scale 3D concrete printing for horizontal structural components is challenging due to large unsupported spans, early-age material instability, and geometric limitations of extrusion-based processes. A practical solution is to fabricate modular slab units by printing only the structural ribs of the slab while casting the top and bottom layers conventionally and achieving composite action through post-tensioning. This paper presents a computational pipeline for the integrated design and feasibility evaluation of such hybrid slab units. A design pipeline generates topology-optimized rib layouts, segments the slab into prefabricated units, refines local structural features, and performs constructability checks before producing a detailed BIM model. A complementary simulation pipeline evaluates fabrication and feasibility of erection within the same workflow. Motion-level simulations in Gazebo assess reachability, collision avoidance, and lifting trajectories for production cells, while rule-based risk evaluators identify constraints beyond rigid-body simulation.

Keywords -

3D concrete printing; Constructability evaluation; Hybrid construction; Ribbed slab units; Topology optimization; Robotic simulation.

1 Introduction

Recent advances in 3D concrete printing have enabled efficient automated fabrication of vertical components, such as walls and columns, where material is deposited layer by layer in a predominantly vertical direction and is continuously supported[12, 19]. In contrast, full-scale slab printing remains largely infeasible. Slabs require depositing fresh material horizontally over large spans, which requires traditional formwork and cannot be printed. In addition, many current extrusion-based systems are designed for prismatic, single-direction geometries that are not well suited to multi-directional structural behaviour.

An alternative is to prefabricate units in production cells where printing is restricted to the structural ribs of the slab. In such a hybrid system, ribs can be generated using topology optimization to align with principal stress trajectories. The top and bottom layers can be cast conventionally, and post-tensioning can be used to activate composite action and enable large-span performance. The slab can be segmented into prefabricated units to satisfy transportation and lifting constraints. However, this hybrid approach produces a highly coupled workflow involving rib printing, concrete casting, unit lifting, on-site assembly, and post-tensioning. Assessing feasibility across this workflow is challenging due to geometric, structural, and robotic limitations.

In this work, we formulate a computational pipeline for the integrated design and feasibility evaluation of such slab units. The pipeline is structured into two tightly coupled components:

1. **Design**: design of hybrid ribbed slab units, from initial input conditions to parametric BIM geometry, with a focus on topology optimization. This workflow not only serves to provide input for simulation of the system as a whole, it also forms the basis for a fully parametric and automated design system for eventual production of such slab units.
2. **Simulation**: simulation of the fabrication process that integrates robot motion and 3D printing equipment with rule-based scheduling and risk evaluation, and simulation of the erection and post-tensioning process on site.

The paper provides a background review of the state-of-the art for fabrication of horizontal elements with 3D printing in building construction, software for structural design and topology optimization, software for simulation of robotic and 3D printing production cells, and software for 4D planning and analysis of construction operations. It then details feasible computational workflows for each of the two steps listed above.

2 Related work

2.1 3D printing of structural components

3D printing of cementitious materials, particularly 3D concrete printing (3DCP), is gaining interest for enabling

complex geometries and material-efficient structural design. This is increasingly relevant given the difficulty of realizing optimized concrete structures using conventional formwork-based construction.

3DCP allows formwork-free fabrication of complex geometries, but applications have primarily focused on vertical elements. Horizontal members remain challenging due to bending-dominated response and limited reinforcement options, which motivates compression-dominated designs. For beams and slabs, prestressing enables such behavior and improves structural performance [11], while also supporting segmental post-tensioned and modular construction.

Hybrid construction, combining printed stay-in-place formwork with cast concrete, has emerged as an alternative approach. Initially applied to vertical elements, it has recently been extended to horizontal members [9]. These developments highlight the potential of 3DCP and the need for integrated computational workflows that link structural design, optimization, fabrication, and construction.

2.2 Structural optimization

Structural optimization, particularly topology optimization, enables substantial material savings by aligning geometry with internal force flow. Owing to its design freedom, topology optimization can be tailored to address multiple design stages, from conceptual layout to fabrication-aware realization.

A simultaneous shape and topology optimization framework for prestressed concrete systems was introduced in [1, 2] and later integrated with 3DCP through CAD-based interpretation and post-tensioned fabrication [16]. This demonstrated its potential for segmented, prestressed printed structures, while also highlighting the need for tighter design–fabrication integration. The framework has since been extended to fully three-dimensional free-form optimization of prestressed beams and slabs [14], which is adopted in the present study.

An additional key challenge in realizing optimized geometries with 3DCP is early-age material behavior during printing. To address this, optimization formulations incorporating buildability constraints have been proposed to ensure printability [7, 13].

Overall, these developments demonstrate the potential of structural optimization for efficient 3DCP, particularly when structural, material, and fabrication considerations are integrated within a unified design framework.

2.3 Robotics simulation in construction

Robotics simulation environments such as Gazebo and V-REP have been increasingly used in construction research to visualize and validate robotic workflows [5]. However, most studies treat simulation as a visualization or debugging tool, focusing on kinematics and collision avoidance, rather than using it as part of a risk-evaluated construction logic. The proposed methodology embeds motion-level simulation into a validation pipeline, combining Gazebo-based action simulation with external rule-based evaluators to assess constructability, printability, and erection risks of full slab systems—bridging the gap between motion simulation and feasibility-driven design.

2.4 4D CAD simulation for construction

4D CAD is a well-established method for evaluating construction methods and processes [10]. It is commonly used for complex construction projects and numerous software tools offer 4D functionality. However, they are restricted to predetermined motion paths and fixed element geometries - they lack the operational detail and the physics engines needed for planning and validating the motion of robotic and 3D concrete printing machinery needed for design of automated production cells contemplated in this work. For this reason, we use Gazebo Simulation[8] with Robotic Operating System (ROS) integration to plan and validate the constructability of slab units.

2.5 Software interoperability

The increasing use of BIM, parametric modeling, and robotics in construction demands robust software interoperability. However, workflows often remain fragmented, with tools such as Revit, Rhino/Grasshopper, FEM solvers, and ROS/Gazebo used in isolation. Prior efforts have explored parametric and BIM-integrated workflows, but few address interoperability from early design to robotic fabrication [6, 15, 18]. The proposed pipeline demonstrates a connected chain: BIM authoring $\rightarrow$ parametric modeling $\rightarrow$ structural analysis $\rightarrow$ robotic simulation, with data exchanged through mesh conversion, scripting, and task encoding—supporting a full feedback loop across design and construction domains.

3 Solution overview

The proposed method integrates design and simulation into a two-stage computational pipeline.

First, a Design Pipeline processes an input architectural slab layout into a manufacturable set of hybrid precast units. This design stage encompasses geometry extraction, global topology optimization, segmentation into units, local structural design, constructability checks, and parametric BIM geometry generation.

Second, a Simulation Pipeline takes the BIM model as input and evaluates feasibility and safety. It converts geometry into formats suitable for robotic simulation, defines tasks, generates toolpaths and trajectories, sets up Gazebo

scenes, runs simulations for both fabrication and erection, and complements Gazebo with rule-based risk evaluators.

The two pipelines are linearly connected by default: the output of the Design Pipeline feeds into the Simulation Pipeline sequentially. Critically, the framework also supports an iterative feedback loop (stage S7) whereby detected risks in simulation prompt design modifications in earlier stages, enabling design-for-constructability through repeated cycles if needed. This ensures that the slab system not only meets structural and architectural requirements but can also be fabricated with robotic 3D-printing and assembled on-site.

4 Design pipeline

4.1 D1 – Input and boundary conditions

The Design pipeline (Figure 1) begins with a formal definition of the slab design problem, consolidating all relevant architectural, structural, and constructability parameters. In this stage, the system gathers and encodes the boundary conditions, design objectives, and fabrication constraints that govern the remainder of the pipeline.

Architectural input includes the slab layout, openings, and support configuration, typically extracted from BIM models in Revit or IFC format. Structural input includes material properties , design load cases, and permissible deflection criteria. Constructability-related constraints are also explicitly defined. These include limits on maximum unit weight based on crane capacity, unit dimensions based on transportation and printer workspace, and minimum rib thickness or curvature radius based on extrusion nozzle geometry.

All inputs are consolidated into a structured configuration file, which may be implemented as a .json or .yaml file and is readable by downstream modules. Each parameter is associated with its source and its status. This configuration serves as the canonical reference for the remainder of the pipeline, guiding geometry extraction, optimization, segmentation, constructability checks, and simulation. This stage enhances clarity, reusability, and cross-project consistency.

4.2 D2 – Geometry extraction and pre-processing

This stage converts architectural slab definitions from BIM into a clean and analysis-ready geometric domain. The process begins by extracting the slab's physical outline and internal voids using Dynamo for Revit or Python scripts with IfcOpenShell for IFC-based models. Structural supports—such as columns, load-bearing walls, or beams—are identified by intersecting BIM elements with the slab geometry. These intersections are translated into support boundary conditions for structural analysis. Unlike conventional approaches that assume regular or rectangular shapes, this method accepts arbitrary slab boundaries, including non-convex, curved, and multiple-voided geometries.

The extracted geometry is then pre-processed to remove inconsistencies and modeling noise. Small fillets, disconnected edges, and planar irregularities are cleaned. The cleaned geometry is exported as a three-dimensional solid mesh and used as input for 3D topology optimization in stage D3.

4.3 D3 – Global topology optimization

This stage applies three-dimensional topology optimization to generate the global rib-and-void geometry of the slab. Using the meshed slab domain from Stage D2 and the material and boundary conditions from Stage D1, the slab is modeled as a three-dimensional solid domain. The optimization follows the prestressed concrete topology optimization framework developed in [14], incorporating common prestressed concrete design practices in the objective formulation and volume constraint, including the structural effects of post-tensioning on load transfer and stiffness. We note that the framework incorporates simultaneous optimization of the concrete distribution and of the tendons' geometry, such that the effect of prestressing is captured from the early design stage by means of equivalent forces.

An illustrative example is presented for a simply supported prestressed concrete slab with dimensions $12.0 \times 12.0 \times 0.36$ m, subjected to uniformly distributed dead and live loads of 10 kN/m^2 each. The top and bottom two element layers are prescribed as solid material, corresponding to a thickness of 0.06 m for the top and bottom slab parts, while the optimization is restricted to the intermediate region to identify an efficient rib layout connecting the lower and upper concrete layers. The overall allowable concrete volume fraction, including the top and bottom parts, is limited to 50%. A mid-height cross-section illustrating the top and bottom parts of the optimized design is shown in Figure 2.

The resulting rib geometry is freeform, shaped by the optimized layout of post-tensioning cables and additional rib stiffeners. The output is a three-dimensional solid geometry capturing the full layout of ribs and internal voids, which is exported as an STL mesh or converted into editable BREP surfaces representing the printable and structurally informed volume of the slab core.

4.4 D4 – Unitization (segmentation into prefabricated units)

After the generation of the global rib geometry, the slab must be divided into constructible units suitable for robotic fabrication, transport, and on-site lifting. This unitization

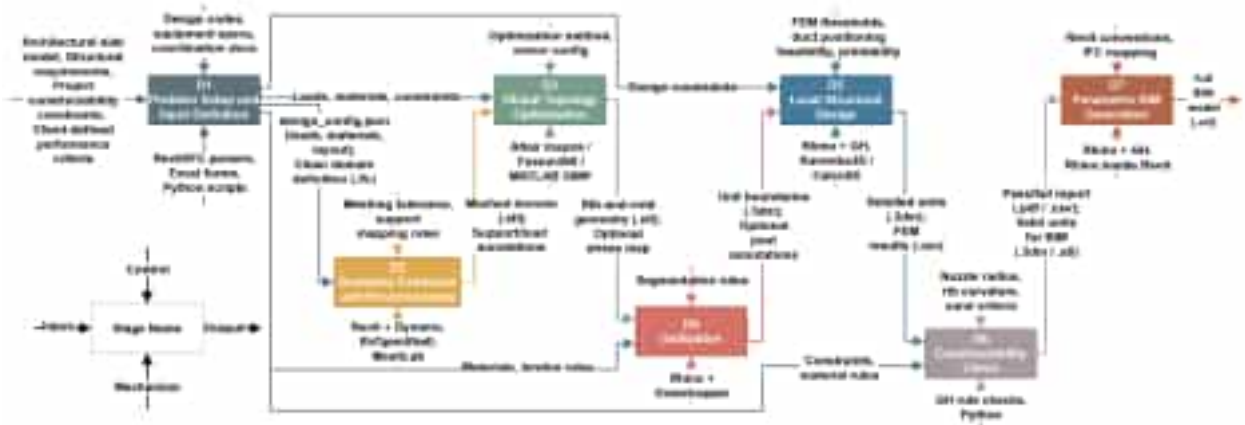

Figure 1. Design pipeline using IDEF0 notation

(a) Top layer.

(b) Bottom layer.

Figure 2. Optimized slab geometry.

stage defines the boundaries between slab modules and directly affects their structural continuity, printing feasibility, and assembly workflow. This modular decomposition aligns with DFMA-oriented prefabrication approaches [4].

Segmentation begins by identifying regions of the rib network where natural breaks can occur. Cutting lines are guided by the rib topology: they are deliberately routed through void zones or rib junctions, and avoid slicing directly through the middle of major load-bearing ribs. The goal is to minimize the disruption of continuous load paths and reduce the total rib cross-sectional area that must be interrupted. Curved or angled segmentation lines are allowed if they better follow the rib architecture, rather than imposing an artificial rectilinear grid.

Each proposed unit is then evaluated against fabrication and logistics constraints defined earlier in stage D1. These include limits on unit footprint, estimated weight for lifting, and clearance requirements for handling equipment. At this stage, the evaluation is rule-based and geometric—no finite element analysis is performed. Units that violate basic constraints are iteratively re-partitioned. Where unavoidable, segmentation boundaries that intersect rib regions are marked for later reinforcement or anchorage detailing in stage D5.

The unitization workflow is implemented in Rhino using Grasshopper, with rib geometry imported as STL or mesh files from D3. Segmentation curves are generated and refined parametrically, then exported as BREP sub-volumes. These definitions are passed to downstream detailing (D5) and BIM integration (D7), ensuring traceability and continuity across design stages.

4.5 D5 – Local structural design and detailing

Once the slab has been divided into prefabricated units, each segment undergoes local structural design to ensure printability, post-tensioning feasibility, lifting safety, and full structural performance. This stage converts the global optimization mesh into detailed, buildable geometry.

Since the ribs generated in stage D3 are non-parametric and typically represented as STL meshes, a geometric reconstruction process is performed. The discrete optimization mesh is converted into parametric BREP geometry through cross-section sampling and lofting to enable downstream detailing.

Tendon ducts are embedded within the rib volume using solid Boolean operations. Each duct follows a defined path from one anchorage point to another, and is constrained by minimum curvature, wall clearance, and interface geometry. At rib intersections, ducts are either limited to principal structural directions or offset vertically to avoid conflict. This ensures smooth threading and successful anchorage during post-tensioning. Void regions between ribs form unoccupied spaces that are temporarily filled with sand to support the top concrete layer during casting. Rib spacing and topology are adjusted to avoid excessive overhangs and ensure that voids remain accessible for sand placement and removal.

The slab unit is completed with a bottom and top concrete layer, each containing its own steel mesh reinforce-

ment. The three components form a sandwich structure. For enhanced interlayer shear resistance, starter bars may be embedded into or alongside the ribs. In high-curvature or support-bearing regions, ribs may be thickened, or vertical reinforcement zones introduced. Each unit undergoes structural validation using lightweight finite element models, such as Karamba3D or CalculiX, to evaluate lifting deformation, internal stress distribution, and tendon alignment, reflecting the influence of prestressing on structural response. Units that fail to meet structural or fabrication constraints are flagged for revision of rib geometry, duct routing, or anchorage region shaping.

The output of stage D5 is a fully detailed, fabrication-ready slab unit model—including solid ribs, tendon ducts, sand-supportable voids, and cast concrete layers—passed to stages D6 for constructability verification and D7 for BIM integration.

4.6 D6 – Constructability check

Before the slab unit models proceed to simulation and BIM integration, each unit undergoes a constructability check to ensure that the geometry complies with fabrication, transportation, and assembly constraints, verifying whether the geometry can be realistically fabricated, lifted, and handled. This stage checks a series of rule-based geometric and physical constraints, such as: minimum rib thickness and printable curvature radius to avoid nozzle failure or material sagging; maximum unit dimensions and weight based on gantry size, crane capacity, and transport limits; duct minimum bending radius to ensure tendon threading is possible.

These checks are implemented in Grasshopper using parametric scripts. Thresholds and constraints are imported from stage D1 and updated as needed. Units that fail any criteria are flagged for revision in rib geometry, segmentation boundary, or detailing logic.

The constructability check also produces embedded metadata such as center of gravity, expected lifting points, and estimated assembly tolerances. This information is essential for planning site erection (S5) and exporting to BIM (D7).

The output of stage D6 is a verified set of slab units with constructible geometry and constraint-satisfying properties. These models are then passed to the simulation pipeline.

4.7 D7 – Parametric BIM generation

After structural and constructability validation, each slab unit is converted into a parametric BIM representation for coordination, documentation, and integration with broader project workflows. This ensures the design outputs from previous stages are compatible with industry-standard BIM platforms and ready for simulation, fabrication, and site operations.

Each slab unit is composed of multiple components—including cast-in-place top and bottom concrete layers, 3D-printed rib structures, embedded tendon ducts, temporary voids, and reinforcement meshes. These are modeled in Rhino and Grasshopper, then transferred into Revit using the Rhino.Inside.Revit framework. Geometries are classified into appropriate Revit categories (e.g., floors, structural framing, and generic models) with embedded metadata as Revit instance parameters to support scheduling and clash detection.

The final output of stage D7 is a complete, structured BIM model comprising all prefabricated slab units, their internal components, and associated metadata. It serves as the authoritative digital representation of the system and links design, fabrication, and erection phases into a unified digital workflow.

5 Simulation pipeline

5.1 S1 – Model conversion

The Simulation Pipeline (Figure 3) begins by converting the detailed BIM output from D7 into simulation-ready assets for robotic and construction environment modeling. Each slab unit is exported from BIM (Revit or Rhino3D) as a triangulated mesh in STL or OBJ format. Supporting elements such as columns, walls, and floors are also extracted to define the physical context for virtual erection. Prior to export, a mesh simplification step is applied using tools like MeshLab or open3D to reduce polygon count, improving simulation efficiency without altering the slab's global shape. Geometry export is automated via scripting, while the assignment of lifting points and tendon tags currently requires manual annotation in Grasshopper or Revit. These assets are converted into Gazebo-compatible formats: static objects are encoded in Simulation Description Format (SDF), while movable objects (e.g., slab units subject to lifting) are converted into Unified Robot Description Format (URDF) with optional joint definitions and inertial tags.

Embedded metadata (e.g., element ID, volume, mass) are extracted automatically from the BIM model. Additional metadata, such as tendon duct alignment or grouting zone tags, can also be embedded using Gazebo plugins for later validation. The result is a library of simulation-ready models reflecting the BIM geometry, but optimized for robot control and physical simulation in Gazebo. This library is used in later stages (S4–S6) for kinematics, task execution, and collision-based validation.

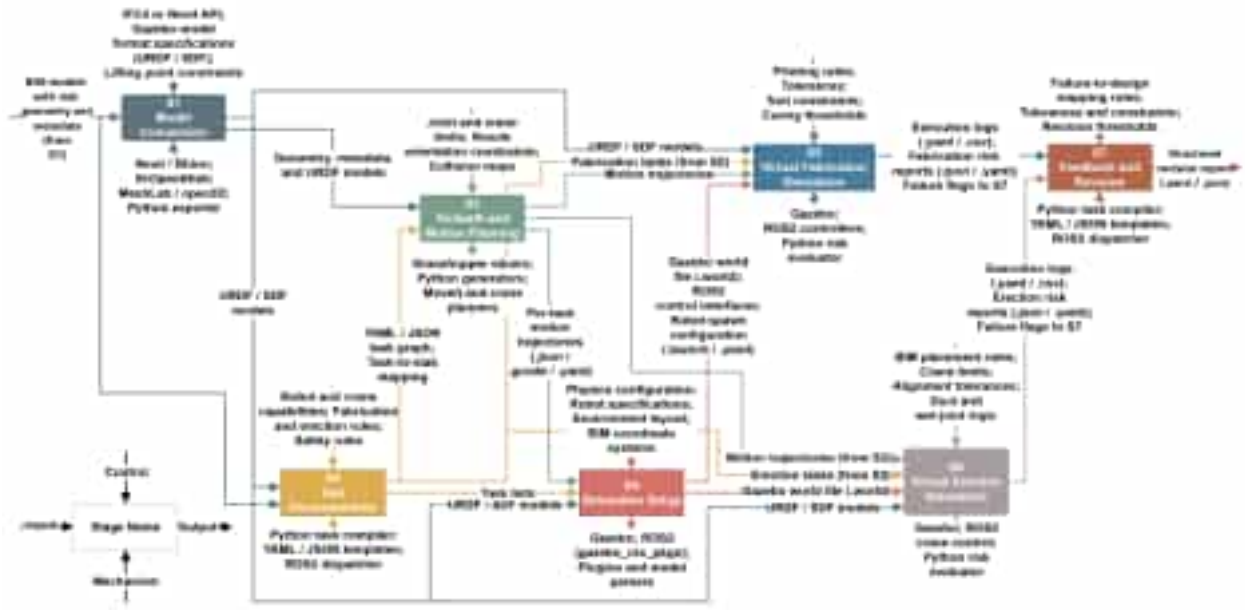

Figure 3. Simulation pipeline using IDEF0 notation

5.2 S2 – Task decomposition and sequencing

This stage defines a structured execution plan for fabrication and erection, decomposing the overall slab construction process into discrete, simulation-ready tasks. Based on the BIM-derived models and metadata from S1, each slab unit is associated with a specific sequence of robotic or crane-based operations. There are eight fabrication steps, three storage and transportation steps, and six erection steps. Most geometry-to-task mappings—such as identifying target slab units and assigning agents based on lifting points or print zones—are automatically inferred from BIM metadata or spatial relationships, while certain parameters (e.g., pour speed or human involvement) still require manual annotation at this stage.

Each task is encoded in a machine-readable YAML or JSON format that specifies: 1) Task type (e.g., print_ribs, place_ducts) 2) Target slab unit or geometry 3) Assigned agent (gantry, robotic arm, crane) 4) Required inputs (e.g., toolpath file, lifting anchor) 5) Temporal dependencies (e.g., curing complete before lifting).

This results in a Directed Acyclic Graph (DAG) of tasks that enables logical sequencing and parallelization. The task graph can be parsed and executed by ROS2 nodes, providing a control interface between planning and simulation. Task definitions can also be linked to BIM elements for 4D scheduling or progress monitoring. Where available, task hints embedded in BIM models—such as lifting zones or build order tags—are incorporated. The generated graph serves as the input for motion planning (S3) and simulation execution (S5–S6).

5.3 S3 – Toolpath and motion planning

This stage translates each task from the construction graph (S2) into executable robot motion. For fabrication, geometric inputs from S1 are automatically sliced into layer-based toolpaths, exported as .json or .gcode files. Each path includes 3D positions, print speed, nozzle orientation, and pause points. Ducts are inserted using a "pause-and-insert-from-above" method. After printing several layers of the rib, ducts are lowered vertically into grooves and sealed by continuing the print (conceptually consistent with in-process insertion and pause-and-insert strategies reported in [17, 3]). This method avoids lateral interference and fits well with robot-assisted insertion.

For each path, ROS2 MoveIt performs inverse kinematics and collision checks. Gantries and arms are automatically evaluated for reachability, joint limits, and obstacle avoidance. Unreachable or unsafe segments are flagged for revision. Tasks like sand filling and mesh placement are handled as partially scripted, parametric sweeps or pick-and-place motions, with manual definition of start/end poses.

Erection planning uses simplified crane kinematics. Given start/end poses from S2, safe lifting paths are automatically generated considering swing limits and clearance from obstacles. The planner ensures loads stay within the crane's envelope and avoids sharp accelerations.

All results are saved in ROS2-compatible formats (.json, .yaml), indexed by unit ID and task name. These trajectories are passed to the simulation system in S5–S6, forming the robotic execution layer.

5.4 S4 – Simulation environment setup in Gazebo

This stage builds a simulation-ready digital twin in Gazebo that replicates both the fabrication and site environments for the slab system. The environment integrates geometric models (from S1), robotic tasks (from S2), and planned motion trajectories (from S3), enabling time-sequenced motion playback, real-time collision checking, and dynamic constructability validation. The simulation environment comprises two zones: 1) a factory layout containing the printing gantry, formwork, and manipulators, and 2) a site layout including BIM-derived structural supports, the crane system, and positioning frames.

Each object is instantiated from its SDF or URDF model with its physics properties. ROS2 control plugins are attached to each robot to enable real-time command execution. For instance, the gantry receives Cartesian print trajectories; the crane interprets lifting paths and winch cable lengths; and all actions are synchronized via ROS2 messages. Slab units spawn with embedded metadata to support accurate tracking and placement.

Environmental dynamics such as gravity, surface contact friction, and optional wind disturbances are enabled. The goal is to achieve realistic behaviour of printed structures, suspended loads, and placement operations. Contact modeling between slab units and supports allows validation of alignment and load transfer.

By the end of S4, a complete virtual environment is assembled, with all elements positioned in BIM-coherent coordinates. This environment forms the runtime context for executing and analyzing fabrication and erection tasks in S5 and S6.

5.5 S5 – Fabrication simulation

This stage executes each prefabrication task in the virtual environment built in S4, validating robotic execution under physical constraints. Using ROS 2 controllers, each robot agent performs the motion trajectories generated in S3. Gazebo simulates kinematics, contact, and collisions based on physical parameters, while task scheduling and execution follow the construction graph from S2.

The fabrication sequence includes: bottom mesh placement, bottom-layer concrete casting, rib printing with duct insertion pauses, sand filling, top mesh placement, and top-layer casting. The rib printing process follows layered paths; at designated heights, the print head pauses and a duct insertion motion is executed.

A custom Risk Evaluator monitors execution in real-time, flagging issues such as nozzle collisions, reachability violations, or curing time constraints based on task timestamps and predefined rule-based thresholds (e.g., minimum clearance distance, reach limits, and time intervals). All fabrication actions are logged with timestamps, unit IDs, task names, and pass/fail tags. Warnings from the Risk Evaluator are saved in structured YAML/JSON reports and linked to slab unit metadata. If a failure is detected the system records which unit and stage requires revision. These reports are forwarded to stage S7 for design iteration.

5.6 S6 – Erection simulation

This stage simulates the robotic and crane-assisted assembly of prefabricated slab units in a virtual construction site, evaluating geometric feasibility, placement accuracy, and interface alignment. Using the digital twin environment established in S4, each slab unit is lifted, positioned, and logically integrated into the structural frame.

A crane model, a URDF with boom joints and winch mechanism, is commanded via ROS2 controllers to follow the lifting trajectories defined in S3. Each unit is lifted from the ground or factory bed, transported across the site, and lowered onto structural supports derived from the BIM geometry. Upon placement, the system verifies whether the unit rests stably on pre-positioned temporary supports. Contact is evaluated using bounding box intersections and pose thresholds (e.g., allowable tilt angle and support coverage ratio). If a corner lacks adequate support or the unit exceeds tilt limits, the Risk Evaluator flags it for temporary shoring.

Adjacent slabs undergo geometric validation for duct alignment and wet joint feasibility. Co-oriented duct outlets within tolerance (e.g., positional and angular deviation limits) enable logical tendon threading, while misalignments trigger a redesign flag. Post-tensioning is abstracted as a logic state rather than a physical simulation, while its structural effects are incorporated in the design stage through topology optimization and structural analysis, set only when valid alignment and closeable joint gaps are confirmed.

All outcomes—placement success, duct alignment, propping needs, and tendon connection feasibility—are logged per slab unit in structured YAML/JSON records. These records are passed to the feedback module (S7), enabling targeted revision in design.

5.7 S7 – Feedback loop and design revision

This stage closes the simulation-design loop by interpreting the results from virtual fabrication (S5) and erection (S6), and routing issues back to the appropriate stages of the design pipeline (D3–D6) for revision. The goal is to enable targeted design refinement without restarting the entire process.

6 Discussion and conclusion

This paper proposed a dual-pipeline method for the design and simulation of 3D-printed slab systems with

embedded post-tensioning, integrating a D-stage design pipeline (D1–D7) with a S-stage simulation pipeline (S1–S7). Unlike prior work focusing on small-scale printing or isolated robotic tasks, our pipeline supports full-scale prefabricated units with embedded structural logic, and accounts for site-level erection and post-tensioning.

A key contribution is the integration of rule-based feedback between simulation and design, enabling early-stage decisions to be evaluated against real-world constraints. The structured task graph format and use of ROS2+Gazebo ensure that both fabrication and erection steps can be virtually tested before deployment.

Limitations include the simplification of material behaviors and the lack of full automation in geometry-to-task mapping in the simulation stage . Future work will extend risk evaluation to cover time-dependent rheology and incorporate real-world feedback from physical trials. The proposed pipeline serves as a foundation for digital twin–enabled robotic prefabrication in building-scale applications.

Abstract –

Quality control is critical for off-site construction, but it still depends heavily on individual expertise and manual inspection. The management and coordination of heterogeneous and fragmented knowledge among the stakeholders involved in quality control of off-site construction remains challenging. To address this knowledge gap, this paper proposes QuosRA, a novel framework for **qu**ality control in **o**ff-**s**ite construction empowered by a hybrid **r**etrieval-augmented generation (RAG)-driven multi-**a**gent system. In particular, QuosRA breaks down multi-disciplinary quality control tasks into role-based subtasks handled by dedicated large language model agents with specific expertise. Each agent is assigned a particular role, expertise, and abilities for automatic quality compliance checking and quality control task guidance. The performance of QuosRA is evaluated using 30 quality inspection cases and 10 task guidance queries, compared against single-agent hybrid RAG and unstructured multi-agent system baselines. The results indicate that structured task coordination in QuosRA achieves better performance in both quality compliance checking (retrieval precision of 82.4% and determination accuracy of 93.3%) and quality control task guidance (retrieval precision of 92.9% and high-quality response score of 80.0%). Overall, QuosRA improves the efficiency and consistency of quality control workflows in off-site construction projects, offering an effective pathway toward scalable and knowledge-driven quality management in the construction industry.

Off-Site Construction; Quality Control; Large Language Model; Multi-Agent System; Retrieval Augmented Generation

1 Introduction

Off-site construction (OSC) is an innovative construction method that refers to the manufacturing and pre-assembly of building elements, components, or modules before their installation at their final locations [1]. It has attracted growing attention with its potential benefits in enhanced productivity, shortened construction periods, improved safety, and minimization of construction waste [2]. Quality control (QC) refers to a set of measures and procedures implemented to ensure that OSC complies with predefined quality standards and satisfies relevant regulatory requirements [3], involving quality compliance checking, quality data collection, and quality issue remediation. In particular, the widespread production of prefabricated components imposes stringent QC requirements to reduce potential quality defects before delivery to the construction site. This highlights the crucial importance of precisely monitoring and controlling the quality of prefabricated components during manufacturing.

Despite its importance, existing research on implementing QC in OSC, spanning design to construction activities, remains inadequate [3], and the current practice is still challenging. QC is highly specialized and complex, wherein quality knowledge is diverse and scattered among different stakeholders and markets [4]. OSC quality inspections highly depend on cross-disciplinary participants with varying knowledge, experiences, and responsibilities. The vast and intricate body of regulations and standards involved across regions further exhibits multi-role practitioners to track, identify, and enforce quality requirements for OSC projects [5]. Besides, the shortage and frequent turnover of skilled QC personnel greatly hinder knowledge sharing and circulation within teams, resulting in limited collective understanding and overreliance on individual capabilities in quality diagnoses [6]. Ultimately, existing quality information systems remain constrained by static rule-based mechanisms and offer limited capacity to interpret diverse QC contexts, integrate fragmented knowledge, or support the interactive decision processes required in complex OSC environments [7].

Recent advancements in LLMs, retrieval-augmented generation (RAG), and multi-agent systems (MAS) provide a promising solution to address these complexities. LLMs offer strong natural language

interpretation and context-aware reasoning capabilities for knowledge-intensive tasks in construction, while MAS coordinates multiple intelligent agents to manage complex and distributed workflows [8]. Meanwhile, RAG synergistically merges intrinsic knowledge of LLMs with dynamic and domain-specific information, enhancing the accuracy and credibility of response generation [9]. The integration of LLM-based semantic understanding, RAG-driven knowledge retrieval, and MAS-supported collaborative orchestration could automate highly specialized tasks that demand nuanced comprehension and flexible coordination, such as QC in OSC. This integrated paradigm moves beyond the limitations of traditional agent systems in construction [10], enabling richer interpretation, trustworthy knowledge reuse, and adaptive multi-role coordination.

However, how the complementary strengths of LLMs, RAG, and MAS can be integrated into a coherent and domain-oriented framework for QC in OSC is still underexplored. Such integration is essential for managing fragmented knowledge, reducing inspection inconsistencies, and coordinating multiple roles across distributed off-site settings. To fill this knowledge gap, this paper aims to propose a novel framework for **qu**ality control in **o**ff-**s**ite construction empowered by a hybrid **R**AG-driven multi-**a**gent system, named QuosRA, that supports dynamic interaction, collaborative analysis, and systematic decision-making of QC-related tasks in OSC. The feasibility and efficiency of QuosRA are also demonstrated by comparing with the single-agent hybrid RAG and native MAS baselines.

2 Literature Review

2.1 Quality Control in Off-site Construction

Quality issues have been identified as one of the most critical factors affecting the implementation and development of OSC. Yin et al. [11] emphasized that OSC projects require increased emphasis on quality control measures to address prevalent quality issues. However, QC in OSC projects predominantly relies on traditional construction management guidelines, with relatively slow progress in knowledge and technological advancements [3].

Studies have explored the applications of advanced informatics technologies for quality management in OSC projects, such as building information modeling [12] and ontology [13]. However, current approaches still face limitations that result in fragmented and labor-intensive workflows, impeding effective domain knowledge capture, retrieval, and reuse. In particular, research rarely provides a systematic workflow for QC in OSC to support efficient decision-making, cross-stakeholder collaboration, and consistent quality assurance.

2.2 LLM-based Multi-agent Applications

LLMs demonstrate great potential for knowledge-intensive tasks without labor-intensive and time-consuming efforts in knowledge representation, which have been increasingly applied in construction, such as construction compliance checking and automated reporting [14]. RAG has been used to further strengthen LLM performance by mitigating hallucinations in domain-specific tasks. In the construction domain, RAG contributes to complex information retrieval and question answering in domain document parsing and regulation inquiry tasks. He et al. [7] designed an improved RAG framework for regulation information extraction in construction quality checks. Wan et al. [15] explored a hybrid RAG strategy by incorporating knowledge graph metadata into vector retrieval, supporting design for additive manufacturing tasks.

However, these RAG methods remain reactive and primarily respond to the given query, offering limited capability for complex task breakdown and multi-step task handling. Recent attention has concentrated on LLM-based MAS, since it allows agents with different roles to integrate diverse inputs, initiate internal reasoning, and coordinate planned, goal-oriented actions rather than passively reacting to user queries [16]. Each agent in the multi-agent system has been assigned a specific responsibility and specializes in a particular task. This highlights a transition from RAG-based reactive retrieval to MAS-enabled proactive orchestration, offering a more autonomous and proactive paradigm for complex and dynamic construction scenarios.

Currently, LLM-based multi-agent systems have gained increasing attention in construction, mainly on automated building design [17], building energy analysis [18], and human-machine collaboration [19]. However, few studies have explored how to employ RAG-driven reliable retrieval and deeper reasoning to enhance LLM-based MAS in handling domain-specific and knowledge-intensive tasks, such as QC in OSC projects. Meanwhile, there is still a lack of a well-designed agentic workflow for QC in OSC that enables multiple stakeholders to achieve more accurate knowledge retrieval, trustworthy compliance checking, coherent guidance generation, and coordinated decision-making.

3 Methodology

This study proposes a novel LLM-based multi-agent system for QC in OSC, named QuosRA, that integrates hybrid RAG with a centralized orchestrator architecture, as shown in Figure 1. Within QuosRA, QC-related tasks are explicitly broken down into specialized subtasks, such as query analysis, knowledge retrieval, and output evaluation, with responsibilities assigned to dedicated agents driven by LLMs tailored to distinct subtasks.

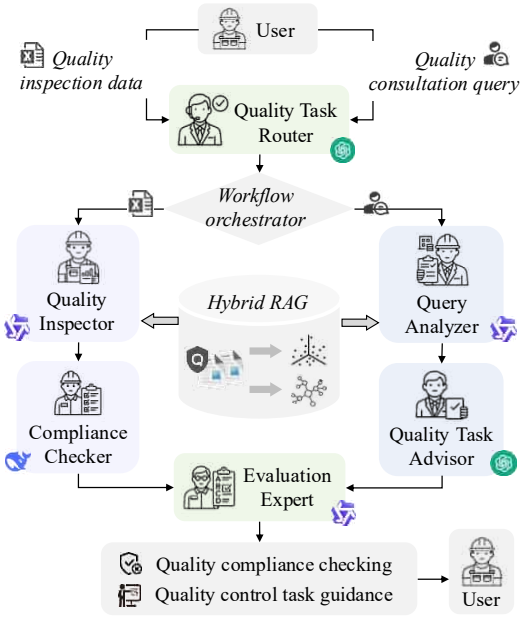

Figure 1. Conceptual framework of QuosRA

QuosRA is organized around a central workflow orchestrator that governs the overall interaction workflow. When a user query is input, Quality Task Router determines and dispatches it to the corresponding processing workflow. Quality inspection data recorded in Excel files are directed to the left-side workflow, where Quality Inspector processes data and searches requirements for Compliance Checker to check compliance. Task guidance queries are routed to the right-side workflow, where Query Analyzer parses user intent and retrieves interpretations for the downstream Quality Task Advisor to generate context-aware guidance. Quality Inspector and Query Analyzer are supported by a shared domain-specific knowledge base empowered by a hybrid RAG [20]. Evaluation Expert further reviews the synthesized results for both workflows to provide coherent and reliable QC assistants.

This centralized-orchestrated architecture of QuosRA adopts the hybridization of hierarchical and decentralized mechanisms, which has been identified as a promising approach for achieving scalability and robustness in MAS [21]. The central orchestrator ensures stable workflow sequencing, whereas the domain-specific agents perform specialized subtasks with local autonomy. It enables a balance between centralized oversight and decentralized adaptability for complex QC-related tasks.

3.1 Hybrid RAG for Knowledge Retrieval and Reasoning

Domain-specific knowledge of QC tasks in QuosRA is provided by the hybrid RAG [20], which integrates vector-based search for semantic matching with graph-based retrieval for explicit relational reasoning, aiming to enhance retrieval accuracy, trustworthiness, and reliability. The hybrid RAG pipeline is illustrated in Figure 2 and briefly elaborated below. More details can be found in previous work [20].

Quality-related documents are preprocessed and segmented into text chunks. Entities and relationships are extracted from text chunks and stored as node and edge chunks. Based on this representation, subgraphs are constructed and subsequently merged into a unified knowledge graph. Simultaneously, both node and edge chunks are encoded into vector embeddings to capture semantic features. The knowledge graph is further consolidated by assigning importance weights to nodes and edges, where edge weights are determined using frequency-based scores ($Weight_{edge}$) and node weights are computed using PageRank scores (PR_{node}).

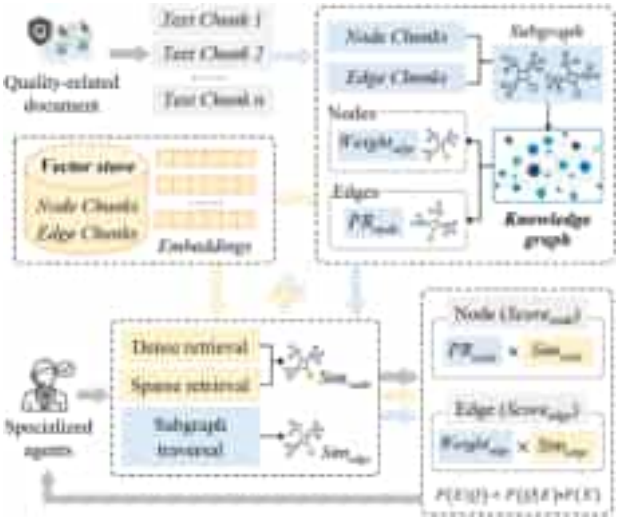

Figure 2. Procedural pipeline of the hybrid RAG

Following the role constraints encoded in the system message, Quality Inspector and Query Analyzer perform external knowledge retrieval and subsequent reasoning by invoking the hybrid RAG. The retrieval process integrates dense and sparse retrieval, as well as subgraph traversal. Specifically, dense and sparse retrieval are employed to support embedding-level and keyword-level search for entity matching. Dense retrieval measures semantic similarity using cosine similarity ($Socre_D$), while sparse retrieval adopts a Robertson-Sparck Jones Inverse Document Frequency (RSJ-IDF)-based weighting scheme without term frequency, with named entity recognition (NER) and part-of-speech (POS) tagging information to prioritize related entities ($Socre_S$). The similarity score of nodes is integrated based on the relative score fusion (RSF) (see Equation 1). In addition, subgraph traversal is employed to enable multi-hop reasoning over the knowledge graph (see Equation 2), where h denotes the hop distance.

$$Sim_{node} = 0.7Score_D \times 0.3Score_S \quad (1)$$

$$Sim_{edge} = \frac{Sim_{node}}{h+2} \quad (2)$$

To align semantic similarity with graph structural importance, a fusion scoring strategy is designed inspired by Bayes' theorem (see Equations 3-4). Driven by hybrid RAG, agents retrieve and prioritize QC domain knowledge under task-specific contexts to support the execution of their assigned tasks.

$$Score_{node} = Sim_{node} \times PR_{node} \quad (3)$$

$$Score_{edge} = Sim_{edge} \times Weight_{edge} \quad (4)$$

3.2 Agent Responsibilities Analysis

QuosRA is a distributed intelligence mechanism where specialized agents handle distinct QC subtasks in OSC, coordinated through a central router. QuosRA consists of six key agents, each with one particular role, expertise, and specialized abilities:

- ***Quality Task Router*** serves as the initial interface with users and processes both Excel and textual inputs. This agent analyzes queries, classifies them into compliance checking or guidance tasks, and routes them to the appropriate workflow handled by specialized agents.
- ***Quality Inspector*** processes structured quality inspection data recorded in Excel files and extracts inspection items. This agent is allowed to retrieve the corresponding quality requirements associated with each inspection item through the hybrid RAG. The responsibility is limited to focusing on mapping inspection items to relevant regulatory requirements.
- ***Compliance Checker*** performs quality compliance determinations based on processed inspection data and quality requirements provided by the upstream Quality Inspector. To reduce the spread of potential uncertainties, this agent only conducts compliance checking reasoning without extra retrieval behaviors.
- ***Query Analyzer*** rewrites user queries of task guidance and extracts domain-specific entities as keywords for retrieval. Based on query analyses, the agent invokes the hybrid RAG to retrieve supporting quality knowledge for query intent interpretation, which is passed downstream to guidance generation.
- ***Quality Task Advisor*** receives retrieved knowledge from Quality Analyzer to further generate coherent task guidance, which can include the clarification of quality issues, preliminary cause analysis, and recommended remediation measures, synthesized with explicit consideration of applicable standards, engineering practices, and project-specific contexts.
- ***Evaluation Expert*** consolidates and reviews the outputs produced by Quality Task Advisor and compliance checker agent to ensure accuracy and consistency of the response. Based on the final verification, this agent sends validated compliance results and QC task guidance to the user.

Through coordinated interactions among specialized agents, QuosRA adopts clear responsibility divisions and constrained interactions, which help mitigate the spread of potential uncertainties across subtasks, enabling more reliable and consistent QC in OSC.

3.3 Model Selection

In this study, agents within QuosRA are powered by three open-source medium-sized LLMs, selected based on their complementary strengths. Each model is chosen to align with subtask requirements of specialized agents, such as knowledge retrieval, reasoning, or structure output generation. Table 1 summarizes the mapping between selected open-source LLMs and agents, highlighting capability alignment.

Table 1 Model selection for agents in QuosRA

Open-source LLM	Agent	Capability	References
GPT-OSS-20b	Quality Task Router Quality Task Advisor	Task abstraction capability; Instruction-following robustness High-quality synthesis; Logically long-form coherence; Well-structured expression	[20, 22]
Qwen3-14b	Quality Inspector Quality Analyzer Evaluation Expert	Information retrieval stability Conservative yet rigorous style; Low hallucination tendency	[20, 23]
Deepseekr1-14b	Compliance Checker	Strong logical reasoning capability	[20, 24]

GPT-OSS-20B is chosen to drive Quality Task Router and Quality Task Advisor. Previous studies have shown that GPT-OSS exhibits strong logical coherence, concise expression, and clear structural organization in output generation [20, 22], which is suitable for task orchestration and guidance synthesis grounded in reliably retrieved evidence. Qwen3-14B powers Quality Inspector, Quality Analyzer, and Evaluation Expert, leveraging its reliable and stable knowledge retrieval capabilities. Qwen3-14B has been proven to show a

cautious yet rigorous and robust style in knowledge retrieval and reasoning performance [20], making it particularly effective for retrieval-oriented tasks [23]. Moreover, the low hallucination tendency and balanced performance of this model ensure reliability and consistency, which are critical for comprehensive evaluation tasks. Compliance Checker is powered by DeepSeek-R1-14B, chosen for its robust logical reasoning capability [24]. Although DeepSeek-R1 excels in structured reasoning tasks, it exhibits a higher risk of hallucination compared to more conservative models [20]. To reduce the risk of uncertainty spread and improve overall trustworthiness, Compliance Checker is strictly restricted from any knowledge retrieval behaviors, relying exclusively on inspection data and pre-retrieved requirements provided by Quality Inspector.

4 Experiments

The proposed QuosRA is validated considering quality compliance checking and quality control task guidance. QuosRA builds upon the capabilities of the hybrid RAG that have been shown in prior work to provide reliable retrieval and reasoning performance [20]. Accordingly, the validation focuses on assessing the efficiency of the structured workflow design, as well as the feasibility of explicit responsibility division and constrained agent interactions in QC of OSC, rather than pursuing further improvements in domain knowledge retrieval or reasoning performance.

4.1 Experimental Design

The evaluation is conducted based on an OSC quality reference integrating both regulatory documents and practical field knowledge, including twelve regulations and standards issued by mainland China, Hong Kong SAR, and Macao SAR, and five industry guidelines and confidential project documents from industry practitioners to capture procedural knowledge and field practices in precast concrete production.

Baseline configurations are designed to isolate the impact of structured subtask coordination in QuosRA. Specifically, two baselines are applied to validate the overall performance of QuosRA. The first is a single-agent hybrid RAG powered by Qwen3-14B, which reactively responds to the given query for all QC tasks without agent decomposition. The second baseline is a native MAS with an unstructured workflow, in which both the hybrid RAG and all agents are powered by Qwen3-14B. The agent roles set in this baseline are identical to those defined in QuosRA. However, role-specific responsibilities are not enforced through explicit task decomposition or coordination mechanisms. All agents are allowed to directly access the hybrid RAG and independently process the complete QC-related task in parallel, without interaction constraints or subtask assignments. This baseline is designed to examine the impact of structured subtask decomposition and constrained coordination in QuosRA under equivalent agent and retrieval configurations. Furthermore, the LLM configurations of specialized agents in QuosRA are illustrated in Table 1, where the hybrid RAG setting is identical to baseline methods. This experimental design ensures consistent retrieval behavior across all settings, enabling a focused examination of the impact of role specialization and structured coordination.

4.2 Evaluation Task and Metrics

To fully capture real-world tasks faced by quality inspectors and decision makers in OSC projects, two types of QC-related tasks are designed.

Quality compliance checking involves determining compliance with regulatory requirements. For instance, a measured deviation of 7 mm indicates that the longitudinal reinforcement spacing in precast concrete column satisfies the ±10 mm allowable limit defined in clause 4.3.8 of DBJT 15 171-2019 and is therefore determined as compliant. The outputs are required to both extract relevant normative clauses and reasonably judge correctly. This evaluates the accuracy of compliance determinations and the relevance of the supporting references to the ground-truth, which were manually annotated to include specific normative clauses and guideline provisions. An Excel file recording 30 inspection items was provided as input, covering inspection objects, inspection points, measured data, inspectors, and inspection time. For each inspection item, QuosRA and tested baselines are asked to provide the corresponding regulatory requirements and explicit compliance determination. Two metrics are adopted to reflect the reliability of supporting evidence and the correctness of compliance judgment. ***Retrieval precision (RP)*** measures the proportion of given references that are actually correct and relevant among N inspection items, which is defined in Equation (5).

$$Retrieval\ precision = \frac{1}{N}\sum_{i=1}^{N}\frac{|S_i \cap R_i|}{S_i} \tag{5}$$

where S_i denotes the set of references retrieved by the tested method for inspection item i, and R_i refers to the ground-truth set. ***Determination accuracy (DA)*** measures the proportion of inspection items for which the correct compliance determination is given.

Quality control task guidance, which represents complex queries requiring procedural or planning advice, such as "*what is the definition of cellular defects, and how to deal with them*?" Such task involves analyzing query intention and rewriting the retrieved knowledge according to the indications made by the user query. This task emphasizes professional relevance, response

coherence, and content completeness. A total of 10 representative QC task guidance queries are designed based on common quality concerns in OSC projects [20], such as defect clarification, regulatory interpretation, and measure suggestions. Two metrics are used. ***Retrieval precision (RP)*** is adopted as the same metric used in quality compliance checking to explore the reliability of supporting references. ***High-quality response score (HQS)*** evaluates the overall quality of the generated guidance, emphasizing how effectively retrieved knowledge is synthesized into actionable and coherent guidance. Specifically, this metric jointly assesses the response coherence and content completeness of outputs based on five criteria: (1) whether the quality issue is explicitly identified; (2) whether at least one relevant regulatory clause is clearly referenced; (3) whether clear and actionable measures are provided; (4) whether the guidance is logically consistent without obvious contradictions; and (5) whether the response sufficiently addresses the key aspects of the query without major omissions. A response is considered high-quality if it satisfies at least four criteria. Over a set of R responses, HQS is computed as:

$$HQS = \frac{1}{R}\sum_{r=1}^{R} 1\left(\sum_{j=1}^{5} c_{r,j} \geq 4\right) \quad c_{r,j}\epsilon\{0,1\} \qquad (6)$$

where r indexes the responses and $c_{r,j}$ indicates whether the j-th criterion is satisfied for response r (1 if satisfied, 0 otherwise).

5 Results and Analyses

For quality compliance checking, Table 2 illustrates the results of the retrieval precision and determination accuracy across three tested methods. Experimental results demonstrate that QuosRA exhibits a modest yet systematic improvement over two baseline methods, underscoring the effectiveness of its role-specialized architecture and constrained agent interactions. Specifically, compared with the hybrid RAG baseline (RP 80.6%, DA 90.0%), QuosRA achieves a moderate increase in RP (82.4%) and a more noticeable improvement in DA (93.3%). The limited enhancement in RP suggests that the primary contributions of QuosRA are not centered on greatly improving retrieval precision, but on stabilizing the downstream determination process once relevant regulatory knowledge has been retrieved. This observation aligns with the design intent of QuosRA and highlights its ability to promote greater stability and reliability in decision-making, particularly in quality compliance scenarios that require precise interpretation and integration of regulatory knowledge. For example, when retrieving the allowable deviation of the centerline position of reserved holes in concrete prefabricated slabs, Quality Inspector passes validated outputs (no more than 5 mm) to Compliance Checker, which performs consistent and reliable determinations under the structured workflow. The explicit separation between retrieval and compliance checking stages facilitates a direct and dependable translation of accurate retrieval results into compliance decisions, highlighting the scaling principle that coordination architecture can stabilize model capabilities in complex logical tasks [25]. In addition, the comparatively lower performance of the native MAS (RP 76.32%, DA 86.67%) provides empirical evidence of the negative returns from unstructured coordination [25], which indicates that multi-agent interaction without explicit role separation and coordination constraints often introduces logical interference and inconsistent interpretation of retrieved references, thereby undermining overall compliance accuracy. In contrast, QuosRA exhibits a closer alignment between RP and DA, mitigating the influence of irrelevant or conflicting references and supporting more consistent determinations of retrieved requirements.

Table 2 Experimental results of compliance checking

Method	Description	RP	DA
Hybrid RAG	Single-agent hybrid RAG	80.6%	90.0%
Native MAS	Multi-agent hybrid RAG without role separation	76.3%	86.7%
QuosRA	Role-specialized Multi-agent hybrid RAG	82.4%	93.3%

For quality control task guidance, responses produced by QuosRA show stronger reliability and higher quality than the other two baselines. The results are illustrated in Table 3. For RP, QuosRA attains the highest score (92.9%), outperforming both the hybrid RAG (88.2%) and the native MAS (83.3%). This improvement indicates that the role-specialized workflow in QuosRA contributes to more accurate alignment between query intent and retrieved regulatory references. By comparison, the native MAS shows a modest degradation in RP compared to the hybrid RAG, suggesting that solely introducing multiple agents without structured workflow design and explicit role constraints may lead to coordination noise and overlapping knowledge retrieval. Regarding HQS, both the hybrid RAG and the native MAS achieve the same HQS of 60.0%. This indicates that without structured design in agentic workflows, baseline methods may struggle with fragmented and incoherent guidance outputs. QuosRA improves the HQS to 80.0%, reflecting a higher proportion of responses that provide clear problem identification, explicit regulatory grounding, actionable measures, and logically consistent guidance. Besides, a cross-metric comparison further reveals that although the hybrid RAG achieves relatively strong retrieval precision, its overall quality of generated guidance remains limited, highlighting a clear gap

between accurate retrieval and effective task-level synthesis. This observation further corroborates our previous findings in [20], which showed that Qwen3-14b exhibit more reliable and conservative retrieval behavior, yet tend to underperform in generating well-structured and coherent task guidance. By decoupling knowledge retrieval and guidance generation and assigning specialized agents powered by different LLMs, QuosRA demonstrates that a well-architected MAS can transform raw model capacity into superior task-oriented performance through strategic labor division [25]

Table 3 Experimental results of QC task guidance

Method	Description	RP	HQS
Hybrid RAG	Single-agent hybrid RAG	88.2%	60.0%
Native MAS	Multi-agent hybrid RAG without role separation	83.3%	60.0%
QuosRA	Role-specialized Multi-agent hybrid RAG	92.9%	80.0%

Regarding time efficiency, experimental results under both standalone (all-on-server) and distributed (laptop-server coordination) deployment modes indicate that QuosRA introduces a 2.7- to 3.2-fold increase in latency compared with the hybrid RAG baseline. Compared with the native MAS baseline, QuosRA achieves a 41%-49% reduction in execution time through explicit role separation and structured task decomposition. Considering that QC in OSC does not usually require strict real-time responses, the increased latency could be an acceptable trade-off for the improved reasoning reliability and structured decision support.

6 Discussion

This study proposes a centralized-orchestrated architecture multi-agent system tailored for QC in OSC. The evaluation results across QC-related tasks, involving quality compliance checking and quality control task guidance, demonstrate the effectiveness of QuosRA in supporting complex QC scenarios in OSC. Specifically, the clear responsibility divisions and constrained interactions in QuosRA mitigate interference and inconsistency in unconstrained multi-agent systems, leading to more accurate compliance checking and coherent, actionable QC guidance outputs. This design echoes the necessity of structured knowledge sharing among stakeholders in OSC [26] and offers a strategic solution to the pervasive challenges of labor shortages and expert scarcity. By mimicking a professional labor division where expert-level agents supervise technique-specific agents, QuosRA also provides a resilient management template for hierarchical workforce division, expert-level oversight, and task decomposition for QC in OSC. The cross-metric analysis further suggests that baseline methods are often limited in simultaneously achieving retrieval rigor, reasoning reliability, and generating structured responses. This finding further verifies that the lack of communication and cooperation may struggles in vital information sharing, leading to inefficiencies, conflicts, and knowledge misuse [21]. QuosRA exhibits promising potential to facilitate the transformation of retrieved knowledge into decision-relevant outputs, which demonstrates the strength of LLM-based multi-agent applications in cross-coordination and evaluation for more accurate, reliable, and robust solutions [17].

Practically, QuosRA enables non-experts to conduct QC-related tasks through natural language interactions without requiring expertise in regulatory coding or rule formalization, allowing QC to be implemented in an automated and consistent manner. Natural language can be used to obtain domain knowledge, check compliance, and access expert-level guidance in OSC. Although these interactions can also be implemented through RAG pipelines [6, 15, 20], such approaches remain reactive and limited in capability for proactive task breakdown and subtask coordination. In this regard, this paper also contributes to a scalable paradigm to expand the application of RAG and LLM-based MAS into QC coordination in OSC, and can be generalized to other complex engineering scenarios.

7 Conclusions

This study proposes QuosRA, a novel framework for QC in OSC driven by a hybrid RAG-driven multi-agent system, and validates its feasibility and efficiency through quality compliance checking and quality control task guidance. Evaluation results demonstrate that QuosRA improves the reliability and logical consistency of outputs for relevant queries. This research contributes an agentic workflow that explicitly decomposes QC-related tasks into coordinated subtasks, supported by a centralized orchestration mechanism. QuosRA provides an effective solution to address the challenges in QC of OSC projects, containing fragmented knowledge utilization, high manual effort, and limited decision support. Overall, this study establishes a solid foundation for applying LLM-based MAS for knowledge-driven management tasks in construction. Future work will extend QuosRA toward a multimodal assistant by integrating vision-language models for QC scene-aware perception. Furthermore, comprehensive ablation studies and resource efficiency analysis will be conducted to evaluate the contributions of different agent roles and further optimize system performance across diverse deployment settings.

Abstract -

Highway project information delivery using building information modelling (BIM) often suffers from inefficiencies when converting 3D Industry Foundation Classes (IFC) models into network representations that conform to agency-specific asset data standards. These inefficiencies primarily arise from inconsistent object classification and mismatches in modelling granularity. To address this challenge, this paper proposes a novel method to automatically classify multi-granularity IFC BIM models and decompose coarse elements into finer components that satisfy asset information exchange requirements. A context-aware mesh neural network (CA-MNN) is developed to incorporate contextual geometric information, enabling more accurate prediction of face-level mesh semantics for IFC elements. Triangulated faces are then grouped based on connectivity, and predictions are smoothed using a majority voting strategy, enabling the decomposition of coarse elements into finer-grained asset models. The proposed method is evaluated using 6,058 IFC elements from real-world highway BIM models in the UK. The results demonstrate that the CA-MNN with smoothing achieves the highest classification accuracy of 86.38%. This study contributes a new BIM object classification and decomposition approach that supports the identification and segmentation of coarse IFC elements for infrastructure project delivery.

Building information modelling (BIM); project information delivery; highway infrastructure management; geometric deep learning

1 Introduction

Highway infrastructure systems comprise roads, bridges, tunnels, traffic signs, drainage, utilities, lighting, and road restraint systems [1]. Effective information delivery is essential for highway construction and reconstruction projects, as reliable asset data strongly influence decisions in subsequent operation and maintenance (O&M) phases. Building information modelling (BIM) technology [2] is widely adopted for information exchange and project data delivery in construction projects. BIM provides semantically rich 3D models representing the geometry and functionality of buildings and civil infrastructure, which can be exchanged across stakeholders and software systems using vendor-neutral Industry Foundation Classes (IFC) specifications [3]. In recent years, BIM-based information delivery has been adopted for infrastructure projects in several countries. For example, Norway has implemented nationwide road project delivery using a common data environment (CDE) platform (Trimble Quadri), where heterogeneous virtual models are uploaded and transformed into IFC-compliant software data models [4]. BIM-based delivery provides more accurate and structured as-built data for operation and maintenance (O&M). Furthermore, when combined with sensing technologies, artificial intelligence, and robotics, infrastructure-BIM (I-BIM) models can evolve into digital twins [5], enabling dynamic asset monitoring and intelligent maintenance decision-making.

Despite this potential, several challenges hinder BIM-based information delivery in highway infrastructure projects. First, there is a mismatch between IFC BIM standards and the asset data standards used by different road agencies [6]. These local asset standards are typically developed around existing asset databases and legacy systems; without clear mappings between data models, contractors have limited incentive to produce well-classified IFC models. Second, the coverage and usability of IFC standards remain limited in the infrastructure domain. For example, a Federal Highway Administration (FHWA) report highlights that road-related IFC entities, such as earthworks, drainage, and ancillary facilities, require further extension to support BIM-based infrastructure management [7]. Third, although recent IFC versions (e.g., IFC 4.3 [3]) introduce broader civil infrastructure concepts, few BIM authoring tools support seamless exchange based on the latest standards; for instance, the highest officially supported IFC export option in Autodesk Revit 2026 remains IFC4 [8]. Consequently, IFC models for highway project delivery are often misclassified or exported using generic types such as *IfcBuildingElementProxy* [9]. In addition, granularity mismatches are common: a single BIM object (e.g., a "deck") may need to be decomposed into multi-

ple asset components (e.g., slabs, pavement, girders) to support downstream asset management, whereas multiple fine-grained objects (e.g., railings) may need to be aggregated into a single asset such as a "pedestrian restraint system."

Previous studies have proposed various technical solutions for automatic BIM object classification using geometric features [10, 9], materials [11], attributes [12], and topological relationships [13, 14]. These approaches generally assume that BIM object instances are already modelled at an appropriate level of granularity and therefore focus on reclassifying objects to assign correct IFC types. However, real-world I-BIM models often exhibit not only typing errors but also inappropriate granularity, where object instances must be either aggregated or decomposed to meet the requirements of hierarchical asset data standards. This shifts BIM object classification from the object level to the part level, requiring finer-grained semantic understanding of 3D models.

To address these challenges, this study proposes an automated method for multi-granularity infrastructure-BIM (I-BIM) object classification and decomposition. The method performs per-face classification of BIM object meshes and decomposes coarse object instances into multiple parts that can be mapped to asset components defined by asset data standards. A context-aware mesh neural network (CA-MNN), built on the MeshNet backbone [15], is developed to incorporate geometric context by selecting K-nearest neighbouring objects and learning both object-level and context-level features to predict semantic labels for each triangulated face. A smoothing and clustering algorithm is then applied to both improve classification and automatically split coarse objects into meaningful parts when multiple asset types are present. The method is evaluated using three types of real-world IFC models, i.e., bridge, culvert, and road, aligned with asset classes defined in the UK Asset Data Management Manual (ADMM) [16]. ADMM provides a tree-structure asset class hierarchy, covering 10 parent asset types (e.g., ancillary, drainage, lighting, pavement), subtypes, and asset components. The best performing model achieves a per-face accuracy of 86.38% on a dataset of 6058 object instances with varying levels of granularity.

The remainder of the paper is structured as follows. Section 2 reviews related work. Section 3 describes the proposed method. Section 4 presents the evaluation results. Section 5 concludes the paper.

2 Literature review

Existing approaches for automatic BIM object classification can be broadly categorized into rule-based methods, machine learning-based methods, and hybrid methods.

Early studies primarily relied on manually defined domain-specific rules. Belsky et al. [17] developed a semantic enrichment engine for BIM (SeeBIM) that enables the composition of inference rule sets based on properties, geometry, topology, and functional relationships. Sacks et al. [13] further extended the SeeBIM engine with additional operators to classify BIM models of highway bridges. Ma et al. [14] developed matching algorithms for object identification by incorporating domain knowledge of shape features (e.g., orientation, volume) and pairwise relationships. Wu and Zhang [10] proposed an algorithm for classifying structural objects using inherent geometric features, such as the number of subcomponents, number of faces, and cross-sectional profiles.

Rule-based methods tend to be rigid and difficult to scale across diverse object types and features. Consequently, machine learning- and deep learning-based approaches have been increasingly explored. Wu et al. [18] proposed invariant signatures based on geometric and material features to describe IFC entities and evaluated classification performance using five machine learning models (e.g., random forest). Kim et al. [19] proposed an approach for automatically classifying building object instances in BIM models using a 2D convolutional neural network (CNN). Koo et al. [9] applied two geometric deep learning models, i.e., multi-view CNN and PointNet [20], to classify I-BIM objects such as culverts, retaining walls, and wing walls, and further extended this work to classify subtypes of BIM elements for walls and doors. Collins et al. [21] developed a graph convolutional network-based approach that operates on native triangle meshes and automatically generated local features for BIM object classification. Emunds et al. [22] proposed SpaRSE-BIM, a neural network based on sparse convolutions for classifying IFC-based geometry. Wang et al. [23] applied graph neural networks for room type classification and semantic enrichment of BIM models. More recently, Teclaw et al. [24] proposed Context-NET, which integrates contextual information from surrounding components by incorporating spatial relationships to improve object classification performance.

Recent studies have also explored hybrid approaches that integrate multiple types of features to improve classification accuracy. Utkucu et al. [25] applied an ensemble framework using a stacking strategy that combines four BIM classification tools: keyword search, rule-based inference, machine learning based on geometric features, and deep learning based on visual shape features. Luo et al. [26] introduced a two-branch geometric–relational deep learning framework that fuses geometric and relational features for IFC element classification. Yang et al. [27] proposed IFCGeoNet, which integrates explicit shape features and implicit representation features through graph learning. Similarly, Han et al. [28] and Wang and Ying

[29] developed generic graph neural network-based frameworks that embed semantic, spatial, and topological features of BIM models, where BIM element classification is treated as one of the downstream tasks.

In summary, existing context-aware methods (e.g., Context-NET) perform object-wise classification, where each IFC element in a BIM model is treated as an independent instance. However, they do not address granularity mismatch issues commonly observed in BIM-enabled infrastructure project delivery, where coarse IFC elements should be decomposed and overly fine-grained elements should be aggregated. Addressing this challenge requires hierarchy-aware classification and part-level semantic segmentation of infrastructure-BIM (I-BIM) objects.

3 Proposed solution

3.1 Overview

In this study, we propose a CA-MNN-based approach to automatically classify I-BIM object instances while enabling the decomposition of coarse elements. Figure 1 presents an overview of the proposed framework. The method begins with preprocessing I-BIM models exported from IFC-authoring software. The geometry is tessellated into triangulated meshes composed of vertices and faces. Quadric edge collapse is then applied to obtain decimated meshes that preserve the core geometry. The decimated mesh of each object instance is stored together with its GUID, which serves as a reference for generating contextual geometry.

For each object instance in an IFC model, the goal of CA-MNN is to predict the class types of all triangulated faces. The class types are derived from asset data standards used by highway agencies. In this study, three types of I-BIM models (i.e., bridge, culvert, and road) are used, covering a total of 30 asset classes defined in ADMM (see Table 2). The predicted face semantics are used to determine (a) the type of the IFC element and (b) whether its modelling granularity is too coarse and therefore requires decomposition. If an IFC element contains faces belonging to different asset classes, it is segmented into multiple parts by clustering faces of the same class.

The CA-MNN pipeline consists of three steps (see Figure 1). First, the K-nearest IFC elements surrounding the target element are retrieved. The decimated meshes of these neighbouring elements are combined as contextual faces until a maximum size is reached to satisfy memory constraints. Using decimated meshes instead of raw meshes allows more contextual elements to be incorporated. Second, a mesh neural network architecture is designed to embed both target geometry and contextual geometry into dense feature descriptors. The contextual feature descriptor is concatenated with the feature vectors of each triangulated face of the target element. A multilayer perceptron (MLP) then outputs class scores for each asset type. Third, connected faces are grouped and overlapping groups are merged. A final class is assigned to each group using majority voting, where the most frequent predicted class within a cluster is selected.

Based on these three steps, IFC object instances are classified and coarse elements are decomposed into parts with appropriate granularity according to asset data standards. The processed IFC models can then be seamlessly exchanged with infrastructure asset management systems (AMS). The following subsection details the architecture of CA-MNN.

3.2 Context-aware mesh neural network

The architecture of CA-MNN is illustrated in Figure 2. The network extends the original MeshNet [15] backbone with (a) a lightweight context branch and (b) a face-wise classifier. The inputs consist of meshes for both the target element and its surrounding context: the target geometry contains F_t faces, while the context mesh provides up to F_c faces. Each face includes a center point, three corner points, one normal vector, and neighbourhood indices.

The target mesh and context mesh are processed independently through the same descriptor modules and mesh convolution pipeline. First, center vectors ($n \times 3$), where n denotes the number of faces, are processed by a spatial descriptor, implemented as a multilayer perceptron (MLP) that embeds spatial features into a 64-dimensional vector. In parallel, corner points and normal vectors are processed by a structural descriptor that captures shape features. In the MeshNet [15] backbone, two types of structural descriptors are used. The first performs face rotation convolution over corner vectors to capture intra-face structural features. The second applies face kernel correlation, which uses normal vectors of each face and its neighbours to encode local geometric affinities.

In both branches, spatial and structural features are passed to two mesh convolution layers to expand the receptive fields of faces by aggregating information from neighbouring faces. The mesh convolution layer includes two parts. The first part combines spatial and structural features and applies a MLP to generate 512-dimensional global features. The second part aggregates the structural features of a face with those of connected faces through vector concatenation.

After two mesh convolution layers, spatial and structural features are concatenated in each branch, respectively. Regarding target branch, we apply an MLP to generate feature vectors for all faces ($F_t \times 1024$). In terms of context branch, we employ an adaptive average pooling layer that collapses the variable-length face dimension to size of 1, meaning that per-face features are transformed into a

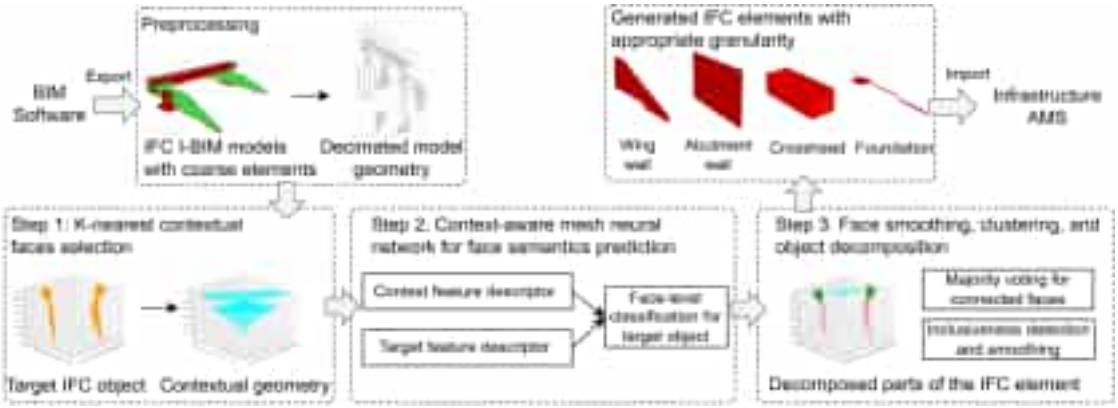

Figure 1. Overview of the proposed CA-MNN-based approach for granularity-aware I-BIM object classification and decomposition.

global feature of context geometry. Further, we use one MLP to generate a 256-dimensional vector, which is concatenated with per-face feature of target geometry (F_t × (1024+256)). Finally, we exploit a 1d convolutional layer to output final scores(F_t ×num_classes) for face-level classification, where num_classes represents the total number of asset class types.

4 Performance evaluation

4.1 Experiment design

We evaluate the proposed method using real-world BIM models from UK highway projects. The dataset includes five bridge models, five culvert models, and five road models, covering 30 asset classes defined in ADMM. All IFC models were imported into Blender for manual annotation. Specifically, ground-truth labels were assigned to each IFC element in the I-BIM models. For coarse IFC elements containing multiple asset units, Blender tools were used to split the geometry and generate finer IFC elements with corresponding ADMM labels. The dataset was further expanded by synthesizing coarse IFC elements through recombination of real elements from the original models. The generation process follows the statistical distribution of element types and group sizes observed in the original dataset, while applying controlled sampling to balance the occurrence of different object classes. Semantic consistency is preserved via asset hierarchy constraints, and duplicate combinations are eliminated based on source element IDs to ensure the uniqueness of all samples.

The final evaluation dataset contains 6,058 IFC elements, including 5,376 coarse elements requiring decomposition. The proportion between synthetic and original samples is 51:1. The class distribution is illustrated in Figure 3. The dataset was split into training and test sets using an 8:2 ratio, resulting in 4,845 training samples and 1,213 test samples.

The CA-MNN model was trained using the training set. The maximum numbers of target faces and context faces were set to 30,000 and 10,000, respectively. The batch size was set to 2, and the model was trained for a fixed number of 100 epochs to ensure sufficient convergence during training. Convergence is evidenced by the stabilisation of the training loss, where the relative decrease in loss is less than 1% over 10 consecutive epochs, occurring around the 90th epoch. The final model obtained after 100 epochs was used for evaluation on the test set.

4.2 Test results

We evaluate the proposed method using face-level classification accuracy. As shown in Table 1, CA-MNN correctly classifies 8,919,146 faces out of 10,325,920, achieving an accuracy of 80.80%. After applying the face smoothing operation, the accuracy increases significantly to 86.38%, demonstrating the effectiveness of smoothing and clustering connected faces to eliminate local misclassifications caused by ambiguous geometric features. However, although connectivity-based smoothing improves overall performance, it may introduce additional errors for tightly connected components such as abutment walls and wing walls.

In comparison, the mesh neural network without the context branch achieves an accuracy of 74.68%, which increases to 80.0% after smoothing. The performance gap indicates that the context branch in CA-MNN effectively incorporates surrounding information for better understanding of IFC geometry semantics and granularity.

Per-class classification performance is reported in Table 2. The macro-average accuracy across classes is 77.65%, indicating that performance is influenced by the imbalanced distribution of face counts across classes, which stems from disparate mesh complexity. Major

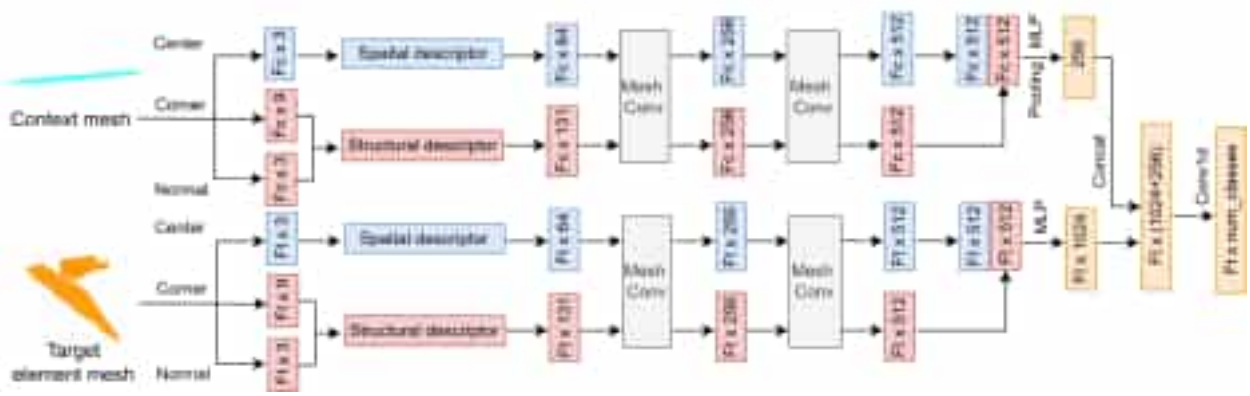

Figure 2. The architecture framework of the context-aware mesh neural network for face-level IFC geometry classification.

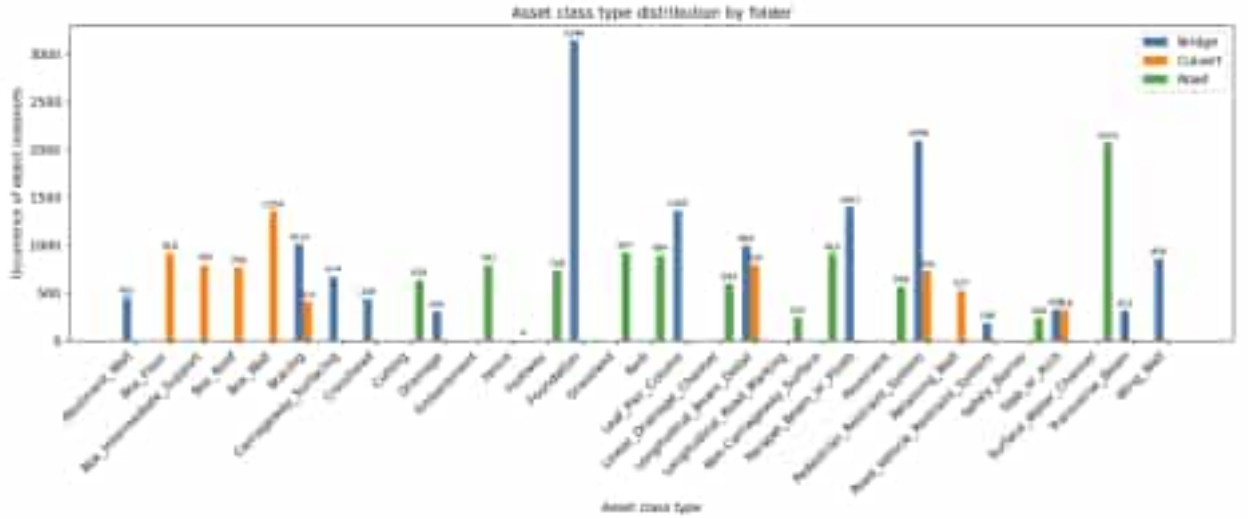

Figure 3. The distribution of different asset class types in the dataset.

classes with more faces generally achieve accuracies above 90%, whereas minority classes perform worse. For example, the accuracy for abutment walls (428 faces) is only 44.9%. Accuracy rates for bridge, culvert, and road models are 82.05%, 89.18%, and 78.84%, respectively, indicating reasonably balanced performance across infrastructure types.

Classification errors arise from several factors. First, CA-MNN struggles with geometrically featureless object types such as carriageways, footways, and safety barriers, which are often represented as simple cuboids. Table 2 shows consistently lower accuracy for these classes, and they are frequently misclassified as one another. For example, safety barriers are most often misclassified as linear drainage systems (16.6%). These errors typically occur across the entire element, indicating that CA-MNN fails to correctly interpret the object as a whole. Incorporating additional features, such as colour for recognising road markings, could be beneficial. However, as noted by Sacks et al. [13], semantic enrichment methods should ideally function under the worst-case scenario where only geometry is available, and the integration of additional features depends on the quality of the input BIM models. Second, the imbalanced distribution of mesh quantities across classes reduces performance on minority classes. Third, the current context extraction strategy may retrieve surrounding objects with large mesh sizes, which can dilute the representation of global contextual information. In addition, K-nearest neighbour retrieval is based on distance to the centroid of the target object, which is suboptimal for objects consisting of spatially separated components, such as groups of bridge foundations.

In terms of part decomposition performance, the mIoU achieves 0.701 across the entire test set and 0.667 for

Table 1. Model performance comparison

Model	Correct faces	Accuracy (%)
CA-MNN + smoothing	8919146	86.38
CA-MNN	8343047	80.80
MNN + smoothing	7692810	79.20
MNN	8178128	74.50

coarse IFC elements that contain multiple classes. In comparison, the overall mIoU drops to 0.603 without smoothing operation.

5 Conclusion

BIM-based highway information delivery faces challenges in aligning IFC models with agency-specific asset data standards, particularly due to granularity mismatches between construction and operation requirements. This often leads to labour-intensive manual processing in BIM or CDE platforms. To address this, this paper proposes a mesh neural network-based method for automatic classification of multi-granular infrastructure-BIM (I-BIM) objects, where coarse elements are identified and decomposed into finer components that better satisfy asset data requirements.

The proposed geometric deep learning (GDL)-based approach begins by tessellating IFC models into triangulated meshes, followed by geometry decimation using quadric edge collapse. The inference process of CA-MNN consists of three steps. First, the K-nearest surrounding objects of a target element are retrieved to form the contextual mesh. Second, the CA-MNN processes both target and contextual meshes through dual network branches to capture spatial and structural features, respectively. The global context feature is then concatenated with per-face features of the target object to perform face-level classification. Third, connectivity-based smoothing and clustering are applied to group faces with the same class labels, enabling both classification of IFC elements and decomposition of coarse elements into finer parts for downstream integration with infrastructure AMS.

The proposed approach is evaluated using 6,058 IFC elements from real-world BIM models, covering 30 asset classes defined in the Asset Data Management Manual (ADMM) used in the UK highway industry. The results show that CA-MNN with smoothing correctly classifies 8919146 faces out of 10325920, achieving an accuracy of 86.38%. Without smoothing, the accuracy decreases to 80.80%. We further evaluate a mesh neural network without the context branch, where accuracy drops to 79.20% with smoothing and 74.50% without smoothing. These results demonstrate the effectiveness of incorporating contextual geometry into GDL models for capturing semantic and topological relationships among infrastructure elements.

The contributions of this study are twofold. First, we propose a novel pipeline for automatic classification of multi-granular I-BIM objects using face-level semantics, which enables coarse IFC elements to be decomposed into parts with suitable granularity. Second, by combining geometry decimation, K-nearest context selection, and a dual-branch CA-MNN architecture, the method effectively learns contextual geometry and improves classification accuracy, as confirmed by the experimental results.

This study also has some limitations. First, CA-MNN struggles to reliably recognise elements with featureless geometry, such as roadways. Second, model training is negatively affected by class imbalance, leading to poorer performance on minority classes. Third, the current context selection strategy may retrieve irrelevant surrounding geometry. Future work will focus on improving context selection strategies and mesh neural network architectures to further enhance performance. In addition, a comprehensive AI-assisted workflow will be developed to support fully automated BIM-based information delivery for highway projects.

Abstract – Flood damage estimation for residential buildings is a critical component of post-disaster recovery planning, budgeting, and construction management. Conventional depth–damage curves, which remain the standard tool in flood risk assessment, rely on deterministic and monotonic assumptions that fail to capture the considerable variability observed in real-world flood losses. As a result, these methods often provide limited support for uncertainty-aware cost estimation and decision-making. This study proposes a probabilistic framework for residential flood damage cost estimation based on Bayesian inference and Markov Chain Monte Carlo simulation. Building damage is modeled as a percentage of replacement value and represented using beta distributions. The framework sequentially updates damage distributions as new post-flood observations become available and propagates uncertainty into cost estimates through Monte Carlo simulation. The proposed approach is demonstrated through case studies in Manville and Cranford, New Jersey, using residential flood damage data from Hurricane Ida. Results show that posterior predictive cost estimates consistently encompass observed damage costs within credible intervals, while traditional depth–damage curve-based estimates exhibit limited agreement with observations. The findings highlight the value of probabilistic, uncertainty-aware modelling through improved representation of cost uncertainty, thereby providing useful insights for residential construction cost estimation and post-disaster recovery management.

Keywords –
Flood damage cost estimation; Probabilistic modelling; Markov Chain Monte Carlo simulation; Uncertainty quantification

1 Introduction

Flooding is among the most impactful natural hazard worldwide, affecting the built environment and residential buildings that underpin community lifelines. As damage to residential buildings directly drives recovery needs and resource demands, accurate damage estimation is essential for construction-related decision-making, including defining repair scopes, allocating contingencies, and evaluating mitigation alternatives such as home elevation or buyout programs [1][2]. In practice, however, even small errors in translating physical flood characteristics into monetary losses can distort cost estimates. Such uncertainty complicates budget approval, delays reconstruction efforts, and weakens the economic justification for long-term residential flood mitigation investments [3].

The most commonly used approach for estimating flood damage to residential buildings is the depth–damage curve (DDC), which relates floodwater depth to an expected percentage of structural or contents loss. In the United States, standardized residential DDCs developed by the U.S. Army Corps of Engineers (USACE) and the Federal Emergency Management Agency (FEMA) are widely applied in housing damage assessments, insurance analyses, and construction cost estimation workflows [4][5]. Their simplicity makes them particularly attractive during early post-disaster stages, when rapid estimates are required and detailed building condition data are limited.

Despite their widespread adoption, existing studies have identified several critical limitations of DDC-based methods when applied to cost estimation. Specifically, standard DDCs are typically derived from aggregated historical data or expert judgment and represent an "average" response for broad residential building categories [6]. This approach doesn't consider the variability in residential construction practices, such as foundation type, framing systems, finish materials, and construction quality [3]. As a result, DDCs are typically used for high-level cost estimation, with limited ability to account for cost variability across individual homes.

Moreover, most conventional DDCs are built on the assumption that flood damage is a monotonic function of water depth, meaning that expected losses increase continuously as water levels rise [6]. However, recent

study reveals that observed flood losses are often not monotonic and instead follow a bimodal distribution where losses are concentrated at the minimal and maximal extremes [6]. As a result, residential flood losses at a given depth exhibit variation, with similar inundation levels leading to different damage levels. From a construction management perspective, such systematic bias can influence residential recovery budget allocation and hinder effective sequencing and resourcing of repair activities, which highlights the importance of uncertainty-aware estimation approaches [7][3][8].

Although multivariate damage models that incorporate additional variables such as flood duration or building condition have been proposed [9][10][11], their extensive data requirements and limited transferability restrict their use in residential contexts. As a result, there is a need for probabilistic damage estimation frameworks tailored to residential buildings that can represent uncertainty while remaining practical for construction-oriented cost estimation. Probabilistic approaches, with particular emphasis on Bayesian inference–based approaches, are capable of addressing these limitations by producing distributions of cost estimates rather than single-point values. By combining prior knowledge of building information with post-flood damage observations, these methods enable uncertainty quantification and reliable cost estimation.

This study proposes a Bayesian framework that integrates residential building attributes with Markov Chain Monte Carlo (MCMC) simulation for building cost estimation following flood impacts. Rather than assuming a monotonic depth–damage relationship, building damage is modelled independently at each inundation depth. For each depth and residential building type (e.g., two-story buildings with basements), the proportion of building damage, bounded between zero and one, is modelled using a beta distribution. MCMC is then employed to update these distributions as new damage observations become available. The resulting damage distributions are subsequently converted into cost distributions by incorporating building replacement values. Through this updating process, cost estimates are continuously refined while uncertainty is explicitly quantified, thereby supporting more robust budgeting, contingency planning, and construction management decision-making in flood-prone residential areas.

2 Literature Review

One of the most widely used approaches for estimating flood damage to residential buildings is the DDC, which relates inundation depth directly to expected economic loss. Although there is no universally accepted framework for assessing flood damage in urban build environments, most existing damage models rely on DDCs because of their conceptual simplicity and ease of implementation [12]. In practice, these curves are frequently used to support cost estimation, post-disaster budgeting, and recovery planning, particularly during early-stage damage assessments when detailed building inspections are not yet available.

DDCs are typically constructed under the assumption that flood damage increases monotonically with water depth. In practice, however, this assumption is frequently violated. Recent analyses of more than two million National Flood Insurance Program (NFIP) claims show that observed losses are often non-monotonic and instead exhibit a bimodal distribution, with damage clustered near both minimal and maximal loss levels [6]. From a construction management perspective, this behaviour complicates repair cost estimation, as similar flood depths can lead to vastly different repair needs, ranging from minor finishes replacement to full system and structural rehabilitation [3]. Studies further indicate that conventional DDCs tend to overestimate damage from shallow flooding while underestimating losses associated with deep inundation. In many cases, their predictive performance is sufficiently limited that a simple mean of observed damages outperforms the curve-based estimates [6]. Another limitation of traditional DDCs is their reliance on a “one-to-one” relationship between depth and damage, where each inundation depth is associated with a single representative damage value, typically expressed as the median or modal loss. Empirical evidence suggests that flood damage at a given depth is highly variable and poorly described by central tendency measures. For example, at one foot of inundation, the middle 50% of observed claims may span from approximately 4% to 30% of building value [6].

The inability to explicitly model uncertainty is widely recognized as a major bottleneck in flood risk assessment, as deterministic approaches typically produce single-point estimates that obscure the inherent variability and stochastic nature of flood damage processes. To address this limitation, numerous studies have developed multivariable flood damage models that extend beyond depth–damage formulations by incorporating additional factors, such as flood duration, the timing and quality of early warnings, building quality, and residents’ socioeconomic characteristics [9][10][11]. A range of statistical techniques has been applied, including random forest models [13], tree-structured models [14], and empirically derived equations [15]. Despite being useful, these approaches require large, high-quality datasets, and limitations in data availability and consistency can introduce bias [16]. Moreover, these multivariable models are often highly site-specific, limiting their transferability across regions.

A growing body of research has shifted toward

probabilistic flood vulnerability modeling to improve the reliability and transparency of flood damage cost estimates [8][3]. Probabilistic frameworks, particularly those grounded in Bayesian inference, allow uncertainty in depth–damage relationships to be explicitly represented and propagated into cost estimates. By combining prior knowledge with limited empirical data, Bayesian methods yield robust, observation-informed cost estimates while explicitly quantifying uncertainty [17][18]. When empirical damage and cost data are scarce, prior information, such as established damage functions or historical repair cost data, can guide early-stage cost estimation and budget planning. As additional building-specific damage observations become available, estimates can be progressively refined to reflect observed cost estimates. Rather than producing single-point damage or cost estimates, Bayesian models generate probability distributions of expected losses, with credible intervals that reflect data availability. For residential building categories with small sample sizes, wider credible intervals reflect increased uncertainty, whereas narrower intervals correspond to greater confidence under improved data availability.

3 Methodology

This study proposes a Bayesian framework that integrates residential building attributes with MCMC simulation for building cost estimation following flood impacts. The detailed steps are illustrated in Figure 1.

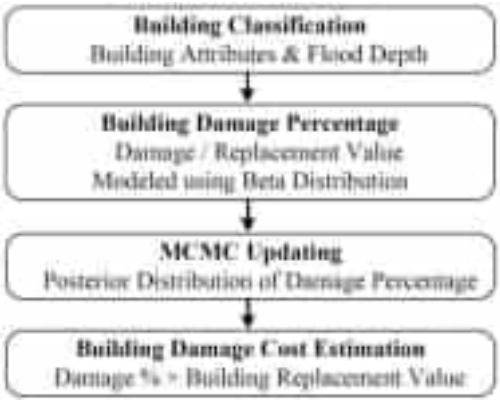

Figure 1. Methodology framework.

First, buildings are classified according to the following attributes: occupancy type, which describes the building use (e.g., single-family residence or two- to four-unit residential building); number of stories (e.g., one-story or two-story structures); basement type (e.g., no basement, finished basement, or crawlspace); and flood depth, defined as the difference between the flood elevation and the building's first-floor elevation.

Next, beta distributions are used to model the distribution of building damage percentage. This percentage is used as the damage metric because depth–damage curves, which remain the standard tool in flood damage assessment, express damage as the percentage of the estimated building damage value to the total building replacement value. Modelling damage in percentage terms provides a normalized representation of loss that is independent of absolute building value and allows direct compatibility with existing depth–damage–based cost estimation workflows. The resulting damage ratios are subsequently converted into monetary losses by incorporating building replacement values.

The beta distribution is selected to model building damage percentage because this metric is defined as a proportion bounded between zero and one. Unlike unbounded distributions, the beta distribution ensures physically meaningful damage ratios and can flexibly represent a wide range of empirical damage patterns, including skewed and highly variable loss behaviour observed in flood events. In addition, the beta distribution is well suited for Bayesian inference and MCMC updating, enabling progressive refinement of damage estimates as new observations become available.

For a given inundation depth and residential building class, observed damage is expressed as a percentage,

$$y_i = \frac{estimated\ building\ damage\ value_i}{building\ replacement\ value_i} \quad (1)$$

where $y_i \in (0,1)$, with 0 indicating no damage and 1 indicating total loss. These observations are modelled using a beta likelihood, which inherently enforces the physical bounds of building damage percentages. The parameters of the beta distribution, $\theta = (\alpha, \beta)$, are updated using Bayes' rule as new building damage percentage observations D_{new} become available:

$$p(\alpha, \beta | D_{old}, D_{new}) \propto p(D_{new}|\alpha, \beta) \times p(\alpha|D_{old}) \times p(\beta|D_{old}) \quad (2)$$

with the likelihood given by:

$$p(D_{new}|\alpha, \beta) = \prod_{i=1}^{n} Beta\,(y_i|\alpha, \beta). \quad (3)$$

The parameters α and β are assigned as independent gamma prior distributions,

$$p(\alpha|D_{old}) = Gamma(\alpha|a_1, b_1), \quad (4)$$
$$p(\beta|D_{old}) = Gamma(\beta|a_2, b_2), \quad (5)$$

which can also be specified as informative or weakly informative depending on data availability. When substantial prior knowledge of residential building damage exists, informative priors can be selected to reflect established damage behaviour. In data-scarce contexts, weakly informative priors (e.g.,

$\mathrm{Gamma}(0.001, 0.001)$) can be used minimize prior influence.

MCMC sampling is used to approximate the posterior distribution of building damage percentage. Each MCMC draw represents a plausible realization of damage percentage for the given depth and building class. These sampled damage percentages are subsequently converted into building damage cost samples by multiplying them by the corresponding building replacement value. This transformation propagates uncertainty from damage percentage directly into cost estimation, resulting in a probabilistic representation of residential flood damage cost estimation.

4 Results

To demonstrate the applicability of the proposed framework, a case study was conducted using residential flood damage data from Hurricane Ida. Two townships in New Jersey—Manville and Cranford—were selected due to their repeated exposure to riverine flooding and their history of residential flood damage. Both communities experienced inundation during Hurricane Ida, resulting in a large number of reported residential losses. The analysis focuses on a representative residential building class: single-family dwellings with two stories and basements, evaluated at an inundation depth of 1 ft above the first-floor elevation. Building damage percentage data for this building class were obtained from the OpenFEMA National Flood Insurance Program (NFIP) dataset [19], which provides publicly available, claim-level flood damage information derived from post-event assessments.

Figures 2 and 3 illustrate three posterior predictive distributions (mean, lower 95%, upper 95%) of building damage percentage for Manville and Cranford, respectively, obtained through Bayesian updating using MCMC simulation. Weakly informative gamma priors were assigned to the beta shape parameters α and β to represent minimal prior knowledge of building damage behaviour. In the figures, the histogram shows the empirical distribution of observed damage percentages. The three curves represent beta distributions corresponding to the posterior mean and the lower and upper 95% credible bounds of the shape parameters, derived from the updated MCMC samples. While only three representative distributions are shown for clarity, they reflect two sources of uncertainty implied by the posterior: variability within each beta distribution, which represents the range of possible damage percentages for a given set of shape parameters, and variability across beta distributions arising from uncertainty in the shape parameters themselves. Together, these distributions capture the range of plausible damage behaviours, including cases with density concentrated near both low and high damage extremes, demonstrating the flexibility of the beta model to represent outcomes from minimal damage to near-total loss.

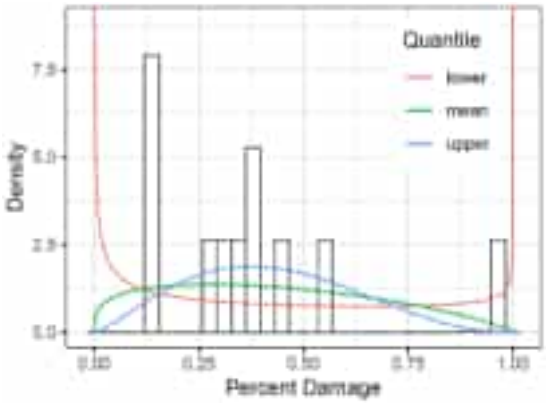

Figure 2. Posterior predictive distributions (mean, lower 95%, upper 95%) of residential building damage percentage for Manville, NJ.

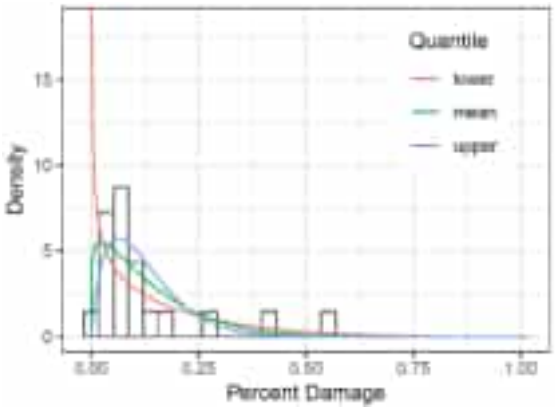

Figure 3. Posterior predictive distributions (mean, lower 95%, upper 95%) of residential building damage percentage for Cranford, NJ.

For practical cost estimation, these damage percentages can be directly translated into monetary losses by multiplying them by the building replacement value. As a result, each beta distribution corresponds to a distribution of potential damage costs rather than a single estimate. This enables probabilistic cost estimation, allowing practitioners to quantify not only expected losses (e.g., using the mean) but also the associated uncertainty (e.g., using credible intervals), which is critical for risk-informed decision-making, budgeting, and resilience planning.

Figure 4 compares estimated residential flood damage costs against observed damage costs for Manville, including results from both the proposed probabilistic approach and traditional depth–damage curves. For the probabilistic approach, the vertical lines

represent the 95% credible intervals of damage cost derived from posterior predictive distributions of building damage percentage, with blue circles indicating the corresponding mean estimates. These cost estimates are obtained by transforming the predicted damage percentages into monetary values using building replacement costs. The diagonal line represents perfect agreement between estimated and observed costs. Intersections between the credible intervals and the diagonal line indicate that the observed damage cost is captured within the uncertainty bounds of the proposed method. The results show that a substantial portion of the observed costs fall within the estimated credible intervals, demonstrating the ability of the probabilistic framework to represent uncertainty and capture observed outcomes.

In contrast, the red triangles represent deterministic cost estimates obtained from traditional depth–damage curves. These point estimates are frequently farther from the diagonal line and, unlike the probabilistic intervals, do not account for uncertainty. Comparing the mean probabilistic estimates (blue circles) with the deterministic estimates (red triangles), the probabilistic approach generally yields estimates closer to the diagonal, indicating improved agreement with observed costs. While a few cases show the deterministic estimates performing comparably or slightly better, this is likely due to limited data informing the posterior in those instances. Overall, the results highlight the advantage of the proposed method in providing uncertainty-aware estimates while maintaining improved accuracy relative to traditional approaches.

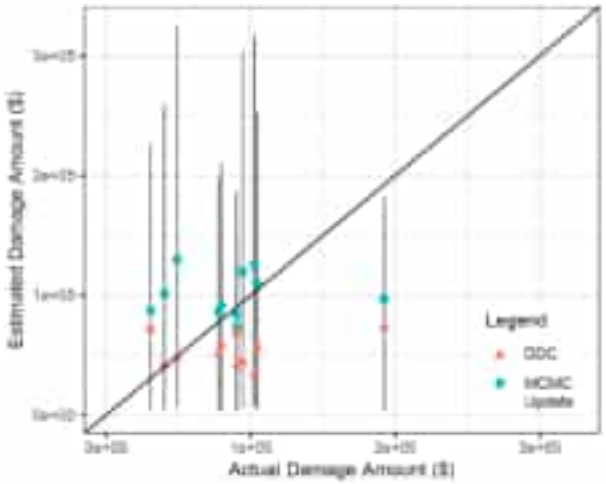

Figure 4. Observed versus estimated residential flood damage costs for Manville, NJ: probabilistic (95% credible intervals) and deterministic comparisons.

Figure 5 compares estimated and observed residential flood damage costs for Cranford, NJ, including both the proposed probabilistic approach and traditional depth–damage curve estimates. Similar to the Manville results, the posterior predictive cost estimates are represented by 95% credible intervals, with mean estimates shown as blue circles. A large proportion of these intervals intersect the diagonal line, indicating that the observed costs are well captured within the uncertainty bounds of the proposed method. In contrast, the deterministic depth–damage curve estimates (shown as red triangles) are more frequently distant from the diagonal.

With a larger dataset available for Cranford, the posterior distributions of the model parameters are better constrained, resulting in more accurate and consistent cost estimates. This is reflected in the mean probabilistic estimates, which are generally closer to the diagonal line than the deterministic estimates. The results demonstrate that, with sufficient data, the proposed probabilistic framework not only captures uncertainty but also provides improved accuracy compared to traditional depth–damage approaches.

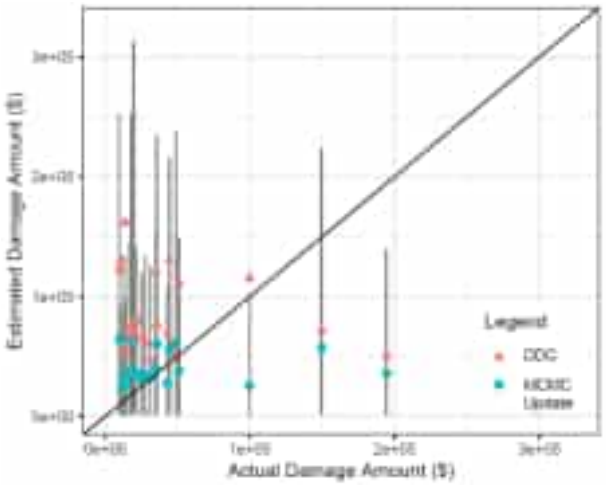

Figure 5. Observed versus estimated residential flood damage costs for Cranford, NJ: probabilistic (95% credible intervals) and deterministic comparisons.

Overall, the Manville and Cranford case studies demonstrate the practical applicability of the proposed Bayesian framework for residential flood damage cost estimation. Across both communities, the probabilistic approach consistently captures observed damage costs within estimated uncertainty ranges, while traditional depth–damage curve–based estimates show more limited agreement with observed outcomes. Additionally, with increased data availability in Cranford, the probabilistic approach provides not only reliable uncertainty quantification but also improved accuracy in mean cost estimates compared to the deterministic method. These results highlight the value of uncertainty-aware modelling for residential flood damage cost estimation.

5 Conclusion

This study presents a probabilistic framework for estimating residential flood damage costs that explicitly accounts for uncertainty in building damage behaviour. By modelling building damage percentage using a Bayesian inference through MCMC simulation, the proposed method moves beyond conventional deterministic depth–damage curves that rely on single-point estimates and monotonic assumptions. Modelling damage independently at each inundation depth allows the framework to represent multiple plausible damage states for the same flood level, better reflecting observed residential flood loss patterns.

The case studies conducted in Manville and Cranford, New Jersey, using post-event data from Hurricane Ida, demonstrate the practical applicability and advantages of the proposed approach. Across both communities, posterior predictive cost estimates consistently encompassed observed residential damage costs within their credible intervals, whereas traditional depth–damage curve–based estimates showed limited agreement with observations. These results highlight the limitations of deterministic damage functions for construction cost assessment and illustrate the value of uncertainty-aware modelling for capturing the variability inherent in residential flood damage.

From a construction management perspective, the proposed framework provides decision-support outputs that are directly applicable to budgeting, contingency planning, and post-disaster recovery management. Rather than producing a single expected cost, the method generates distributions cost estimations, enabling stakeholders to assess financial risk and allocate resources more effectively under uncertainty. The ability to update damage estimates as new data become available further enhances the framework's suitability for post-disaster contexts, where information is often incomplete and evolves over time. While this study focuses on a specific residential building class and flood depth, the framework is flexible and can be extended to additional building types, inundation levels, and geographic regions as data become available. Future research will incorporate additional building attributes to enable more detailed cost estimation. Overall, this research demonstrates that probabilistic, Bayesian-based damage modelling offers a robust and practical alternative to traditional depth–damage curves for residential flood damage cost estimation, thereby informing reliable planning and budget allocation for residential building construction and recovery.

Abstract -

Building permit applications usually consist of multiple heterogeneous, unstructured, and non-machine-readable data. To efficiently check and process applications, relevant information must be extracted, and documents must be classified and linked to the application and process steps in the review. To address this, this study presents an end-to-end method for generating ontology-structured information containers from PDF-based building permit applications by combining Large Language Models with a hybrid Retrieval Augmented Generation (RAG) layer. The proof-of-concept demonstrates that the proposed pipeline can populate OntoBPR entities while producing standard-compliant container structures in accordance with ISO 21597. Remaining challenges relate to scalability, handling of ambiguous regulatory language, and quantitative evaluation of the pipeline. Overall, the study demonstrates the potential of retrieval-augmented LLM pipelines for advancing automation and semantic integration in digital building permit processes.

1 Introduction

Building permit authorities typically receive application submissions as heterogeneous collections of documents: (scanned) PDF application forms, text-based reports, drawings, exports from specialist software, and occasionally models from Building Information Modeling (BIM) serialized in the Industry Foundation Classes (IFC) [1]. Even when these materials are available in digital form, they are usually not structured to support automated reasoning, traceability, or even code-compliance checking [2]. In particular, the formal review is identified as an essential step in building permit review, because missing documents and information delay the permit procedure, as it is depicted in the study of Fauth et al. [3] reporting that 65 % of building applications were delayed because of missing or erroneous application documents. Moreover, previous research has identified the relevant taxonomy for the building permit process [4], which has been incorporated into an ontology representing processes, stakeholders, and documents in the building permit review, denominated as the OntoBPR framework. The OntoBPR framework initially included a set of ontologies as the formal semantic representation of permit-related terms [2]. In recent research, this approach was integrated with the Information Container for linked Document Delivery (ICDD) to model not only the documents but also the interconnections between them [5], and here, in particular, between the documents submitted in an application package. While ICDD containers in the OntoBPR framework are generated manually, the objective of this article is to automatically generate information containers and ontology-based structures from the submitted documents and to classify the submitted documents with metadata to facilitate formal checks of the application's completeness.

Recent advances in Large Language Models (LLMs) and multimodal AI systems enable automatic extraction, structuring, and semantic classification of information from heterogeneous, unstructured documents [6]. These capabilities allow for the generation of metadata and knowledge representations that support automated reasoning, traceability, and completeness checks [7, 8]. The capabilities to generate and summarize text, as well as to adapt to additional given context, also known as few-shot learning, are the significant benefits of LLMs that are identified in the review of Ploennings et al. [9], who analyzed the potentials, challenges, and research directions for applying LLMs and Large Vision Models (LVM) in the Architecture, Engineering, and Construction (AEC) domain. Moreover, document generation and compliance checks were identified as one of the main use cases for Large Language Models (LLMs) in the construction domain in a literature review by Kampelopoulos et al. [10]. Wu et al. [11] argue that LLMs are trained on general knowledge rather than AEC-specific knowledge. While

training an LLM on AEC knowledge is an option, it is impractical due to the enormous costs and training time [11]. A solution to this issue is Retrieval Augmented Generation (RAG), in which information or documents are segmented into smaller chunks, vectorized, and injected into LLMs [11]. Based on the literature, this research aims to employ LLMs and customize them for the use case of analyzing building permit documents by a state-of-the-art RAG implementation. Following up on this aim, the research question formulated in this article is the following: *How can unstructured building permit applications be converted into standard-compliant ICDD containers and OntoBPR-aligned RDF metadata?*

To answer this research question, the remainder of the paper is structured as follows: First, related work on customizing LLMs for specific document processing is provided. Second, the methodology and concept of this approach are described. Third, results from implementing the conceptualized pipeline are presented, and, lastly, the results are discussed and conclusions drawn.

2 Related Work

2.1 OntoBPR and Information Containers

Structuring building permit applications in information containers was introduced with OntoBPR in [2] and offers advantages, including facilitating formal checks on the application, increasing transparency in the permit review by sharing progress updates, and supporting decision-making through rule-based checks of machine-readable reports. The OntoBPR schema is implemented as an ontology, which is available at *https://w3id.org/ontobpr#*. For structuring the submission of a building application, the ontology is instantiated in an ICDD container, which itself is compliant with ISO 21597-1 [12]. Fig. 1 depicts an exemplary OntoBPR ICDD container of a submitted building application in the file system

These ICDD containers have a predefined structure defined through ontologies, thus semantically describing documents and their interconnections. OntoBPR is a semantic layer on top of the generic description of documents, adding context to the meaning of documents and to the purpose of the information container as a building application container. Main classes that are relevant to this study are the `ct:Document` class and its subclasses (c.f. [12]), as well as the classes `obpr:BuildingApplication` and `obpr:Building` from OntoBPR. The OntoBPR framework and the ICDD use a shared technology stack comprising the Resource Description Framework (RDF) and the Web Ontology Language (OWL) for the formal description of the knowledge graph, and Shapes and Constraint Language (SHACL) for validation [2].

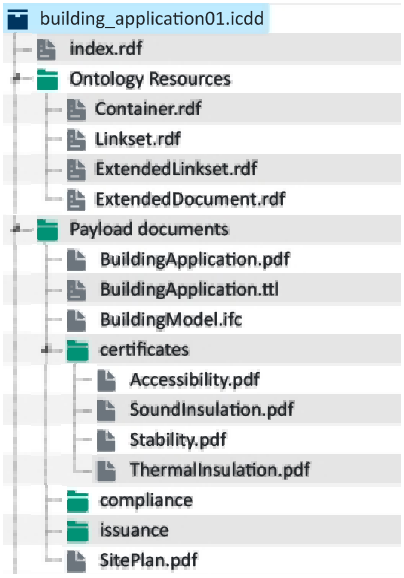

Figure 1. OntoBPR ICDD Container example

2.2 Extraction from Documents

Recent methodological developments have shifted information extraction in the AEC domain from rule-based systems to approaches driven by LLMs. This transition is primarily motivated by the need to handle heterogeneous, complex, and weakly structured data sources that are common in construction projects. The extraction of metadata from engineering drawings remains a longstanding challenge due to limited standardization across documents. Recent research introduces multimodal processing pipelines that combine lightweight Convolutional Neural Networks with visual language models to detect and interpret title blocks and embedded annotations. Empirical evaluations demonstrate clear performance gains over classical optical character recognition techniques, particularly in terms of robustness to layout variability [13].

A further emerging direction is the use of LLMs for knowledge graph construction. This line of work focuses on the automated extraction of entities and relations from unstructured text to populate graph-based representations. Recent studies demonstrate the direct generation of RDF triples from natural language inputs and the population of domain-specific ontologies through zero-shot and few-shot prompting strategies. Applications include knowledge models, e.g., for building materials, indicating the growing maturity of generative approaches for semantic structuring in the AEC domain [14, 15, 16].

2.3 Retrieval Augmented Generation (RAG)

Conventional RAG systems often exhibit limited performance when operating on flat data representations (i.e., lacking explicit structural, relational, or semantic mod-

eling). Therefore, recent research focuses on hybrid retrieval-augmented generation to address the structural complexity of heterogeneous documents that combine text, tables, and code. Structure-aware RAG extends classical pipelines by explicitly modeling structural relations. Approaches such as *GraphRAG*, *StructRAG*, and *LightRAG* integrate knowledge graphs into the retrieval stage. Context retrieval is no longer based on isolated text segments but on linked entities and relations, such as document hierarchies or citation networks. This strategy yields a coherent, semantically connected context. The explicit coupling of neural language models with symbolic knowledge graph structures also aligns these approaches with contemporary interpretations of neuro-symbolic artificial intelligence. Empirical studies report improved answer diversity and superior performance on multi-hop reasoning tasks compared to standard RAG [17, 18].

Ontology-guided retrieval augmented generation addresses domain-specific requirements by embedding formal ontologies into the retrieval and generation pipeline. Systems such as *GrOWL RAG* and *OntologyRAG* use structured domain knowledge to constrain and guide language model outputs, which is particularly relevant for tasks that require strict schema compliance, including document-level relation extraction and code-to-concept mapping. Reported results indicate reduced hallucination rates and increased precision in specialized application scenarios [19, 20]. Hybrid and collaborative RAG aims to overcome the limitations of single retrieval strategies. State-of-the-art systems combine sparse retrieval methods, such as BM25 for lexical matching, with dense retrieval based on vector embeddings for semantic similarity. This combination improves recall and robustness across query types [21, 22]. Recent work introduces a concept called *retrieval augmented retrieval*, in which LLMs generate candidate answers or query expansions prior to retrieval. This mechanism expands the effective query space and improves zero-shot performance in low-resource settings [23].

3 Methodology and Concept

This article presents a proof-of-concept pipeline that uses a hybrid RAG approach to ingest building application documents and generate a compliant ICDD container populated with the OntoBPR knowledge graph. Therefore, a pipeline is implemented and evaluated using a use case as a proof-of-concept. The hybrid RAG approach was chosen after studying several methods of RAG that are referred to in the literature in the previous section.

3.1 Ingestion and Preprocessing

The implemented pipeline comprises four main steps, as shown in Fig. 2, which are described in detail. In the first step, the ingestion component stages and cleans a ZIP file containing a building application submission. The included files are copied into an ICDD-like layout under a case-specific output directory `Payload documents/<CASE_ID>/`. During this process, the system constructs the ICDD container description (index.rdf) using *rdflib*[1]. It creates a `ct:ContainerDescription` individual for the container. Each payload file is registered as a `ct:InternalDocument` with a relative path and MIME type derived from the file extension and heuristics.

The text extraction focuses on PDF documents identified in the first step of the MIME type analysis. The system first attempts to use *pdfminer.six*[2] to read any text layer directly. If this yields insufficient output, an OCR fallback is triggered: pages are rasterized using *pdf2image*[3], and *pytesseract*[4] is applied to recognize text in the resulting images. The extracted text is segmented into overlapping chunks of configurable size. Each chunk is represented by a *TextChunk* record that carries the case identifier, a document identifier, page information, a sequence index, and a generalized role specification inferred from the source filename using a small set of patterns. These chunks, stored in a JSON Lines[5] file, form the basis for retrieval.

3.2 Hybrid Indexing and Retrieval

The retrieval layer combines vector-embedded semantic similarity search with a simple notion of document structure in a temporary knowledge graph. On the vector side, each text chunk is encoded using a SentenceTransformers model (*all-MiniLM-L6-v2*)[6]. The resulting embeddings are stored and indexed for fast cosine-similarity search. Given a textual query describing an information need (for instance, ”application reference” or ”site address”), this index returns chunks whose content is semantically similar, even when the exact query phrase does not appear. On the graph side, a Neo4j[7] database temporarily stores relationships between cases, documents, and chunks. This graph records which chunks belong to which document and preserves their sequence. When answering a query, the system can follow these edges to retrieve contextually neighbouring chunks within the same document or section, thereby complementing vector search with structural context. A dual retrieval function draws from both the vector index and the graph, merges the results, removes duplicates, and orders them into a single context window. This combined context is provided to the LLM for extraction in the next step.

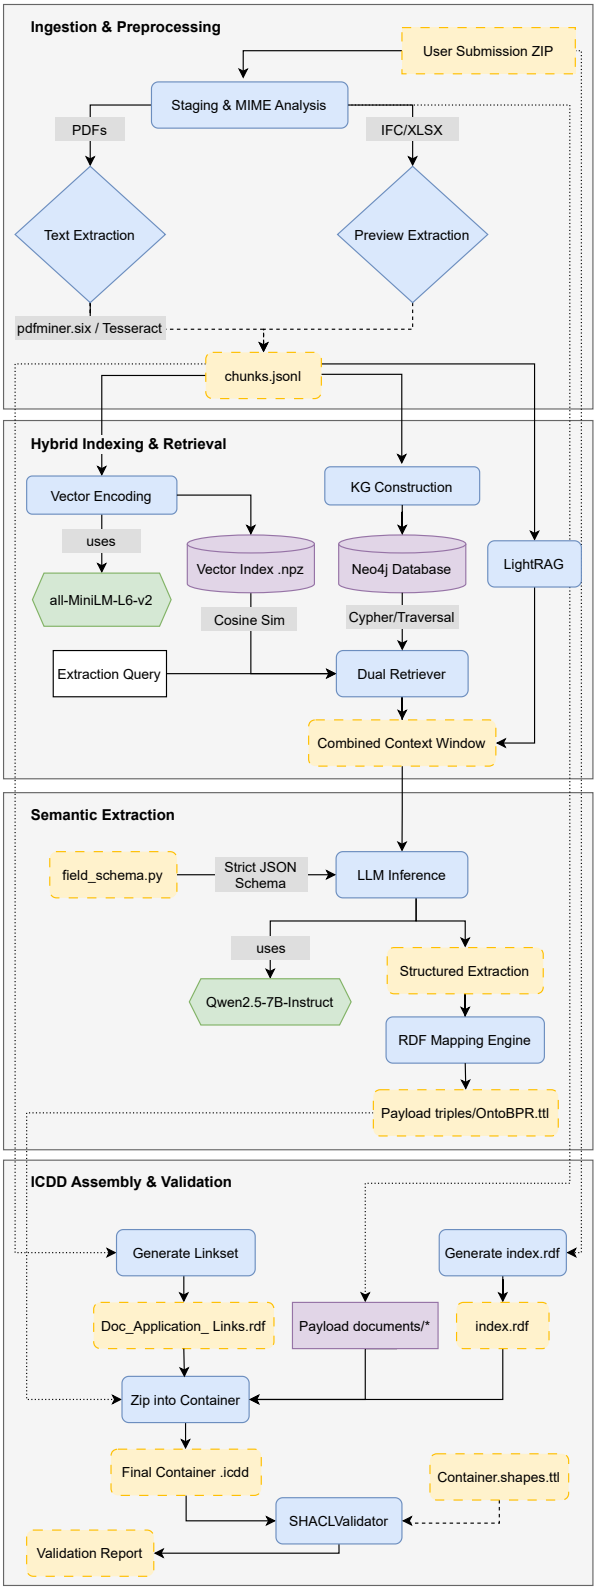

Figure 2. Implementation overview

3.3 Semantic Extraction

In Step 3, the utilized *Qwen 2.5-7B-Instruct*[8] LLM is not required to generate novel RDF structures or arbitrary JSON formats (c.f. also in Fig. 2). Instead, the pipeline relies on a predefined schema, which delineates all relevant data fields. At the current development stage, this schema covers application-level information, such as an internal identifier, application type, authority name, and site address, as well as building-level information, including the building's intended use and, where available, simple quantitative descriptors. For each case, the prompt provided to the LLM combines both the dual retrieval context and the JSON schema. The accompanying instructions emphasize that the model must rely exclusively on the supplied context, leave fields blank when no information is available, and produce syntactically valid JSON that is schema-compliant. The result is a structured JSON document containing the predicted values for all fields, organized under entities such as `building_application` and `building`. These JSON files are stored alongside the other case-specific outputs and subsequently serve as inputs to the OntoBPR mapping and evaluation script.

The JSON extraction in Step 5 is then transformed into an RDF graph aligned with the OntoBPR ontology. The mapping logic implemented using *rdflib* creates individuals representing the building application and, where applicable, the building itself. JSON fields are converted into datatype properties, e.g., an extracted application reference is mapped to `ontobpr:applicationIdentifier` or a site address to `ontobpr:siteAddress`, while the building use type is mapped to `ontobpr:buildingUseType`.

Moreover, for employing also the capability of the LLM to classify the documents based on the extracted terms semantically, OntoBPR does include the class `ontobpr:DocumentClassification` with a set of named individuals with German and English labels, such as `ontobpr:ApplicationForm`, `ontobpr:EngineeringProofs`, `ontobpr:PlotRelatedPlans`, or `ontobpr:Unclassified`.

The mapping uses a fixed set of OntoBPR classes and properties defined in code. The LLM therefore contributes the values, but the ontology vocabulary and URI patterns remain under deterministic control. This choice avoids the common problem of LLMs inventing nonexistent ontology terms (hallucinating) and keeps the RDF graph compliant with OntoBPR for the implemented subset. The resulting triples are written to a Turtle file in the output directory and later included as part of the container's semantic payload.

[8] https://huggingface.co/Qwen/Qwen2.5-7B-Instruct

3.4 ICDD Assembly and Validation

To maintain traceability between semantic data and source documents, a simple linkset is generated using the ICDD linkset vocabulary. This file expresses relationships between documents and, where appropriate, between documents and semantic entities. Before packaging, the combined RDF graph, including the container description, internal documents, linksets, and OntoBPR triples, is validated using SHACL. The prototype employs *pySHACL*[9] together with SHACL shapes `Container.shapes.ttl` derived from the ICDD standard validation resources. Finally, the container description, payload documents, ontology resources, linksets, and generated triples are assembled into a directory and compressed as a *.icdd* file. The overall pipeline and the assembly of generated artifacts are displayed in detail in Figure 2.

4 Proof of Concept and Results

The current prototype has been tested on a representative real-world permit application (`Apl_25-04543-FULL`). The corresponding submission archive is approximately 25 MB in size and consists of twelve distinct files, including text-based PDF forms, scanned or image-based PDFs, and several additional attachments such as images and spreadsheets (see Tab. 1). The documents exhibit typical characteristics of administrative practice: overlapping content across versions, varying terminology for similar concepts, and partial mixing of languages. Some information is distributed across different sources, for example, addresses that appear only in headers or footers, or quantitative data that appears only in drawings.

The system was executed in an environment with a single NVIDIA A100 GPU. *Qwen-2.5-7B-Instruct* was used as the extraction model, and *all-MiniLM-L6-v2* served as the sentence embedding model for the vector index. The hybrid retrieval layer combines dense vector search with a small *Neo4j*-based document graph. The precise configuration details (such as quantization settings or batch sizes) are less critical for the analysis presented here than the overall architectural pattern: retrieval-supported extraction followed by deterministic mapping to RDF.

For the examined case, the pipeline successfully produced an ISO 21597-1 container. The resulting `index.rdf` file lists all payload documents as internal documents, assigns the expected MIME types based on file extensions, and attaches a container description node with the required core metadata. SHACL validation against the available container shapes confirmed that the basic structural constraints of Part 1 are satisfied for this example, after the usual relaxation of strictly closed shapes to allow additional metadata. A simple linkset was generated to demonstrate the integration of Part 2. The linkset associates documents with each other and, where applicable, connects them to semantic entities. In the tested container, these links were successfully resolved to internal paths, and the linkset passed the structural checks applied in this prototype.

[9] pySHACL, v.0.30.1,https://github.com/RDFLib/pySHACL/

Table 1. Composition of the submission archive

Type	Count	Description
Administrative documents	3	Application form, receipt of application, and cover letter.
Planning documents	1	Planning Statement providing policy-based and contextual justification.
Technical drawings and plans	3	Architectural and technical drawings submitted as part of the application.
Supporting documents	6	Consultation, notification, and objection documents, including schedules, photographs, and spreadsheets.
Total	13	**6.53 MB zipped archive**

The OntoBPR payload produced by the mapping step is intentionally modest in scope. For the examined case, the pipeline created a `ontobpr:BuildingApplication` individual and associated it with a small number of datatype properties, such as an application identifier, an authority name, and a site address (see Fig. 3, lines 6–16). From a purely syntactic and ontological point of view, the graph is consistent in that it uses declared OntoBPR properties and datatypes and does not introduce ad hoc vocabulary (hallucination). However, this does not imply that all values are correct or complete; it only confirms that the mapping logic respects the chosen subset of the ontology. The behavior of the hybrid retrieval layer is best understood through concrete examples. For fields whose mentions are relatively explicit in the text, such as the application identifier or the name of the authority, vector-based retrieval generally retrieves appropriate chunks from application forms or covering letters. In such cases, the LLM can fill the JSON schema with plausible values, and the subsequent mapping to OntoBPR is straightforward.

For more distributed or abstract fields, such as building use type (see Fig. 3, line 20), the benefit of combining vector and graph retrieval becomes more apparent. When the relevant information is spread across a design statement and other supporting documents, vector search alone may return passages that are topically related but do not contain a clear, machine-readable statement of the use type. In these situations, extending the context with structurally neighboring chunks from the same document, identified via the graph, can provide the model with enough continuity to extract a meaningful value. This observation is

Figure 3. Excerpt of the generated OntoBPR-KG

qualitative but suggests that structural information helps guide the model toward relevant parts of long documents.

The classification of documents (see Fig. 3, lines 30ff.) according to OntoBPR classified ~39 % of the submitted documents, while eight documents remain unclassified after the procedure. While this classification is not the main achievement of this research, it requires a dedicated evaluation on a large-scale dataset and with variations in the classification descriptions in future work.

The complete pipeline during the case study execution required approximately 170 seconds on the described hardware, with retrieval preparation accounting for the majority of the overall runtime (see Tab. 2). Preprocessing of PDF documents, particularly OCR for scanned pages, accounts for a substantial portion of the overall runtime. Building the vector index and populating the *Neo4j* graph adds additional overhead but remains manageable for a single case. LLM inference for the relatively small schema used here contributes comparatively little to total runtime.

Table 2. Reported runtime for the test case

Pipeline Component	**Runtime (s)**
Ingestion and staging	0.12
Text extraction and chunking	28.00
Retrieval preparation	135.50
Retrieval query execution	3.84
LLM extraction and OntoBPR mapping	1.85
Container generation and validation	0.42
Total Runtime	**169.73**

In terms of container generation, the prototype was able to create basic link relations from the semantic layer back to the primary application document, and SHACL validation showed no structural violations for these links. This demonstrates that the principle of traceability from semantic statements to source documents can be implemented within the ICDD framework.

5 Discussion and Conclusions

OntoBPR was introduced in prior work as an ontology-based framework to support digital building permit review processes. This study extends that work by operationalising OntoBPR through standardized semantic information delivery using the Information Container for linked Document Delivery (ICDD) and by integrating a retrieval-augmented generation (RAG) approach to support information access during the building permit phase. Rather than proposing a new ontology, the study demonstrates how OntoBPR can be embedded into an interoperable, AI-supported submission and review mechanism that addresses fragmentation in digital building permitting.

Many digital permitting approaches remain limited to isolated functions, particularly automated code checking, and rely on document-centric information exchange. Integrating OntoBPR with ICDD bundles heterogeneous documents, datasets, and models into a semantically enriched container, where relationships between regulations, submitted evidence, and procedural steps are explicitly represented using RDF. This shifts the building application from a static document collection to a machine-interpretable information package that supports validation, traceability, and reuse. The integration of a RAG approach further extends this capability. By using the structured semantic content of ICDD containers as a trusted knowledge base, RAG enables context-aware retrieval and synthesis of relevant regulatory provisions and decision-relevant information, supporting building officials while maintaining transparency through semantic grounding.

The pipeline can generate an ISO 21597-1 container with an embedded OntoBPR application graph for a realistic building-permit submission, passing all SHACL checks. The results of this study must be interpreted in light of several intentional design constraints and limitations of the prototype implementation. OntoBPR is employed in a deliberately restricted manner. Only a subset of classes and properties related to the building application and core building attributes is instantiated. More expressive components of the ontology, such as workflow stages, involved actors, decision-making processes, and explicit representations of building-code knowledge graphs, are intentionally excluded in the first step of this research. Con-

sequently, the findings should be understood as a proof-of-concept for semantic extraction and representation using LLMs with the presented hybrid RAG approach, rather than a comprehensive OntoBPR instantiation.

The evaluation dataset is small, and the quantitative metrics produced by the evaluation script should therefore be considered indicative rather than statistically conclusive. The reported values primarily demonstrate overall feasibility and expose typical error patterns in document restructuring, attribute extraction, and semantic mapping. Although the ingestion pipeline is conceptually capable of handling heterogeneous document types, the current experimental focus is predominantly on PDF-based submissions. Other common artifacts in building permit applications include IFC models, which are central to the future development of digital building permitting. These artifacts are not yet analyzed with comparable semantic depth. Extending the pipeline towards multimodal extraction and tighter integration of model-based information remains an important avenue for future research, particularly given IFC's role in digital building permitting.

While this study is a first approach towards the automatic processing of building applications in practice, larger and more heterogeneous datasets in a real-world scale will be required to enable statistically meaningful evaluations and comparative benchmarking, which will be provided in future work. Finally, although the system can operate in a fully automated manner once configured, the generated ICDD containers and RDF graphs still require expert review for critical or legally relevant use. Integrating systematic human-in-the-loop refinement mechanisms for assessing the quality of the generated container and annotations would not only increase trust and adoption but also enable iterative quality improvement through expert feedback loops. Future research must therefore focus on empirical validation through pilot deployments with building authorities, assessing the scalability, usability, and acceptance of OntoBPR-enabled ICDD submissions and RAG-based decision support.

Acknowledgments

This research uses publicly available and research-oriented data sources. Annotated building permit documents were obtained from the ACCORD dataset, supplemented by real-world permits from public application portals (e.g., the City of Westminster). All documents were used solely for research, processed locally, and any identifying information was anonymized or excluded. JF received funding through the R&D project "Development of a process model and identification of innovative approaches to the building permit procedure in the building life cycle" funded by brain-SCC GmbH.

Abstract

With the growing use of artificial intelligence in architectural design, BIM models now need to record not only geometric shapes but also process information and external knowledge for intelligent design and optimization. This paper introduces an enhanced semantic IFC (Industry Foundation Classes) model to transmit process and semantic data during design. By aligning large-scale model data and leveraging RAG for intelligent design, we extend the IFC standard to support multi-stage design exchanges. Additionally, blockchain and AES encryption are integrated into the IFC model to address copyright and security concerns, enabling traceable verification and encrypted storage. This approach improves the intelligence, security, and integrity of architectural design data, offering new directions for the future of information modeling technologies.

Intelligent Design; LLM; Blockchain; Enhanced Semantic; IFC

1 Introduction

Building Information Modeling (BIM) is the cornerstone of digital transformation in architecture, enhancing management accuracy and cross-stage interoperability [1, 5]. Recently, Generative AI and Large Language Models (LLMs) have shifted the design paradigm from manual exploration to human-machine collaboration, offering exceptional capabilities in conceptual generation and parameter recommendation [2, 3]. However, while these intelligent workflows significantly boost efficiency, they introduce complex semantic contexts, reasoning chains, and implicit knowledge that are vital for downstream visualization and review [4].

Despite its maturity, the Industry Foundation Classes (IFC) standard exhibits significant deficiencies in capturing these AI-driven outputs. Existing IFC schemas excel at encoding geometry but struggle to represent design intent, knowledge associations, and the generative reasoning produced by LLMs [6]. This results in semantic fragmentation within BIM-integrated workflows. Current academic efforts—primarily focused on RDF/OWL-based lightweight annotations—lack a comprehensive mechanism to map the multi-dimensional semantic structures of generative models directly to the IFC framework [7].

To bridge this gap, this study integrates Knowledge Graph (KG) technology into the semantic enhancement of IFC [8]. KGs excel at modeling complex entity-relationship structures and support multi-hop reasoning, making them inherently compatible with the graph-based outputs of large models [9]. By leveraging the structured nature of KGs, this approach not only improves semantic retrieval and interoperability but also facilitates the construction of controlled, privacy-protected knowledge bases within industrial BIM practices [10].

Based on the above background and needs, this paper proposes an IFC semantic enhancement and encryption method driven by AI large-model generative design. The main contributions of this study are as follows: First, a systematic analysis of the semantic features of large-model generative design is conducted, identifying key elements in terms of semantic types, structured requirements, and visualization integration. Second, the IFC data schema is extended in a targeted manner, mapping knowledge graph representation mechanisms into IFC or its associated external files, thereby increasing semantic coverage while maintaining compatibility with BIM visualization software. Third, a corresponding encryption verification process is established based on smart contracts and encryption algorithms, ensuring the security of IFC design data during transmission and the adaptability of each design version.

Existing BIM semantic enrichment (e.g., ASK-BIM [11]) fully converts the BIM physical model into a Large-Scale Knowledge Graph (KG) for LLM-based query. However, this approach faces significant challenges in full-scale IFC conversion, token costs during reasoning, and computational redundancy. In contrast, our proposed SE-IFC architecture achieves

critical breakthroughs, as summarized in Table 1.

Table 1. Comparison: ASK-BIM vs. SE-IFC

Item	ASK-BIM	Proposed SE-IFC	Advancement
Graph Strategy	Full-Scale conversion of all physical BIM data	Partial Mounting on-demand semantic enrichment	Token Efficiency & Scalability for LLM reasoning
Structure	Difficult to align BIM with external datasets	On-demand Mounting: Seamlessly links multi-layer external VLM data	High Scalability & Ease of implementation
Reasoning	Monolithic graph lacking versioning capabilities	Records reasoning chains and knowledge-base rules	Full Traceability of the design process

2 Intelligent Design Based on LLM

This study introduces an intelligent design paradigm leveraging the contextual reasoning of LLMs, rather than data-intensive deep learning. By utilizing few-shot prompting with exemplar-based learning, the system generates layouts via linguistic reasoning without manual annotation. To ensure controllability and interpretability, three mechanisms are implemented:

- semantic knowledge-base: Explicitly structures design codes and spatial logics as hard constraints.
- self-verification: Automatically inspects and corrects LLM outputs based on knowledge-base feedback.
- Cross-platform parametric generation: Translates structured instructions into 3D models via BIM APIs

This integrated pipeline—from linguistic reasoning to autonomous verification and parametric modeling—balances model flexibility with practical engineering deployability.

2.1 Preprocessing of Housing Layout Data

To support the LLM-based intelligent design, this study utilizes the 3D-FRONT dataset [12] as a source of high-quality spatial priors. Rather than traditional energy-intensive training, a subset of 980 bedroom and living room layouts is employed to construct a structured example library. Each layout, comprising components like tables, beds, and wardrobes (Figure 1), is preprocessed into a standardized format.

(a)Front view (b)Top view (c)Side view (d)Oblique view

Figure 1. Original indoor layout data

To support the LLM-based design process, 3D-FRONT layout data are preprocessed and standardized into a consistent format. Key geometric features—including room dimensions and object-level attributes (type, size, coordinates, and orientation)—are extracted and serialized into structured JSON. This machine-readable representation ensures that the LLM can efficiently parse both spatial and semantic information through few-shot prompting, facilitating high-fidelity layout generation without manual intervention. Table 2 illustrates the extracted parameters and their structured representation.

Table 2. JSON Schema for Indoor Layouts

Parameter Group	Description	Example
Spatial Envelope	Room type, length, width (m)	LivingRoom, 6.0, 5.0
Object Geometry	Type, L, W, H, Depth (m)	wardrobe, 2.2, 2.4, 1.1
Position	Left/top offsets (m), Orientation (°)	1.8, 1.4, 90°

2.2 Adaptive Knowledge Base and Agent Updates in RAG Framework

In intelligent design systems, especially for complex tasks such as residential layout planning, large language models (LLMs) can efficiently generate design solutions based on preloaded datasets. However, they often rely on fixed rules and historical data, which limits flexibility for iterative and interactive design. Traditional digitized floor-plan methods lack dynamic rule-update capabilities, constraining adaptive design processes. To overcome the rigidity and "black-box" nature of traditional LLMs, this study integrates an external Retrieval-Augmented Generation (RAG) knowledge base. This repository explicitly stores furniture specifications (e.g., 3D-FRONT dimensions), design codes (e.g., clearances), and accessibility constraints. By integrating these knowledge categories into the RAG framework, the system can adaptively update design rules, providing context-aware guidance

that enhances flexibility, safety, and practicality in AI-generated layouts.

Taking residential layout design as an example, the overall process is illustrated in Figure 2. The system employs three functionally distinct agents to collaboratively complete the task. First, the Review agent performs knowledge-base matching and constraint validation on the initial design generated by the LLM, outputting any non-compliant elements in JSON format. Next, the Revision agent leverages these flagged items and invokes built-in operational functions (including move, rotate, and parameter adjustments) to revise and regenerate the layout. Finally, the Modeling agent converts the revised layout into parametric modeling instructions, achieving a complete pipeline from conceptual design generation to practical implementation.

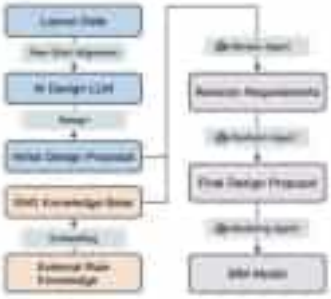

Figure 2. Full process of LLM-Driven intelligent design

2.3 Cross-Platform BIM Visualization

BIM Integration & MCP Execution. The transition from textual layout parameters to physical building components relies on a parametric component library built via BIM software APIs. These components function as a programmable "toolset," ensuring consistent data formats between LLM outputs and internal agents.

As shown in Figure 3, the workflow proceeds from parsing LLM drafts to invoking specific toolset functions. These functions are registered at the Model Context Protocol (MCP) layer and transmitted via TCP communication to a 3D modeling server for execution [13]. Each server-side function maintains a one-to-one mapping with its MCP counterpart, ensuring traceable execution and automated visual reconstruction within the BIM environment.

Figure 3. MCP-Based parametric component visualization in BIM

3 Semantic Enhancement of IFC for LLM-Based Design

In traditional BIM workflows, data interoperability across different software platforms typically relies on the IFC format, which separates geometric information from semantic attributes, ensuring a stable and extensible information structure.However, for the semantic-driven, large-model‐based design paradigm proposed in this study, the native IFC schema is no longer sufficient to capture the full spectrum of design intent, reasoning logic, semantic constraints, and generative context produced by large language models. To address this limitation, we introduce a semantic extension to the traditional IFC format, upgrading it from a geometry-centric exchange standard to a Semantic-Enhanced IFC capable of representing design knowledge, generative context, and the underlying reasoning chain produced during intelligent layout generation.

This study expands the semantic hierarchy of IFC geometry files using the open-source IFCOpenShell library. The enhanced IFC retains the standard spatial organization structure IFCPROJECT → IFCSITE → IFCBUILDING → IFCBUILDINGSTOREY—thereby ensuring full compatibility with mainstream BIM authoring tools.

On this foundation, we introduce two additional semantic carriers: a Display Modification Layer and a Hidden Semantic Layer. These extensions enrich the IFC with design-generation semantics while preserving its original geometric and attribute structure. The overall framework is illustrated in Figure 4, where the blue region represents native IFC content and the pink region denotes the newly added semantic enhancements.

Figure 4. Structural schema of the semantic-enhanced IFC

Display Semantic Layer. Integrated at the IFCBUILDINGSTOREY level, this layer functions as a global annotation container for cross-component design logic. It archives three core elements:

1. **Agent Execution Logs**：Records intelligent agent

types and tool functions (e.g., AgentFunctionCall, ToolName, Timestamp) to ensure full traceability of the generation-validation-optimization chain.

2. **Retrieved RAG Knowledge and Associated Constraint Rules：** Embeds external knowledge retrieved during iterations — such as furniture specifications, safety clearances, and circulation rules — preserving a transparent record of the normative logic guiding design adjustments.
3. **Modification Localization and Interaction Context:** Tracks semantic localization of modifications by logging natural-language prompts and agent rationales. This multimodal documentation transforms the IFC from a static geometry container into an interaction-aware semantic entity.

Through this enriched recording mechanism, the IFC model evolves from a static geometric container into an interpretable, interaction-aware semantic entity.

At the IFCFURNITURE level, an additional Hidden Semantic Layer is introduced to capture deep semantic features that extend beyond the explicit information stored in the display layer. This layer records latent visual and structural attributes that emerge during the later stages of intelligent layout generation, including furniture color composition, material textures, fine-grained structural details, and other non-essential micro-parameters.these types of features are typically difficult to extract directly through conventional parametric design workflows, as their complete representation often depends on the APIs provided by third-party modeling software. However, most commercial BIM platforms expose only limited geometry or attribute parameters, resulting in missing information related to visual details and semantic completeness.

To address this limitation, this study incorporates a Vision-Language Model (VLM) – based semantic enhancement mechanism. Leveraging the visual encoding capabilities of VLMs, the system extracts implicit feature representations of furniture objects directly from rendered images. This enables multimodal alignment between images and textual descriptors, allowing implicit semantic modeling of appearance attributes, material characteristics, and spatial composition relationships—without requiring access to low-level geometric APIs.

Ultimately, the Hidden Semantic Layer serves as a complementary semantic container within the IFC hierarchy. While the display semantic layer focuses on explicit interaction logs and design revisions, the hidden layer concentrates on reconstructing and enriching implicit visual semantics. Together, these two layers establish a dual-semantic structure for the enhanced IFC model, enabling IFC files to describe not only parametric geometric properties but also deep semantic information derived from large-model reasoning. This results in an interpretable and evolvable information representation framework tailored for intelligent design systems.The specific augmented IFC schema is illustrated in Figure 5.

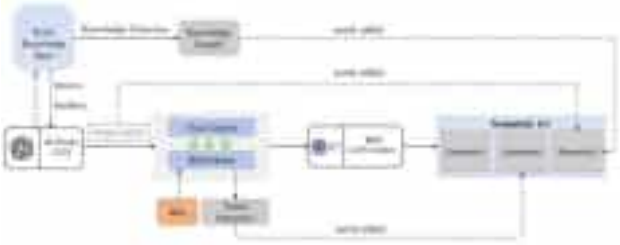

Figure 5. Flowchart of the semantic-enhanced IFC implementation process

Overall, this framework provides a robust foundation for semantic BIM modeling and intelligent reasoning, enabling secure, scalable, and interoperable knowledge integration within intelligent design systems.

4 Blockchain- and AES-Based Secure Management of IFC Files

This paper proposes an innovative IFC information security method that combines blockchain verification with AES encryption to address data integrity and privacy concerns during multi-party collaboration. Rather than conventional full-file encryption or on-chain storage—which introduces prohibitive overhead for large BIM models — our approach employs a selective, layered security architecture that decouples geometric accessibility from semantic confidentiality.

The security framework operates through three distinct layers with strict separation of concerns:

Layer 1: Geometric Data (Off-Chain, Unencrypted)

IFC geometric entities remain in standard cleartext format,Stored via conventional BIM repositories.

Layer 2: Semantic Knowledge (Off-Chain, Encrypted)

Knowledge Graph triples (design intent, reasoning chains, constraint rules) serialized to JSON,AES-256-GCM encryption applied to JSON payload, producing compact ciphertext,Result: Semantic data remains confidential even if IFC file is exfiltrated.

Layer 3: Integrity Verification (On-Chain)

SHA-256 hash of (JSON KG + encryption) anchored to private Ethereum testnet,Only the hash resides on-chain; no geometric data, no semantic content, no IFC file fragments,the complete transmission process follows this Figure 6:

Figure 6. Semantic Encryption Workflow

4.1 The introduction of blockchain technology

In intelligent design applications, ensuring the uniqueness, immutability, and transparency of knowledge graphs is one of the key challenges. Blockchain technology, with its decentralized, tamper-proof, and highly transparent characteristics, provides a feasible technical solution to address these issues. By submitting the JSON sequence of the knowledge graph to the blockchain for smart contract management, each knowledge graph can be effectively recorded, ensuring the reliability and security of its data. The advantages of this approach over traditional IFC-based storage are illustrated in Table 3.

Table 3. Blockchain vs. Traditional IFC Storage

Feature	Traditional IFC Storage	Blockchain Technology
Data Integrity	Lacks immutability	Unique Hash
Traceability	Incomplete/Manual	Interaction-based Blocks
Governance	Centralized (Siloed)	Decentralized (Distributed)

4.2 Construction and Serialization of Blockchain-Based Knowledge Graphs

A primary constraint of blockchain technology is its limited capacity for high-volume data storage, which renders the direct uploading of extensive design documentation computationally expensive and inefficient. To circumvent this, we propose a semantic abstraction and serialization framework. By distilling complex design narratives into structured Knowledge Graphs (Figure 7), we capture essential engineering entities and their interdependencies while stripping away linguistic redundancy. These graphs are subsequently serialized into compact JSON-based triples (Entity – Relationship – Attribute), significantly reducing the storage footprint compared to raw text. This "dehydrated" representation allows for the efficient anchoring of design logic onto the blockchain, ensuring data integrity and traceability without compromising system performance. This approach balances the robust security of decentralized ledgers with the practical requirements of large-scale BIM data management.

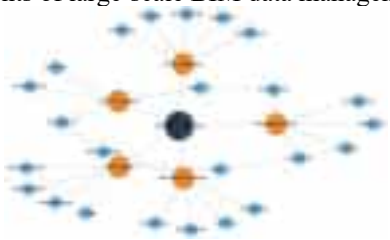

Figure 7. Normalized Knowledge Graph

4.3 Integration of Blockchain-Based Cryptographic Verification in Web-BIM Environment

To circumvent the data redundancy typical of traditional BIM workflows, this study adopts a selective encryption strategy rather than full-scale on-chain storage.he practical implementation within a Web-BIM interface is depicted in Figure 8. As shown in the component property panel, the fields "Knowledge Graph Hash" and "Semantic Ciphertext" confirm that the underlying knowledge graph has been securely processed. Crucially, the geometric data remains decoupled and fully accessible for real-time visualization. This architecture successfully achieves a security-functional decoupling between public geometric representations and private semantic metadata. This ensures that while the model ' s collaborative utility is preserved, sensitive design intelligence is restricted to authorized stakeholders via blockchain-anchored verification.

Figure 8. Layered Encryption Display of BIM

5 Experimental Evaluation

This chapter validates the feasibility of the LLM-driven intelligent design framework and the performance of the SE-IFC data structure. The evaluation focuses on three dimensions: layout reliability, computational efficiency, and blockchain-based cryptographic robustness.

The experimental configuration utilized a workstation equipped with an Intel Core i9-13900H CPU and an NVIDIA GeForce RTX 4070 GPU. On the software and model layer, Qwen3.5-4B was employed as the core design engine, while DeepSeek-VL-7B

served as the vision-language backbone. The programming environment was developed in Python 3.10, utilizing IfcOpenShell (v0.7.0) for the manipulation of IFC 2×3 standardized files. Blockchain integration and smart contract interactions were implemented using the Web3.py library.

5.1 Reliability Assessment of Intelligent Layout Generation

The intelligent design paradigm proposed in this research fully leverages the generative capabilities of Large Language Models (LLMs), enabling the automated transformation from conceptual descriptions to structured spatial layouts through natural language interaction. However, existing studies predominantly employ traditional Natural Language Processing (NLP) metrics—such as ROUGE-1, ROUGE-2, and ROUGE-L to evaluate model performance. These metrics essentially measure n-gram overlap within text sequences, reflecting the surface-level similarity between generated and reference texts rather than the functional rationality or spatial quality of the final design solutions.

This study shifts the evaluation paradigm from "model performance" to a utility-oriented "design outcome assessment," establishing a multi-variate framework that prioritizes spatial physical performance over linguistic fluency. The proposed framework employs three key metrics to quantify the rationality of LLM-generated layouts: Space Utilization Rate, the Coefficient of Variation in Furniture Spacing, and the Minimum Corridor Width. Specifically, the Space Utilization Rate (SUR) measures the ratio of the total furniture area to the floor area, characterizing the "physical saturation" of the space and reflecting the layout's ability to maximize available area while preventing over-congestion. The calculation is defined in Equation (1):

$$R = \frac{\sum_{i=1}^{n} A_i}{L * W} \tag{1}$$

Where **R** represents the Space Utilization Rate , **A** denotes the total area occupied by furniture, and **L** and **W** represent the width and height of the room, respectively.

The Coefficient of Variation in Furniture Spacing (CV) quantifies the structural order and distribution regularity of the layout by calculating the Euclidean distances between the centroids of all furniture pairs. A lower CV indicates higher spatial uniformity, whereas higher values suggest potential clustering or irregular spacing. The calculation is defined in Equation (2):

$$CV = \frac{\sigma_{dist}}{\mu_{dist}} \tag{2}$$

In this， **CV** denotes the Coefficient of Variation of the layout, μ epresents the mean value of the distances between furniture units, and σ signifies the standard deviation.

The Minimum Corridor Width metric simulates the physical clearance between furniture-to-furniture edges and furniture-to-wall boundaries. To ensure the reliability of the spatial analysis, a rationality filter ranging from 0.3m to 3.0m was implemented. This metric primarily evaluates whether the generated layout preserves sufficient circulation space for human movement and accessibility. The calculation process is defined as follows Equation (3):

$$W_{\min} = \min\{\text{gap}(i, j) \mid \delta < \text{gap} < \text{threshold}\} \tag{3}$$

Admittedly, indoor layout design is a relatively open-ended task with high degrees of freedom; therefore, quantitative metrics alone cannot fully capture the nuances of design quality. To address this, this study randomly sampled 100 representative expert designs from the 3D-FRONT dataset to establish a reference benchmark for reasonable spatial distribution. The LLM was then prompted to generate 10 independent layout iterations. If the metrics of the LLM-generated designs fall within the statistical range of the expert samples, the generative results can be considered to possess a high degree of reliability. The statistical distributions of the three key dimensions are illustrated in Figure 9:

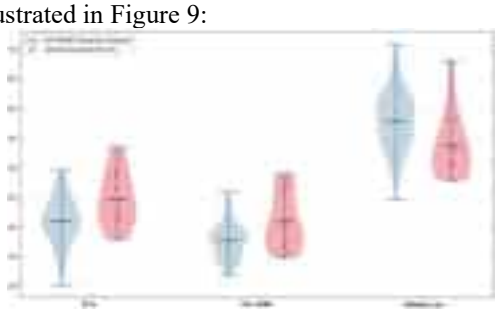

Figure 9. Comparative Distribution of Interior Layout Metrics

Statistical results (Figure 9) indicate that LLM-generated layouts exhibit a high degree of macro-level statistical alignment with expert designs from the 3D-FRONT dataset. Regarding local performance, LLMs enhanced with Retrieval-Augmented Generation (RAG) knowledge bases demonstrate a proactive tendency to increase functional density (e.g., via additional furniture units) to precisely map the multi-scenario requirements defined in user dialogues.

Notably, it was observed that the Minimum Corridor

Width for both expert samples and generated solutions remains within a relatively compact range. This phenomenon is attributed to the inherent spatial constraints of the East Asian residential footprints prevalent in the source dataset. In summary, the current generative model demonstrates remarkable reliability in both semantic synthesis and spatial organization, effectively reaching the statistical thresholds of professional architectural design.

5.2 Storage Overhead Analysis of SE-IFC

To evaluate the SE-IFC framework, we conducted stress tests by scaling metadata by 100x using IfcOpenShell. Storage analysis shows that while a baseline IFC is 3,307 KB, the JSON-serialized semantic layer adds only 79 KB. Due to IFC's internal attribute compression, the integrated package totals 3,349 KB—significantly less than the sum of separate components—confirming minimal storage overhead.

Full-lifecycle loading tests on an i9-13900H workstation (Figure 10) reveal that computational cost is dominated by geometric triangulation (84.3%). The proposed 'Semantic Stream' accounts for only 2.4% of total latency. These results demonstrate that the dual-layer semantic integration achieves seamless model binding with negligible impact on real-time system responsiveness.

Figure 10. Computational Latency Distribution of the BIM Model Loading Pipeline.

5.3 Evaluation and Performance Analysis of BIM Data Anchoring

In this study, a private Ethereum testnet was established using Ganache, with smart contracts deployed via Remix IDE to simulate a real-world BIM data anchoring environment. The experiment involved batch-encapsulating encrypted JSON data packets containing between 10 and 1,000 RDF triples. We recorded the end-to-end latency, encompassing the entire process of "encryption – signing – consensus-based anchoring – retrieval feedback." As illustrated in Figure 11, the total processing time for up to 1,000 triples remained consistently between 0.03s and 0.06s. These results demonstrate exceptional real-time responsiveness and linear scalability, ensuring that the proposed architecture does not impede high-frequency interactions within BIM models.

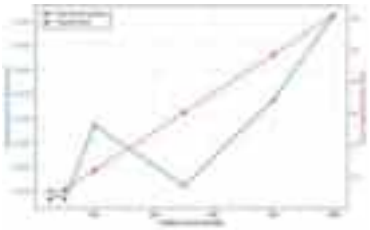

Figure 11. Performance Evaluation of BIM Semantic Data Anchoring

Experimental data further reveals that in a stress-test scenario involving 1,000 BIM semantic triples, the resource consumption for a single anchoring transaction is 1,023,456 Gas. While storage costs on the Ethereum mainnet can be substantial, the smart contracts in this research were authored in Solidity, providing inherent cross-chain interoperability and protocol consistency. This allows the system to dynamically bind to various underlying settlement tokens or blockchain environments (e.g., EVM-compatible Layer 2 solutions or sidechains) based on project budgets and security requirements. In these alternative EVM-compatible environments, the Gas unit price is typically 1% or less than that of the Ethereum mainnet. Consequently, the operational cost for the same scale (1.02M Gas) of BIM data anchoring can be significantly reduced to between 0.07 and 0.28 USD. Given the scale of large-scale construction projects requiring tens of thousands of attribute updates, this cost magnitude offers high economic viability and sustainability.

6 Conclusions and Discussion

In this paper, we propose an IFC semantic enhancement and encryption method driven by large-model generative design. Through a systematic analysis of the semantic features of large-model generative design, we identify key semantic types, structured requirements, and visualization integration elements. The IFC data schema is then extended in a targeted manner, integrating knowledge graph mechanisms to increase semantic coverage while maintaining compatibility with BIM software. Additionally, we design an encryption verification process using smart contracts and encryption algorithms to ensure the security of IFC design data during transmission.

The innovation of this study lies in integrating AI technology with the traditional BIM storage architecture, effectively addressing the limitations of traditional IFC in handling complex design semantics. This approach offers a new perspective for the intelligent transformation of architectural design.

Regarding the inherent limitations of Large Language Models (LLMs) in executing complex architectural design tasks, both academia and industry

have bifurcated into two primary evolutionary trajectories: the "Harness-oriented" approach and the "Model-oriented" approach. The former advocates for the construction of multi-level, progressive skill sets and knowledge base systems to constrain model outputs through external logic. Conversely, the latter focuses on enhancing the domain-specific reasoning capabilities of the models themselves via domain pre-training and fine-tuning.

This study posits that, compared to the standardized environments of code generation, the challenges of "regulatory abstraction" and "data sparsity" within the architectural design domain are significantly more profound. As noted by industry leaders such as Anthropic (Claude), the acquisition and structural complexity of high-quality architectural drawing data far exceed those of general-purpose code datasets. Consequently, developing a robust "External Architectural Framework"—rather than relying solely on increasing model scale—is of paramount importance for enhancing the practical utility of LLMs in the AEC (Architecture, Engineering, and Construction) sector.

The research focus of this study consistently aligns with the "Harness-oriented" (Architectural Augmentation) pathway, dedicated to constructing a comprehensive automated upgrade system. The specific strategies are as follows:

Multi-stage Task Decomposition: By constructing hierarchical systems and serialized command streams, this approach effectively mitigates "attention dispersion" and "logical drift" caused by excessive one-time context injection. This ensures the stability of the generative process across complex design sequences.

Multi-Agent Cooperation Architecture: The framework introduces functionally diverse Agents for parallel processing and cross-verification, establishing a robust error-correction mechanism.

Abstract -

Geometric measurement is critical for Modular Construction (MC) after fabrication because it helps prevent dimensional mismatches and safety risks that might otherwise be discovered only during on-site assembly. Terrestrial laser scanning (TLS) provides dense 3D measurements, but automated measurement in cluttered MC scenes remains challenging without robust semantic understanding and geometric reasoning. This paper presents an automated TLS point-cloud-based measurement framework for MC, consisting of data collection, deep-learning semantic segmentation, and geometry-driven post-processing. We evaluate PointNet, PointNet++, and Point Transformer V3 under transfer-learning and training-from-scratch settings. Using the segmented point clouds, we estimate room dimensions, assess wall verticality and orthogonality, estimate window dimensions, and evaluate wall flatness using RMS and point-to-plane distance metrics. Experiments on representative MC rooms demonstrate that the proposed pipeline achieves practical measurement accuracy and produces full-coverage deviation maps to locate nonconforming regions.

Modular Construction; Geometric Measurement; Semantic Segmentation in Point Clouds

1 Introduction

Modular Construction (MC) is an innovative and efficient building paradigm in which fully finished or semi-finished functional modules, including structural elements, interior fittings and utility systems, are prefabricated in factories, transported, and assembled on site [1]. However, integrating substandard MC modules can introduce quality and safety risks, potentially leading to demolition, repair, or replacement, which in turn delays construction schedules and increases costs. Therefore, geometric measurement is essential in MC projects.

Typical geometric tasks include room-dimension measurements, verification of the dimensions and placement of doors and windows, and assessment of wall surface flatness.

Conventional geometric measurement in the construction industry largely relies on manual measurements using tools such as measuring tapes and levels. These procedures are time-consuming and highly dependent on workers' experience and skill levels [2]. To mitigate these limitations, emerging sensing technologies, including computer vision [3, 4], laser scanning [5, 6], and infrared measurement technologies [7, 8] have been increasingly explored for construction geometric measurement.

Image-based approaches are easy and cost-effective to deploy and enable rapid data collection. However, due to inherent limitations in imaging and depth recovery, they often struggle to reach the precision required for fine-grained geometric inspection [9]. In contrast, terrestrial laser scanning (TLS) provides accurate 3D spatial information and has been widely used for measuring building elements such as doors and windows [10].

Early studies demonstrated the feasibility of TLS for automated dimensional inspection of prefabricated components. Kim et al. [11, 12] developed TLS-based pipelines to measure the dimensions, positions, and squareness of precast concrete elements by combining geometric feature extraction, error compensation, and BIM-based deviation analysis, achieving millimeter-level accuracy under controlled conditions. To extend TLS-based inspection to indoor environments, Tan et al. [13] proposed a geometry-driven approach to evaluate wall flatness, verticality, and door/window opening dimensions. Despite their accuracy, such methods typically rely on strong geometric assumptions and relatively clean scenes with limited occlusion, which restricts their applicability to complex and cluttered MC environments.

To improve robustness in unstructured scenes, recent studies have explored learning-based semantic understanding and component detection in point clouds. Tang et al. [14] integrated 3D deep learning with morphological processing to reconstruct semantically enriched BIM models from LiDAR and RGB-D data. Boudarbala et al. [15] proposed an automated workflow for door/window detection by jointly exploiting geometric and radiometric cues. Zhang [16] further addressed limited labeled data by training RandLA-Net on BIM-generated synthetic point clouds with data augmentation; real scans were aligned to the

BIM model via manual selection of feature points, after which the trained network was used to segment on-site point clouds and quantify dimensional deviations from the BIM design using cloud-to-cloud distance metrics. Despite improved automation and semantic understanding, these methods often rely on manual tuning or human intervention (e.g., achieving high-accuracy alignment between BIM-derived and as-built point clouds), and may provide limited accuracy for high-precision dimensional measurement.

Beyond dimensional measurement, TLS has also been applied to surface-related indicators. Wei et al. [17] quantified surface flatness of tunnel initial supports using deviation-based metrics on TLS data. Li et al. [18] developed a full-coverage TLS-based flatness inspection method for large-scale industrial floors by virtualizing the traditional 2-m ruler and feeler-gauge procedure on dense point clouds. However, existing TLS-based surface flatness methods are often tailored to relatively structured and simplified scenarios, making them difficult to extend directly to component-level surface inspection in cluttered, diverse, and heterogeneous environments.

In summary, existing workflows for building inspection can be broadly categorized into purely geometry-driven methods and learning-based point-cloud segmentation methods. Geometry-driven approaches can be accurate under controlled conditions but rely on strong assumptions and are best suited to isolated components in structured scenes. Learning-based methods improve automation, yet in complex MC environments they may suffer from degraded segmentation and limited accuracy for fine-grained geometric measurement. Moreover, many pipelines still require substantial manual tuning and support only a limited set of component types.

To address these limitations, this paper proposes an automated geometric measurement framework based on TLS point clouds for MC applications. We adopt a more efficient point-cloud semantic segmentation model to improve component-level recognition accuracy in MC scenes, and develop more geometry-aware post-processing algorithms to enable reliable room-scale dimensional measurement. The main contributions of this paper are summarized as follows:

- A real-world TLS dataset of MC modules with diverse structural configurations is collected, providing practical data support for geometric measurement research in complex MC environments.
- An automated geometric measurement framework for MC is proposed based on TLS point clouds that integrates semantic segmentation with geometry-aware post-processing to enable robust component-level geometric measurement and analysis.

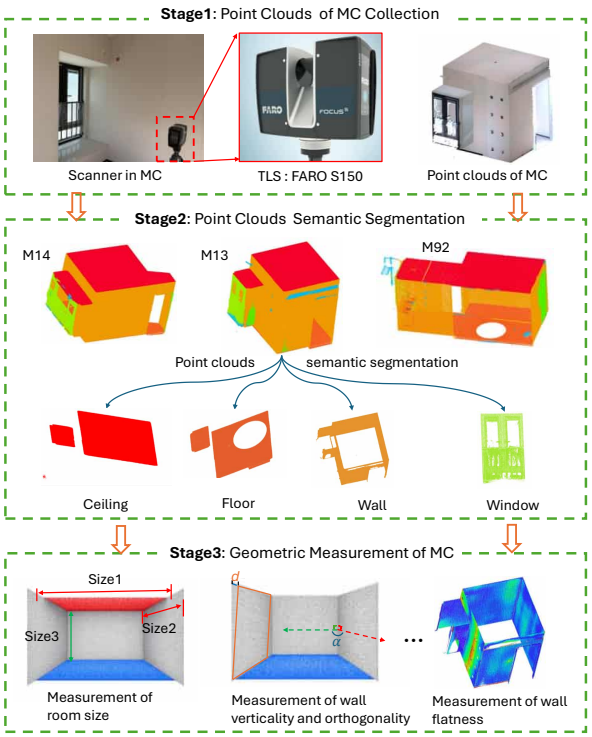

Figure 1. Proposed MC geometric measurement pipeline. TLS-acquired point clouds are first segmented by a semantic segmentation model, and geometric measurements are then performed for each predicted class.

2 Methodology

This paper proposes an automated geometric measurement workflow tailored to MC scenarios, as illustrated in Fig. 1. The framework consists of three stages. First, TLS point clouds of MC modules are acquired and organized. Second, a neural-network-based semantic segmentation model is used to identify key building components in the point clouds. Third, geometry-aware analysis is applied to the segmented components to compute dimensional and surface-flatness metrics, enabling fine-grained inspection in complex indoor environments.

2.1 Semantic Segmentation

To automatically identify MC components in raw scanner point clouds, we employ neural network-based semantic segmentation. Given the variety of MC elements and the complexity of indoor scenes, learning-based segmentation offers a practical alternative to purely geometry-driven pipelines. We evaluate three representative point cloud segmentation models on the proposed MC dataset: PointNet [19], PointNet++ [20], and the recently proposed

Point Transformer V3 [21]. These models cover different design paradigms, including point-wise global feature learning (PointNet), hierarchical local feature aggregation (PointNet++), and transformer-based representation learning for large-scale point clouds (Point Transformer V3).

Each point is represented using scanner-provided attributes, including 3D coordinates (xyz), RGB color, and surface normals (nx, ny, nz). These features are concatenated as the network input to capture both geometric cues and appearance-related information of MC components.

To evaluate learning-based semantic segmentation on MC point clouds, we consider two training strategies: (1) transfer learning from a large-scale indoor dataset followed by staged fine-tuning on MC data, and (2) training from scratch using only the collected MC dataset. All models are evaluated using the same train–test split.

Pretraining on S3DIS and two-stage fine-tuning. Given the limited amount of annotated MC point cloud data and the similarity between MC scenes and indoor environments, we initialize the networks with S3DIS-pretrained weights. The segmentation head is re-initialized to predict the MC classes. Fine-tuning on the MC dataset is performed in two stages to stabilize optimization:

- **Stage I (head-only training):** the backbone is frozen and only the segmentation head is trained on the MC dataset to adapt to the new class taxonomy.
- **Stage II (full fine-tuning):** the backbone is unfrozen, and the entire network is further fine-tuned on the MC dataset to better fit MC-specific geometry and component distributions.

Training from scratch on MC data. In addition to transfer learning, we train each model from scratch using only the MC dataset as an alternative training strategy. In this setting, all network parameters are randomly initialized and optimized end-to-end on MC data under the same train–test split and evaluation protocol.

Segmentation performance is evaluated using Intersection over Union (IoU), defined as the ratio of the intersection between the predicted segmentation and the ground-truth region to their union. A higher IoU indicates more accurate and complete segmentation of the MC components, thereby reducing subsequent measurement errors.

2.2 Geometric Measurement

This subsection presents geometric measurement modules operating on segmented MC point clouds, including (i) room size measurement, (ii) ceiling/floor elevation range evaluation, (iii) wall flatness evaluation, (iv) verticality/orthogonality assessment, and (v) window size measurement.

2.2.1 Room Size

Given a semantically segmented point cloud $\mathcal{P} = \{(\mathbf{x}_i, \ell_i)\}_{i=1}^{N}$, we estimate the room dimensions (length, width, and height) using the ceiling, floor, and wall regions, which provide stable planar references. The corresponding point subsets are $\mathcal{P}^{\text{ceil}} = \{\mathbf{x}_i \mid \ell_i = \ell_{\text{ceil}}\}$, $\mathcal{P}^{\text{floor}} = \{\mathbf{x}_i \mid \ell_i = \ell_{\text{floor}}\}$, and $\mathcal{P}^{\text{wall}} = \{\mathbf{x}_i \mid \ell_i = \ell_{\text{wall}}\}$.

For each structural subset, isolated points are first removed using a radius-based filter. Plane candidates are then extracted by RANSAC, and DBSCAN is subsequently applied to separate spatially disconnected but geometrically coplanar fragments. For each candidate plane, only the largest connected component is retained, and its parameters are finally refined by least-squares fitting (SVD) to obtain a unit normal $\mathbf{n}$ and centroid $\mathbf{c}$.

For the ceiling and floor subsets, the dominant plane is selected as the coherent patch with the largest number of inliers, yielding $(\mathbf{n}^{\text{ceil}}, \mathbf{c}^{\text{ceil}})$ and $(\mathbf{n}^{\text{floor}}, \mathbf{c}^{\text{floor}})$, respectively. For the wall subset, an iterative RANSAC procedure is used to extract multiple planar candidates. After connected-component filtering and SVD refinement, the minimum distance from each wall plane to the floor plane is computed. Only planes satisfying $h_{\min} \le t_{\text{touch}}$ are retained as valid wall candidates. These candidates are then ranked by the number of inliers, and the top four dominant walls are selected for subsequent analysis.

Finally, the room height is computed as the average perpendicular distance from the points in the dominant ceiling patch to the floor plane. The room length and width are estimated as the distances between two pairs of parallel walls among the four selected dominant walls.

2.2.2 Ceiling/Floor Elevation Range

Based on the dominant ceiling/floor plane estimated in Section 2.2.1, we compute a corner-level elevation range using four local patches. Let the plane be $\pi : \mathbf{n}^\top \mathbf{x} + d = 0$ with $\|\mathbf{n}\|_2 = 1$, and let $\mathbf{x}_{\text{corner}}^{(i)}$ $(i = 1, \ldots, 4)$ denote the four 3D corners of the fitted room rectangle. For each corner, we define a square patch (with side length s) whose center is given by

$$\begin{aligned} \mathbf{x}_{\text{center}}^{(i)} &= \mathbf{x}_{\text{corner}}^{(i)} + o\,\widehat{\mathbf{t}}^{(i)}, \\ \widehat{\mathbf{t}}^{(i)} &= \frac{(\mathbf{I} - \mathbf{n}\mathbf{n}^\top)(\mathbf{c} - \mathbf{x}_{\text{corner}}^{(i)})}{\|(\mathbf{I} - \mathbf{n}\mathbf{n}^\top)(\mathbf{c} - \mathbf{x}_{\text{corner}}^{(i)})\|_2} \end{aligned} \tag{1}$$

where $\mathbf{c}$ is the rectangle center and o is an inward offset along the plane.

Using an orthonormal in-plane basis $(\mathbf{u}, \mathbf{v})$, we collect points $\mathcal{X}^{(i)}$ within each $s \times s$ patch centered at $\mathbf{x}_{\text{center}}^{(i)}$ to obtain a robust local estimate. The average point of each patch is computed and its signed distance to the plane is evaluated as $\delta(\mathbf{x}) = \mathbf{n}^\top \mathbf{x} + d$. Finally, the elevation

range is defined as the difference between the maximum and minimum average distances among the four corner patches.

2.2.3 Wall Flatness

We quantify wall surface flatness using a patch-level root-mean-square (RMS) deviation as a global indicator, complemented by a dense per-point distance-to-plane map $\{D_i\}$ to capture localized deviations.

Given a contiguous planar patch extracted in Section 2.2.1, denoted as $\mathcal{S} = \{\mathbf{x}_1, \ldots, \mathbf{x}_M\}$, we fit a plane via SVD to obtain the centroid $\mathbf{c}$ and unit normal $\mathbf{n}$ ($\|\mathbf{n}\|_2 = 1$). The absolute deviation of each point from the fitted plane is defined as

$$D_i = \left|\mathbf{n}^\top (\mathbf{x}_i - \mathbf{c})\right|, \qquad \mathbf{x}_i \in \mathcal{S} \tag{2}$$

and the patch-level RMS deviation is computed as

$$\mathrm{RMS} = \sqrt{\frac{1}{M}\sum_{i=1}^{M} D_i^2} \tag{3}$$

The set of values $\{D_i\}$ forms a dense deviation map that can be used for visualization and analysis of local surface irregularities.

2.2.4 Wall Verticality and Orthogonality

We evaluate wall geometry quality from two aspects: (i) wall-to-floor verticality and (ii) orthogonality between adjacent walls. The dominant floor plane $(\mathbf{n}_f, \mathbf{c}_f)$ is estimated from $\mathcal{P}^{\text{floor}}$ (Section 2.2.1), where $\|\mathbf{n}_f\|_2 = 1$. Four dominant wall patches $\{\mathcal{W}_k\}$ are extracted using the same decomposition procedure as described in Section 2.2.1, and each patch is refitted via SVD to obtain a unit normal $\mathbf{n}_k$ and centroid $\mathbf{c}_k$.

Wall-to-floor verticality. For each floor-connected wall patch $\mathcal{W}_k$, we define the height of a point $\mathbf{x} \in \mathcal{W}_k$ along the floor normal as $h(\mathbf{x}) = (\mathbf{x} - \mathbf{c}_f)^\top \mathbf{n}_f$. The verticality deviation is quantified by the angular deviation between the wall normal and the floor normal:

$$\theta_k = \arcsin\left(\left|\mathbf{n}_k^\top \mathbf{n}_f\right|\right) \tag{4}$$

To provide an interpretable geometric measure, we further approximate the lateral deviation along the wall height as

$$d_k \approx \theta_k \, (h_{\max} - h_{\min}), \tag{5}$$

where $h_{\min} = \min_{\mathbf{x}\in\mathcal{W}_k} h(\mathbf{x})$ and $h_{\max} = \max_{\mathbf{x}\in\mathcal{W}_k} h(\mathbf{x})$

Wall-to-wall orthogonality. Adjacency between two wall patches $\mathcal{W}_i$ and $\mathcal{W}_j$ is determined by the minimum Euclidean distance between their inlier point sets; a pair is considered adjacent if $d_{ij}^{\min} \le t_{\text{conn}}$. For each adjacent pair, the orthogonality error is defined based on their unit normals as

$$e_{ij} = \left|\arccos\left(\left|\mathbf{n}_i^\top \mathbf{n}_j\right|\right) - \frac{\pi}{2}\right| \tag{6}$$

2.2.5 Window Size

We first extract the window points $\mathcal{P}^{\text{win}} = \{\mathbf{x}_i \mid \ell_i = \ell_{\text{window}}\}$ and apply DBSCAN to remove noise, obtaining a denoised point set $\mathcal{P}^{\text{win}}_{\text{db}}$. A planar model is then fitted to $\mathcal{P}^{\text{win}}_{\text{db}}$ using RANSAC, and the largest inlier set is retained as $\widetilde{\mathcal{P}}^{\text{win}}$. Next, the normal of the window plane is estimated from $\widetilde{\mathcal{P}}^{\text{win}}$ via PCA. Among the wall planes extracted in Section 2.2.1, the one whose normal is most parallel to the window-plane normal is selected as the supporting wall plane. The points in $\widetilde{\mathcal{P}}^{\text{win}}$ are orthogonally projected onto this wall plane and then mapped to a 2D local coordinate system, yielding the 2D point set C^{2D}.

To reduce the influence of boundary artifacts, we iteratively trim the point set along both axes by removing boundary points whose distances to their nearest interior neighbors exceed a threshold τ.

Finally, we compute the 2D convex hull of the trimmed points and fit a minimum-area bounding rectangle using OpenCV `minAreaRect`. The window width and height are defined as the side lengths of this rectangle.

3 Experiments and Results

3.1 Data Collection and Preparation

The data used in this study were collected at an MC manufacturing base in Zhuhai, China. Terrestrial laser scanning was conducted using a FARO Focus S150 to acquire as-built point clouds of MC modules with different structural types, including both steel-structured and concrete-structured modules. According to the device specifications, the ranging accuracy is better than 0.7 mm within 10 m. Under the adopted scanning configuration, the point density is approximately 87,507 pts/m^2 at a distance of about 1 m from the scanner, corresponding to an average point spacing of roughly 3 mm on surfaces perpendicular to the laser beam direction. In total, 44 point cloud files were collected and organized for subsequent semantic segmentation and geometric measurement experiments.

For semantic segmentation, all point cloud files were manually annotated. The labeling scheme follows the S3DIS class definitions and is extended to better reflect the structural characteristics and functional components specific to MC modules. As a result, the annotation taxonomy was expanded to a total of 22 semantic classes: ceiling, floor, wall, beam, column, window, door, table, chair, sofa, bookcase, board, clutter, electronic hole, electronic box, electronic pipe, water pipe, basin, toilet, ceramic tile, rebar, and lamp. Here, the electronic-related classes refer to openings, boxes, and conduits associated with electrical installations commonly found in MC modules.

From the 44 collected point cloud files, three representative scenes were selected for testing, and the remaining

Table 1. Semantic segmentation results on the MC TLS test set.

Model	Training data	$mIoU_{rep}$	Ceiling	Floor	Wall	Window	Door
PointNet	S3DIS+MC	0.69	0.93	0.93	0.86	0.59	0.12
PointNet++	S3DIS+MC	0.73	0.93	0.94	0.90	0.69	0.20
PT V3	S3DIS+MC	0.72	0.90	0.93	0.90	0.49	0.40
PointNet	MC	0.73	0.93	0.90	0.86	0.57	0.38
PointNet++	MC	0.57	0.83	0.89	0.84	0.29	0
PT V3	MC	**0.89**	**0.94**	**0.95**	**0.93**	**0.89**	**0.74**

files were used for training. This split was adopted because several scans contain relatively simple, repetitive layouts; as a result, a conventional 80/20 split would yield a test set that is not sufficiently representative. The test set was therefore curated to better reflect typical MC environments and to provide a more meaningful evaluation of generalization. The selected test scenes are shown in Fig. 1 (Stage 2), labeled from left to right as M14, M13, and M92. Although the test set is small, each test scene contains multiple components and cluttered structures commonly observed in MC modules, enabling component-level geometric measurement under realistic conditions.

3.2 Semantic Segmentation in Point Clouds

We evaluate semantic segmentation on the proposed MC TLS dataset using three representative architectures: PointNet, PointNet++, and Point Transformer V3. The results are summarized in Table 1. For concise presentation, Table 1 only reports the classes whose IoU exceeds 0.5 in our experiments. Classes whose IoU remains below 0.5 across all architectures are omitted because their predictions are insufficiently distinguishable from other categories, which can lead to unreliable inputs and reduced accuracy in subsequent geometric measurement. Accordingly, we report $mIoU_{rep}$, defined as the mean IoU over the reported classes.

As shown in Table 1, the highest $mIoU_{rep}$ is achieved by Point Transformer V3 trained from scratch (0.89), with consistently high IoU on the dominant structural classes (Ceiling/Floor/Wall) and strong performance on opening-related components such as *Window* and *Door* (0.89/0.74). Under S3DIS initialization, PointNet++ benefits from pretraining, improving $mIoU_{rep}$ from 0.57 (scratch) to 0.73 (fine-tuned), suggesting that pretrained hierarchical local features can be helpful when MC supervision is limited.

In contrast, Point Transformer V3 shows degraded performance after S3DIS pretraining, with mIoU dropping from 0.89 (scratch) to 0.72 (fine-tuned). A plausible explanation is the domain gap between S3DIS and our MC scenes. Since Transformer-based models rely heavily on global context, the pretrained representations may be biased toward S3DIS-specific scene priors, causing negative transfer on MC data. Therefore, the subsequent geometric measurement experiments use predictions from Point Transformer V3 trained from scratch.

3.3 Geometric Measurement

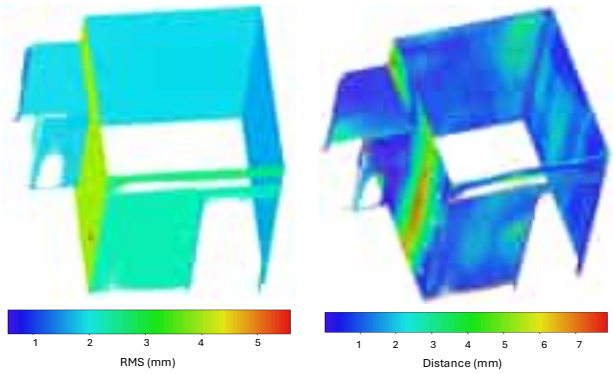
Based on the semantic segmentation results of MC point clouds, we develop geometry-aware algorithms to measure room size, ceiling/floor elevation range, wall flatness, wall verticality and orthogonality, and window size. The quantitative results are summarized in Table 2, which compares our measurements with manual measurements from the point clouds, and reports the corresponding errors. Detailed analyses of each measurement item are provided in the following sections.

3.3.1 Room Size

For M13, the measured room length, width, and height are 2346 mm, 2569 mm, and 2769 mm, respectively, compared with the corresponding manual measurements of 2344 mm, 2568 mm, and 2769 mm, yielding absolute errors of 2 mm, 1 mm, and 0 mm. For M14, the estimated length, width, and height are 3116 mm, 3057 mm, and 2767 mm, respectively, corresponding to absolute errors of 2 mm, 2 mm, and 1 mm.

These results demonstrate that the proposed method can reliably recover global room dimensions with millimeter-level precision. Compared with Truong-Hong et al. [22], who reported a 2.9% error in ceiling area measurement, our method achieves a substantially smaller ceiling-area error of 0.1% (assuming the ceiling area is approximated by length × width).

3.3.2 Ceiling/Floor Elevation Range



In this study, the inward offset is set to $o = 300$ mm and the patch side length to $s = 10$ mm. As shown in Table 2, the automatically measured ceiling elevation ranges are 2.8 mm for M13 and 2.3 mm for M14, corresponding to absolute errors of 0.3 mm and 0.9 mm relative to manually obtained reference values. For the floor, the measured elevation ranges yield errors of 0.2 mm (M13) and 0.0 mm (M14), demonstrating similarly high measurement accuracy for floor surfaces.

3.3.3 Wall Flatness

Figure 2a presents the RMS flatness of the extracted wall patches in room M13. All major wall patches exhibit an RMS ≤ 4 mm, indicating good overall planarity at the patch level. Among the four walls, the left wall shows the largest RMS value (4.0 mm), primarily due to irregular openings and voids that introduce larger local deviations and consequently inflate the RMS metric. In contrast, the right wall demonstrates the best flatness performance, with

Table 2. Geometric measurement results of major MC components from M13 and M14 point clouds.

Items	M13			M14		
	Measurement	Manual	Error	Measurement	Manual	Error
Length (mm)	2346	2344	2	3116	3114	2
Width (mm)	2569	2568	1	3057	3055	2
Height (mm)	2769	2769	0	2767	2766	1
Ceiling elevation range (mm)	2.8	2.5	0.3	2.3	3.2	0.9
Floor elevation range (mm)	1.3	1.1	0.2	0.9	0.9	0.0
Wall flatness (RMS, mm)	1.6, 1.9 2.3, 4.0	1.7, 1.9 1.8, 3.9	0.1, 0.0 0.5, 0.1	2.6, 2.3 2.1, 3.2	2.4, 1.8 2.2, 4.1	0.2, 0.5 0.1, 0.9
Wall verticality (mm)	0.6, 1.5 1.7, 1.1	0.1, 3.2 0.5, 1.5	0.5, 1.7 1.2, 0.4	5.2, 4.2 1.3, 0.1	5.6, 4.1 1.0, 0.1	0.4, 0.1 0.3, 0.0
Wall orthogonality (°)	0.2, 0.3 0.4, 0.3	0.2, 0.2 0.4, 0.3	0.0, 0.1 0.0, 0.0	0.1, 0.0 0.0	0.1, 0.0 0.0	0.0, 0.0 0.0
Window size (mm)	1730, 1037	1743, 1028	13, 9	1766, 2476	1750, 2469	16, 7

(a) RMS map. (b) Distance-to-plane map.

Figure 2. Wall flatness visualization for the M13 room.

an RMS of only 1.6 mm. When compared to manual measurements, the maximum and minimum absolute errors are 0.5 mm and 0.0 mm, respectively. Furthermore, the proposed method achieves substantially improved measurement accuracy over the work of Li et al. [23], who reported an average flatness measurement error of 7.5 mm for the M4 room in their dataset.

Figure 2b further shows that most wall regions have absolute point-to-plane distances within approximately 1 mm, indicating that the major wall surfaces remain close to an ideal plane. Notably, deviations exceeding 3 mm are mainly concentrated around the opening regions and electrical box areas. Using a practical acceptance criterion of 3 mm for point-to-plane deviation, room M13 is assessed as broadly compliant. Similarly, for room M14, the RMS values range between 2 and 4 mm. Compared to manual measurements, the maximum and minimum absolute errors for this room are 0.9 mm and 0.1 mm, respectively.

Overall, the TLS data and the proposed method enable both quantitative evaluation and intuitive visualization of wall flatness.

3.3.4 Wall Verticality and Orthogonality

In this experiment, we set $t_{\text{touch}} = t_{\text{conn}} = 0.15$ m. For the M13 room, the estimated verticality deviations of the four dominant wall planes are 0.6 mm, 1.5 mm, 1.7 mm, and 1.1 mm, respectively. Compared with the corresponding manual measurements, the absolute errors are 0.5 mm, 1.7 mm, 1.2 mm, and 0.4 mm, yielding a mean absolute error of 0.95 mm. This result is lower than the average verticality measurement error of approximately 1.33 mm reported by Tan et al. [13], demonstrating the higher accuracy of the proposed method. Under the commonly adopted tolerance requirement that the wall verticality deviation should be within 4 mm for walls lower than 3 m, the M13 room satisfies the verticality criterion.

We also assess the orthogonality of adjacent wall planes in room M13. The computed deviations for the four wall pairs are 0.2°, 0.3°, 0.4°, and 0.3°, with corresponding absolute errors of 0.0°, 0.1°, 0.0°, and 0.0° relative to manual measurements. As all values are well below the standard tolerance of 1°, room M13 satisfies the orthogonality requirement with a large margin.

For the M14 room, the estimated verticality deviations are 5.2 mm, 4.2 mm, 1.3 mm, and 0.1 mm, with corresponding absolute errors of 0.4 mm, 0.1 mm, 0.3 mm, and 0.0 mm, respectively. The mean absolute error is 0.2 mm. Although the estimated values are in close agreement with the manual measurements, two walls exceed the 4 mm tolerance limit, indicating that M14 does not fully satisfy the verticality criterion. For wall orthogonality in the M14 room, the computed deviations are 0.1°, 0.0°, and 0.0°, which are consistent with the manual measurements and all well below the tolerance threshold of 1°. Therefore, the M14 room satisfies the orthogonality requirement.

3.3.5 Window Size

Considering the 3 mm point density, we set the threshold $\tau = 3$ mm. For the M13 room, the measured window

height and width are 1730 mm and 1037 mm, respectively. Compared with the manual measurements, the absolute errors are 13 mm in height and 9 mm in width. For the M14 room, the measured window height and width are 1766 mm and 2476 mm, respectively, while the corresponding manual measurements are 1750 mm and 2469 mm. The resulting absolute errors are 16 mm in height and 7 mm in width. Despite these deviations, the results still show good agreement with the manual measurements, indicating that the proposed method can provide reliable window-size estimation in different room layouts.

Compared with Tang et al. [14], who reported door/window location deviations exceeding 120 mm in BIM reconstruction, our proposed method achieves substantially higher geometric accuracy in these case studies.

3.3.6 Error Analysis

This subsection analyzes the measurement errors between the proposed automatic geometric measurement method and manual measurements. Since the scanner used in this study is highly accurate, the analysis focuses primarily on other error sources.

The results show that the measurement errors are small for room dimensions and the geometric attributes of ceilings, floors, and walls. This is mainly because these components achieve high semantic segmentation performance, with IoU values all above 0.93, indicating only limited point misclassification. Moreover, these targets are relatively large, and the proposed post-processing method is robust to minor segmentation errors, thereby maintaining high measurement accuracy. The remaining errors may be partly attributed to manual measurement, which is usually performed on selected points or local regions and may therefore be less comprehensive and more sensitive to local irregularities. In contrast, the proposed method evaluates the geometry of the entire component, providing more comprehensive and stable results.

The window measurement errors are relatively larger than those of other components, mainly because of lower segmentation accuracy for windows. It should be noted that this measurement refers to the installed window within the wall opening rather than the outer structural window frame. Consequently, during semantic segmentation, the boundary between the window and the surrounding wall may be ambiguous, causing some wall points to be misclassified as window points, as observed in the length measurement of M13 and the height measurement of M14. In the current window-size measurement procedure, a rectangle is fitted to the segmented window points, making the result sensitive to such boundary misclassification and potentially leading to overestimation or underestimation. Although denoising strategies are applied to mitigate this effect, their influence cannot yet be fully eliminated.

4 Conclusion

This paper presents an automated TLS point-cloud-based geometric measurement framework tailored to MC scenarios. Using FARO-scanned MC point cloud data, we first perform learning-based semantic segmentation with PointNet, PointNet++, and Point Transformer V3 in both transfer-learning and training-from-scratch settings, and then integrate geometry-driven post-processing for quantitative measurement. The proposed framework supports a range of measurement tasks, including room-level dimensional measurement, evaluation of wall verticality and orthogonality, analysis of ceiling/floor elevation range, window size measurement, and wall surface flatness assessment. Experiments demonstrate practical accuracy for room-scale measurements and effective localization of non-conforming regions in flatness maps, enabling tolerance-based decision-making.

Limitations mainly stem from the current dataset scale and the difficulty of segmenting extremely sparse classes. Future work will expand the dataset, improve robustness to long-tailed class distributions and occlusions, and extend the framework to additional MC geometric-measurement items, such as opening squareness, door/window verticality, and geometric measurements of embedded components (e.g., their dimensions and locations), with more comprehensive validation against industrial standards.

Abstract -

Crack segmentation is a critical yet challenging task in structural health monitoring, as cracks typically appear as thin, low-contrast structures that are easily confounded by complex background textures. Although recent deep learning methods have substantially improved crack segmentation accuracy in conventional RGB imagery, they often overfit dataset-specific textures, resulting in poor cross-domain generalization. As an alternative, RGB-D methods provide complementary geometric cues but are limited by costly and imperfect depth sensors. To address these limitations, we propose the Dual-Stream Spectral-Spatial State Space Network (DS4Net), a hardware-free framework that injects pseudo-depth priors estimated by a frozen depth foundation model into crack segmentation. First, instead of physical depth, we introduce a Pseudo-Depth Injection strategy driven by the zero-shot capability of Depth Anything V2, effectively transferring universal geometric priors to the crack segmentation task. Second, to resolve the conflict between global topology and local edge sharpness, we design a Dual-Path Frequency-Mamba (DFM) Block. It synergizes the linear complexity of State Space Models (Mamba) for long-range dependency modeling with a Fast Fourier Transform (FFT) branch that explicitly enhances high-frequency edge details in the spectral domain. Third, to handle cross-modal distribution discrepancy and varying modality reliability, we propose an Information-Theoretic KL-Gating mechanism, which uses Kullback-Leibler divergence to adaptively weight RGB and pseudo-depth features, thereby suppressing unreliable signals and promoting more informative cues. Experimental results show that DS4Net outperforms state-of-the-art RGB and RGB-D methods in both in-domain and cross-domain settings.

Keywords -

Crack segmentation; Pseudo-depth injection; Multimodal fusion; Visual state space model; Domain generalization

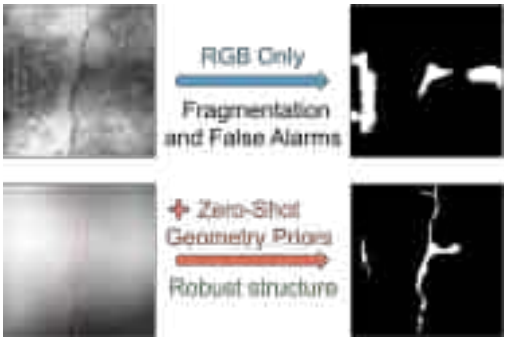

Figure 1. **Motivation**. RGB-only crack segmentation is vulnerable to environmental noise and domain shifts, causing fragmented masks and false alarms. In contrast, pseudo-depth estimated by a depth foundation model reveals more stable geometric crack structures. By injecting such zero-shot geometric priors, DS4Net achieves robust segmentation without auxiliary sensors.

1 Introduction

Critical infrastructure, such as bridges, tunnels, and pavement systems, faces an accelerating aging crisis globally. As the earliest and most prevalent symptom of structural degradation, surface cracks serve as vital indicators for Structural Health Monitoring (SHM)[1]. Traditionally, crack inspection relied on manual visual assessments, which are labor-intensive, subjective, and often hazardous [2]. In recent years, the rapid advancement of deep learning has revolutionized this field, enabling automated pixel-level crack segmentation. State-of-the-art methods, ranging from Convolutional Neural Networks (CNNs) [3, 4] to recent Vision Transformers (ViTs) [5] and State Space Models (SSMs/Mamba) [6, 7], have achieved impressive performance on standard benchmarks.

Despite these advancements, a fundamental bottleneck remains: most existing approaches rely exclusively on the RGB modality. While effective in controlled environments, purely RGB-based models suffer from inherent visual ambiguity in complex, real-world scenarios [8]. Cracks, characterized by low pixel intensity, are often visually indistinguishable from shadows, oil stains, water spots, and dark aggregate textures. This ambiguity leads to two critical issues: (1) In-domain precision loss: Even within standard datasets, models frequently generate false positives in cluttered regions (e.g., mistaking a tire mark for a crack) or fail to detect fine cracks in low-light areas. (2) Cross-domain generalization failure: RGB models tend to overfit to the color distributions and textures of the training domain (e.g., asphalt), leading to severe performance degradation when transferred to unseen materials (e.g., concrete) or varying lighting conditions. This suggests

that relying solely on appearance cues is insufficient for robust and precise segmentation. As shown in Fig 1, under cross-domain settings and challenging illumination, RGB-only crack segmenters often yield fragmented masks and false alarms.

In principle, integrating depth information can resolve this ambiguity, as cracks represent physical geometric discontinuities that are invariant to illumination and surface texture. However, the adoption of RGB-D fusion has been hindered by a practical hardware paradox. High-precision sensors such as LiDAR are prohibitively expensive for large-scale deployment, while consumer-grade depth cameras often suffer from limited resolution and sensor-camera misalignment, introducing artifacts that impair boundary segmentation [9]. Fortunately, the emergence of Vision Foundation Models, such as Depth Anything V2[10], offers a paradigm shift. Trained on massive-scale data, these models possess strong zero-shot capability to estimate fine-grained geometric structures from single RGB images. This presents a unique opportunity: **can we distill these universal, hardware-free geometric priors to improve both the accuracy and robustness of crack segmentation?** Indeed, Fig 1 suggests that pseudo-depth predicted by Depth Anything V2 highlights a more stable crack structure than RGB, making it a promising source of geometric priors for robust segmentation.

To harness this potential, we propose the Dual-Stream Spectral-Spatial State Space Network (DS4Net), a novel framework that synergizes geometric priors with efficient structural modeling. Our approach addresses two key technical challenges. First, simply concatenating RGB and pseudo-depth features is suboptimal due to their distinct characteristics: RGB contains rich texture details but high noise, while pseudo-depth offers clean structure but may lack high-frequency edge sharpness. To resolve this, we design the Dual-Path Frequency-Mamba (DFM) Block. This module combines the linear complexity of State Space Models (Mamba) for modeling long-range crack topology with a Fast Fourier Transform (FFT) branch that enhances high-frequency signals in the spectral domain, preserving fine crack edges. Second, to handle the dynamic reliability of the two modalities (e.g., RGB is unreliable in shadows; pseudo-depth is unreliable on flat markings), we introduce an Information-Theoretic KL-Gating mechanism. By dynamically measuring the Kullback-Leibler divergence between feature distributions, the network adaptively re-weights fusion, suppressing unreliable modality cues and prioritizing the more informative modality under challenging conditions.

The main contributions of this work are summarized as follows:

- We propose a hardware-free RGB-D segmentation framework that leverages zero-shot geometric priors from Foundation Models (Depth Anything V2), significantly enhancing robustness without the cost of physical sensors.
- We design the DFM Block, a hybrid unit that integrates the global modeling capability of Mamba with spectral-domain learning (FFT). This design effectively balances long-range crack connectivity with local boundary precision.
- We introduce an Information-Theoretic KL-Gating mechanism that dynamically regulates multimodal fusion based on distributional divergence.
- Extensive experiments demonstrate that DS4Net achieves State-of-the-Art (SOTA) results on standard benchmarks and exhibits superior robustness in cross-domain scenarios compared to existing CNN, Transformer, and RGB-D-based methods.

2 Related Work

2.1 Crack Segmentation using deep learning methods

Deep learning has shifted crack segmentation from handcrafted pipelines to pixel-level prediction using CNN and Transformer models. CNN approaches such as FCN [11], U-Net [3], DeepLabV3+ [4], and DeepCrack [12] learn strong local cues but may produce fragmented masks for long curvilinear cracks under occlusion or low contrast. Transformer designs such as CrackFormer [13] and SCDeepLab [2] improve connectivity via self-attention, yet their computational and memory costs hinder large-scale training and edge deployment. Both paradigms rely mainly on RGB appearance, making them sensitive to illumination changes and background clutter such as shadows, oil stains, water marks, and patch repairs, which limits cross-domain generalization and motivates the use of complementary cues beyond photometric appearance.

2.2 Visual State Space Models

Visual State Space Models, abbreviated as VSSMs, offer a linear-time alternative to self-attention, capturing global context through selective scanning [14, 15]. Vision adaptations such as VMamba [6] extend selective scanning to multidirectional two-dimensional passes and have been integrated into encoder-decoder segmenters such as U-Mamba [16] and VM-UNet [17] to improve the accuracy-efficiency balance in dense prediction. For crack segmentation, CrackMamba [7] and SCSegamba [18] adapt serialization and scanning to curvilinear topology, improving long-range continuity while remaining more deployment-friendly than Transformers. Nonetheless, existing VSSM-based pipelines operate mainly in the spatial domain and may under-represent high-frequency boundaries of extremely thin cracks, motivating explicit frequency cues.

2.3 Foundation Models for Geometry Estimation

Monocular depth estimation has evolved from supervised learning on scarce RGB-depth pairs to foundation models that learn transferable geometric priors from diverse data. MiDaS [19] improves cross-dataset generalization via mixed-domain training, while foundation depth models further strengthen zero-shot transfer. Depth Anything V2 [10] improves fine-detail recovery through synthetic-to-real distillation, helping resolve thin structural discontinuities. These priors enable hardware-free pseudo-depth for crack inspection without costly RGB-D sensors such as LiDAR [20] or active depth cameras [9], improving robustness and cross-domain generalization.

2.4 Multi-modal Fusion and Frequency Domain Learning

Frequency-domain learning uses the Fast Fourier Transform (FFT) to emphasize high-frequency edges while decoupling low-frequency illumination, benefiting crack segmentation dominated by thin boundaries [21]. Yet frequency cues are rarely integrated with VSSM or Mamba encoders, leaving the combination of linear-complexity topology modeling and explicit edge enhancement underexplored. Meanwhile, RGB and depth priors are often fused by concatenation, summation, or cross-attention [22, 8], but such designs assume both modalities are reliable, even though RGB suffers from shadows and stains and pseudo-depth fails on textureless or reflective surfaces. Measuring cross-modal distributional discrepancy can adaptively weight modalities for robust inspection.

Recent works introduce multimodal cues or frequency analysis for crack segmentation to improve robustness and boundary quality [22, 8, 21]. However, multimodal systems often require extra sensors, while VSSM or frequency designs still rely mainly on RGB. Moreover, spatial token mixing alone fails to explicitly preserve high-frequency edges. To bridge this gap, we transfer foundation depth priors, combine VSSM global modeling with spectral enhancement, and use discrepancy-aware gating to weight modalities, enabling robust crack segmentation.

3 The Proposed DS4Net

3.1 Overview of DS4Net

We propose the **Dual-Stream Spectral-Spatial State Space Network (DS4Net)** to achieve robust crack segmentation without physical depth sensors. The overall architecture of DS4Net is depicted in Fig 2. The architecture follows a hierarchical encoder-decoder design driven by two parallel streams: the RGB Stream (processing texture) and the Pseudo-Depth Stream (processing geometry injected from the frozen Depth Anything V2 foundation model). To effectively fuse these heterogeneous modalities, we introduce two key components at each encoder stage: the **Dual-Path Frequency-Mamba (DFM) Block** for intra-modal feature refinement, and the **Information-Theoretic KL-Gating** for inter-modal adaptive fusion.

3.2 Dual-Path Frequency-Mamba (DFM) Block

Cracks exhibit a unique dual characteristic: they possess global topological continuity but define their presence through high-frequency local edges. To capture these complementary cues, the DFM Block processes the pre-fused feature through two parallel branches: a spatial Mamba branch for modeling long-range topological dependencies and a spectral attention branch for enhancing high-frequency boundary cues. The outputs of both branches are then concatenated and fused by a 1×1 convolution.

3.2.1 Spatial Mamba Branch

We employ the Visual State Space (VSS) module based on the Mamba [14] architecture to capture long-range dependencies with linear complexity $O(N)$. This branch ensures that the connectivity of cracks is preserved even when partially occluded. Since the implementation follows standard SS2D scanning mechanisms [6], we omit the details here for brevity.

3.2.2 Learnable Spectral Attention Branch

Standard convolutions often struggle to decouple high-frequency crack details from low-frequency background variations, such as illumination gradients. We propose a **Learnable Spectral Attention** mechanism to explicitly filter spectral components.

Let $X \in \mathbb{R}^{H\times W\times C}$ be the input feature map. We first transform it to the frequency domain via 2D Fast Fourier Transform (FFT):

$$F(X) = \mathrm{FFT}(X) \in \mathbb{C}^{H\times W\times C} \tag{1}$$

We decouple the complex spectrum into Amplitude $\mathcal{A}(X)$ and Phase $\mathcal{P}(X)$ components:

$$\mathcal{A}(X) = |F(X)|, \quad \mathcal{P}(X) = \angle F(X) \tag{2}$$

To adaptively highlight crack-sensitive frequencies, we employ a channel-wise attention mechanism in the spectral domain. We first aggregate spectral statistics using both Average Pooling and Max Pooling along the channel dimension, followed by a 7×7 convolution layer to generate the attention masks. Formally, the Amplitude Attention Map $M_{\mathcal{A}}$ is computed as:

$$M_{\mathcal{A}} = \sigma\left(\mathrm{Conv}_{7\times 7}\left([\mathrm{AvgPool}_c(\mathcal{A}); \mathrm{MaxPool}_c(\mathcal{A})]\right)\right) \tag{3}$$

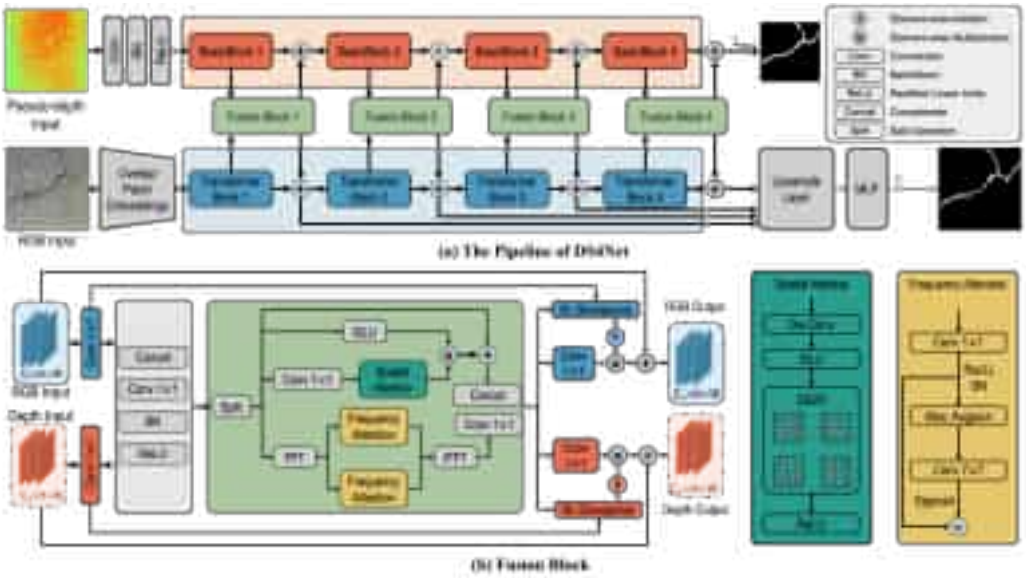

Figure 2. (a) Architecture of the proposed DS4Net, including a dual-stream encoder–decoder with an RGB stream and a pseudo-depth stream generated by a frozen depth foundation model. (b) The fusion block integrates the Dual-Path Frequency-Mamba (DFM) module for spectral–spatial refinement and employs KL-Gating to adaptively reweight cross-modal fusion.

Similarly, the Phase Attention Map $M_{\mathcal{P}}$ is computed as:

$$M_{\mathcal{P}} = \sigma\left(\text{Conv}_{7\times7}\left([\text{AvgPool}_c(\mathcal{P}); \text{MaxPool}_c(\mathcal{P})]\right)\right) \tag{4}$$

where $[\cdot;\cdot]$ denotes concatenation along the channel dimension, and σ is the Sigmoid activation function. These masks effectively learn to suppress background noise in the amplitude spectrum while preserving structural cues in the phase spectrum. The modulated features are reconstructed via Inverse FFT:

$$X_{freq} = \text{IFFT}\left((\mathcal{A}(X) \odot M_{\mathcal{A}}) \cdot e^{j(\mathcal{P}(X)\odot M_{\mathcal{P}})}\right) \tag{5}$$

This branch acts as a frequency-domain high-pass filter, explicitly sharpening crack boundaries before fusion with the parallel Mamba branch.

3.3 Information-Theoretic KL-Gating

Simply adding or concatenating RGB and Pseudo-Depth features assumes both modalities are equally reliable. However, in real-world scenarios, one modality may fail (e.g., RGB in shadows, Depth on flat stains). To address this, we propose an **Information-Theoretic Gating** mechanism that dynamically assesses the "Information Gain" of each modality at the image level.

3.3.1 Global Distribution Modeling

We interpret the feature channels as a semantic probability distribution. Let $F_{rgb}, F_{depth} \in \mathbb{R}^{B\times C\times H\times W}$ be the features from the two branches, while F_{mamba} represents the intermediate feature processed by the Mamba fusion block that serves as a context-aware consensus.

To capture the **holistic reliability**, we first apply Global Average Pooling (GAP) to compress the spatial dimensions, followed by a Softmax normalization along the channel dimension:

$$p_k = \text{Softmax}(\text{GAP}(F_k)), \quad k \in \{rgb, depth, mamba\} \tag{6}$$

where $p_k \in \mathbb{R}^{B\times C}$ represents the global channel activation distribution of modality k.

3.3.2 Divergence-Based Weight Generation

We employ the **Kullback-Leibler (KL) Divergence** [23] to measure how much unique information each modality contributes relative to the fusion consensus (p_{mamba}). A higher divergence implies that the modality contains distinct, potentially complementary information that the current consensus lacks.

$$D_{KL}(p_k||p_{mamba}) = \sum_{c=1}^{C} p_k^c \log \frac{p_k^c}{p_{mamba}^c + \epsilon} \tag{7}$$

This yields a scalar reliability score for each modality. The final fusion weights α_{rgb} and β_{depth} are generated by normalizing these divergence scores:

$$[\alpha_{rgb}, \beta_{depth}] = \text{Softmax}([D_{KL}(rgb), D_{KL}(depth)]) \tag{8}$$

3.3.3 Residual Injection

Finally, the fused features are dynamically re-weighted and injected back into the main streams via residual connections:

$$F_{out}^{rgb} = F_{in}^{rgb} + \alpha_{rgb} \cdot \Psi(F_{mamba}) \quad (9)$$

$$F_{out}^{depth} = F_{in}^{depth} + \beta_{depth} \cdot \Psi(F_{mamba}) \quad (10)$$

where Ψ denotes a projection layer (implemented as 1×1 convolution). This mechanism allows the network to prioritize the modality with higher information value for the current scene, achieving **Sample-Adaptive Fusion**.

4 Experiments and Results

4.1 Dataset

We evaluate DS4Net on a public RGB-T asphalt pavement crack segmentation benchmark [22], which provides RGB images and pixel-wise crack annotations. The benchmark contains 448 images with a resolution of 640×480, and we follow the standard split of 358 images for training and 90 images for testing using a predefined random seed to guarantee experimental consistency and reproducibility. To construct RGB-D inputs without additional sensing hardware, we employ Depth Anything V2 [10] to generate a pseudo-depth map for each RGB image, producing aligned RGB-D pairs for both training and evaluation.

To further assess cross-domain robustness, we additionally introduce the TUT dataset [24] as an unseen test set. Unlike the relatively structured benchmark, TUT features dense and cluttered backgrounds and cracks with more elaborate, intricate geometries, which better reflects challenging real-world conditions. It contains 1,408 RGB images covering diverse materials, backgrounds, and surface conditions; in our experiments, it is used exclusively for cross-domain testing without any fine-tuning.

4.2 Implementation Details

To enhance the diversity of the training data and improve the model's robustness, spatial, color, and numerical transformations were applied to the training set, such as random horizontal or vertical flips in spatial, randomly altering brightness or contrast in color. For images in the validation set, only resizing to 480×480 pixels and normalization processes were applied. The proposed DS4Net was implemented using the PyTorch framework and optimized with AdamW, incorporating a weight decay of 1e-4. A batch size of 8 and 150 training epochs were designated for training. All experiments were performed on an NVIDIA GeForce RTX 4090 for training and testing.

4.3 Evaluation Metrics

To accurately and objectively evaluate the performance of various models, we employed four widely used evaluation metrics in image segmentation: Dice, IoU (Intersection over Union), Accuracy and Precision [25]. Higher values for these metrics indicate superior segmentation performance. Simultaneously, these metrics are also used as the evaluation criteria for the RGB-D asphalt pavement crack segmentation benchmark.

4.4 Comparison with State-of-the-Art Methods

To validate the effectiveness of DS4Net, we compared it with nine representative methods on the Infrared dataset. Specifically, U-Net[3], DeepLabV3[4], DeepCrack[12], and CrackFormer[13] rely only on RGB inputs. In contrast, CRM_RGBT_Seg[26], PotCrackSeg, Evi-RoadSeg, CMNeXt[27], and IRFusionFormer take both RGB and depth images as inputs. Quantitative results are summarized in Table 1 and Table 2. Table 1 reports in-domain performance on the benchmark test set, whereas Table 2 evaluates cross-domain generalization on TUT. Qualitative visualizations are provided in Fig 3.

Table 1. In-domain quantitative comparison on the Infrared dataset. The best results are highlighted in **bold**, and the second-best results are underlined.

Model	Type	Dice ↑	IoU ↑	Acc. ↑	Prec. ↑
Unet	RGB	0.7890	0.6515	0.9794	0.8160
DeepLabV3	RGB	0.8337	0.7149	0.9828	0.8133
DeepCrack	RGB	0.8211	0.6964	0.9831	0.8806
CrackFormer	RGB	0.8487	0.7372	0.9847	0.8458
CRM_RGBTSeg	RGB-D	0.8391	0.7286	0.9809	0.8311
PotCrackSeg	RGB-D	0.8220	0.6978	0.8222	0.8109
Evi-RoadSeg	RGB-D	0.8380	0.7212	0.9775	0.8172
CMNeXt	RGB-D	0.8589	0.7527	0.9808	0.8565
IRFusionFormer	RGB-D	0.8795	0.7850	0.9879	0.8808
Ours	**RGB-D**	**0.8982**	**0.8152**	**0.9898**	**0.9053**

Results on in-domain setting. Table 1 shows that DS4Net delivers the best performance across all four metrics, achieving a Dice score of 0.8982 and an IoU of 0.8152. It substantially outperforms the strongest RGB-only baseline, CrackFormer, with Dice and IoU of 0.8487 and 0.7372, as well as the best RGB-D competitor, IRFusionFormer, with corresponding values of 0.8795 and 0.7850. DS4Net also improves accuracy and precision, suggesting more reliable crack delineation under in-domain setting.

Results on cross-domain setting. As shown in Table 2, DS4Net achieves the strongest cross-domain performance on TUT, attaining the highest Dice score of 0.6806, IoU of 0.5158, and accuracy of 0.9790. Although some methods yield higher precision under domain shift, such as PotCrackSeg, DS4Net maintains strong precision at

Table 2. Cross-domain generalization on the TUT dataset (trained on the Infrared dataset, tested on TUT without fine-tuning). The best results are highlighted in **bold**, and the second-best results are underlined.

Model	Type	Dice ↑	IoU ↑	Acc. ↑	Prec. ↑
Unet	RGB	0.3012	0.1773	0.9507	0.2729
DeepLabV3	RGB	0.3594	0.2191	0.9534	0.3180
DeepCrack	RGB	0.5231	0.3542	0.9687	0.5044
CrackFormer	RGB	0.4694	0.3067	0.9512	0.3576
CRM_RGBTSeg	RGB-D	0.5471	0.4095	0.9466	0.4743
PotCrackSeg	RGB-D	0.3118	0.1847	0.4721	**0.7472**

IRFusionFormer	RGB-D	0.5340	0.3643	0.9654	0.4648
Ours	**RGB-D**	**0.6806**	**0.5158**	**0.9790**	0.6545

0.6545 while substantially improving overlap-based metrics, which indicates more complete and consistent crack segmentation in cluttered scenes. A category-wise analysis on TUT indicates that DS4Net performs best on the road category, with a Dice score of 0.7158, while alternator, weld, and pipeline remain more challenging, with Dice scores of 0.4895, 0.5398, and 0.5488, respectively.

4.5 Ablation Study

Our DS4Net comprises two core components, the DFM block and the information theoretic KL-Gating mechanism. Accordingly, we conduct ablation studies to assess the contribution of each component under both in-domain and cross-domain settings.

Ablation protocol. We construct three variants by progressively enabling the proposed components while maintaining an identical SegFormer backbone, training schedule, and evaluation protocol. DS4Net (Backbone) denotes an RGB-only baseline that excludes the depth branch and RGB-D fusion, and is used as the reference model. DS4Net (Fixed) introduces the pseudo-depth branch and DFM fusion, but replaces adaptive gating with fixed late fusion, in which RGB and depth features are combined with constant weights of 0.5 and 0.5 at each fusion site. DS4Net (without KL-G) further employs the proposed gating network, but removes KL-based discrepancy supervision, such that the gating is learned solely from the segmentation objective. DS4Net (Full) uses the complete design, incorporating pseudo-depth priors, DFM fusion, and KL-Gating together with KL-based regularization.

Ablation analysis across settings. Quantitative comparisons in Tables 3 and 4, reported using Dice, IoU, Accuracy and Precision, show that incorporating depth cues and fusion improves upon the RGB-only backbone. However, fixed-weight fusion becomes suboptimal when modality reliability varies across spatial locations. Moreover, removing the KL loss consistently degrades performance relative to the full model, which indicates that KL-based discrepancy supervision is critical for learning robust, sample-adaptive fusion and for maintaining stable segmentation quality under domain shift.

Table 3. Ablation study of the proposed components on the Infrared dataset (in-domain). The best results are highlighted in **bold**, and the second-best results are underlined.

Model	Dice ↑	IoU ↑	Acc. ↑	Prec. ↑
DS4Net (Backbone)	0.8518	0.7419	0.9839	0.7939
DS4Net (Fixed)	0.8834	0.7911	0.9885	0.9003
DS4Net (without KL-G)	0.8858	0.7950	0.9886	0.8916
DS4Net (Full)	**0.8982**	**0.8152**	**0.9898**	**0.9053**

Table 4. Cross-domain ablation study on the TUT dataset (trained on the Infrared dataset). All models are trained on the Infrared dataset. The best results are highlighted in **bold**, and the second-best results are underlined.

Model	Dice ↑	IoU ↑	Acc. ↑	Prec. ↑
DS4Net (Backbone)	0.5126	0.3446	0.9580	0.4048
DS4Net (Fixed)	0.6536	0.4855	0.9778	0.6452
DS4Net (w/o KL-G)	0.6669	0.5003	0.9765	0.6046
DS4Net (Full)	**0.6806**	**0.5158**	**0.9790**	**0.6545**

5 Conclusion

This paper presented DS4Net, a hardware-free dual-stream framework for robust crack segmentation that integrates foundation-model geometric priors with efficient spectral–spatial modeling. By injecting pseudo-depth generated from a frozen depth foundation model, DS4Net augments RGB appearance with geometry-aware cues without requiring additional sensing devices. To reconcile the inherent conflict between global crack continuity and local boundary sharpness, we introduced the Dual-Path Frequency-Mamba (DFM) block, which combines linear-complexity state space modeling for long-range topology with an FFT-based spectral attention branch that explicitly strengthens high-frequency edge details. Furthermore, we proposed an information-theoretic KL-Gating mechanism to dynamically regulate cross-modal fusion, enabling the network to suppress unreliable modality signals and emphasize the more informative modality under challenging conditions.

Extensive evaluations on the in-domain benchmark and cross-domain TUT dataset demonstrated that DS4Net achieves state-of-the-art performance and substantially improves generalization under domain shift. Ablation studies further verified the effectiveness of both the DFM block

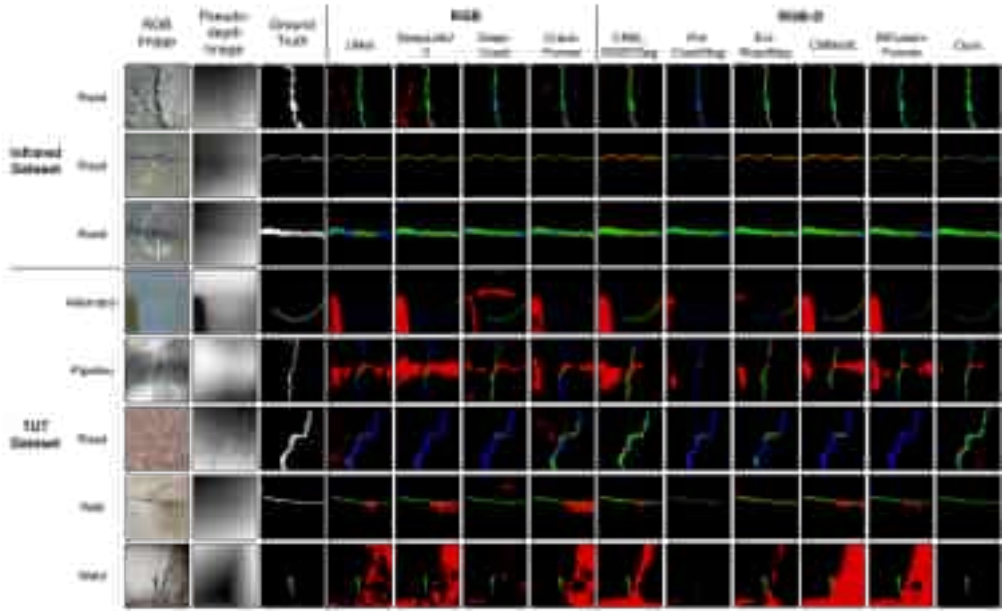

Figure 3. Qualitative results on in-domain and cross-domain scenes. Columns show RGB input, pseudo-depth prior, ground truth, and predictions. Error maps denote TP (green), FP (red), and FN (blue). DS4Net yields more continuous masks with fewer false alarms under noise and domain shift.

and KL-guided adaptive fusion, showing consistent gains when each component is enabled. In future work, we plan to further improve pseudo-depth robustness in textureless, reflective, and low-contrast scenarios, where modality reliability may degrade, explore lightweight designs for real-time edge deployment, and extend the proposed sensor-free paradigm to broader surface-defect segmentation tasks in large-scale infrastructure inspection.

Abstract –

Falls from height (FFH) remain a leading cause of construction injuries and fatalities, necessitating proactive Design-for-Safety (DfS) approaches. While Building Information Modeling (BIM) facilitates safety checks, existing Automated Rule Checking (ARC) models rely on rigid, manual rule-coding and lack the spatial reasoning required to interpret complex safety regulations. This paper proposes a Retrieval-Augmented Generation (RAG) Large Language Model (LLM) pipeline integrated with BIM for automated FFH identification and prevention. The methodology incorporates a domain-specific ontology that maps unstructured regulatory constraints to BIM geometry, enabling the precise detection of spatial hazards. Additionally, the system automates the placement of preventive measures, such as Occupational Safety and Health Administration (OSHA)-compliant guardrails, directly within the design model. By bridging the gap between semantic regulatory interpretation and geometric analysis, this approach overcomes the spatial limitations of current LLM-BIM frameworks, empowering designers to eliminate fall hazards early in the project design.

Keywords –

Retrieval augmented generation; Large language models; Building information modeling; Automated rule checking; Design for Safety; Fall hazards

1 Introduction

The construction industry remains the most hazardous sector worldwide, despite safety improvements, legislation, and technological advancements [1]. Falls from height (FFH) are the leading cause of severe injuries and fatalities at construction sites [2]. Research shows that over 50% of construction accidents stem from design decisions [3], and 60-90% can be prevented through decisions made during the design phase [4]. Consequently, there is a growing shift from reactive, site-based safety management to proactive Design-for-Safety (DfS) approaches that eliminate hazards before construction begins [5].

Building Information Modeling (BIM) offers an effective platform to implement DfS principles by enabling designers to visualize construction scenarios and identify spatial risks [6]. However, current BIM-based safety tools have key limitations, such as high initial costs and interoperability issues between software. It also relies on manual expertise, and designers lack safety knowledge. Similarly, Automated Rule-Checking (ARC) systems use rigid, manually created rules [7]. ARC systems can assess BIM models against safety requirements, but converting safety regulations from natural language to computer code requires extensive programming expertise and regular updates [8]. Furthermore, fall hazard identification is particularly challenging as regulations involve context-based judgments and semantic understanding. Terms like "unprotected edges" and "openings" are difficult to define in traditional logic-based systems. As a result, most existing ARC systems function primarily as post-design compliance checkers rather than adaptive decision-support tools.

Recent advances in Artificial Intelligence (AI), particularly Large Language Models (LLMs), offer new opportunities to address these challenges. LLMs can process complex regulatory texts and, when combined with Retrieval-Augmented Generation (RAG), dynamically reference safety standards. Studies have demonstrated the potential of LLM-based approaches for code compliance and rule extraction [9]. However, existing studies largely frame safety as a general management problem, focusing on guidance generation and inspections rather than specific prevention mechanisms. Current LLM approaches lack spatial reasoning capabilities and cannot accurately identify fall

hazards within building geometry without deep BIM integration. Consequently, FFH regulations, which rely heavily on spatial dependencies, remain inadequately addressed by existing AI-driven frameworks.

To bridge the gap between unstructured regulations and spatial hazard analysis, this paper proposes a RAG-LLM-augmented BIM pipeline for the automated identification and prevention of fall hazards in building design. The approach uses LLMs to interpret safety regulations and connects regulatory logic with BIM geometry to enable automated hazard analysis. By reducing manual rules encoding and providing early safety feedback, this method advances DfS and BIM-based safety automation.

2 Literature review

2.1 Embedding DfS rules in BIM

BIM serves as an effective platform for operationalizing DfS principles through its representation of geometric, semantic, and spatial information. Early research emphasized visualization and coordination for safety planning, while later studies explored embedding DfS knowledge to enable systematic hazard detection and prevention. Advanced implementations utilize rule-based reasoning engines to evaluate designs against encoded safety requirements. Safety ontologies further strengthen these systems by formalizing relationships between building components and risk categories [10]. Despite advances, embedding DfS into BIM faces limitations due to fragmented safety knowledge and rigid rule representations [11]. Most rule libraries are difficult to update or adapt across jurisdictions. Moreover, safety requirements are context-dependent, influenced by construction methods and temporary conditions, and are inadequately represented in static BIM models. Consequently, existing systems function primarily as post-design compliance checkers rather than adaptive decision-support tools.

2.2 Automated rule checking systems

ARC systematically evaluates BIM models against regulations using frameworks like CORENET X, FORNAX™, and Solibri Model Checker (SMC). Various studies have developed specific rule-checking algorithms for fall protection, job hazard analysis, and temporary structure assessment. Others have employed ontology-based schemas and voxelization techniques to enhance hazard detection. However, ARC effectiveness is constrained by reliance on manual rule creation, which requires domain expertise and programming skills. This dependency limits scalability, particularly for regulations involving qualitative descriptions. Fall protection requirements, such as identifying "exposed edges," demand spatial and contextual understanding beyond logic-based models. The gap between unstructured natural language regulations and computational rules highlights the need for adaptive compliance verification methods.

2.3 LLM-Enhanced Compliance Checking

LLMs present a transformative solution to current ARC limitations. Their Natural Language Processing (NLP) capabilities allow for the interpretation of regulatory text and the creation of machine-readable formats without manual coding. When combined with RAG, LLMs can dynamically reference authoritative sources to ensure accuracy. Recent research demonstrates the potential of LLMs in this domain. Zheng et al. [12] and Madireddy et al. [13] developed frameworks for interpreting building codes and checking compliance. Chen et al. [14] and Du et al. [15] focused on rule extraction and code generation. Other studies have integrated knowledge graphs and visual language models to enhance safety monitoring. Despite these advancements, existing studies largely frame safety as a general management and inspection problem. A critical limitation is that current LLM approaches lack spatial reasoning capabilities and cannot accurately identify fall hazards without deep BIM integration. Consequently, FFH regulations involving implicit spatial dependencies remain inadequately addressed. This paper proposes a RAG-LLM-augmented BIM framework to bridge this gap by aligning semantic interpretation with BIM geometry for automated hazard prevention in building design.

3 Methodology

This study proposes a RAG-LLM-augmented BIM pipeline to integrate DfS principles into early design stages. As illustrated in Figure 1, the framework formally bridges regulatory knowledge and BIM geometry through a domain-specific ontology. The workflow proceeds through five integrated phases: (1) collection of fall hazard rules and regulations; (2) fall hazard ontology development; (3) automated fall hazard identification and visualization; (4) rule-based fall prevention via OSHA-compliant guardrail generation; and (5) an intelligent advisory layer powered by RAG-LLM reasoning to provide context-aware safety decision support. The proposed framework employs deterministic, rule-based methods for fall hazard detection and guardrail generation to ensure reliable safety compliance, while the RAG-LLM component serves as an advisory layer providing regulatory knowledge and contextual guidance for user decision-making rather than directly generating geometric elements.

3.1 Fall hazard rules and regulations

To standardize safety requirements, this study analyzed fall hazard regulations from Hong Kong's Labour Department and China's Ministry of Housing and Urban-Rural Development (MOHURD), classifying hazards into three categories: elevated works, openings, and access-related works (Table 1). Although numerous FFH rules exist, this study considered only those predefined in the BIM model, as they can be applied effectively.

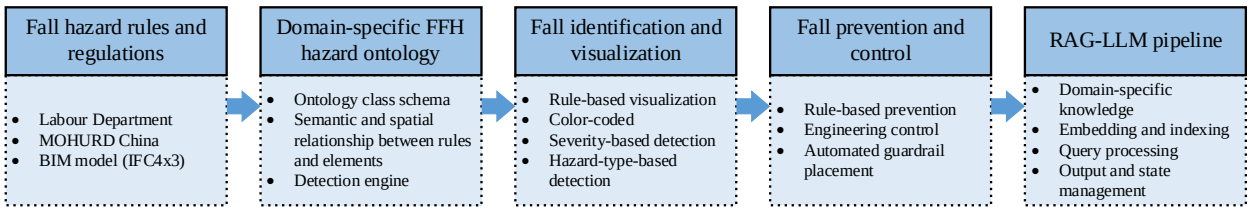

Figure 1. Overview of research methodology.

Table 1. Fall hazard rules and regulations.

Fall hazard category	Specific type	Definition	Threshold (mm)	Regulation
Elevated work hazards	Falls from height	Risk of falling from elevated work areas	≥ 2000	JGJ80-2016
	Unprotected sides and edges	Edges of floors, roofs, or platforms without fall protection	≥ 1800	Reg. 38B, CSSR Part VA
Opening hazards	Floor openings (Horizontal)	Uncovered holes or openings in floors	≥ 500	GB10000-88
	Wall openings (Vertical)	Uncovered holes or openings in walls	≥ 500	GB10000-88
Access hazards	Stairways	Use of stairways without adequate safety measures	≥ 760	Reg. 38C-F, CSSR Part VA

3.2 Fall hazard ontology development

This study uses an ontology-based approach to represent regulatory knowledge and establish semantic and spatial relationships between FFH rules and BIM elements, enabling automated reasoning. A domain-specific ontology was developed through regulatory analysis, BIM-IFC mapping, and rule-based spatial-logic encoding.

By mapping fall hazards to IFC entities (e.g., IfcSlab, IfcOpeningElement, IfcStair), semantic relationships were established through IFC property sets, aggregation hierarchies, and filling relationships. Spatial relationships were derived from bounding-box analysis and perimeter-edge detection. The ontology defines these hazard classes and executes detection through a ten-stage pipeline: IFC file loading, geometry extraction, unit normalization, opening classification, protection analysis, edge detection, stair-railing spatial analysis, threshold comparison, severity assignment, and result export. The pipeline generated JSON output containing OntologyID, SpecificHazard, DetectedValue_mm, Threshold_mm, Severity, Location coordinates, ElementContext, and Notes, supporting visualization, prevention planning, and LLM-based reasoning.

3.3 Fall identification and visualization

The fall hazard identification workflow comprises three steps: data parsing, IFC coloring, and report generation. This approach integrates ontology-driven hazard data (stored in JSON) with the IFC model to produce a color-enriched representation that enables intuitive interpretation of fall risks during design review and construction planning.

First, the hazard visualization controller processes input JSON files containing semantic and geometric attributes, including hazard type, severity, and spatial location. Second, the IFC-based colorizer embeds hazard information by classifying risks by their physical and representational characteristics within IFC. Element-based hazards (e.g., slabs, walls) are visualized through surface styles, while void-based hazards (e.g., floor

openings) are represented using proxy-based 3D markers. Finally, hazard integration is executed using IfcOpenShell for hierarchical element identification. For hazards requiring independent markers, the system generates extruded geometry as IfcBuildingElementProxy objects linked to the building's spatial hierarchy. The outputs include a color-enriched IFC model and JSON and text-based reports summarizing visualization success rates, hazard distributions, marker creation statistics, and IFC-based coloring limitations. These outputs support visual inspection and systematic assessment of fall hazards, meeting automation-focused construction research requirements.

3.4 Fall prevention

Following FFH identification and visualization, the system prioritizes engineering controls by automatically generating OSHA-compliant guardrail systems at detected and identified hazard locations. The prevention system implements three layers: 1) data, 2) logic, and 3) output, using Python libraries: IfcOpenShell for IFC analysis, NumPy for geometric computation, and SciPy for boundary extraction. For stairways, walking edges are identified to place continuous top and mid rails at 1100 mm and 550 mm heights. For elevated slabs, a wall-aware safety classification evaluates edges, and guardrails are installed only where adjacent walls are insufficient (<1070 mm). Components are created as IfcRailing objects with safety coloring and proper storey assignment, enabling proactive BIM-based safety planning.

3.5 Integrated RAG-LLM pipeline

To address the limitations of rigid rule checking, this study proposes a RAG-LLM system that introduces a knowledge-augmented reasoning layer combining BIM hazard data with expert reasoning.

Since current LLMs struggle to interpret complex regulatory requirements outside their pretraining scope, a specialized knowledge base was developed where hazard instances are converted into regulatory standards, prevention best practices, and case-based documents. The hazard instances are structured into five fall hazard types, unprotected sides and edges, floor openings, wall openings, stairways, and FFH, which are derived from regulatory classifications (Table 1) and consistently used across the ontology development, detection, and prevention stages. These knowledge base documents are transformed into dense 384-dimensional vector representations using the *all-MiniLM-L6-v2* model and stored in an in-memory vector database for real-time access.

Upon receiving a user query, the system computed semantic relevance using cosine similarity to retrieve the top-k (k=5) documents. Subsequently, the system utilizes prompt engineering to integrate these retrieved contexts with a BIM-derived hazard summary, comprising hazard frequencies, severity distributions, and geometric measurements. The final structured prompt incorporates role-specific instructions, regulatory guidelines, best practices, case-based knowledge, BIM hazard context, conversation history, and the user query. The system interfaces with a DeepSeek-based LLM via an OpenAI-compatible API, utilizing a temperature setting of 0.7 to balance analytical precision and interpretability. By functioning as a processor of retrieved safety knowledge rather than an independent source, this architecture ensures regulatory compliance and substantially reduces the risk of hallucination during safety advisory interactions. The system maintains conversation continuity by storing user-assistant exchanges in a JSON-based history.

The system implements comprehensive monitoring for evaluation and optimization. Key performance indicators include response latency, token usage, response length, and retrieval efficiency, with data logged per query and aggregated across sessions. The evaluation framework comprises test cases covering hazard prioritization, regulatory compliance, and mitigation strategies, enabling systematic comparison of embedding models, retrieval parameters, and LLM configurations. To assess classification performance, the system utilizes confusion matrix metrics (precision, recall, and F1 score) across five fall hazard types corresponding to those in the BIM model. True Positives (TP) represent fall hazards correctly identified and categorized, False Positives (FP) indicate elements incorrectly classified as fall hazards, and False Negatives (FN) represent fall hazards in the BIM model that were either unidentified or misclassified. The metrics are defined by Eqs. (1)-(3).

$$\text{Precision} = \frac{\text{TP}}{\text{TP} + \text{FP}} \tag{1}$$

$$\text{Recall} = \frac{\text{TP}}{\text{TP} + \text{FN}} \tag{2}$$

$$\text{F1} - \text{score} = 2\text{x}\frac{\text{Precision x Recall}}{\text{Precision} + \text{Recall}} \tag{3}$$

4 Results

4.1 Fall detection engine

The system employs an ontology-driven detection engine that analyzes IFC-based BIM geometry through spatial reasoning. Fall hazards are identified using bounding box analysis, elevation stratification, proximity detection, and semantic validation of protection elements.

The ontology encodes safety regulations as machine-interpretable constraints, enabling hazard classification based on regulatory non-compliance rather than purely geometric analysis. This approach successfully detects unprotected openings, exposed edges, stair hazards, and multi-story fall risks while excluding protected elements. The results demonstrate that ontology-guided spatial logic effectively formalizes and detects fall hazards, enabling automated safety assessment during the design phase.

After running the ontology, the processing statistics showed a geometric success rate of 97.7%, with a total of 115 hazards identified. These included 75.7% elevated work hazards, 20.8% opening hazards, and 3.5% access hazards. The total processing time was 0.68 s. As illustrated in Figure 2, the total number of fall hazards was 85 for unprotected sides and edges, 16 for wall openings, 8 for floor openings, 4 for stairways, and 2 for FFH. These hazards were stored in a JSON file, and the subsequent phases, such as fall identification, fall prevention, and LLM reasoning advisory, were based on this JSON file. For fall identification, the extracted hazards were further visualized using a color-coded scheme to clearly distinguish different fall-risk categories.

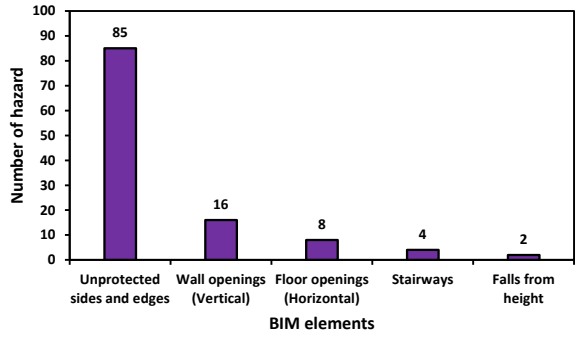

Figure 2. Element-based detection.

4.2 Fall identification and visualization

The results demonstrate that the proposed ontology-driven and BIM-based framework effectively identifies, classifies, and visualizes fall hazards in construction environments. The results support fall hazard identification through color-coded visualization, as shown in Figure 3. Each detected hazard is mapped to its corresponding IFC element or spatial location and rendered using a predefined hazard-based color scheme. Solid building components like slabs, stairways, and structural elements are colored directly, while void-related hazards (floor and wall openings) are represented using 3D markers to overcome IFC visualization limitations. This visual differentiation allows users to distinguish between unprotected edges, openings, stair-related risks, and FFH scenarios within the 3D model, transforming abstract hazard data into interpretable spatial information.

From a safety prevention perspective, the results enable proactive decision-making by making fall risks visible during design and planning stages rather than during construction. The results indicate the potential of automated hazard identification and visualization to support improved coordination and reduce reliance on manual inspections. Although these aspects are not quantitatively evaluated in this study, color-coding indicates each hazard type associated with BIM elements, allowing stakeholders to easily identify the hazard type, its location, the responsible element, and prevention measures. The color-coded BIM model provides a shared awareness platform for designers, planners, and safety officers, enabling earlier design revisions, clearer safety briefings, and informed construction sequencing. The results confirm that the proposed approach achieves accurate fall hazard identification while strengthening safety prevention strategies and supporting data-driven construction management practices.

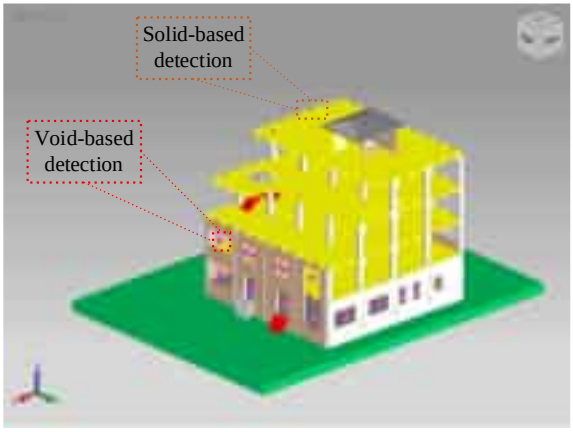

Figure 3. Rule-based fall hazard visualization.

4.3 Fall prevention

The guardrail placement demonstrates that fall prevention measures can be automatically generated and embedded into BIM models in an OSHA-compliant manner. Guardrails were placed at locations identified as unsafe or partially protected, including stair flights without railings, elevated slab perimeters, and floor openings. The placement logic evaluated existing protective elements and skipped compliant locations to avoid redundant safety

components, explaining why guardrails appear only along unprotected areas. The correctness and compliance of generated guardrails are ensured through a rule-based validation mechanism, where OSHA safety requirements, such as guardrail height, mid-rail placement, and edge protection conditions, are explicitly encoded into the system. Guardrail geometries are directly derived from these regulatory constraints, ensuring that all generated elements conform to predefined safety standards without requiring additional manual validation.

As illustrated in Figure 4, the system placed guardrails using geometric and semantic reasoning from the IFC model. For stairs, the code analyzed step geometry across elevations, identified edges, and generated continuous top and mid rails with posts at OSHA-specified spacing. For slabs, the algorithm extracted perimeter and opening loops, classified edges based on adjacent wall height relative to OSHA's 1070 mm parapet threshold, and generated guardrails where needed. Wall-aware inset logic offset guardrails to prevent clashes, reflecting constructability requirements. The results demonstrate fall prevention operationalization in construction sites. By enclosing unprotected edges, openings, and stairways with properly dimensioned guardrails, the system blocks fall paths and reduces height-related hazards. This approach translates detected risks into preventive controls, bridging hazard analysis and mitigation. The BIM integration enables safety strategy review and communication before construction.

From a management perspective, automated guardrail generation improves consistency, efficiency, and traceability. Safety measures are applied uniformly according to rules rather than manual modeling or subjective judgment, reducing missed hazards. The BIM model serves as a digital safety plan supporting inspections, method statements, and stakeholder coordination. Integration of hazard detection and prevention strengthens proactive safety management. However, these guardrail placement methods are hard-coded, rule-based, and deterministic, making them time-consuming to develop, error-prone when conditions deviate from assumptions, and difficult to generalize, motivating the need for an LLM-based approach to overcome these limitations.

Figure 4. Rule-based guardrail placement.

4.4 RAG-LLM reasoning advisor

This section evaluates the advisory and reasoning stage using confusion matrix analysis. As shown in Figure 5, a 5×5 confusion matrix assessed fall hazard classification accuracy against ontology-identified ground truth labels across five categories: unprotected edges, floor openings, wall openings, stairways, and FFH. The ground truth labels are generated through an ontology-based hazard detection process, where regulatory rules and spatial logic are explicitly encoded to deterministically classify fall hazards. These ontology-derived classifications serve as a rule-based reference for evaluating the consistency of predicted hazard categories. Strong diagonal dominance confirmed high classification consistency and validated the ontology-based hazard extraction and rule-based reasoning. Overall performance achieved precision, recall, and F1-score of 0.940 based on 113 true positives, 2 false positives, and 2 false negatives. Classification was achieved for floor openings (0.934), wall openings (0.940), and stairways (0.960), while unprotected edges (0.941) showed minimal misclassification. Compared to recent LLM-based ARC studies [13, 16], which primarily focus on regulatory text interpretation and rule extraction, the proposed approach demonstrates comparable classification performance while introducing a key advancement through integrating ontology-driven spatial reasoning with BIM geometry. Unlike prior works that treat compliance checking as a text-based or post-processing task, this framework directly links semantic regulatory understanding with geometric hazard detection and extends functionality to automated prevention (e.g., guardrail generation). This integration enables spatially grounded hazard identification and mitigation within the BIM

environment.

To evaluate practical usability, a query table (Table 2) tested structured safety-related questions about critical hazards, fall prevention recommendations, and mitigation priorities. The queries successfully retrieved hazard instances from the JSON-based repository and combined them with regulation-informed guidance from the knowledge base. This shows the system can translate visualized, color-coded fall hazards and implemented guardrail measures into actionable safety insights. Combined with previous results on automated hazard detection and preventive modeling, these findings confirm that the framework identifies and mitigates fall hazards while supporting safety decision-making and construction safety management. However, the evaluation of LLM-generated advisory responses is limited to structured query-based testing and does not include validation against expert judgment, robustness analysis under varying prompts or model parameters, or detailed error analysis. These limitations will be addressed in future work to further assess the reliability and robustness of the RAG-LLM advisory module.

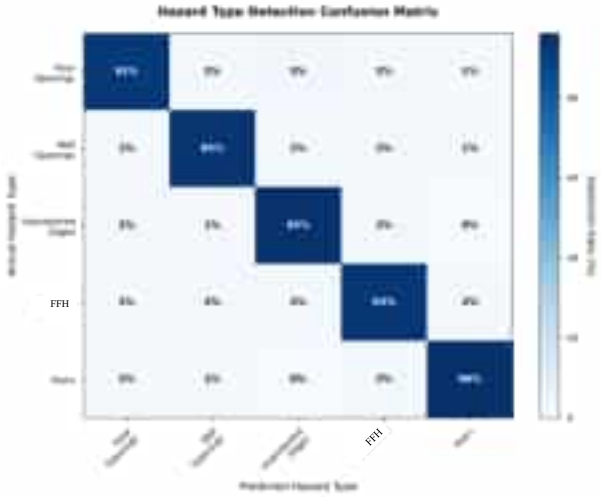

Figure 5. Confusion matrix for fall hazard classifications.

Table 2. RAG-LLM safety-related questions.

Role: How many hazards do I have? **Content**: User uploaded hazard report: 115 hazards detected.
Role: How many high-risk hazards do I have to cover? **Content**: Based on the information provided in your hazards summary, you have 75.7% elevated wor hazard. This number is specifically categorized under elevated work hazards.
Role: How do I fix slab opening hazards according to fall rules? **Content**: To address slab opening hazards in compliance with Hong Kong Labour Department and MOHURD rules, you must follow specific guidance to ensure worker safety and prevent falls through guardrails.

5 Conclusion

This study proposes a RAG-LLM-augmented BIM pipeline for automated identification and prevention of fall hazards in building design, advancing DfS beyond traditional rule-based approaches. By integrating BIM geometry with a domain-specific ontology and enhancing it through an RAG-enabled LLM, the framework bridges unstructured safety regulations and spatial building data. This integration enables precise, context-aware detection of fall hazards, like unprotected edges, floor and wall openings, and stairway risks, within BIM environments. The system demonstrates effectiveness through three functions: (1) ontology-driven hazard detection with 97.7% geometric processing success, (2) color-coded visualization of hazards within the BIM model, and (3) automated generation of OSHA-compliant guardrails at identified hazard locations. The RAG-LLM layer provides dynamic, knowledge-augmented safety advice, reducing reliance on rule coding and delivering regulation-aware recommendations.

The contributions are threefold. First, the study introduces a semantic-spatial ontology that translates safety regulations into machine-interpretable logic linked to IFC entities. Second, it operationalizes prevention by connecting hazard detection with real-time guardrail placement. Third, it incorporates RAG-LLM as an adaptive reasoning layer to enhance regulatory compliance and support proactive safety decisions.

The study identifies key limitations affecting its applicability. Validation on a single BIM case limits generalizability across diverse project types and scales. Guardrail placement relies on deterministic, rule-based methods that cannot adapt to complex geometries or regulatory changes. The ontology and LLM knowledge base derive primarily from Hong Kong and Chinese safety standards, restricting broader applicability. Future directions include expanding the regulatory knowledge base to international standards, enhancing LLM spatial reasoning through BIM-specific fine-tuning, incorporating sensor data for real-time construction-phase monitoring, and developing generative design approaches for hazard-free alternatives.

This research presents a scalable framework that shifts BIM-based safety checking from compliance verification to proactive hazard prevention. By combining semantic regulatory understanding, geometric analysis, and LLM-augmented reasoning, the pipeline

supports earlier design decisions and advances automated, human-centric safety management in digital construction.

Abstract

Assembly Sequence Planning (ASP) is a critical decision-making problem in construction automation, affecting productivity, cost, constructability, and system robustness. ASP is NP-hard (Non-deterministic Polynomial-time hard) due to the factorial growth in feasible assembly sequences as product complexity increases. While artificial intelligence (AI) and soft computing methods have been widely applied to ASP, existing research remains fragmented, algorithm-centric, and largely rooted in manufacturing contexts, limiting its transferability to construction automation. This paper presents a construction-oriented synthesis of AI-based ASP approaches, emphasizing decision-level insights rather than algorithmic mechanics. This paper reviews ASP modelling strategies, constraints, assembly scales, and objectives from a construction perspective. AI-based optimization methods are organized into major algorithm families and evaluated according to scalability, computational effort, and construction suitability. The paper further discusses emerging considerations such as parallel assembly, BIM-enabled digital twins, and data-driven learning approaches within a construction automation context. Key research gaps are prioritized to guide future research and development. The synthesis provides guidance for researchers and practitioners seeking to design scalable, realistic, and implementable ASP solutions for automated and industrialized construction.

Keywords –

Assembly Sequence Planning; Construction Automation; Artificial Intelligence; Prefabricated and Modular Construction; Optimization Methods

1 Introduction

The increasing adoption of automation, prefabrication, and modular construction is transforming how construction systems are designed, planned, and executed. As construction adopts manufacturing-inspired production paradigms, assembly-related decisions, such as component ordering, assembly directions, and tool usage, have become critical determinants of productivity, cost efficiency, and constructability [1,2]. Assembly Sequence Planning (ASP) addresses these challenges by determining feasible and efficient assembly sequences under technical and operational constraints.

ASP is NP-hard combinatorial optimization problem, as the number of feasible sequences grows factorially with the number of components [3,4]. In construction applications, this complexity is amplified by large-scale components, heterogeneous materials, diverse connection types, and varying degrees of automation [5]. Poor sequencing can result in excessive tool changes, frequent reorientation, unbalanced workloads, and increased human or robotic effort, reducing overall system efficiency [6,7].

Figure 1 positions ASP within the construction automation decision framework, highlighting its role as a coordinating function linking product design, production planning, and execution. Unlike manufacturing ASP (rigid, sequential, controlled), construction involves parallelism, variability, and human–robot interaction [8,9]. These characteristics increase planning complexity and limit the transferability of manufacturing-oriented solutions.

This distinction is illustrated in Figure 2, which contrasts manufacturing- and construction-oriented assembly systems in terms of component scale, assembly parallelism, and operational variability, clarifying the need for construction-specific modelling assumptions and decision criteria.

To address ASP's combinatorial complexity, AI and soft computing methods, such as genetic algorithms, ant colony optimization, particle swarm optimization, simulated annealing, and hybrid approaches, have been widely applied [12–14]. However, much of the literature remains algorithm-centric, emphasizing method-specific implementations rather than decision-level applicability. In addition, several construction-critical considerations remain underrepresented, including flexible or deformable components, ergonomic and human–machine interaction constraints, sustainability objectives, and explicit treatment of parallel or collaborative assembly processes [13]. These limitations are synthesized in Figure 3.

In this context, this paper presents a focused synthesis of AI-based ASP approaches from a construction automation perspective, emphasizing decision-level insights rather than algorithmic mechanics. The paper: (i) reframes ASP as a construction decision problem spanning design, planning, and execution; (ii) introduces assembly scale as a key

determinant of modelling and algorithm suitability; (iii) synthesizes ASP modelling approaches and constraint types relevant to construction systems; (iv) compares AI-based optimization methods according to their suitability across different assembly scales; and (v) identifies prioritized research gaps to guide future development of practical ASP solutions for construction automation.

Figure 3. ASP limitation in construction automation research

This study adopts a structured narrative review approach. Literature was identified from Scopus, Web of Science, and Google Scholar using keywords such as 'assembly sequence planning' and 'construction automation'. The review focuses on studies (2000–2024) relevant to ASP modelling, constraints, and optimization, covering approximately 120 papers.

2 Assembly Sequence Planning as a Construction Decision Problem

ASP has traditionally been formulated as a combinatorial optimization problem within manufacturing-oriented research, where it is treated as a technical sequencing task aimed at generating feasible or near-optimal assembly orders under predefined precedence constraints [3,4,8]. While this formulation has enabled significant algorithmic advances, it captures only part of ASP's role in construction automation.

In construction-oriented systems, ASP is more appropriately viewed as a system-level decision problem spanning product design, production planning, and execution. Construction assemblies differ fundamentally from manufacturing assemblies due to larger components, heterogeneous materials, variable environments, and differing levels of automation [1,2,5]. Consequently, ASP decisions influence not only feasibility but also constructability, system efficiency, and automation readiness. Across the construction lifecycle, ASP acts as a coordinating function, shaping component segmentation and accessibility at the design stage [6,10], interacting with resource allocation and line balancing during production planning [2,11], and guiding task scheduling and human–robot coordination during execution [13].

The limited transferability of existing ASP research largely stems from manufacturing-oriented assumptions, including rigid components, sequential processes, and controlled environments [8,9,12]. These assumptions rarely hold in construction, where parallel sub-assembly, distributed production, and semi-automated operations are common, and where human–robot collaboration introduces additional ergonomic and safety constraints [2,13]. In prefabricated and modular construction, parallel assembly further increases ASP complexity by introducing concurrency, synchronization, and resource-sharing constraints [11,12], requiring ASP to address not only component sequencing but also coordination across parallel sub-assemblies.

Reframing ASP as a construction decision problem has direct implications for modelling and optimization. Models must capture system-level characteristics such as parallelism, resource coupling, and human–robot interaction, while optimization objectives must extend beyond local efficiency to include constructability, safety, and robustness [6,7]. Algorithm selection should therefore be guided by assembly characteristics and system requirements rather than algorithm popularity alone. This reframing provides the foundation for the next section, which introduces assembly scale and system characteristics as key determinants of modelling strategies and AI-based optimization suitability

in construction-oriented ASP.

3 Assembly Scale and System Characteristics in Construction-Oriented ASP

Building on the decision-oriented framing introduced in Section 2, this section operationalizes that perspective by formalizing assembly scale as a determinant of modelling and optimization suitability. Assembly scale remains an underexplored dimension in ASP research, where modelling and optimization strategies are often assumed to scale uniformly with problem size. In construction automation, however, assembly scale fundamentally influences solution space growth, constraint dominance, modelling feasibility, and algorithm suitability, making its explicit consideration essential for practical ASP solutions.

3.1 Definition of Assembly Scale in Construction Contexts

In manufacturing-oriented ASP research, assembly scale is often defined solely by the number of components. While component count remains relevant, it is insufficient to characterize construction assemblies. In construction automation, assembly scale is more appropriately defined by the combined effects of component count, presence of sub-assemblies, degree of parallelism, and level of system coordination required.

Based on the literature and construction practice [2,5,11], construction-oriented ASP problems can be classified according to assembly scale, as summarized in Table 1, providing a decision-oriented basis for selecting modelling and optimization strategies.

While assembly scale is presented conceptually, future work should define quantitative thresholds based on component count, degree of parallelism, and interaction density to enable more objective classification across construction scenarios.

Table 1. Assembly scale classification for construction-oriented ASP

Assembly Scale	Typical Characteristics	Implications for ASP
Small	Few components; mostly sequential	Exact or simple meta-heuristics feasible
Medium	Multiple sub-assemblies; mixed sequencing	Evolutionary or swarm methods effective
Large	Parallel sub-assemblies; system coupling	Hierarchical, hybrid, or memetic methods

3.2 ASP Solution Space Growth and Assembly Scale

Sequential assembly represents the baseline ASP case, where components are assembled one at a time under precedence constraints; parallel assembly generalizes this formulation by allowing concurrent sub-assemblies subject to synchronization and resource constraints

For a purely sequential assembly of n components, the theoretical upper bound of feasible sequences is:

$$S_{seq} = n! \qquad (1)$$

For a system composed of k independent sub-assemblies with component counts $n_1, n_2, \ldots, n_k$, the number of possible interleavings can be approximated as:

$$S_{par} = \frac{(n_1+n_2+\cdots+n_k)!}{n_1!+n_2!+\cdots+n_{k!}} \qquad (2)$$

Parallel sub-assembly, common in prefabricated and modular construction, therefore, expands the solution space dramatically relative to sequential assemblies, explaining the limited scalability of many manufacturing-oriented ASP approaches [12,14].

3.3 Scale-Dependent Dominance of ASP Constraints

Assembly scale strongly influences which constraints dominate ASP outcomes. In small-scale assemblies, feasibility constraints, such as precedence, geometric, and stability constraints, are dominant, as ensuring feasible assembly orders constitutes the primary planning challenge [20,21]. In medium-scale assemblies, optimization-oriented constraints, including assembly direction changes, tool changeovers, and operation-type variation, increasingly influence sequence quality and cycle time [6,7].

In large-scale construction assemblies, typical of modular and prefabricated systems, system-level constraints often dominate. These include workstation coordination, resource sharing, ergonomic limits in human–robot collaboration, and synchronization of parallel tasks [13,15]. At this scale, local sequencing decisions can significantly affect overall system performance. This transition in constraint dominance is illustrated in Figure 4.

Figure 4. Dominant ASP constraints across assembly scales

3.4 Implications for Modelling and Algorithm Selection

Assembly scale directly informs the suitability of ASP modelling approaches. Part-based modelling offers high fidelity and is effective for small-scale assemblies

but becomes computationally prohibitive as scale increases. Task-based modelling reduces problem dimensionality through operation aggregation [15], while connector-based modelling is well suited to large-scale modular systems, where standardized interfaces support hierarchical planning [18,19].

The interaction between assembly scale, modelling complexity, and constraint dominance also guides algorithm selection: small-scale assemblies can be addressed using evolutionary or physics-inspired methods, medium-scale assemblies benefit from swarm intelligence approaches, and large-scale assemblies typically require hybrid or memetic strategies that combine global search with hierarchical decomposition. By explicitly incorporating assembly scale into ASP formulation, algorithm selection becomes a decision-driven process rather than a methodological preference, providing a foundation for the comparative analysis of AI-based ASP methods in the next section.

4 ASP Modelling Approaches and Constraint Formulation

ASP performance and applicability in construction automation are strongly influenced by how the assembly problem is modelled and how constraints are formulated. Modelling choices define the structure of the search space, the types of constraints that can be represented, and the computational feasibility of optimization. In construction-oriented ASP, models must account for large-scale components, heterogeneous connections, and parallel assembly processes, which are often inadequately captured by manufacturing-focused formulations.

4.1 Overview of ASP Modelling Approaches

Existing ASP research typically adopts one of three modelling approaches: part-based, task-based, or connector-based representations [15,16,18]. These approaches differ in abstraction level and exhibit distinct advantages and limitations when applied to construction assemblies.

4.1.1 Part-Based Modelling

Part-based modelling treats individual components as the fundamental assembly units. Precedence relationships are derived from geometric interference, mechanical feasibility, and stability conditions [16,17]. This approach offers high modelling fidelity and is well suited to small-scale assemblies where component interactions remain manageable.

In construction automation, part-based models are commonly used for detailed prefabrication tasks or small modular assemblies. However, as assembly scale increases, the precedence graph grows rapidly, leading to significant computational challenges. As a result, part-based modelling becomes impractical for large-scale construction assemblies with extensive parallelism.

4.1.2 Task-Based Modelling

Task-based modelling abstracts the assembly process into sequences of operations rather than individual components. Tasks may represent fastening, positioning, or tool-specific actions [15]. This abstraction reduces problem dimensionality and enables direct incorporation of operational constraints such as tool usage and assembly direction.

Task-based models are particularly suitable for medium-scale assemblies, where multiple sub-assemblies exist but full part-level modelling is computationally prohibitive. However, this abstraction may obscure detailed geometric constraints, which can be critical for large or irregular construction components.

4.1.3 Connector-Based Modelling

Connector-based modelling organizes the assembly process around connection mechanisms such as bolts, welds, or standardized interfaces [18,19]. Components associated with a common connector are grouped, enabling hierarchical or multi-stage planning.

This approach aligns well with modular and prefabricated construction systems, where standardized connections are prevalent. Connector-based modelling supports scalable ASP by reducing effective problem size and enabling decomposition into manageable sub-problems, although it often requires more complex model formulation and multi-level optimization.

4.2 Constraint Categories in Construction-Oriented ASP

ASP constraints can be broadly classified into feasibility constraints and optimization-oriented constraints [6,15], with their relative importance varying by assembly scale, as discussed in Section 3.

4.2.1 Feasibility Constraints

Feasibility constraints determine whether an assembly sequence is physically and functionally admissible and typically include precedence constraints that enforce required assembly orderings [20], geometric constraints that prevent collisions and ensure accessibility [21], and stability constraints that maintain structural integrity during intermediate assembly states [22]. These constraints dominate small-scale assemblies and must be satisfied before optimization objectives are considered.

4.2.2 Optimization-Oriented Constraints

Optimization-oriented constraints influence the efficiency and quality of feasible sequences. In construction automation, commonly considered constraints include assembly direction changes, tool changeovers, operation-type variation, and task sequencing consistency. These factors directly affect cycle time, energy consumption, and operational complexity, particularly in robotic and semi-automated systems [6,7].

4.2.3 System-Level Constraints

In large-scale construction assemblies, system-level constraints become increasingly important. These include

workstation coordination, resource sharing across parallel tasks, ergonomic and safety constraints in human–robot collaboration, and synchronization of parallel sub-assemblies. Such constraints link ASP with higher-level planning functions and require models capable of representing system-wide interactions [13,15].

System-level constraints such as ergonomic limits, resource sharing, and workstation coordination can be integrated through multi-layered modelling approaches, where local sequencing decisions are coupled with higher-level scheduling and resource allocation models, enabling synchronized optimization across parallel sub-assemblies.

4.3 Relationship Between Assembly Scale, Modelling, and Constraints

The interaction between assembly scale, modelling approach, and constraint formulation is central to construction-oriented ASP. Part-based models are most effective when feasibility constraints dominate, task-based models balance feasibility and optimization concerns, and connector-based models support system-level constraint representation in large-scale assemblies. Table 2 summarizes the suitability of ASP modelling approaches as a function of assembly scale and dominant constraint types.

Table 2. Relationship between assembly scale, modelling approach, and dominant constraints

Assembly Scale	Dominant Constraints	Suitable Modelling Approach
Small	Feasibility	Part-based
Medium	Optimization-oriented	Task-based
Large	System-level	Connector-based/Hierarchy

4.4 Implications for Construction Automation

The analysis highlights that no single ASP modelling approach is universally applicable across construction scenarios. Effective ASP solutions must align modelling fidelity with assembly scale and dominant constraints. Overly detailed models risk computational infeasibility, while overly abstract models may fail to capture critical construction constraints.

This reinforces the need to treat modelling and constraint formulation as decision problems, guided by construction system characteristics rather than algorithmic convenience. The next section builds on this foundation by examining AI-based optimization methods under varying modelling and constraint conditions.

5 AI-Based Optimization Methods for Construction-Oriented ASP

The combinatorial nature of Assembly Sequence Planning has led to extensive adoption of AI-based and soft computing optimization methods. However, much of the literature evaluates these methods in isolation, emphasizing algorithmic performance rather than decision-level suitability for construction systems. As established in Sections 3 and 4, the effectiveness of an optimization method in construction-oriented ASP depends strongly on assembly scale, modelling abstraction, and dominant constraint types.

Accordingly, this section synthesizes AI-based ASP methods by algorithm family, focusing on their strengths, limitations, and applicability to construction automation rather than their internal mechanics.

While quantitative benchmarking across ASP studies remains challenging due to differences in problem formulation and evaluation metrics, a comparative summary of reported scalability characteristics and typical problem sizes has been incorporated to enhance analytical depth

5.1 Evolutionary Algorithms

Evolutionary algorithms, particularly Genetic Algorithms (GA), are among the most widely applied methods for ASP [27–30]. GA-based approaches encode assembly sequences as chromosomes and evolve solutions through selection, crossover, and mutation. Their flexibility enables straightforward incorporation of multiple objectives and constraint penalties.

In construction contexts, evolutionary algorithms perform well for small- to medium-scale assemblies, particularly when part-based or task-based models are used. However, their performance degrades as assembly scale increases due to premature convergence and reduced exploration efficiency [23,24]. GA-based methods are therefore poorly suited to large-scale construction assemblies involving parallel sub-assemblies and system-level constraints.

5.2 Swarm Intelligence Methods

Swarm intelligence methods, including Ant Colony Optimization (ACO) and Particle Swarm Optimization (PSO), exploit collective search mechanisms to explore large solution spaces [25–27]. ACO is especially effective for sequencing problems, as pheromone trails provide structured guidance through discrete search spaces.

In construction-oriented ASP, swarm intelligence methods are well suited to medium-scale assemblies, where optimization-oriented constraints dominate. ACO-based approaches have demonstrated greater robustness than GA in problems with complex precedence relationships [25,26]. PSO offers computational efficiency but is less effective for highly discrete or heavily constrained ASP formulations [27].

5.3 Physics- and Bio-Inspired Optimization Methods

Physics-inspired methods, such as Simulated Annealing, have been applied to ASP due to their ability to escape local optima via probabilistic acceptance of inferior solutions [25–27]. These methods are simple to implement and require fewer parameters than population-based approaches.

In construction applications, Simulated Annealing is

most effective for small-scale assemblies or as a local refinement mechanism. Its slow convergence and limited scalability restrict its applicability to large-scale assemblies with extensive parallelism and system-level constraints.

Bio-inspired methods, including Artificial Immune Systems and Shuffled Frog Leaping Algorithms, emphasize exploration and adaptability in complex search spaces [27]. While capable of handling complex constraint landscapes, these methods often incur high computational cost and require careful parameter tuning.

Hybrid and memetic algorithms combine complementary strategies, such as global search with local refinement or hierarchical decomposition [25–27]. In construction-oriented ASP, hybrid approaches show strong potential for large-scale assemblies where system-level constraints dominate. These methods align naturally with connector-based and hierarchical modelling approaches, although they require greater implementation effort and domain knowledge.

5.4 Learning-Based and Data-Driven ASP Approaches

Recent advances in machine learning have stimulated interest in learning-based ASP approaches, particularly reinforcement and imitation learning, which aim to learn sequencing policies that generalize across similar assembly configurations [28–30]. In RL-based ASP, assembly is formulated as a sequential decision-making problem, where an agent selects actions based on the current assembly state to maximize cumulative reward [28,30].

Although conceptually attractive for construction automation, current learning-based ASP research remains largely experimental. Most studies focus on simplified environments or small assemblies, with limited consideration of construction-specific challenges such as large components, parallel sub-assembly, and human–robot collaboration [29,31]. In addition, learning-based methods typically require substantial training data and careful reward design, which are difficult to obtain in construction contexts.

Related approaches, including case-based reasoning and graph-based learning, have been proposed to exploit prior solutions or structural patterns [28–30], but their applicability to large-scale construction systems remains constrained by data availability and interpretability concerns. From a decision-level perspective, learning-based methods are therefore best viewed as complementary tools, particularly suited to repetitive or data-rich contexts such as standardized modular systems or digital twin environments, rather than as replacements for established optimization methods.

Recent advancements in synthetic data generation and sim-to-real transfer techniques are increasingly addressing data scarcity and generalization challenges, suggesting that learning-based ASP approaches may become more practically viable in construction contexts than previously assumed.

5.5 Decision-Level Suitability of AI Methods for Construction ASP

The synthesis above confirms that no single AI-based optimization method is universally optimal for ASP. Algorithm suitability depends on assembly scale, modelling abstraction, and dominant constraint types. Treating algorithm selection as a decision problem is therefore essential for construction automation.

While quantitative benchmarking across ASP studies remains challenging due to differences in problem formulation and evaluation metrics, a comparative summary of reported scalability characteristics and typical problem sizes has been incorporated to enhance analytical depth.

5.6 Implications for Construction Automation

The prevalence of algorithm-centric ASP research has obscured the importance of decision-level alignment in construction automation. Algorithms that perform well on benchmark problems may be unsuitable for real construction systems if assembly scale, parallelism, and system-level constraints are ignored. Future ASP development should therefore prioritize integration, scalability, and decision transparency over incremental algorithmic novelty.

The next section synthesizes insights from Sections 3–5 to provide a comparative, construction-oriented perspective on ASP decision-making.

6 Decision-Oriented Synthesis and Research Directions

The preceding sections examined assembly scale, modelling approaches, constraint formulation, and AI-based optimization methods individually. This section synthesizes these elements to provide decision-oriented insights for construction-oriented ASP. Rather than comparing algorithms based solely on performance metrics, the synthesis emphasizes *when* and *why* specific modelling and optimization strategies are appropriate given construction system characteristics.

6.1 Alignment Between Assembly Scale, Modelling, and Optimization

A central insight from the literature is that ASP effectiveness depends on alignment between assembly scale, modelling abstraction, and optimization strategy. Mismatches between these elements are a common cause of poor scalability and limited practical applicability in construction automation.

For example, applying part-based modelling with population-based optimization to large-scale modular assemblies often leads to prohibitively large search spaces and excessive computation time [16,18]. Conversely, overly abstract models applied to small-scale assemblies may fail to capture critical geometric or stability constraints, resulting in infeasible or unsafe sequences [20,21].

Effective ASP therefore requires balancing modelling fidelity with computational tractability. Assembly scale

provides a unifying lens for achieving this balance by guiding both modelling choices and algorithm selection.

6.2 Trade-offs Between Feasibility, Optimization, and System-Level Objectives

ASP objectives shift systematically with assembly scale. In small-scale assemblies, feasibility dominates, and performance differences among feasible sequences are often marginal. In medium-scale assemblies, optimization objectives, such as minimizing tool changes, direction changes, or operation-type variation, become increasingly important [6,7].

In large-scale construction assemblies, system-level objectives, including resource coordination, ergonomic considerations, and synchronization of parallel sub-assemblies, frequently outweigh local optimization goals [13,15]. ASP solutions that focus solely on local efficiency may therefore degrade overall system performance by creating bottlenecks or underutilized resources.

These observations highlight the need to frame ASP objectives in terms of overall construction system performance rather than isolated task-level efficiency.

6.3 Decision-Oriented Synthesis Framework

Integrating the insights from Sections 3–5, Table 3 presents a decision-oriented framework linking assembly characteristics, dominant constraints, modelling approaches, and suitable AI-based optimization strategies.

Table 3. Decision-oriented synthesis of ASP approaches for construction automation

Assembly Characters	Dominant Constraints	Model Method	Optimize Method
Small, sequential	Feasible	Part-based	GA, SA
Medium, mixed parallelism	Optimize-oriented	Task-based	ACO, PSO
Large, parallel, modular	System-level	Connector-based / hierarchical	Hybrid, memetic
Repetitive, data-rich	Adaptive / dynamic	Hierarchical / learned	RL-assisted, learning-based

Rather than prescribing specific algorithms, this framework supports informed decision-making by aligning ASP strategies with construction system requirements.

6.4 Implications for Practical Deployment

From a practical perspective, the synthesis explains why many ASP approaches reported in the literature have seen limited adoption in real construction automation systems. Algorithm-centric solutions that neglect assembly scale, modelling abstraction, and system-level constraints often fail to scale beyond laboratory examples.

For industrialized construction applications, such as off-site modular fabrication and robotic prefabrication facilities, ASP solutions must integrate with production planning, resource allocation, and execution control. Decision-oriented ASP frameworks are therefore more likely to support practical deployment than isolated optimization algorithms.

6.5 Research Gaps and Future Directions

Another critical gap is the limited integration of human–robot collaboration and ergonomic constraints in ASP models. Construction automation often operates in semi-automated settings where humans and robots interact closely, yet safety limits, ergonomics, and task handovers are rarely embedded explicitly in sequence planning. Incorporating these factors is essential for improving both feasibility and acceptance of automated assembly solutions.

Existing ASP formulations also commonly assume rigid components and deterministic conditions, assumptions that rarely hold in construction. Flexible or semi-deformable components, tolerance variability, and environmental uncertainty remain difficult to represent, highlighting the need for advanced modelling approaches, including hybrid geometric and data-driven representations.

While learning-based ASP methods, such as reinforcement and imitation learning, have gained interest, their practical applicability remains limited by data scarcity, training cost, and interpretability challenges. In the near term, these methods are more likely to augment traditional optimization, through solution initialization, adaptation, or digital twin integration, rather than replace established approaches.

Finally, scalability and the lack of construction-specific benchmarks remain major obstacles. Many studies rely on small or idealized examples, limiting insight into industrial-scale performance. Developing standardized datasets and benchmark problems (e.g., modular frames or panelized façade systems) would significantly improve comparability and accelerate translation to practice.

Addressing these gaps requires a shift from algorithm-centric experimentation toward integrated, system-aware, and decision-oriented ASP frameworks capable of supporting real-world automated and industrialized construction.

Future work should focus on validating the proposed decision-oriented framework through pilot case studies and real-world construction scenarios, particularly in modular and prefabrication contexts, to assess its practical applicability and scalability.

7 Conclusions

This paper presented a focused synthesis of AI-based Assembly Sequence Planning from a construction automation perspective, reframing ASP as a decision problem spanning design, production planning, and execution rather than an algorithm-centric optimization task.

A central contribution is the introduction of assembly scale as a unifying concept for understanding ASP complexity in construction. Distinguishing between small-,

medium-, and large-scale assemblies clarifies how solution space growth, constraint dominance, and algorithm suitability vary systematically, explaining the limited scalability of many manufacturing-oriented ASP approaches in construction contexts involving parallel sub-assembly and system-level coordination.

The synthesis further demonstrated that ASP modelling approaches and constraint formulations are inherently coupled. Part-based, task-based, and connector-based models involve distinct trade-offs in fidelity and scalability, and no single AI-based optimization method is universally optimal; effective ASP solutions instead arise from decision-level alignment between assembly scale, modelling abstraction, and optimization strategy.

By positioning learning-based methods alongside classical meta-heuristics, the paper identified reinforcement learning and related approaches as complementary tools rather than replacements for established frameworks. Overall, this work advances ASP research toward practical applicability, scalability, and decision support, providing a structured foundation for future construction-oriented ASP development.

***Abstract*—Generating accurate Digital Twins of existing buildings remains a persistent bottleneck in Scan-to-BIM workflows, especially for Mechanical, Electrical, and Plumbing (MEP) systems. Although recent deep learning methods can segment MEP components from point clouds with good accuracy, the next step for converting segmented point sets into metrically consistent cylindrical primitives for downstream BIM integration remains brittle and heavily dependent on manually tuned geometric hyperparameters. On active construction sites, especially timber frames, severe clutter, occlusion, and variable point density make such tuning labor-intensive and unstable. This paper presents a novel approach called "Cognitive Fitting," in which a Large Language Model (LLM) is integrated into a closed-loop optimization process as a proposal engine for hyperparameter search. The LLM does not generate geometry directly. Instead, it receives structured geometric feedback, including coverage and dispersion for candidate ranking together with fragmentation-related diagnostic signals for iterative reasoning, and proposes improved clustering, fitting, and merging parameters. The proposed framework was validated on a challenging residential timber dataset from Canada containing heavily occluded wiring and piping. Results show the strongest gains on the thin and fragmented *Wires* class, where coverage improved from 66.19% to 71.81% relative to a budget-matched non-LLM search condition, while the number of merged output primitives decreased from 341 to 302, indicating improved continuity recovery. For *Pipes*, the gains were smaller but still consistent, with the proposed method achieving the best overall objective score while reducing dispersion relative to the fixed classical baseline. These results show that LLM-guided reasoning can reduce manual hyperparameter tuning in post-segmentation MEP primitive fitting, particularly for thin and fragmented structures in cluttered timber environments.**

I. Introduction

A paradigm shift is underway in the Architecture, Engineering, and Construction (AEC) industry, aligned with Industry 4.0. Central to this shift is the Digital Twin concept. These are not static models. They are dynamic, living systems for full lifecycle asset management [1, 2]. Creating them starts with Scan-to-BIM. This is the process of transforming terrestrial laser scanning (TLS) data into semantic Building Information Models. TLS hardware today captures geometry rapidly and with millimeter accuracy. The bottleneck has moved downstream. Converting raw point clouds into parametric BIM objects is now the major constraint. Studies indicate this phase can consume 70% of the total modeling effort on a project, all due to manual work [3].

This bottleneck tightens dramatically around MEP systems. Structural elements like walls are large and planar. MEP components are not. They have small cross-sections. Their topologies are complex and curvilinear. They are highly susceptible to occlusion by other building elements [4]. Timber construction compounds these issues. Temporary supports, insulation, and general site clutter further obscure pipes and wires. Standard automated fitting algorithms struggle here. They frequently fail to reconstruct continuous runs. Instead, they output fragmented geometry. Practitioners often call it "spaghetti." This output requires extensive manual rework, defeating the purpose of automation.

We contend the core problem is not the algorithms themselves. Efficient Random Sample Consensus (RANSAC) for shape detection and density-based clustering like Hierarchical Density-Based Spatial Clustering of Applications with Noise (HDBSCAN) are mathematically sound [5, 6]. The problem is their parameter sensitivity. RANSAC, which finds shapes by randomly sampling points and checking for consensus, needs a distance threshold. A threshold ideal for a large pipe will completely miss a thin wire. HDBSCAN, which groups points based on local density, has settings like minimum cluster size. Clustering settings tuned for a dense mechanical room will catastrophically over-segment sparse attic wiring. Today, finding the right set of parameters for a given scan is manual. It is a trial-and-error process that leans heavily on the modeler's tacit knowledge. There is no systematic method.

This study proposes an automated solution. We introduce an optimization framework driven by a Large Language Model (LLM). Our hypothesis is straightforward. The heuristic reasoning a BIM engineer applies to diagnose poor fits and adjust

tolerances can be emulated by an LLM operating as a proposal engine inside a closed-loop geometric search process. In our framework, the LLM does not generate geometry, parse BIM entities, or replace the fitting algorithms. Instead, it receives structured geometric feedback from the pipeline, reasons about likely failure modes, and proposes adjusted hyperparameters for the next candidate evaluation. The geometric engine then evaluates those candidates objectively and retains the best-scoring result.

This distinction is important. The contribution of this paper is not "LLM-generated reconstruction." It is LLM-guided hyperparameter search for post-segmentation primitive fitting in cluttered residential timber scenes. The system is therefore scene- and class-specific: given a semantically segmented point cloud class such as pipes or wires, it searches for better clustering, fitting, and merging settings without requiring manual trial-and-error from an expert modeler.

The diagram illustrates the closed-loop cycle of our framework. At its core is an LLM Agent, instantiated in our experiments with Qwen-2.5-14B under local inference. This agent proposes a set of hyperparameters, θ_t. A Geometric Engine then takes these parameters and the input point cloud. It runs HDBSCAN for clustering and a cylinder fitting stage for primitive estimation, followed by rule-based merging and refinement. Next, an Evaluator module scores the resulting geometry. It computes a scalar objective score J from coverage and dispersion, while also recording additional diagnostic signals such as primitive count and fragmentation. The scalar score is used for candidate ranking, whereas the auxiliary signals are formatted as plain-text feedback and passed to the LLM to support reasoning about the next parameter set, θ_{t+1}. This cycle repeats, pushing the search toward parameter settings that generate cleaner, more continuous, and metrically valid primitives from the segmented point cloud.

To make the feedback loop concrete, the text sent to the LLM may include a short summary such as: "Iteration 7. Parameters used: `min_cluster_size`=45, `ransac_dist`=0.008. Results: Coverage = 58%, Dispersion = 5.2 mm, Merged Primitive Count = 310. The output is still highly fragmented, though fitting error is acceptable." The LLM then reasons over this summary and proposes a new candidate, for example by relaxing clustering conservatism or widening a merge tolerance. This iterative proposal-and-evaluation dialogue is the core of the Cognitive Fitting approach.

II. Related Work

A. Scan-to-BIM: From Manual to Automated Methods

Initial Scan-to-BIM techniques depended on user guidance. They used primitive fitting or constructive solid geometry (CSG) [1]. These methods worked for basic structures. They cannot deliver the semantic depth modern Digital Twins require. The field changed with deep learning. Current state-of-the-art relies on networks like PointNet++ and Point Transformers [7, 8]. They segment point clouds with high per-point accuracy. But segmentation is just the beginning. The

crucial next step is reconstruction. Turning labeled points into parametric IFC entities still uses classical geometric fitting algorithms. And these algorithms have a well-known weakness. They are fragile. Their performance degrades badly with real-world noise, occlusion, and uneven point density [9]. You can have perfect segmentation and still get a useless model if the fitting step fails.

B. Why MEP Reconstruction is Especially Hard

MEP systems break the assumptions of most reconstruction pipelines. Their cylindrical, curvilinear geometry is fundamentally different from planar elements. Agapaki and colleagues made this distinction clear, noting industrial pipes demand unique handling [10]. Some recent work tries to solve this with more AI. Yue *et al*. (2025) developed deep learning networks to complete occluded pipes [11]. These show potential for better connectivity. But they come with a heavy cost. They require large, labeled, domain-specific datasets for training. For residential construction, such datasets are rare and expensive to create. The alternative is procedural methods like RANSAC or Hough Transforms [5]. They need no training data. Their flaw is brittleness. Success hinges on a few hyperparameters. A poor choice for a distance threshold or minimum cluster size can ruin the entire output, merging objects or missing them entirely [12]. This creates a clear gap. We need an approach that adapts like deep learning but does not need massive training sets. Our framework targets this gap directly.

C. LLMs as Optimization Engines

Large Language Models are now being applied beyond text. Researchers are testing them as reasoning tools for complex tasks. Romera-Paredes *et al*. (2024) demonstrated LLMs solving combinatorial puzzles [13]. In engineering, Yang *et al*. (2023) used them to tune optimization parameters [14]. More relevant to us, new studies position LLMs as optimization agents. Work by Wang *et al*. (2025) and van Stein *et al*. (2025) shows LLMs can navigate parameter spaces more efficiently than random search [16, 17]. They use semantic cues to guide the process. This suggests hyperparameter tuning is not just a random walk. It can be a reasoning task.

So, when these three areas are taken together, a specific research gap comes into focus. On one side you have powerful but data-hungry deep learning methods for MEP reconstruction. On the other you have lightweight but brittle geometric algorithms that need expert tuning. The tuning process itself is a kind of heuristic reasoning problem. But the application of LLMs as reasoning agents for this specific task in AEC for tuning geometric reconstruction hyperparameters in the face of real-world clutter has not been explored. Previous LLM work in optimization is general. No one has plugged an LLM into the Scan-to-BIM loop to deal with the conditions of an active construction site. That is the gap this paper addresses.

III. Methodology

The MEP reconstruction task is framed as a black-box optimization problem. The goal is to maximize the geometric quality of the final fitted primitives. The proposed framework eliminates static configuration. A dynamic LLM Agent iteratively tunes the hyperparameters for standard geometric algorithms.

A. Data and Pre-processing

Validation data comes from a Leica BLK360 G1 scanner. It captured an under-construction residential timber building in Canada. This site represents a worst-case test for automation. The raw scans have high geometric noise from wood grain texture. Stud framing creates severe occlusion. The mix includes rigid pipes and flexible electrical wires, each presenting different challenges. The raw point clouds were pre-processed. This involved statistical outlier removal and voxel down-sampling. The data is then semantically segmented into two target classes: 'Pipes' and 'Wires'. These labeled clouds are the input to the system.

B. Cognitive Fitting Engine Components

The pipeline has three core modules, all parameterized by the LLM.

Adaptive Clustering with HDBSCAN: HDBSCAN is used [6]. It handles variable density better than DBSCAN, which is critical for TLS data. In the final reported search space, the primary HDBSCAN parameter optimized by the LLM is *min_cluster_size*, which controls the smallest group of points that forms a valid object. Additional HDBSCAN controls such as *min_samples* and *cluster_selection_epsilon* were explored in preliminary tuning and then fixed before the main reported experiments.

Shape Fitting with RANSAC: Each cluster is processed by an Efficient RANSAC algorithm [5] to find cylindrical models. The key parameter here is *ransac_dist*. This is the maximum allowed distance from a point to the cylinder surface to be considered an inlier. Set it too high and the cylinder swallows noise. Set it too low and valid surface points get rejected.

Graph-Based Merging: Initial cylinders are often broken. A graph traversal step stitches compatible ones into continuous runs. In the final reported search space, the primary merge parameters optimized by the LLM are *merge_angle* (how much cylinder axes can deviate) and *merge_gap* (maximum spatial gap to connect). Additional compatibility guards, including radius-related constraints, were tuned in preliminary runs and then fixed before the main experiments.

C. The LLM Feedback Loop

This is the novel part of the system. The automated reasoning loop.

For each iteration, t:

1) The pipeline runs with the current parameters, θ_t. Performance metrics are computed: **coverage** (C), the percentage of input points assigned to accepted primitives; **dispersion** (D), the average point-to-cylinder fitting error; and structural continuity indicators such as raw and merged primitive counts. These signals are useful because thin MEP structures may exhibit acceptable

(a) Raw Cluttered Environment

(b) Isolated 'Wires' Class

(c) Isolated 'Pipes' Class

Fig. 2. Input Data Characteristics. Vertical breakdown showing (a) the heavy timber clutter, (b) the disjointed nature of the 'Wires' class, and (c) the spatial interference in the 'Pipes' class. Note: Views are zoomed to highlight density.

local fitting error while still remaining globally over-fragmented.

2) A compact plain-text diagnostic summary is produced and provided to the LLM together with recent search context. The LLM was executed locally using Qwen-2.5-14B-Instruct through LM Studio with fixed low-temperature decoding to reduce stochastic variance. The prompt followed a fixed structured template containing the current parameter set, the latest evaluation metrics, and a short instruction to return only the next bounded candidate configuration — acting as a constrained proposal policy rather than an unconstrained conversational assistant. All candidate parameters were clamped to physically meaningful search ranges before evaluation. A salvage stage using a secondary lightweight DBSCAN pass was applied to residual noise before final merging; this used fixed settings across all compared methods and was not part of the LLM-tuned search space.
3) Candidate solutions are ranked using the scalar objective

$$J(\theta) = w_c \times C - w_d \times \left(\frac{D}{0.01}\right), \qquad (1)$$

where the normalization by 0.01 reflects a 10 mm MEP prefabrication tolerance. In all experiments $w_c = 1.0$; $w_d = 0.15$ for wires (favoring continuity) and 0.20 for pipes (favoring precision). These weights were fixed *prior* to running the optimization loop and were not adjusted by observing search outcomes, avoiding circularity. This formulation follows the standard weighted-sum scalarization approach in multi-objective optimization, where weights encode *a priori* preference trade-offs between competing objectives rather than universal constants [15]. In the present study, the selected weights reflect an engineering preference for continuity in wires and geometric precision in pipes. Fragmentation-related signals and primitive counts are treated as auxiliary diagnostic context for the LLM and as secondary evaluation criteria; they are not directly optimized by Eq. (1).

This formulation was chosen deliberately for the present feasibility study. More sophisticated formulations, such as explicit multi-objective optimization or multimodal diagnostic feedback, are promising extensions left outside the scope of this first study.

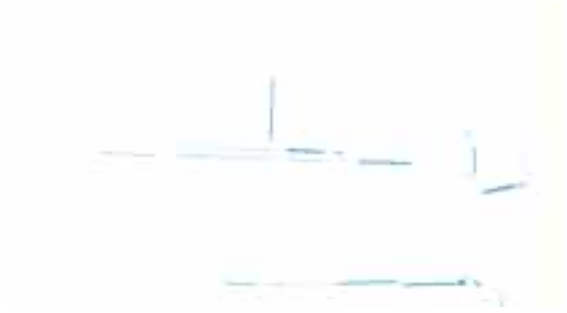

TABLE I
HYPERPARAMETER SEARCH SPACE

Parameter	Unit	Range	Description
hdb_min_cluster	points	[8, 1200]	Minimum points to form a cluster
ransac_dist	meters	[0.001, 0.03]	Max point-to-cylinder distance
merge_angle_deg	degrees	[2, 15]	Max axis deviation for merging
merge_gap	meters	[0.01, 0.12]	Max spatial gap to connect cylinders

Note: The active LLM-tuned search space reported in this paper consists of the four primary parameters above. Additional clustering and merge-guard parameters, including *min_samples*, *cluster_selection_epsilon*, radius-compatibility, axis-offset, and minimum-overlap constraints, were explored in preliminary runs and then fixed prior to the main reported search.

IV. RESULTS

The proposed framework was compared with two baselines. **Baseline A** uses a standard DBSCAN+RANSAC pipeline with fixed, expert-suggested parameters. **Baseline B** is a budget-matched non-LLM search condition using the same autotuning scaffold but with LLM proposals disabled. The search budget was matched by using the same total round count for each class (24 rounds indexed from 0 to 23 for wires, and 32 rounds indexed from 0 to 31 for pipes), thereby isolating the value of LLM-guided search from generic iterative search. We acknowledge that stronger baselines such as Bayesian optimization or TPE would further strengthen this comparison and are identified as future work. Note that Baseline A uses standard DBSCAN whereas the proposed method uses HDBSCAN; the comparison therefore reflects practitioner-style

(a) Fragmented Wires Output (Before fix)

(b) Continuous Wires Run (After LLM fix)

LLM Agent Reasoning Step	
Observation:	Too many pieces (312 fragments)
But:	Fitting is accurate (3.1mm error)
Diagnosis:	`merge_gap=0.02m` too small
Fix:	Increase to `merge_gap=0.08m`
Result:	θ_5: {merge_gap: 0.08m, ...}

The Cognitive Loop:

$\boxed{\theta_t} \xrightarrow{\text{Run}} \boxed{\text{Metrics}} \xrightarrow{\text{LLM thinks}} \boxed{\theta_{t+1}} \xrightarrow{\text{Run}} \ldots$

Fig. 3. Example of parameter tuning driven by the LLM. The agent observes a diagnostic summary indicating high fragmentation despite acceptable fitting error. It therefore adjusts merge-related parameters, and the next iteration produces a more continuous wire run. Fragmentation is used here as reasoning context, not as a direct term in the scalar objective.

fixed-parameter fitting against the full proposed framework, while Baseline B provides the controlled ablation of the LLM guidance component specifically.

A. Quantitative Performance

The data shows a consistent benefit from LLM-guided parameter proposals, with the largest gains observed on the more challenging *Wires* class.

TABLE II
PERFORMANCE COMPARISON SUMMARY

Method	Class	Coverage (%)	Dispersion (mm)	J-Score
Baseline A (DBSCAN)	Wires	56.03	1.54	0.5372
Baseline B (Budget-Matched Non-LLM Search)	Wires	66.19	1.33	0.6420
Ours (LLM-Guided)	**Wires**	**71.81**	**1.40**	**0.6971**
Baseline A (DBSCAN)	Pipes	75.08	4.42	0.6625
Baseline B (Budget-Matched Non-LLM Search)	Pipes	74.15	3.65	0.6685
Ours (LLM-Guided)	**Pipes**	**74.53**	**3.63**	**0.6727**

For wires, the proposed method achieved the clearest advantage. The best LLM-guided solution reached 71.81% coverage with 1.40 mm dispersion and a best objective score of $J = 0.6971$. Relative to the budget-matched non-LLM search condition, which achieved 66.19% coverage and $J = 0.6420$, the proposed method recovered more wire points while preserving low fitting error. The slight increase in dispersion relative to Baseline B (1.33 to 1.40 mm) reflects the coverage–dispersion trade-off encoded in the objective; the net J-score gain of 0.0551 confirms that the additional coverage outweighs the marginal fitting cost. In addition, the number of merged output primitives decreased from 341 to 302, indicating improved continuity recovery and reduced over-fragmentation in the final reconstructed runs. Notably, fragmentation was not a term in the optimized objective J; this improvement therefore appears as an emergent consequence of the LLM's use of auxiliary diagnostic signals rather than direct optimization pressure.

For pipes, the gains were smaller but still consistent. The best LLM-guided solution reached 74.53% coverage with 3.63 mm dispersion and $J = 0.6727$. Compared with the budget-matched non-LLM search condition, the improvement in objective value was modest ($0.6685 \rightarrow 0.6727$), suggesting that the pipe-fitting search landscape is less ambiguous than the wire case. However, compared with the fixed DBSCAN baseline, the proposed method achieved substantially lower dispersion (4.42 mm to 3.63 mm) while maintaining comparable coverage. Notably, Baseline B achieved slightly lower coverage than Baseline A for Pipes (74.15% vs 75.08%), suggesting that undirected search can occasionally degrade fixed-parameter performance on less ambiguous classes within a limited budget.

Taken together, these results support the central claim of the paper. The LLM does not replace the geometry engine; rather, it improves the proposal stage of the search process in those settings where manual tuning would otherwise depend heavily on expert intuition.

B. Convergence Analysis

The search trajectories provide additional insight into how the proposed method behaves. On the *Wires* class, the optimization progressed from an initial score of $J = 0.6215$ in the first evaluated round to a final best score of $J = 0.6971$ by the end of the 24-round search budget. This is not a single-step jump. It is a progressive improvement across the search horizon, indicating that the proposal mechanism moved the search toward increasingly useful regions of the parameter space rather than relying on isolated luck.

By contrast, the budget-matched non-LLM search condition improved more gradually and plateaued earlier, reaching a final best score of $J = 0.6420$. The gap between the two trajectories widened in the later rounds, which is consistent with the quantitative results reported for the *Wires* class. This supports the interpretation that LLM-guided proposals are particularly useful when the reconstruction problem is dominated by fragmentation, continuity recovery, and difficult local trade-offs between clustering and merging.

For *Pipes*, the gains were smaller, which is consistent with the weaker separation observed in the final scores. Taken together, these convergence patterns suggest that the proposed method is most beneficial in the harder thin-class regime, where manual tuning would otherwise rely heavily on qualitative expert judgment.

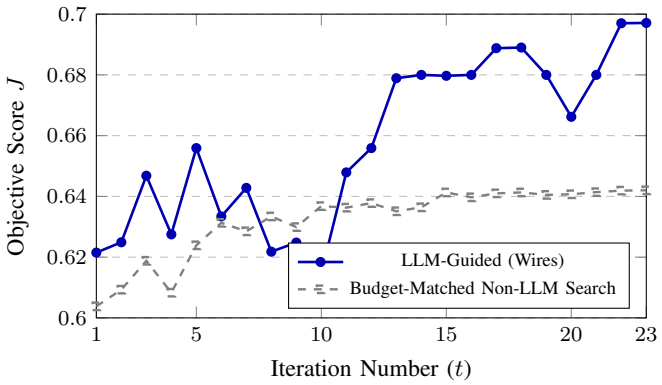

Fig. 4. Measured convergence on the *Wires* class. The LLM-guided search reaches a higher final objective value than the budget-matched non-LLM search condition and exhibits a more directed improvement trajectory over the 23 evaluated rounds.

C. Qualitative Results

Visual inspection supports the numbers. In complex areas like junctions, baseline outputs were often broken or missed curves. The LLM-optimized results show cleaner, more continuous centerlines that navigate occluded spaces more plausibly.

(a) Input Points (Fragmented & Noisy)

(b) Baseline Output (Broken 'Spaghetti')

(c) Cognitive Fitting (Continuous Runs)

Fig. 5. Qualitative Results: Wires. By stacking the views, the continuity improvements in (c) over the baseline (b) become visible. The LLM successfully bridged gaps caused by occlusion.

V. Discussion

The presented results support the core hypothesis of the paper. It was posited that a portion of the heuristic reasoning normally applied by a BIM engineer during primitive-fitting calibration could be approximated by an LLM operating inside a closed-loop search process. The results indicate that this is plausible. The LLM-guided method consistently outperformed the fixed classical baseline and also improved upon the budget-matched non-LLM search condition. This suggests that the search is not purely random and not purely geometric. There is value in a proposal mechanism that can interpret compact diagnostic summaries and steer the next candidate toward more promising regions of the parameter space.

At the same time, the experiments clarify where the benefit is strongest. The largest gains occur on wires rather than pipes. The remaining uncovered wire points are likely a mixture of severe occlusion, sparsity in partially observed runs, and upstream segmentation imperfections, rather than solely a failure of the fitting loop itself. This is an important finding. Wires are the more difficult class because they are thinner, more fragmented, less regular, and more easily confused with clutter or partial observations. The stronger improvement on wires therefore indicates that the proposed framework is particularly relevant for the thin-class frontier in Scan-to-BIM automation, where manual tuning remains most labor-intensive. A natural question is whether a Bayesian optimizer would achieve similar gains within the same iteration budget. We cannot rule this out; comparison with Bayesian optimization or TPE under equivalent budgets remains an important next step. However, the budget-matched non-LLM condition serves a distinct purpose: it isolates whether LLM reasoning over geometric diagnostics provides value beyond generic iterative search of the same space, and the positive result for *Wires* suggests that the LLM's interpretation of structured textual feedback, particularly fragmentation indicators, steers the search in ways that purely numerical methods with no domain-semantic context may not replicate as efficiently under

(a) Input Points (High Occlusion)

(b) Baseline Output (Missing Junctions)

(c) Cognitive Fitting (Recovered Connections)

Fig. 6. Qualitative Results: Pipes. The baseline (b) fails to connect segments separated by structural framing. The proposed method (c) successfully merges these into coherent runs.

small iteration budgets.

The study also makes clear what the current method does *not* yet solve. First, the scalar objective remains intentionally simple. It trades off coverage against dispersion, while fragmentation-related measures are used only as auxiliary diagnostics and secondary quality indicators. This simplicity was useful for a first feasibility study, but it also means the objective is not a complete description of reconstruction quality. Second, the present implementation provides the LLM only with structured text feedback. This isolates the reasoning contribution, but it limits the context available to the agent. Certain failure modes such as false merges in spatially adjacent bundles may be systematically harder to diagnose from scalar summaries alone. Visual residual maps, rendered overlays, or registered RGB cues could plausibly improve diagnosis of failure modes such as under-coverage versus false merging. Third, the current evaluation is based on a single real residential timber project. While this is a practically relevant and difficult testbed, broader cross-site validation is still needed before strong generalization claims can be made.

There are also practical considerations. The weighting in the scalar objective was selected heuristically to reflect class-specific priorities in this dataset. The low-temperature local inference setting improves reproducibility, but prompt sensitivity and repeated-run variance were not exhaustively characterized in the present paper. Finally, the use of an LLM introduces computational overhead that would not exist in a purely geometric optimization loop. A detailed runtime decomposition was not included in the present study and remains an important target for future experimental validation. As a measured reference on the hardware used in this study (RTX 4080, Qwen-2.5-14B-Instruct via LM Studio), each geometric evaluation step required a mean of 30.7 s per candidate across 116 evaluations, while each LLM inference call required a mean of 3.2 s. The full 24-round wire search completed in approximately 61 minutes, this is a one-time autotuning cost per scene class rather than a per-model overhead. For this reason, Cognitive Fitting should be viewed as a targeted autotuning stage for difficult classes and difficult scenes, rather than as a universal replacement for all simpler reconstruction tasks.

Despite these limitations, the practical implications are favorable. The framework automates a stage that is normally dominated by repeated manual trial-and-error. It does so without replacing the underlying geometry engine and without requiring large new training datasets. In that sense, it offers a pragmatic middle ground between brittle classical fitting and fully data-hungry end-to-end learning.

VI. Conclusion and Future Work

This paper presented a Cognitive Scan-to-BIM framework that uses a Large Language Model as a proposal engine for hyperparameter search in post-segmentation MEP primitive fitting. The central contribution is not direct geometry generation by the LLM. Instead, the contribution lies in coupling structured geometric evaluation with LLM-guided parameter proposals inside a closed-loop optimization process.

On the challenging residential timber dataset, the method produced its strongest gains on the *Wires* class, where the best result reached 71.81% coverage with 1.40 mm dispersion and improved continuity relative to both fixed classical fitting and a budget-matched non-LLM search condition. For *Pipes*, the improvements were smaller but still consistent, with the LLM-guided method achieving the best overall objective score while reducing dispersion relative to the fixed baseline. This class-dependent behavior is itself an important result: it indicates that LLM-guided search is most beneficial in thin, fragmented, and topologically ambiguous regimes.

Several limitations remain. The current scalar objective is a practical surrogate rather than a complete multi-objective quality model. Fragmentation is used as diagnostic context but is not yet directly optimized. The LLM receives only textual feedback, not visual or multimodal evidence. The evaluation is limited to one real project dataset, and prompt sensitivity as well as runtime overhead deserve more systematic analysis.

Immediate future work will focus on four directions. First, the objective function will be extended toward a more explicit multi-objective formulation that better reflects continuity and topology preservation. Second, multimodal diagnostic feedback will be investigated by augmenting scalar summaries with rendered residuals and overlap visualizations. Third, broader validation across additional site conditions will be conducted to assess transferability beyond a single timber project. Fourth, the reconstructed primitives will be integrated into a direct Scan-to-Revit workflow through Dynamo or an equivalent API-based bridge, enabling automatic generation of native BIM elements from the optimized cylinder sets.

Overall, the results show that LLM-guided reasoning can be integrated into a classical geometric reconstruction pipeline in a technically meaningful way. This does not eliminate the need for robust geometry processing, but it does reduce the dependence on manual hyperparameter tuning in one of the most difficult parts of Scan-to-BIM automation.

Abstract

Tunnel engineering specifications are critical normative documents for compliance verification and decision support. Existing text-based retrieval methods do not sufficiently exploit the hierarchical structure between clauses, making it difficult to reliably locate evidence and prioritize core clauses. This paper proposes a clause-level retrieval and evidence localization method for tunnel specifications that explicitly leverages document structure as retrieval evidence. A two-stage framework is adopted, where text-based candidate retrieval is followed by structure-aware reranking. A lightweight structural knowledge graph is constructed to encode clause hierarchy and document membership, enabling the derivation of interpretable document-level aggregation and clause-level structural cues. These features provide an explainable structural bias for ranking without training reranking models or requiring additional annotation. Experiments on actual tunnel specifications with 50 engineering queries show improved top-ranking accuracy and evidence coverage over lexical and semantic baselines, while keeping millisecond-level retrieval latency. The results indicate that modeling structural cues is an effective foundation for evidence-based question answering.

Keywords –

Tunnel specifications; Clause retrieval; Structural knowledge graph; Structure-aware reranking.

1 Introduction

Tunnel engineering is characterized by strong compliance requirements and high complexity, involving the coordination of multiple systems such as electrical and ventilation systems [1]. Misinterpretation or omission of any key clauses can lead to significant safety consequences. Thus, tunnel specifications and technical standards documents play a crucial role as "traceable compliance evidence" throughout the entire operations management process [2]. In current practice, engineers typically rely on manual browsing or keyword search within document management systems to locate relevant clauses, a process that becomes increasingly time-consuming as specification sets grow in size and complexity. The risk of overlooking a critical clause or retrieving a similar but incorrect provision is amplified when related requirements are distributed across multiple hierarchical levels within a single document. Given the volume and depth of such documents, quickly locating the specific clauses that directly support decision-making remains a persistent challenge. Traditional information retrieval based on chapters or documents is insufficient to meet the needs of refined compliance retrieval and specification question answering (QA) [3, 4]. Therefore, clause-level retrieval and evidence location have become foundational for tunnel intelligent applications.

Existing document retrieval methods for specific domains often rely on keyword matching or semantic similarity calculations, treating clauses as independent text units [5, 6]. When dealing with tunnel specifications, these methods lack the application of explicit hierarchical organization and document-level aggregation patterns. At the clause level, simply ranking based on text similarity easily leads to scattered evidence clauses and core clauses being placed at the end; while retrieval granularity at the document or chapter level is insufficient to directly support the output of locatable and citable clause-level evidence. Specification clauses carry implicit structural context—such as document membership, hierarchical depth, and clause adjacency [7]—that, if left unexploited, limits the interpretability and traceability of retrieval results [8]. However, how to transform the specification structure into a computable and interpretable ranking criterion without introducing costly annotation or complex semantic modeling remains the core problem facing tunnel specification retrieval.

To address this issue, this paper proposes a clause-

level retrieval method for tunnel specifications that explicitly models document hierarchy as structural evidence for ranking. The method adopts a two-stage pipeline: (i) text-based candidate recall over clause content, followed by (ii) structure-aware reranking within the candidate set. We construct a lightweight structural knowledge graph (KG) with clauses as nodes to encode document membership and hierarchical position, from which interpretable structural cues are derived to bias ranking toward coherent and citable evidence. This design avoids complex semantic KG and trained reranking models, while capturing the "structure-as-evidence" property of specification texts.

The main contributions of this paper are as follows:

- A clause-level retrieval and evidence localization framework for tunnel specifications that outputs traceable clauses.
- A lightweight structural KG with clauses as nodes to encode document membership and hierarchy as a unified source of provenance information.
- A structure-aware reranking scheme, which uses document-level aggregation and clause-level structural cues.

The remainder of this paper is organized as follows. The following sections review related work, describe the proposed method, present the experimental results, and conclude with key findings and future directions.

2 Related Works

This section reviews prior work on tunnel specification retrieval, retrieval and reranking methods for domain-specific documents, and summarizes the key research gaps motivating this study.

2.1 Tunnel Specification Retrieval

Existing research mainly focuses on the digital management of specification texts, keyword retrieval, and rule-based clause location [9, 10]. Some works have integrated with engineering management systems to support the querying, browsing, and citation of specification clauses. However, these methods often use documents or chapters as the basic retrieval unit, emphasizing information organization and retrieval efficiency, and making limited use of the explicit hierarchical organization and clause structure within the specification texts. For specification of QA and compliance verification scenarios addressing specific engineering problems, these methods often struggle to directly output locatable and citable clause-level evidence, thus limiting their applicability in complex tunnel engineering practices.

2.2 Retrieval and Reranking Methods

In the broader processing of technical documents, information retrieval research often employs a two-stage retrieval paradigm [11, 12]. This involves initial candidate recall through keyword matching or semantic similarity models, followed by finer-grained reranking on the candidate set to improve ranking performance. This paradigm has been widely validated in balancing retrieval efficiency and result quality. Regarding retrieval tasks involving long documents and normative texts, some research has begun to focus on the role of document structure information (such as chapters, levels, or metadata) in evidence localization. It has attempted to improve retrieval or QA performance through structure-aware mechanisms [13-16]. However, it should be noted that research explicitly leveraging document structure for clause-level retrieval in normative texts is still relatively limited. Existing studies mainly explore the use of structural information as auxiliary context or organizational metadata, such as for text segmentation, navigation, or result presentation, rather than treating document structure as a computable and interpretable ranking signal. In addition, the retrieval granularity in most existing works is typically defined at the document or chapter level, which poses challenges when directly addressing fine-grained, hierarchically organized clauses in specification documents.

2.3 Research Gaps

Despite these initial efforts, research on structure-aware clause-level retrieval for normative engineering documents remains limited, leaving several open challenges. The review of existing research reveals several shortcomings in retrieval methods for tunnel engineering specifications. First, retrieval granularity is generally limited to the document or chapter level, failing to directly support the location and citation of clause-level evidence required in engineering practice. Second, while structure-aware retrieval is gaining attention, most methods rely on learned reranking models or complex semantic modeling, failing to explicitly incorporate structural cues into the ranking decision process in a low-cost, highly interpretable manner. Third, in applications such as retrieval-augmented generation, structural information is primarily used for text segmentation or organization, lacking research on systematically modeling document-level aggregation and clause-level hierarchical cues on candidate clause sets. Unlike approaches that rely on learned reranking models or complex semantic knowledge graph construction, this study treats structural cues as directly computable ranking features derived from document metadata, without model training or manual ontology design. This positions the approach as an interpretable and low-cost

alternative suited to engineering applications where deployment simplicity and model transparency are practical priorities.

3 Research Methodology

This section introduces the proposed clause-level retrieval method and system framework, including the overall process, clause-level structural representation, and structure-aware reranking strategy.

As shown in Figure 1, the system takes natural language queries as input, performs candidate recall and structure-aware reranking on a clause-level corpus, and outputs the ranked relevant clauses and their evidence fragments. The overall process adopts a two-stage design.

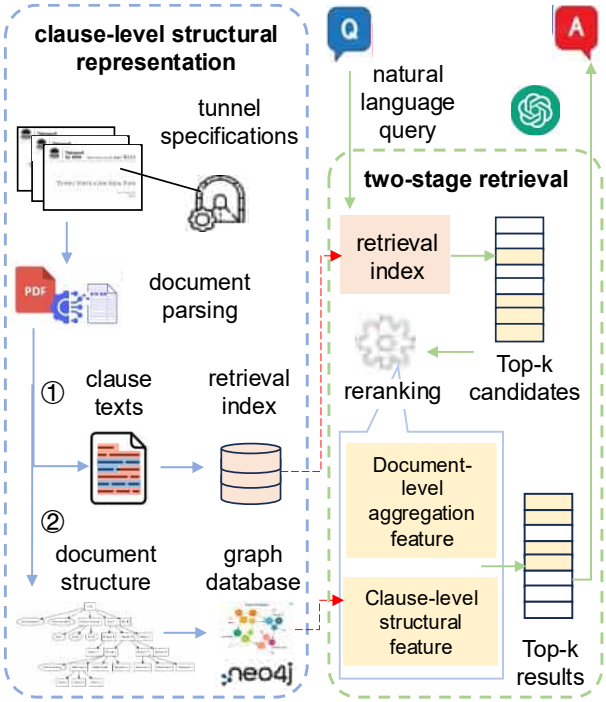

Figure 1. Framework of the proposed clause-level retrieval and evidence-based question answering system.

3.1 Clause-Level Structural Representation

The first step is parsing the specification document into a corpus with clauses as the basic unit. Each clause corresponds to an explicit entry in the specification. It is associated with structural meta-information such as its text content, clause number, the specification document it belongs to, and its hierarchical depth. The clause number and hierarchical depth are automatically inferred from the original chapter structure, used to characterize the relative position of the clause in the overall specification. Based on the above information, a lightweight structural knowledge representation is built, in which clauses are treated as nodes, and their hierarchical and membership relationships are explicitly encoded as node attributes. This structural representation can be regarded as a structural KG of the specification, serving as a unified structural basis in the subsequent ranking stage, without relying on complex semantic relation extraction or manual ontology modeling. Engineering specifications frequently contain explicit internal cross-references between clauses (e.g., "refer to Clause 6.3"). The current implementation does not parse such references at the indexing stage. However, the document-level aggregation mechanism in the reranking stage partially addresses this limitation: when multiple related clauses from the same specification appear in the candidate set, their shared document membership reinforces their ranking, indirectly capturing within-document co-referencing patterns. Explicit cross-reference parsing and graph-based linking represent a direction for future structural enrichment.

3.2 Candidate Retrieval

During the candidate retrieval phase, the system performs text-based retrieval over the clause corpus and returns the Top-k candidate clauses, narrowing the search space while maintaining high recall for subsequent structure-aware reranking. Each candidate corresponds to a complete clause text at the smallest granularity, ensuring a uniquely locatable and citable unit. All subsequent reranking operations are conducted on this unified Top-k candidate set.

3.3 Structure-Aware Reranking

Specification documents exhibit a highly explicit hierarchical structure, with relevant evidence typically distributed in “clause groups” within the same document or adjacent levels, rather than appearing as isolated clauses. When ranking solely based on text similarity, models often struggle to leverage this structured evidence distribution, leading to core clauses with stronger responsiveness failing to consistently appear at the top.

To address this, the reranking strategy incorporates document-level and clause-level structural cues from the KG into the initial text relevance ranking, applying a structured evidence bias that guides results toward more representative clauses without altering the candidate set.

The reranking process utilizes two complementary structural signals: first, document-level aggregation signals, where multiple candidate clauses originate from the same specification, indicating stronger overall relevance within the current query context. Therefore, candidate clauses within the same document are weighed to reinforce the “evidence clustering within the document” pattern. Second, clause-level structural signals,

leveraging attributes such as the hierarchical depth of clause nodes in the structural KG to characterize the functional differences of clauses in normative expression. Thus, they can be seen as structural constraints alongside textual relevance in the ranking process. Through the incorporation of document-level and clause-level structural cues, the reranking mechanism adjusts the relative ordering of candidate clauses in a structure-aware manner without changing the underlying retrieval results.

4 System Evaluations

To evaluate the proposed method, this paper conducts experimental analysis from aspects such as components ablation and external comparison and discusses the retrieval effectiveness and answer quality.

4.1 Experimental Setup

The corpus used is the design compliance specifications from New South Wales, Australia, covering multiple subsystems in tunnels, including electrical and lighting systems. A total of six specifications were selected as the corpus source for the system's retrieval and QA. The documents involved are shown in Table 1.

Table 1. Summary of specifications used in evaluation.

Code	Name	Scope	Clause number	Pages
D&C R153	Tunnel and underpass main switchboard, distribution boards and control panels	electrical boards	33	13
QA R154	Tunnel and underpass electrical services works	electrical services	46	13
QA R158	Road tunnel and underpass lighting	lighting equipment	45	17
D&C R163	Tunnel ventilation axial fans	ventilation equipment	61	27
D&C TS931	Tunnel electrical boards	electrical boards	35	16
D&C R164	Tunnel jet fans	ventilation equipment	65	27

The evaluation experiments were run in a WSL2 (Ubuntu) environment on a Windows host machine. During the experiments, the WSL environment had 12 logical processors (Intel® Core™ i7-8700 @ 3.20 GHz) and approximately 7.7 GB of memory (plus 2.0 GB swap). No graphics processing unit acceleration or model training was used during the experiments; retrieval and reranking were performed on the local central processing unit, and QA generation was completed online through OpenAI large language model interface. This configuration demonstrates the lightweight nature and reproducibility of the proposed method in engineering applications.

The system is evaluated from three aspects: retrieval effectiveness, system efficiency, and QA quality. Retrieval is assessed using standard information retrieval metrics, including Hit@k and Mean Reciprocal Rank (MRR). Hit@k indicates whether at least one relevant evidence clause appears in the Top-k results; MRR measures the reciprocal rank of the first relevant clause. The system efficiency is reported as average query latency. QA quality is evaluated against a small set of reference answers. Over generation, evidence-attribution constraints are enforced to ensure traceability and auditability. Unless otherwise stated, k is set to 5 in all evaluation experiments; the term Top-k is used to describe the general retrieval framework, while Top-5 refers to the specific cutoff adopted for quantitative evaluation.

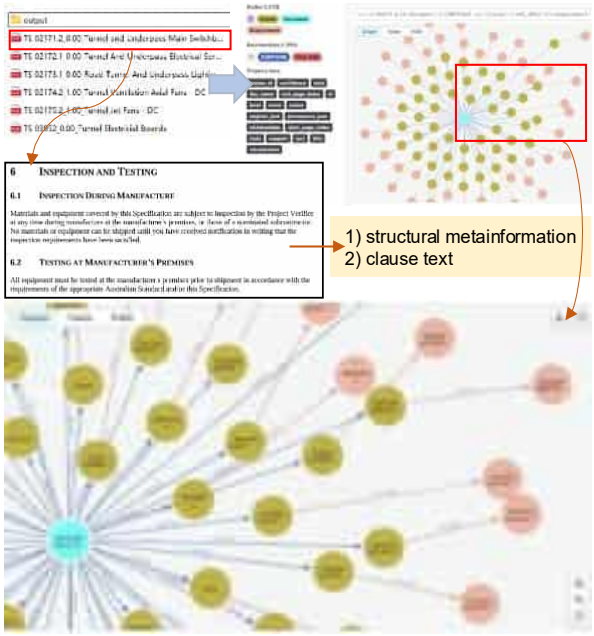

Figure 2. Clause-level KG scaffold constructed from specification documents.

4.2 Results

This subsection evaluates the proposed approach from three aspects: end-to-end functional performance, key component ablation, and comparative analysis.

4.2.1 Functionality Demonstration

This part uses representative cases to demonstrate key system outputs. The proposed system automatically parses specification PDFs into a clause-level index and constructs a KG scaffold encoding clauses, requirement entities, and their hierarchical relationships, as shown in Figure 2.

For the retrieval phase, taking specification QA R154 as an example, the query "What are the requirements for cable routing in tunnel electrical systems?" is selected. The system returned the Top-5 evidence clauses, as shown in Figure 3. Among them, Clause 6.2 "Cable Routing" was consistently ranked first, and its content directly specifies aspects such as cable route selection and support; the remaining returned clauses provide relevant information from aspects such as conduit specifications.

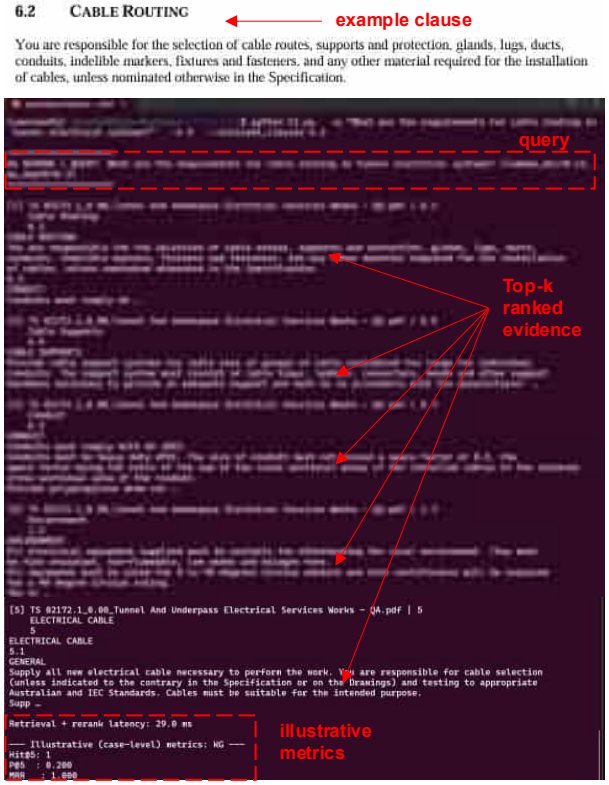

Figure 3. Example clause retrieval results.

Based on this representative case, exemplary (case-level) retrieval metrics are further reported: the system successfully covered the core relevant clauses in the Top-5 results (Hit@5 = 1), and the first relevant clause was ranked first (MRR = 1.00). In addition, the response latency for one retrieval and reranking was approximately 29.0ms, indicating that the system can efficiently return a set of evidence highly relevant to the specification requirements in interactive use scenarios.

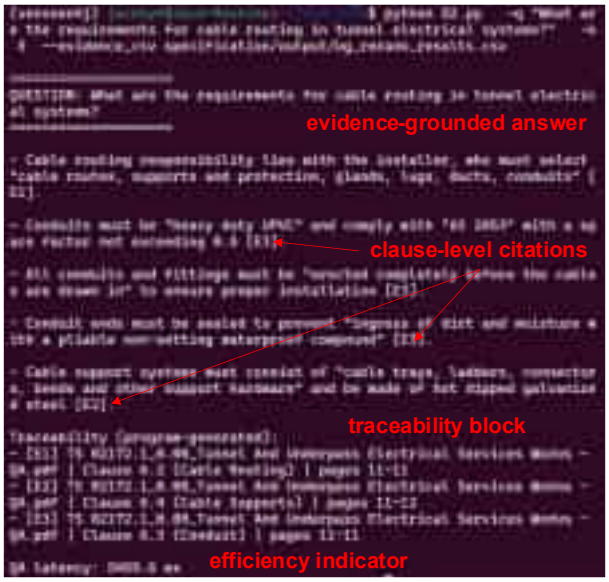

Figure 4. Evidence-based QA output.

During the QA phase, the system generates an answer from the Top-k evidence clauses, as shown in Figure 4. Each conclusion must cite its source clause, and a traceability list maps answers to specific documents, clause numbers, and page numbers, forming a verifiable "answer-evidence" closed loop. The end-to-end QA latency for this example was approximately 5.46 seconds.

4.2.2 Ablation Experiment

This subsection evaluates the impact of two types of rearrangement features derived from the KG structure design, document aggregation features and clause depth features, on the ranking performance of evidence clause retrieval through component ablation experiments.

The experiment was built upon 50 engineering queries designed around the typical information requirements of tunnel specifications. These queries were divided by topic and sampled evenly (e.g., electrical and mechanical, fire protection and safety) to avoid bias caused by queries focusing on a single chapter or term. Each query was expressed as a natural language question, consistent with the clause-level evidence retrieval task. In terms of the experimental procedure, the system first used BM25 [17], a widely used keyword-based ranking function, to generate a candidate clause list. Then, under the same candidate set and parameter settings, the BM25 baseline, a complete model incorporating only a single KG structural feature, and a complete model incorporating both types of KG structural cues were compared. For clarity, we denote the document-level aggregation feature as Doc, and the clause-level hierarchical depth feature as Depth in the ablation variants. Evaluation used Hit@1 and Hit@5, where @1 checks whether the top-ranked clause is relevant and @5 checks whether at least one relevant clause appears

among the top five results; all automatic judgments were manually reviewed and confirmed.

Table 2 shows a comparison of retrieval performance across different ablation variants. The BM25 baseline achieves a Hit@5 score of 0.84, indicating that keyword-based candidate recall is highly usable given the highly structured nature of the specification clause titles. However, its Hit@1 score is only 0.56, suggesting that clauses that directly answer the query are not always prioritized. Introducing document aggregation features derived from the KG structure design improves Hit@1 to 0.62, demonstrating that document-level aggregation using document-clause attribution relationships helps prioritize valid evidence within the same specification document.

Table 2. Ablation experiment results

Variant	Hit@1	Hit@5
BM25	0.56	**0.84**
Depth	0.54	0.82
Doc	0.62	0.80
Full	**0.62**	0.80

In contrast, introducing only clause depth features has limited effect, and the complete model does not improve over the Doc-only variant, indicating that document-level aggregation is the primary source of ranking gain in this task setting. Hit@5 shows little variation across variants, suggesting that the main benefit of structural cues lies in improving top-ranking quality rather than expanding candidate coverage.

4.2.3 Comparative Experiment

This subsection compares the proposed method against lexical, semantic vector, and pretrained embedding baselines under a unified setting to examine the effectiveness of structured evidence bias. A more challenging and application-oriented query set consisting of 50 natural-language specification questions is adopted. These queries were formulated based on domain consultation to reflect typical information needs in tunnel specification compliance workflows, covering electrical, lighting, ventilation, and control panel subsystems. While the queries were authored by the research team rather than extracted from actual engineer search logs, they were designed to span diverse subsystem topics and avoid single-chapter concentration. Integrating real-world search logs from engineering practice is recognized as a direction for future validation.

Compared with the ablation queries, these questions exhibit weaker lexical overlap with clause titles/headings, longer semantic expressions, and less explicit structural cues, making purely keyword-based retrieval substantially harder.

In the comparative experiments, the lexical retrieval method used the standard BM25 model as the baseline; the semantic retrieval method was based on latent semantic analysis, representing clause texts as low-dimensional semantic vectors and ranking them according to cosine similarity [18, 19]; our proposed method, based on the initial BM25 ranking results, introduced document-level aggregation features and clause-level features to perform structure-aware reranking of candidate clauses. All methods returned results under a unified Top-k setting, evaluated using the same weakly supervised judgment rule as the ablation experiments, with all relevance labels manually verified.

As shown in Table 3, our proposed method outperforms the comparative methods on both evaluation metrics. Compared to the Lexical retrieval baseline, the structure-aware reranking strategy achieves a stable improvement in the Hit@1 metric, indicating that introducing document-level and clause-level structural cues helps to prioritize clauses with greater judgment value. On the Hit@5 metric, our proposed method achieves near-saturation retrieval coverage, demonstrating that structured evidence bias can effectively reduce the omission of key clauses.

Table 3. Comparative experiment results

Method	Hit@1	Hit@5
Lexical retrieval	0.16	0.82
Latent semantic vector retrieval	0.12	0.60
Pretrained embedding (text-embedding-3-small)	0.04	0.26
Pretrained embedding (MiniLM-L6-v2)	0.06	0.30
Ours (structure-aware reranking)	**0.18**	**1.00**

To examine whether pretrained text embedding models offer advantages in this setting, two additional baselines were evaluated: OpenAI text-embedding-3-small and all-MiniLM-L6-v2 [20]. Clause texts were encoded into dense vectors and retrieval was performed via cosine similarity ranking. As shown in Table 3, both pretrained models achieved the lowest performance among all methods, falling below even the unsupervised LSA baseline. This result indicates that general-purpose pretrained embeddings, without domain-specific adaptation, do not transfer effectively to normative specification retrieval in the current zero-shot setting, where clause-level functional distinctions are encoded in domain-specific terminology rather than general semantic proximity. Together with the LSA result, these findings confirm that purely semantic approaches—whether corpus-specific or pretrained—are insufficient to capture the functional differences between specification clauses in this retrieval task. Overall, the

results support the effectiveness of structural information in normative clause retrieval tasks.In addition, the Hit@1 performance of the BM25 baseline drops significantly compared to the ablation setting, indicating that lexical matching alone is insufficient for evidence-oriented clause retrieval when queries deviate from structured specification terminology.

4.3 Discussion

The experimental results confirm that the structured organization of specification documents provides natural contextual constraints for retrieval, while purely semantic approaches are insufficient to characterize clause-level functional differences. Incorporating structural information into the ranking process improves both coverage and ranking reliability.

From a practical standpoint, the improvement in Hit@1 from 0.56 to 0.62 in the ablation setting means that for an additional 6% of queries, the most relevant clause is ranked first, reducing the need for engineers to manually inspect lower-ranked results. In the comparative evaluation, the proposed method achieved Hit@5 = 1.00, meaning that for all 50 queries, at least one relevant clause appeared within the top five results. In compliance verification workflows, where overlooking a key regulatory clause can carry safety and legal consequences, this near-complete evidence coverage directly supports the practical goal of reducing clause omission risk in engineering decision-making.

To assess QA generation quality beyond case-level demonstration, ROUGE scores [21] were computed for 44 of the 50 queries for which both retrieval results and matching ground-truth clause labels were available. The scores were computed by comparing system-generated answers against the full text of their ground-truth relevant clauses. The mean ROUGE-L precision reached 0.468, indicating that approximately 47% of generated answer content can be traced back to the source clause text. The corresponding ROUGE-L recall (0.053) and F1 (0.090) were lower, which reflects the expected asymmetry between concise bullet-point answers and full-length reference clauses—the system is designed to extract key provisions rather than reproduce entire clause content. These results confirm that the evidence-grounding constraints imposed during answer generation are effective in maintaining content fidelity to the source specifications.

Overall, the experiments provide consistent evidence supporting the design rationale and practical applicability of the proposed system in specification clause retrieval scenarios. Moreover, while this study focuses on tunnel specifications, the approach can be extended to other road-infrastructure normative documents with similar hierarchical structures to improve evidence-oriented operations management [22].

5 Conclusions

This paper developed a provenance-aware, clause-level retrieval and evidence localization system for tunnel engineering specifications. The proposed approach adopts a two-stage pipeline and a lightweight structural KG. The main contribution of this study lies in explicitly treating document structure as retrieval evidence rather than auxiliary context. Two structural signals, i.e. document-level aggregation and clause-level hierarchical cues, are incorporated into the ranking process without relying on trained reranking models or additional annotation, enabling a lightweight yet explainable retrieval mechanism suitable for engineering applications.

Experimental results demonstrate that the proposed method improves top-ranking reliability, with document-level aggregation increasing Hit@1 from 0.56 to 0.62 and the full approach achieving near-saturated Hit@5 coverage in comparative evaluations. Overall, the results confirm that explicitly modeling structural cues enhances ranking consistency while maintaining low computational overhead.

Future work will explore richer structural signals, extend the evaluation to broader categories of normative documents, and conduct more rigorous assessments of evidence-based QA quality under real-world engineering scenarios.

Abstract –

Ageing bridge infrastructure requires scalable, accurate, and minimally intrusive inspection methods that can reveal subsurface conditions while producing outputs compatible with digital engineering workflows. Muon Flux Technology (MFT) enables passive, non-destructive internal imaging of reinforced concrete elements, producing high-value geometric outputs that can support infrastructure inspection and asset management. A persistent barrier to operational deployment is the limited interoperability between processed MFT-derived outputs and standard Building Information Modelling (BIM) ecosystems. This paper presents a deterministic, programmatic pipeline that converts processed MFT-derived geometries into Industry Foundation Classes 4 (IFC4)-compliant models using a geometry-to-IFC tessellation workflow. Each detected object is provided as an individual Polygon File Format (PLY) file containing either a triangle mesh or a point cloud. Where only point data are available, the workflow reconstructs a surface via Ball Pivoting, applies mesh cleaning for topological stability, and exports the result as an IFC4 tessellated shape. A minimal IFC spatial hierarchy (Project-Site-Building-Storey) is authored to ensure broad compatibility across BIM tools and consistent unit handling. The resulting IFC outputs enable downstream coordination, archival, and integration of MFT-derived 3D information within open BIM workflows, supporting objectives related to data conversion, automation, integration, and standards compliance.

Keywords –

Muon tomography; Non-destructive testing; BIM integration; IFC; Bridge inspection.

1 Introduction

Ageing bridge infrastructure requires inspection methods that can reveal internal condition while minimizing traffic disruption and intrusive testing. Conventional non-destructive testing (NDT) methods, such as ground-penetrating radar, X-ray, and ultrasound, often face practical limitations such as limited penetration depth, operational complexity, cost, and restricted integration into digital workflows. Surface-based capture is widely adopted but does not provide subsurface insight critical for reinforced concrete condition assessment.

Muon Flux Technology (MFT) provides a complementary sensing modality. Muon-based imaging supports 3D internal imaging and can enable detection of internal features such as steel element geometry, voids, and other anomalies by measuring naturally occurring atmospheric muons and their scattering or attenuation through objects.

The M-TABS project aims to advance muon flux tomography for bridge assessment and to incorporate the resulting information stream into established formats such as 3D Building Information Modelling (BIM), thereby enabling integration into broader infrastructure maintenance practices. In this context, the paper addresses the automated conversion of processed MFT-derived outputs into BIM-compatible representations using industry-standard data formats [1]. Although the broader MFT-to-BIM vision is intended for bridge inspection in operational settings, the present paper focuses specifically on the deterministic conversion of processed MFT-derived geometries into IFC4-compliant BIM outputs. Accordingly, validation in this study is limited to processed data generated under simulation-based and controlled specimen conditions.

Recent work on construction digital transformation

increasingly positions scan-to-BIM and digital twins as enabling layers for maintenance-focused decision support, where interoperability and traceable data exchange are recurring challenges [2–6]. Artificial intelligence (AI) techniques, including machine learning and deep learning, have been increasingly adopted to support automated analysis, prediction, and representation learning in complex engineering workflows [7–11]. Scan-to-BIM pipelines that convert reality-capture point clouds into semantic BIM have rapidly evolved from rule-based modelling to AI-assisted segmentation and automated Industry Foundation Classes (IFC) generation, and recent syntheses provide conceptual frameworks and best-practice guidance for reproducible adoption [12]. In parallel, the release of domain-specific datasets and benchmarks is beginning to standardise evaluation of scan-to-BIM methods and support generalisable learning-based approaches.

Beyond general reviews, open-source and benchmark-validated pipelines have been proposed to accelerate large-scale point-cloud-to-IFC conversion [13]. Domain-specific work has also demonstrated automated IFC generation for infrastructure assets such as railways by combining topology priors, parametric assemblies, and mesh-based reconstruction [14], and semi-automated IFC bridge modelling from point clouds has been explored for maintenance-oriented workflows [15]. Complementary efforts and related venues report deep learning-based Scan-to-BIM frameworks capable of reconstructing complex indoor elements from incomplete point clouds, underlining the continued push toward higher automation and robustness [16].

Muon imaging offers a complementary, passive modality for probing internal steel and density anomalies. It has demonstrated feasibility for reinforced concrete specimens and rebar-scale targets [17,18]. Yet, practical uptake in the built environment depends not only on reconstruction quality, but also on integrating outputs into established information-management ecosystems.

A key research gap therefore lies in the information integration layer: muon-tomography reconstructions are naturally produced as volumetric grids, point clouds or triangle meshes that are not readily expressible as parametric BIM objects and there is limited guidance on representing such internal, irregular geometries in openBIM formats while preserving metric integrity, provenance, and auditability. Although IFC4 supports tessellated geometry via IfcTessellatedFaceSet/IfcTriangulatedFaceSet for exchanging meshes in a standards-compliant manner [19], the use of these representations for NDT-derived internal reconstructions remains underexplored.

This paper addresses that gap by providing a deterministic Polygon File Format (PLY)-to-IFC4 conversion workflow for MFT outputs, designed to be reproducible and standards-compliant. The novelty is in (1) targeting subsurface muon-tomography reconstructions rather than surface scan-to-BIM, (2) encoding internal steel geometries and deviation maps using IFC tessellation to enable tool-agnostic exchange, and (3) emphasising auditability through explicit units, consistent spatial structure, and repeatable processing steps aligned with downstream inspection and digital-twin workflows. The main contributions are as follows: A deterministic, programmatic PLY-to-IFC4 conversion pipeline that supports both triangle meshes and point clouds; A robust preprocessing strategy, including surface reconstruction for point clouds, and mesh cleaning for stable IFC tessellation; Standards-based IFC export within a minimal IFC spatial structure, with explicit unit definition to prevent scaling ambiguity.

2 Background and Motivation

MFT uses naturally occurring muons in background radiation to compare incoming and outgoing particle distributions after they pass through a target. Variations in attenuation and scattering reveal internal geometry and material characteristics. Combined with AI-based reconstruction and classification, MFT enables subsurface 3D inspection for identifying embedded steel properties, cross-sections, and defects such as corrosion, voids, and cracking, as outlined in Table 1 against XRF. In the M-TABS project, this approach is applied to reinforced concrete bridge components, with the goal of producing 3D BIM outputs that fit existing inspection and asset-management workflows for operators and infrastructure owners. Figure 1 presents the GScan muon flux detector hardware used to collect the measurement data in this study. Muons are generated when cosmic rays interact with the atmosphere and, due to their high mass, can penetrate significant thicknesses of materials such as steel and concrete. In MFT, the process involves measuring the incoming particle flux, observing how particles are scattered or absorbed as they pass through an object, and measuring the exiting flux and scattering features such as $\Delta\theta$. These measurements are then used with AI to reconstruct internal structures and infer material composition, as different materials produce distinct attenuation and scattering signatures, as illustrated in Figure 2. A key technical challenge is converting tomography-native outputs into BIM-native representations. Tomography generates voxel-based or unstructured geometric data, while BIM represents structured, semantic objects within a spatial hierarchy. IFC, as the main interoperability standard, uses tessellated geometry in IFC4 to encode irregular surfaces as triangulated meshes, preserving geometric fidelity and compatibility with BIM tools, but with reduced parametric flexibility and larger file sizes.

Table 1 Comparison of XRF and muon tomography + AI across key operational criteria.

Criterion	XRF	Muon
Penetration depth	Limited	~10 m
Ability to penetrate shielded materials	Moderate	High
Chemical composition identification	Yes	Yes
Material agnostic / number of materials	High	Very high
Scanning time per m³	Rapid	Extended
Environmental insensitivity	Very low	High
System size / portability	Portable	1.75 × 0.75 m
Resolution / accuracy	Millimetre-scale	~1 mm

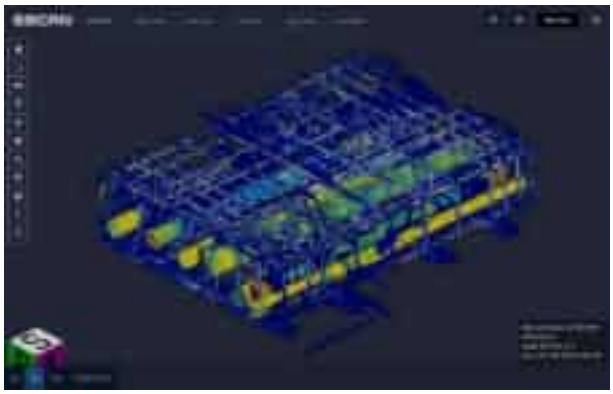
3 Process Context and interdependencies

3.1 Data Acquisition

The first step establishes the foundational data assets required for method development and benchmarking across the project by creating a simulation-based dataset derived from an infrastructure asset. In addition to generating representative synthetic measurements, this step is explicitly responsible for delivering (1) a Universal Simulation Environment and (2) a Benchmark Data Library that provide consistent, controlled inputs for subsequent development and validation in the following steps. In practical terms, first step outputs must support two complementary needs: (a) physics-consistent scene and sensor configuration to enable reproducible simulation studies, and (b) ground-truth geometric or volumetric representations that can be used to benchmark reconstruction fidelity, segmentation accuracy, and downstream model conversion. The attached artefacts exemplify these two output classes: Simulation environment or scene definition, Benchmark volumetric ground truth. Overall, first step outputs operationalize the project's data-first dependency chain: they enable second step to develop and validate processing algorithms under controlled conditions, and they provide the reference geometries and volumetric benchmarks that ultimately support conversion of processed outputs into interoperable BIM deliverables. Figure 3 provides an example first step benchmark environment and associated ground-truth geometry.



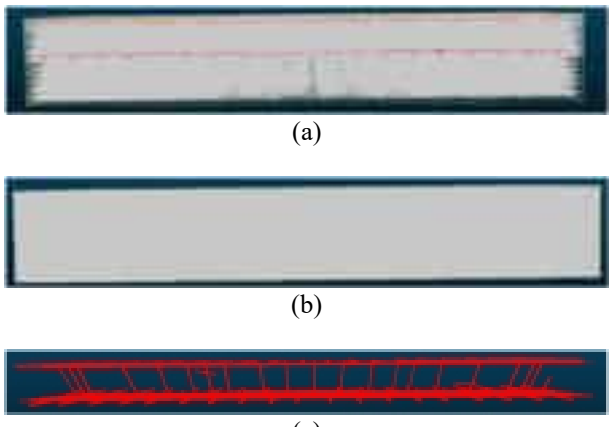


Figure 3. Simulation environment and benchmark volumetric ground truth.

3.2 Data Processing

The next step focuses on transforming muon-derived reconstructions into engineering-consumable, object-level outputs that can be directly ingested by downstream BIM integration workflows. In addition to improving the quality and usability of processed results, second step provides the intermediate representations required for

IFC generation: (1) classified material outputs, (2) instance-level segmentation of reinforcement, and (3) geometry and location descriptors suitable for object placement and semantic assignment. The outputs illustrate a concrete processing chain starting from a volumetric steel representation and culminating in object-level data products: Voxel-to-point conversion and material classification: A vowelized MFT volume is converted into a point-based (PLY) format and classified by material (e.g., concrete and rebar), producing the basic candidate point clouds required for further modelling and export. In the voxel-to-point conversion stage, each retained voxel was represented by a single point located at its centroid. This choice provides a compact object-level representation for downstream classification and export, but it also smooths boundary detail relative to explicit voxel-surface extraction. Consequently, the final mesh quality depends on the voxel resolution and on the subsequent surface reconstruction stage, which together govern the trade-off between data compactness and geometric fidelity. Representative outputs from this conversion and classification step are shown in Figure 4.

(a)

(b)

(c)

Figure 4. Voxel-to-point conversion and material classification outputs from MFT-derived volumes: (a) Point cloud; (b) Concrete classification; (c) Rebar classification.

Instance segmentation to isolate individual rebars: This stage evaluates multiple geometric instance segmentation methods to extract individual rebars from classified point clouds, a prerequisite for correct IFC export. Density-Based Spatial Clustering of Applications with Noise (DBSCAN) leads to over-segmentation, cylinder fitting under-detects rebars, and region growing improves detection but still suffers from fragmentation and missed elements. Overall, these results show that purely geometric approaches struggle with connected, irregular, or partially observed rebars, limiting reliable one-object-per-element IFC generation. This limitation is important for the downstream IFC conversion stage. The geometry-to-IFC workflow assumes that each input PLY corresponds to a single, correctly isolated physical object. Therefore, when upstream segmentation produces merged rebars, fragmented instances, or incomplete separations, the downstream export does not resolve these errors; instead, it deterministically converts the provided geometry into a tessellated IFC element. In this sense, segmentation quality directly governs semantic reliability, object granularity, and the engineering interpretability of the resulting BIM model. Figure 5 illustrates representative qualitative results of instance segmentation.

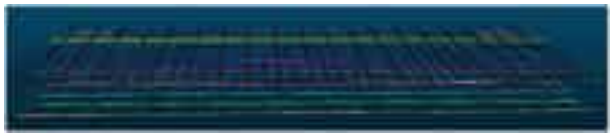

Figure 5. Instance segmentation of steel data.

Few-shot learning-based instance segmentation: This method is introduced to address the limitations of purely geometric approaches, trained on a small manually labelled rebar dataset. This approach improves isolation of individual rebars and more robustly handles connected and irregular shapes, enabling consistent object-level outputs suitable for BIM/IFC generation. A representative output from the few-shot approach is shown in Figure 6.

Although quantitative instance segmentation metrics such as Intersection over Union (IoU), Precision, Recall, and F1-score would strengthen the upstream evaluation, they are not reported in this study because no benchmark dataset with ground-truth instance labels was available for this stage of the MFT processing pipeline. The segmentation assessment is therefore presented qualitatively, with emphasis on the observed failure modes of geometric methods, including over-segmentation, fragmentation, and missed elements, and on the improved object isolation achieved by the few-shot learning approach. Establishing a benchmark dataset with instance-level ground truth remains an important next step for rigorous quantitative evaluation of segmentation performance. Geometry information extraction for downstream modelling: extracts per-instance geometric and location attributes into a structured tabular format, producing instance-level descriptors that support semantic classification, spatial placement, validation, and auditability in downstream BIM/IFC workflows.

Collectively, these outputs provide the two key input families required for IFC authoring: Object-level geometries, including one PLY per segmented rebar instance and meshes derived from those instances, and Instance metadata that support semantic assignment and consistent placement.

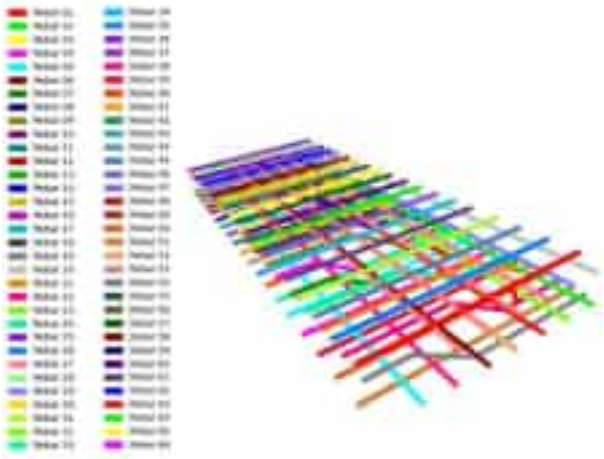

Figure 6. Few-shot learning-based instance segmentation result.

3.3 3D Model Generation and BIM Integration

The next step converts processed outputs into BIM-compatible 3D representations and ensures the resulting models adhere to industry standards for data exchange and integration. Its objectives include (1) data conversion to BIM-compatible formats, (2) automation of 3D model generation from processing outputs, (3) integration into BIM software for accurate 3D representations, and (4) standards alignment for model generation and exchange. The deliverable of this step is an updated front-end for GScan's MFT, which consumes outputs from the previous steps and supports downstream pilot implementation and evaluation in later steps. This paper addresses a specific and critical third step capability: open-standard IFC4 generation from processed, object-level geometries (exported as PLY). The presented methodology implements a deterministic, programmatic geometry-to-IFC tessellation workflow using IFC4 constructs to maximize interoperability.

The third step consumes the output of the second step in the form of per-object geometry files, PLY point clouds and reconstructed meshes for individual reinforcement instances, along with associated instance-level geometry and location descriptors**.** These artefacts enable a direct, automated export pathway: each segmented instance is converted into a discrete IFC element, represented using IFC4 tessellated geometry (IfcTriangulatedFaceSet) and inserted into a minimal IFC spatial hierarchy with explicitly units (metres).

4 Methodology: IFC generation method

The IFC model was generated through a deterministic, programmatic geometry-to-IFC tessellation workflow. Processed MFT-derived geometries were converted into BIM-compatible objects by constructing a minimal IFC spatial hierarchy and embedding each object's surface representation as an IFC4-compliant tessellated shape. The implementation used Open3D for geometry handling and IfcOpenShell for IFC authoring.

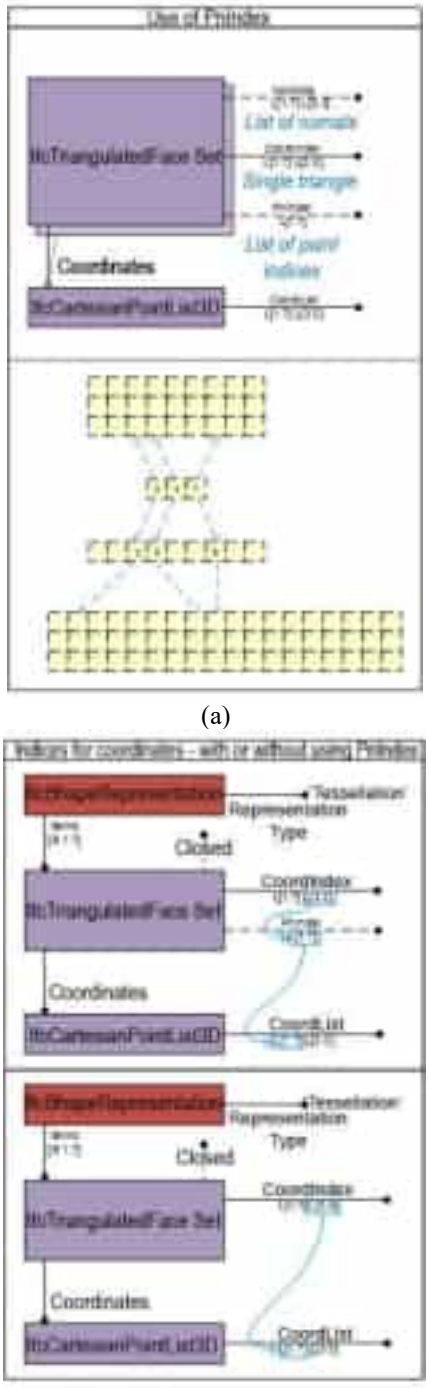
Each input object was provided as an individual PLY file that may contain either (1) a triangle mesh (faces + vertices) or (2) a point cloud (vertices only). For each PLY:

Mesh detection: The file was first read as a triangle mesh. If valid faces were present, the mesh was used directly.

Surface reconstruction (point clouds only): When no faces were present, the point cloud was converted into a triangle mesh using Ball Pivoting Surface Reconstruction. Surface normals were estimated prior to reconstruction. For a point cloud with N points, the average nearest-neighbor spacing was computed as:

$$\bar{d}_{nn} = \frac{1}{N}\sum_{i=1}^{N} d_i^{nn} \quad (1)$$

where d_i^{nn} is the Euclidean distance from point i to its nearest neighboring point. The Ball Pivoting radii were then defined as:



$$R = \{k_1\bar{d}_{nn}, k_2\bar{d}_{nn}, k_3\bar{d}_{nn}\} \quad (2)$$

where k_1, k_2, and k_3 are fixed scale multipliers used consistently across the dataset. In our implementation, $k_1 = [1.5]$, $k_2 = [2.5]$, and $k_3 = [3.5]$. This radius-selection strategy preserves geometric scale consistency across point clouds with different sampling densities.

Mesh cleaning: The resulting mesh (either imported or reconstructed) was cleaned using standard topological repairs, including removal of duplicated and degenerate triangles, non-manifold edge mitigation, and recomputation of vertex normal, to ensure stable downstream tessellation.

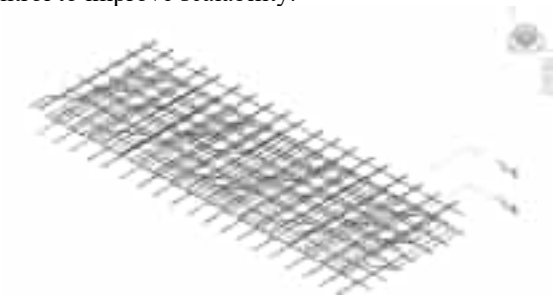
A valid IFC4 container structure was created to ensure compatibility with standard BIM tools. The following spatial entities were instantiated: IfcProject (root), IfcSite, IfcBuilding, and IfcBuildingStorey. Length units were explicitly assigned as meters in "UnitsInContext" to prevent viewer-dependent scaling issues. This structure provides the minimum required context so that imported elements appear correctly in IFC viewers and BIM authoring platforms.

Each mesh was encoded as IFC tessellated geometry using IfcTriangulatedFaceSet, which is the IFC4 entity intended for representing arbitrary triangular surfaces: Mesh vertices were written to IfcCartesianPointList3D (CoordList), preserving the original coordinate system after any required scaling or normalisation. Mesh faces were written to IfcTriangulatedFaceSet (CoordIndex), as illustrated in Figure 7 [19]. Because IFC indexing i**s** 1-based**,** face indices were shifted accordingly during export.

(a)

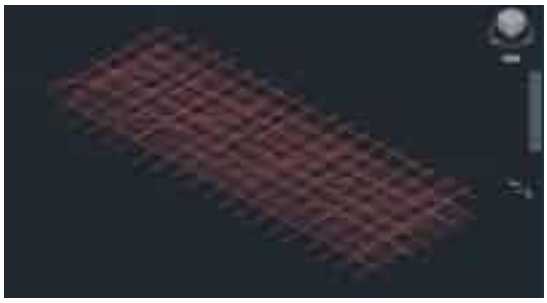
(b)

Figure 7. (a) IfcCartesianPointList3D; (b) IfcTriangulatedFaceSet.



The tessellated geometry was placed into a standard shape representation: (1) IfcShapeRepresentation with: RepresentationIdentifier = "Body", RepresentationType = "Tessellation", Items = [IfcTriangulatedFaceSet]; (2) Wrapped in IfcProductDefinitionShape and assigned to the element's Representation. This approach produces broad interoperability across IFC viewers. For each exported object, an IFC product instance was created and inserted into the spatial structure: (1) Element class assignment: Objects were exported either as IfcReinforcingBar (when the object corresponded to rebar) or as a generic IfcBuildingElementProxy when semantic classification was not available or not required; (2) Placement: Each element was assigned an IfcLocalPlacement (default orientation and origin placement, or a project-defined local reference frame if applied); (3) Containment: Elements were associated with a bridge-relevant spatial container, including IfcBridge and IfcFacilityPart, via IfcRelContainedInSpatialStructure, ensuring correct visibility, hierarchy, and navigation within BIM and digital engineering environments.

5 Results and Discussion



The exported IFC contains a valid spatial hierarchy, one IFC product per input PLY object, a tessellated body representation for each object, and consistent placement, ensuring that the objects appear as expected in standard BIM viewers. The symmetric Chamfer distance between each input geometry and the tessellated geometry re-extracted from the exported IFC was used to assess geometric fidelity. The average Chamfer mean was 0.61 mm, and the average Chamfer p95 was 2.53 mm. When the input was already a mesh, the export was effectively lossless, with a mean Chamfer distance of 0.02 mm and a p95 of 0.09 mm, confirming high-fidelity tessellation-based IFC encoding. For point-cloud inputs requiring Ball Pivoting reconstruction, the average errors increased to a mean of 1.20 mm and a p95 of 4.97 mm, indicating that the dominant source of error arises from surface reconstruction rather than from the IFC encoding itself. In terms of efficiency, end-to-end processing averaged 2.60 s per element. The exported IFC size was 27,774 KB, indicating that the conversion achieves interoperability with only a modest increase in file size. For rebar-representative objects, IfcReinforcingBar provides a semantically meaningful class assignment; otherwise IfcBuildingElementProxy ensures a safe fallback without overstating semantics. While this export strategy provides a robust and conservative pathway for geometry-to-IFC conversion, the present implementation offers only limited semantic enrichment. The current BIM output primarily encodes geometry, placement, and basic class assignment, and does not yet attach richer property information such as reconstruction confidence, uncertainty bounds, estimated bar diameter, or provenance metadata from the upstream MFT processing stages. As a result, the exported model is currently more suitable for visualization, exchange, coordination, and

auditability than for advanced engineering querying or asset-management analytics. Future work should therefore extend the exported entities with infrastructure-relevant property sets and provenance-aware metadata once such attributes can be derived and validated consistently. Figure 8 shows a representative exported model visualised in Autodesk Revit and AutoCAD. The reported results therefore demonstrate the feasibility of standards-compliant geometry-to-IFC conversion under controlled inputs, but they should not yet be interpreted as full evidence of robustness under active bridge operating conditions.

A practical challenge in processing muon-derived outputs is variability in representation: some objects may be exported as watertight meshes, while others may be sparse point clouds. The two-path approach (direct mesh handling vs deterministic surface reconstruction) addresses this variability while maintaining a single IFC export strategy. Mesh cleaning is critical: repairing degenerate triangles and mitigating non-manifold conditions substantially reduces the likelihood of unstable or invalid tessellation in downstream BIM tools. The use of IfcTriangulatedFaceSet was chosen for robustness and compatibility with irregular MFT-derived geometries, but it may be inefficient for large infrastructure models because high-resolution meshes can increase file size and reduce viewer performance. The paper should therefore state that this choice prioritizes reliable geometry preservation over efficiency, while noting that future work will explore parametric rebar modelling, mesh decimation, and level-of-detail control to improve scalability.

6 Conclusion

This paper presented an IFC generation method that converts processed MFT-derived geometries, including PLY meshes and point clouds, into IFC4-compliant BIM deliverables through a deterministic geometry-to-IFC tessellation workflow. Using Open3D for geometry handling and IfcOpenShell for IFC authoring, the approach constructs an IFC spatial hierarchy, explicitly defines meter units, and exports each object as a standard Body/Tessellation representation using IfcTriangulatedFaceSet. The result is a robust, interoperable pathway for integrating muon-derived 3D information into open BIM workflows, supporting objectives related to data conversion, automation, integration, and standards compliance.

An important next step is validation using data acquired from an actively operating bridge, where operational noise, environmental variability, attenuation uncertainty, and site constraints may affect the reliability of the broader pipeline. Future work can extend this foundation in four directions: (1) Richer semantic mapping: expanding beyond IfcReinforcingBar and proxy entities to additional infrastructure-relevant classes and property sets, including provenance metadata and confidence descriptors where available from upstream processing; (2) Parametric reconstruction when feasible: for objects approximating canonical forms, such as cylindrical reinforcement, exporting swept solids or other parametric representations alongside tessellated geometry to improve editability and downstream analytics; (3) Scalability optimization: introducing mesh decimation strategies and level-of-detail management to control file size and improve import performance for large-scale scans; (4) Infrastructure-specific spatial context: where project requirements demand, align the spatial structure with bridge/facility conventions and integrate with wider asset information containers.

Abstract -

Stray animals colliding with moving vehicles is one of the most serious road safety hazards that exists today. Many of these collisions occur at roads that run directly next to important urban spaces like institutional corridors, where stray animals often invade the highways. Since the use of physical barriers and sophisticated sensor technologies can be prohibitively expensive and logistically impractical, this paper proposes a simple yet scalable computer-vision-based approach for detecting stray animals, such as dogs and cows, crossing the roads using existing CCTV cameras installed along highways as part of the regular road surveillance systems. A database of animal intervention images was extracted from the CCTV video recordings along a state highway that runs adjacent to the University campus. Each image contained either a cow or a dog that had invaded the travel lane of the roadway. By using a lightweight YOLOv11 nano object detection model to detect animals within the visual field of the camera, each of the images was then passed through a hybrid classifier that utilised both CNNs and QNNs to refine the object detection and improve the accuracy of the detection under low-light and other challenging operating conditions. The model accomplished a precision of 86.7%, a recall of 63.4% and mAP50 of 79.6%. Through experimentation, it has been demonstrated that the proposed methodology will converge to a stable solution and provide increased robustness to variations in lighting and other environmental factors.

1 Introduction

In the context of Indian roads, vehicle collisions with stray animals like dogs and cattle cause road accidents that are almost persistent and underreported [1].

Recent studies have shown that collisions between animals and vehicles are a major cause of highway crashes and other vehicle accidents, especially in areas where there is a large population of loose roaming (free-roaming) animals. These incidents have several repercussions, including loss of life of humans and animals, economic losses due to property damage and vehicle repair, traffic congestion and disruption of traffic flow, damaged roadway infrastructure, and increased risk for drivers, pedestrians and local residents, particularly on highways and rural roads [2].

Field observations obtained from National and State highways show that dogs and cows are frequently seen crossing the roads, which leads to single or multiple vehicle collisions. This situation requires smart technological solutions, such as automated detection of animal intervention and alert mechanisms to ensure a safe and comfortable environment for road users. The current technological framework of the Indian traffic management system primarily comprises surveillance CCTV cameras that are installed, inspected, monitored, controlled and documented by the highway administration authorities. The fundamental objective of this study is to reframe animal detection as a civil infrastructure resilience problem and propose a scalable solution that takes advantage of the existing edge technologies, instead of deploying any new sophisticated technologies that require additional expensive investments. This study utilised the real-world video footage obtained from the existing CCTV cameras installed in and around the highway adjacent to the university campus. From this, about 453 frames corresponding to different times of the day were generated and labelled as the baseline dataset. This hybrid YOLOv11-CNN-QNN architecture is proposed for the real-time detection of animals using real-world datasets collected using traffic surveillance CCTV camera images under low-light conditions and occlusions, focusing on the detection of animal-related disruptions to road traffic rather than the classification of animals.

2 Background and Literature Review

Animal–Vehicle Collision (AVC) is an omnipresent and rising global concern regarding road safety, which has a multitude of effects like loss of life, severe injury, loss of revenue and loss of biodiversity. Both in the developed world and the developing world, there is a reasonable body of empirical evidence showing that AVCs constitute a substantial proportion of all road accidents, notably on highways and country roads where speeds are higher, and animal crossings are less predictable [3, 4, 5]. Moreover, AVCs occur at a greater frequency during night, and low-visibility conditions when the driver's perception and response time are significantly impaired, and when standard surveillance/warning systems are ineffective [2].

In developing countries, AVCs are further complicated by issues like the presence of feral/stray animals, lack of compliance with laws governing animal control, and inadequate infrastructure to mitigate wildlife conflicts [4]. Literature evidence specifically shows that common domestic animals like cattle and dogs cause the majority of the severe AVCs that occur close to human habitation and/or near agricultural land adjacent to highways [3, 5]. Although the magnitude of AVCs is being recognized globally, the mitigation efforts still remain piecemeal, and many of the current AVC solutions focus on isolated areas rather than providing a scalable system-wide solution.

2.1 Conventional AVC Mitigation Methods

Conventional AVC mitigation methods utilize physical/infrastructure-based solutions, i.e., wildlife fencing, underpasses, overpasses, warning signs and lighting along the roadway [3, 6]. However, these types of AVC mitigation methods are expensive to install, require significant planning and need a commitment to maintenance, limiting their feasibility for large-scale deployment throughout vast highway networks in low- and middle-income countries. Furthermore, these static AVC mitigation methods are unable to accommodate the dynamic nature of animal movement patterns, seasonal migrations and diurnal behaviors [1]. Therefore, AVC mitigation efforts will require dynamic and responsive solutions to supplement conventional infrastructure-based AVC mitigation methods.

2.2 Sensor-Based and Hardware-Dependent AVC Detection Systems

Some studies have proposed AVC detection using sensor-based systems incorporating infrared, thermal imaging, ultrasonic sensors, RFID and GPS-based tracking [7]. Of these, thermal imaging has been of particular interest due to its capability of detecting warm-bodied animals in low light and nighttime conditions. However, while thermal imaging systems can be effective in controlled environments, they have several disadvantages, including limited spatial resolution, inability to differentiate among species, sensitivity to weather conditions and high cost [8, 2]. Sensor-based AVC detection systems are also subjected to significant challenges in terms of installing, calibrating and maintaining hardware, especially along lengthy sections of highways [7]. This has prompted researchers to explore software-centric, vision-based AVC detection methods utilizing existing infrastructure.

2.3 Computer Vision and Deep Learning for AVC Detection

Recent advances in computer vision and deep learning have allowed for substantial improvements in real-time object detection, and several studies have demonstrated the effectiveness of YOLO-based architectures for AVC detection, particularly when coupled with image enhancements to increase visibility in low-light conditions [8, 2]. In addition, vision-based safety monitoring approaches using existing cameras have shown great potential for detecting hazards in infrastructure systems[9]. However, deep learning-based AVC detection systems have several challenges. First, AVC detection performance is heavily reliant upon the quality and diversity of the training dataset used to train the detector, which is often limited in terms of AVC detection in regionalized contexts [8, 10]. Second, most of the studies focus on identifying specific species, limiting the model's ability to generalize to unseen/rare species [10]. From a road safety perspective, identifying the species may not be necessary for AVC mitigation since the primary goal is timely hazard detection, regardless of whether or not the species is identified. Recent studies have shown the efficiency of deep learning-based vision systems in object detection in unstructured and real-world environments, addressing problems such as occlusions [11]. Finally, deployment of AVC detection systems in realistic environments, including low-quality CCTV footage, variable lighting, occlusion, and environmental noise, impairs the accuracy of AVC detection relative to laboratory testing [2]. These issues illustrate the disparity between AVC detection system performance in experiments versus AVC detection system reliability in operational use.

2.4 Road Safety Analysis and Computer Vision Infrastructure

More recently, the field of computer vision has extended beyond the application of detecting animals using video feeds (e.g., AVC) to include the application of computer vision in larger roadway safety assessments (e.g., roadside feature extraction, crash risk prediction) [12]. The majority of this research has focused on static, non-transient hazards (e.g., infrastructure hazards), whereas animal intrusion represents a high-priority, time-sensitive hazard that requires immediate detection and response [12]. Therefore, integrating the capability to detect animals into intelligent transportation systems presents a current research gap [12].

2.5 Research Gap and Motivation

Sensor-based solutions rely on specific hardware and are difficult to deploy in large scale [7]. Although deep learning-based solutions hold a good promise,

many struggle to overcome the issues of data availability, poor lighting, and lack of generalization in real-world settings [2, 10]. Additionally, over-emphasizing the classification of specific species limits the robustness of such solutions in multi-species traffic environments [4]. Therefore, these aspects provide the motivation to develop an intelligent, vision-based animal intervention framework that utilizes existing roadside CCTV infrastructure, focuses on generic animal presence detection, and performs well under real- world constraints.

3 Methodology

Figure 1 explains the flow of work from data collection to frame extraction as the basic input data stage. Post, the data was split into three categories as train, validate and test with the proportion of 80:10:10, respectively and was augmented for better performance. Annotation was succeeded by a hybrid CNN and QNN reinforcement for animal detection and classification to outperform in inclement lighting conditions with the available dataset.

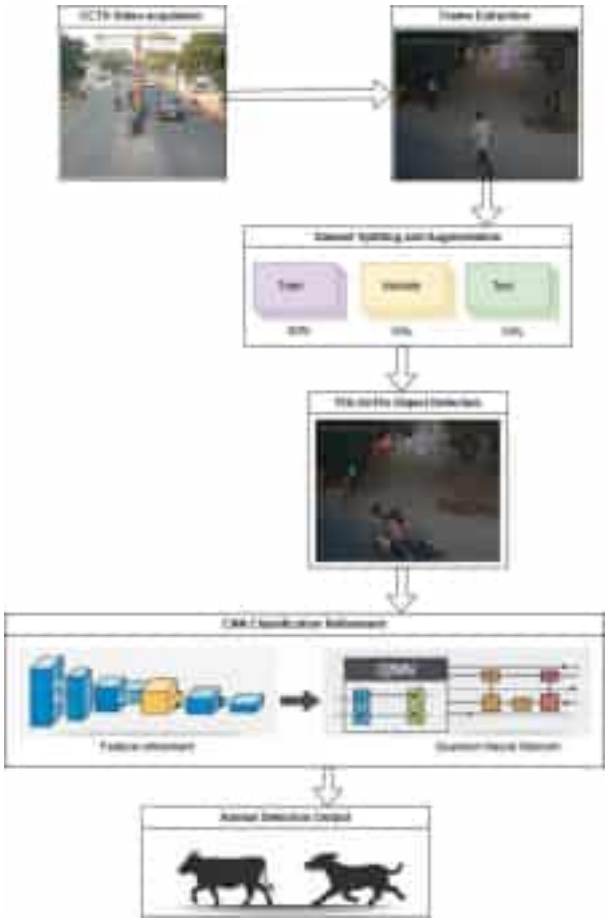

Figure 1. Methodology

3.1 Study Location and Data Collection

Data collection was based upon visual evidence collected from a stretch of state highway with documented recurrent animal crossings of the highway; this location is also proximate to the University campus, located near Vellore, Tamil Nadu, India, increasing the likelihood of animal-vehicle collisions due to increased human settlement influences. Video from existing roadside CCTV cameras was used as the sole source of data for this research to support compatibility with existing infrastructure. Video recording occurred at different times of the day, at night, during dawn, dusk and at low light levels, to provide a diverse range of lighting conditions and traffic scenarios, and the time of collection of data is roughly between 05:00 PM and 7:00 AM for about 5 consecutive days. Based on the CCTV's capabilities, the usual range is between 30 and 50m. To cover a distance of 500m, we would require 12-17 cameras, depending on the overlapping strategy. This model of monitoring systems does exist in real time, and the dataset collected is from the existing infrastructure system established on highways at Katpadi - Vellore.

Figure 2. Data Collection Dog Frame

Figure 3. Data Collection Cow Frame

3.2 Dataset Creation and Labelling

A total of 453 relevant and clear image frames were created from the collected CCTV footage and manually

validated to confirm their relevance and clarity. These images depicted a variety of animals crossing or occupying the highway, including stray dogs and cows, which represent two of the most common types of animals. Labelling of objects was completed using the RoboFlow. To minimise label noise and ensure accurate positioning of bounding boxes, all images were labelled using a standard protocol. In addition, all of the images with bounding boxes were reviewed manually to ensure that the images remained of high quality.

To increase the robustness of the model developed for this research, data augmentation techniques were applied to the training subset. Data augmentation techniques included horizontally flipping the images, scaling, and altering brightness to increase the ability of the model to perform well in various lighting conditions, and to simulate a variety of viewpoints while preventing distortion to the images' realistic characteristics.

Figure 4. Annotated Images

3.3 Object Detection Utilizing YOLOv11(Nano)

YOLOv11(nano), a lightweight version of the YOLOv11 architecture, was selected for the detection of animals because of its ability to provide real-time detection and be deployed on edge devices for the roadside surveillance system. The lightweight version provides a desirable trade-off between the accuracy of detection and the computational requirements of the model, making it suitable for deployment on roadside surveillance systems. The dataset annotated to detect animals in the CCTV frames was used to train the YOLOv11 (nano) model to detect animals in the frames. Since the main objective of the study is rooted in road safety, the focus was on developing a reliable method to detect animal presence in the images, rather than determining the specific type of animal. The proposed YOLO-based detection framework

Figure 5. Annotated Images

with the addition of a post-detection refinement step using CNN and QNN modules improves the reliability of the detection framework by reducing the rate of false positives, especially in low-light conditions.

3.4 CNN-Based Feature Enhancement

In order to improve the reliability of detection, especially in difficult visual environments, a Convolutional Neural Network (CNN) was implemented as a secondary classification module. The cropped region from the YOLO bounding box was input into the CNN for enhanced feature extraction and classification of the cropped region. The CNN architecture was designed to be simple so as to prevent overfitting, considering the small size of the dataset. The architecture of the CNN included stacked convolutional layers to learn spatial features, followed by pooling and fully connected layers for classification. This layer was intended to enhance discrimination of true animal detections versus background artefact detections, and therefore enhance overall precision and recall.

3.5 Quantum Neural Network (QNN)-Assisted Classification

Further improvements to classification performance under data-limited conditions were achieved through the implementation of a Quantum Neural Network (QNN) as an auxiliary learning model. The QNN was implemented as a hybrid quantum-classical model, whereby classical features derived from detected image regions were encoded into a quantum feature space. The motivation for utilizing a QNN is that it can potentially capture the complex relationships of the features and thus improve generalization when the training data is limited. The QNN was trained and tested using simulated quantum

circuits in the Google Colab environment, to ensure reproducibility and independence of physical quantum hardware. Unlike previous studies that replaced classical deep learning models, the QNN was used as a performance-enhancing module to refine classification confidence in conjunction with the CNN. Methodology performance was evaluated on the basis of detection reliability, not species-level detail, since the purpose of the method is to provide an early warning of potential animal hazards to vehicles on roads.

4 Results and Discussion

4.1 Training and Validation Convergence Analysis

The Training and Validation Loss Curves for Box Loss, Classification Loss, and Distribution Focal Loss are shown in Figure 6. They depict a consistent decrease in training loss throughout the epochs. The continuous decline in the box loss clearly illustrates that the YOLOv11n Detector learned and adapted effectively to the task of detecting cows and dogs on the roadways. Validation loss followed the trend in the training loss, showing very little evidence of overfitting, even with a very small number of frames used to train the model. The smooth decline in classification loss shows that the two-Class problem is well defined for the Architecture Chosen; some oscillation was expected due to the size of the dataset (453 Annotated Frames), real-world variability of CCTV imagery, such as occlusion, illumination changes, and motion blur. Overall, the trends illustrated in the graphs confirm that the Baseline Detector achieved reliable localization capabilities and served as a reasonable starting point for subsequent CNN and QNN-based refinements.

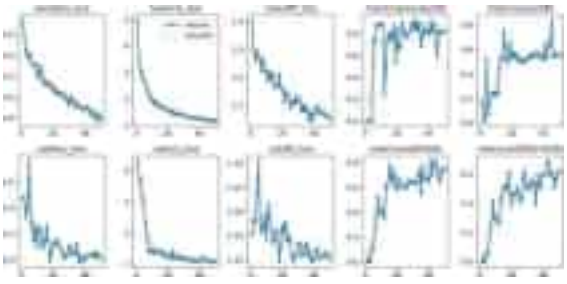

Figure 6. Training and validation Loss Curves

4.2 Precision – Recall Characteristics

The Precision–Recall Curve from Figure 7 provides insights into detection behavior between classes. Cow class exhibits extremely High Recall (99.5%); Cow detection is extremely important for road safety because missing a large animal like a cow represents a significant risk of collision. While the cow class has a very high Recall, it has Lower Precision (65.2%).

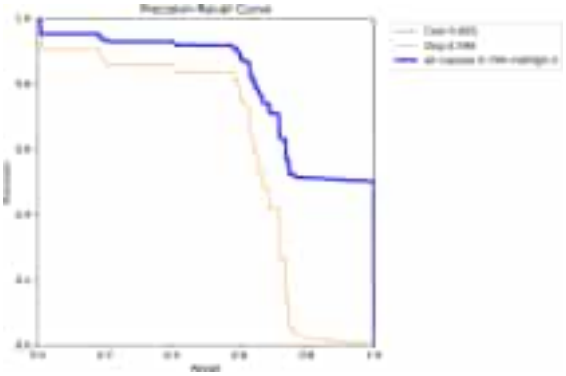

Figure 7. Precision - Recall Curve

This indicates there are many false positives that were detected due to objects in the background that have similar shapes or colors under low-light conditions. The dog class has Higher Precision (73.4%) but Lower Re-call (61.6%) than the Cow Class; Dog Class Detection is more difficult than Cow Class detection because dogs appear smaller and move faster than cows, and therefore have less distinctive visual features. In Addition, dogs often appear Partially Occluded or further away from the camera than cows, which results in Reduced Recall. Although dogs have a lower recall, the dog class has a higher Mean Average Precision (mAP_{50}) (59.6%) than the cow class (45.1%), indicating better localization quality when detections are made. These results are presented in Table1. Combined-Class Precision – Recall Curve shows the model performs effectively when both classes are considered together ((mAP_{50}) = 0.796). This supports the idea of using a Generic Animal Intervention approach, where priority is given to detecting animal presence rather than perfect class separation.

Table 1. Class Separation

Class	Precision	Recall	mAP_{50}
Cow	65.2%	99.5%	45.1%
Dog	73.4%	61.6%	59.6%

4.3 Confidence-Based Performance Analysis

The Recall – Confidence Curve from Figure 8 illustrates that the recalls decrease steadily as confidence thresholds increase. This behavior is consistent with what would be expected of a detector. At lower confidence thresholds, recalls remain high, especially for the cow class, confirming that the model is sensitive to animal presence. This type of behavior is advantageous for Early Warning Systems, where the detection of animals, even at lower

levels of confidence may provide enough time to take action before a potential collision occurs.

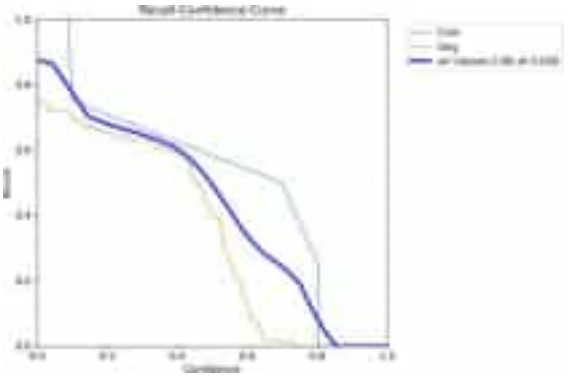

Figure 8. Recall - Confidence Curve

Figure 9 explains the Precision–Confidence Curve that shows a strong increase in precision as the confidence threshold increases, reaching near perfection for combined classes at higher confidence thresholds. This indicates that false positives are progressively filtered out as strict confidence criteria are applied. For system designers deploying the system, this allows them to tune confidence thresholds based on Operational Requirements – favoring either higher recall for safety-critical alerts or higher precision to reduce unnecessary warnings. Figure 9 represents the Precision – Confidence Curve showing a strong increase in precision as the confidence threshold increases, reaching near perfection for combined classes at higher confidence thresholds. This indicates that false positives are progressively filtered out as strict confidence criteria are applied. For system designers deploying the system, this allows them to tune confidence thresholds based on Operational Requirements – favoring either higher recall for safety-critical alerts or higher precision to reduce unnecessary warnings.

4.4 F_1-Confidence Trade-Off and Optimal Operating Point

Figure 10 shows the F1-Confidence curve, which exhibits a clear Optimal Operating Region, where the maximum combined F1-Score of approximately 0.73 occurred at a confidence threshold around 0.33. This operating point represents a balance between Precision and Recall, making it suitable for real-time road safety applications. Importantly, the cow class maintains a higher F1-Score across a wide range of confidence thresholds than the dog class, reflecting more consistent detection performance. The dog class showed a sharper decline at higher confidence- thresholds, again

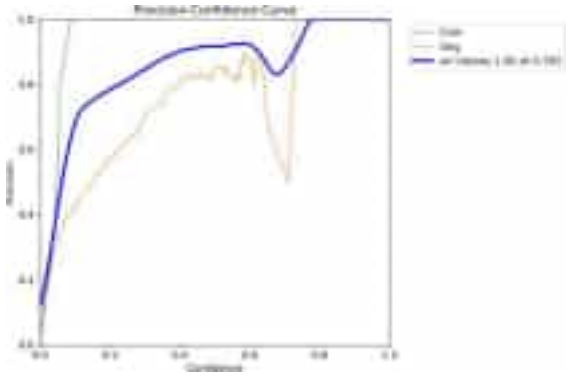

Figure 9. Precision - Confidence Curve

highlighting the difficulty of detecting small animals in unconstrained highway environments.

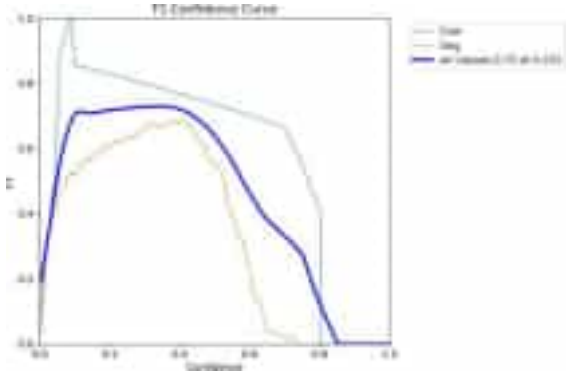

Figure 10. F_1- Confidence Curve

4.5 Impact of CNN and QNN-Based Refining

CNN and QNN Modules played a key role in stabilizing classification confidence and improving overall detection reliability under data-limited conditions. The CNN-enhanced spatial feature refinement for regions of interest identified by the detector resulted in fewer misclassifications caused by background clutter. The QNN contributed to the improvement of generalization by capturing nonlinear relationships between features, leading to smoother confidence distributions. This hybrid enhancement is reflected in the improved Precision-Confidence and F1-Confidence behaviors, especially for ambiguous cases and Low-Light Scenarios. The CNN-QNN Combination does not replace the YOLO Detector, but instead acts as a complementary refinement layer, strengthening the decision confidence without adding excessive computational overhead.

The ablation results shown in Table 2 indicate that the YOLOv11n+CNN+QNN configuration shows better performance in general, as it attains the highest mAP_{50} metric at 79.6% and precision at 86.7%. This shows better robustness and feature representation ability. Although there is a moderate decline in recall, it provides a good trade-off and could be a promising approach.

Table 2. Ablation Study

Configuration	Precision	Recall	mAP_{50}
YOLOv11n	0.713	0.7668	0.7651
YOLOv11n+CNN	0.8653	0.7951	0.7651
YOLOv11n+QNN	0.7401	0.7853	0.7651
YOLOv11n+CNN+QNN	0.867	0.634	0.796

Table 2 indicates that the YOLOv11n+CNN+QNN configuration shows better performance in general, as it attains the highest mAP@50 metric at 79.6% and precision at 86.7%. This shows better robustness and feature representation ability. Although there is a moderate decline in recall, it provides a good trade-off and could be a promising approach.

4.6 Implications for Road Safety and Animal Intervention

As far as road safety is concerned, these results show that the framework has chosen to maximize the large animal recall that will have the greatest impact in reducing serious AVCs. Although small animals like dogs are difficult to detect, the level of performance obtained for detection and early warning/risk reduction is adequate. The results support the key premise of this research, which is that animal intervention can be achieved through existing edge devices like CCTV systems that are in place currently, and through hybrid learning models and light-weight solutions that do not rely upon special sensor technology or large-scale datasets. The fact that the system's performance was tunable for recall, precision, and confidence provides the adaptability required to deploy this type of system on the highways.

Figure 11 presents the proposed system architecture for the implementation of this AVC mitigation framework. The layers involved are elaborated in the figure for the execution of this model. The physical layer includes the hardware present at the site. These devices are connected to the digital layer, where the detection and classification are performed using YOLOv11n and Quantum Computing. The service and user layer is a place where real-time monitoring and a subsequent alert mechanism are triggered.

The proposed system contributes to the infrastructure value chain by assisting real-time monitoring and alerting the intrusion events by animals. It helps the authorities to monitor and label animal intervention zones.

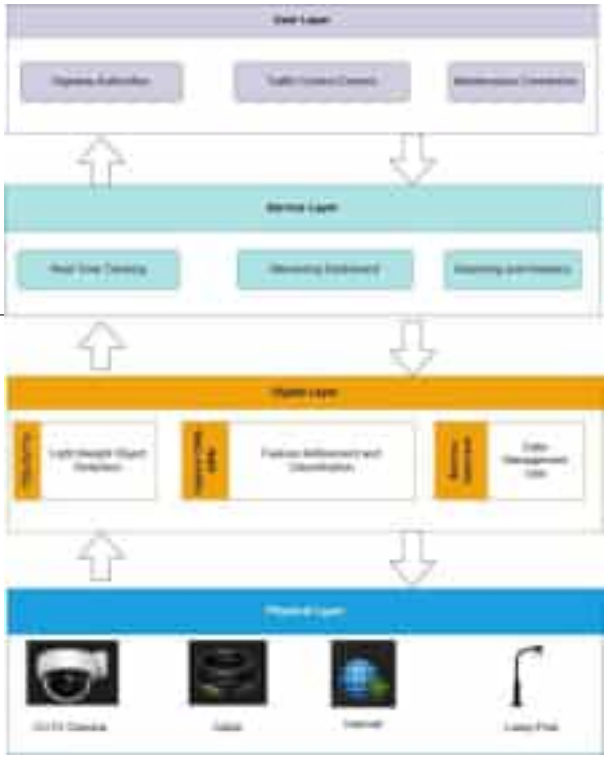

Figure 11. Proposed System Architecture

For the road users and pedestrians, this system, when deployed, serves as an alert mechanism, improving safety and effective usage of existing infrastructure like CCTV cameras.

5 Conclusion and Future Work

This paper demonstrated an effective and cost-effective method to apply Artificial Intelligence (AI) to prevent animal-induced vehicle collisions by using the existing road surveillance systems and lightweight hybrid deep learning models. The study used images taken from highway CCTV cameras and adapted a novel process using object detection and classification algorithms based on YOLOv11n, CNN and QNN for better detecting stray animals on roads with limited amounts of training data and inclement lighting conditions. The experimental results showed that the hybrid model converged steadily, detected over 90% of the larger animals and achieved a mean average precision of about 0.8 when evaluating at a 50% threshold (mAP_{50}). This validates the use of a hybrid approach. It was chosen to identify animals present in the image field of view and then classify them as either an animal or a non-animal because this is a better way to alert the drivers and road safety authorities about potential collisions.

5.1 Limitations and Observed Trends

Although there were encouraging results from the research, the differences in performance between cows and dogs illustrated the effects of object size, motion and visual distinction on classification performance. In addition, though the system performed well given the dataset size used in the research, it may not be possible to achieve optimal levels of accuracy due to the limitations imposed by the dataset size, especially for smaller animals. However, since the hybrid learning model converged consistently, regardless of whether the system was tested for different metrics, it appears to be both robust and scalable based on increased amounts of data. Overall, the authors found that using AI to augment existing surveillance systems can significantly reduce the risk of collisions between vehicles and animals, without needing additional high-level cameras or other hardware. It is recommended that future work in this area explore the following aspects:

1. Expanding the number of animals represented in the database (e.g., buffalo, horse, cat, camel), as well as different environments along roads.
2. Simplifying the detection of any type of animal into a "one animal" category to improve robustness and make it easier to deploy.
3. Deploying the system on the edge and developing a real-time alerting capability to notify traffic control centres.

Abstract -

Construction robots require component-level task specifications that include per-unit dimensions, 6D poses, and assembly sequences respecting construction constraints. However, existing BIM-based robot task planning pipelines rely on either ad-hoc heuristic decomposition or exhaustive pre-modeling, both of which are brittle under design changes and fail to capture the assembly semantics encoded in 2D shop drawings. We propose a two-phase framework that integrates design-stage 3D models and 2D shop drawings to generate component-level task specifications for downstream robotic execution. The framework separates task formalization from task compilation, with two intermediate representations (IRs) serving as the interface between phases. In the formalization phase, a Vision-Language Model (VLM) extracts assembly logic from 2D shop drawings into an Assembly Representation (AsmRep), while geometric constraints are obtained from a design-stage IFC 3D model as a Building Element Representation (ElemRep). In the compilation phase, a deterministic IR compiler integrates both representations to generate robot-executable task specifications, including per-unit 6D poses, dimensions, and assembly sequences. Experiments on bricklaying demonstrate that foundation VLMs can reliably formalize drawing-encoded rules such as layout lines, anchor conventions, and bond patterns, and that varying only the AsmRep under identical ElemRep produces different decompositions and sequences. A preliminary simulation study further shows that the generated task specification can be consumed by a downstream robotics layer. These results support the feasibility of the proposed framework and its integration with downstream robotic execution layers.

1 Introduction

Construction robots require component-level task specifications that are executable on site: the dimensions and 6D pose of each unit, and an assembly order that respects construction constraints. Unlike factory automation, construction is executed in a changing environment: dimensions drift, tolerances accumulate, and design details evolve across phases and trades [1]. As a result, an assembly specification is not just an order of operations; it encodes where work is referenced (e.g., layout lines), how boundary conditions are handled, and how residual errors are absorbed.

Building Information Modeling (BIM) is the dominant digital representation for 3D building geometry in construction. Therefore, many construction robotics studies start from BIM to derive executable task specifications, such as decomposing assemblies, assigning placements, and generating sequences, directly from 3D models. However, geometry-centric planning often shows a limitation in applying to the practice. Existing pipelines either use ad-hoc heuristic decomposition[2, 3], which is rigid and hard to generalize, or rely on exhaustive pre-modeling and manual scripting [4, 5, 6], which is labor-intensive and brittle under inevitable revisions. Crucially, both strategies face practical limitations on large-scale assemblies and dynamic sites. As the number of components increases, these approaches become increasingly difficult to maintain, and they remain brittle under design revisions and site deviations because the required assembly semantics is rarely encoded explicitly.

Construction tasks are developed progressively across project phases by multiple stakeholders. To communicate the maturity and intended use of model elements, the Level of Development (LOD) specification is widely used. LOD 300 typically provides measurable design-stage geometry (size, shape, location, and orientation), while LOD 400 represents the detailed components for fabrication and installation in 3D models [7]. However, the procedural knowledge required for robot execution, such as assembly logic, reference conventions, and sequencing, is rarely encoded explicitly in 3D BIM models. Instead, this semantic information is commonly delivered to the field through 2D shop drawings [8]. While shop drawings are a primary carrier of such semantics, they express it implicitly through

symbolic, human-centric drafting conventions rather than explicit procedural rules, making them not directly usable for generating per-unit placements and sequential robot actions.

Recent progress in vision-language models (VLMs) suggests a path to interpret such drawing content [9, 10, 11]. Yet, using VLMs for long-horizon geometric planning remains unreliable and difficult to constrain, especially when the desired output must be consistent, verifiable, and reproducible at the component level [12]. This motivates a different role for VLMs in construction robotics: not as end-to-end planners, but as formalizers that extract and structure drawing-encoded assembly semantics into a constrained intermediate representation (IR).

These observations raise three research questions: **(RQ1)** What information from design-stage 3D models and 2D shop drawings is necessary for robot assembly, and how can it be structured into intermediate representations? **(RQ2)** How can VLMs reliably extract implicit assembly semantics from 2D shop drawings? **(RQ3)** How can extracted semantics be compiled deterministically into robot-executable task specifications?

To address these questions, we present a two-stage pipeline that separates (1) **task formalization**, which extracts assembly rules from 2D shop drawings and geometric constraints from design-stage 3D models and encodes them into two intermediate representations: the Assembly Representation (AsmRep) and the Building Element Representation (ElemRep); and (2) **task compilation**, in which a deterministic compiler compiles both IRs into a robot-executable assembly task specification (per-unit 6D poses, dimensions, and assembly sequences). Experiments on bricklaying show that, under identical BIM-driven geometry, varying only assembly rules produces different decompositions and sequences. This indicates that our system explicitly captures assembly logic, enabling scalable component-level task planning and providing a foundation for rapid re-planning in a dynamic construction environment.

2 Related works

Existing BIM-based robotics pipelines largely treat task planning as geometric translation from 3D models. Early work mapped IFC to robotic description formats to reconstruct the building environment for robot operation [5]. Subsequent studies attempted to derive component-level information: Brinkhoff and Kolani [2] geometrically slices LOD 300 walls into brick via scripts, Gao et al. [3] generated assembly coordinates with heuristic spatial sorting, and Wong Chong et al. [4] extracted coordinates for wood frame assembly from BIM. To improve site adaptability, Oyediran et al. [13] integrated 4D BIM scheduling and Fingrut et al. [14] employed computer vision for adaptive bricklaying correction. More recently, Kim et al. [6] used an LLM for dialogue-based robot planning, where BIM-derived context serves as a world model.

Despite these advancements, these BIM-based planning efforts demonstrate critical limitations in scalability and robustness. Explicitly modeling every component at an LOD 400 level becomes practically impossible as the scale of construction increases due to massive computational and modeling overhead. Conversely, heuristic-driven decomposition from LOD 300 models lacks the robustness needed for complex geometric scenarios, such as intricate joints or openings. These limitations motivate extracting assembly semantics from 2D drawings and compiling it deterministically with 3D geometry, rather than treating planning as geometric translation alone.

In parallel, VLMs have been applied to interpret assembly instructions in robotics. Manual2Skill [9] extracts hierarchical assembly graphs from furniture manuals to acquire robotic skills, VLM-MSGraph [10] constructs multi-hierarchical scene graphs to guide assembly sequences, and Kyaw et al. [11] utilized VLMs for component decomposition of 3D meshes. However, these systems primarily operate on general-purpose reasoning, such as identifying that a chair requires legs, and typically rely on unique identifiers for a small set of distinct parts. Such methods do not scale to repetitive construction tasks, which involve the massive repetition of identical units where assigning unique IDs to every component is infeasible. Furthermore, interpreting construction drawings requires sophisticated spatial reasoning across multiple views (plans, sections, elevations) and conventions that exceed the general functional cues used in furniture or toy assembly. Moreover, end-to-end VLM planning remains unreliable for long-horizon reasoning; recent work suggests VLMs are more effective as formalizers that translate multimodal inputs into structured representations [12].

These observations motivate our approach: formalized assembly semantics from 2D drawings via constrained VLM extraction and compile them deterministically with 3D model geoemtry.

3 Methodology

We propose a component-level assembly sequence planning framework that synthesizes geometric contexts from 3D Models with assembly rules from 2D architectural drawings to generate robot-executable assembly information.

As illustrated in Figure 1, the framework operates in two phases: (1) **task formalization**, where different levels of construction data are parsed into two structured intermediate representation (IRs), a Building Element Representation (ElemRep) encoding spatial constraints, and

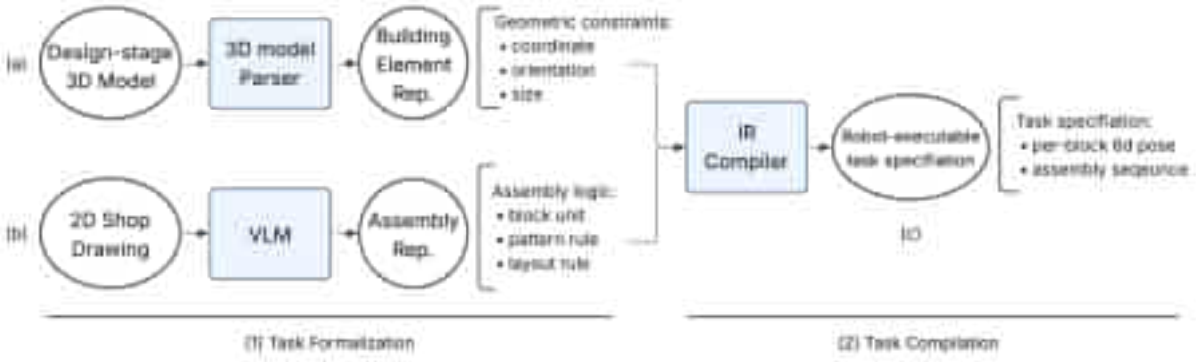

Figure 1. System overview. We separate (1) task formalization into intermediate representations (IRs): (a) Building Element Representation (ElemRep) from design-stage 3D models and (b) Assembly Representation (AsmRep) from 2D shop drawings, and (2) task compilation into (c) robot-executable assembly information via an IR compiler.

an Assembly Representation (AsmRep) encoding assembly rules; and (2) **task compilation**, where a deterministic compiler translates these IRs into a final component assembly sequence, including per-unit 6D poses, dimensions, and assembly sequence. This separation leverages the VLM's strength in semantic formalization while avoiding its unreliability in long-horizon geometric planning.

3.1 Task Formalization from 3D Models

Derived from a design-stage 3D model, the ElemRep encapsulates the geometric location and boundary of the element. We formally define the ElemRep G as a tuple comprising three primary components:

$$\mathcal{G} = (E, O, R) \tag{1}$$

- **Target Element** (E): This component defines the volumetric element to be constructed (e.g., the wall). It is represented as $E = (\mathbf{p}_e, \mathbf{s}_e)$, where $\mathbf{p}_e \in SE(3)$ denotes the global 6D pose of the element's origin, and $\mathbf{s}_e \in \mathbb{R}^3$ represents its volumetric dimensions (length, height, thickness).
- **Opening Entities** (O): This set captures geometric definitions for voids within the target element, defined as $O = \{o_1, \ldots, o_n\}$. Each opening o_k is a tuple $(\mathbf{p}_{o,k}, \mathbf{s}_{o,k})$, specifying the global pose and dimensions required for boolean subtraction.
- **Reference Alignment** (R): When the target element is constrained by an adjacent structure, this component provides the spatial referencing data. It is defined as $R = (\mathbf{c}_{ref}, \mathbf{v}_{ref}, d_{offset})$, containing the reference centroid $\mathbf{c}_{ref} \in \mathbb{R}^3$, the normalized axis direction $\mathbf{v}_{ref}$, and the scalar offset distance d_{offset} relative to the target element.

3.2 Task Formalization from 2D Drawings

Derived from a 2D shop drawing via VLM parsing, the AsmRep S captures the explicit assembly rules for interior masonry. We define $\mathcal{S}$ as a tuple comprising:

$$\mathcal{S} = (B, P, L) \tag{2}$$

- **Block** (B): Identifies the physical attributes of the finishing unit. It is represented as $B = (\mathbf{d}_{unit}, id)$, where $\mathbf{d}_{unit} \in \mathbb{R}^3$ denotes the nominal dimensions (l_u, w_u, h_u) and id specifies the material type.
- **Pattern** (P): Specifies the topological arrangement of units. It is represented as $P = (\tau, \alpha, \mathbf{d}_{joint})$, where τ denotes the bond type (e.g., running bond, stack bond), $\alpha \in [0, 1)$ is the row-wise offset ratio, and $\mathbf{d}_{joint}$ defines the visual joint thickness.
- **Layout** (L): Defines the reference axis and boundary conditions for grid distribution. It is represented as $L = (\lambda_{align}, \lambda_{anchor}, \delta, C_{edge})$. The first three parameters deterministically resolve the pattern origin: λ_{align} selects identifies the semantic reference layout line (e.g., wall center, opening center, structure finish face), δ applies a scalar offset distance from this layout line to account for finish thickness or design shifts, and λ_{anchor} determines which specific feature of the unit (e.g., brick center or edge, joint center) locks onto the layout line. Finally, to manage dimensional remainder at boundaries, C_{edge} defines the edge treatment policy $(\mathbf{s}_{min}, J_{range}, \epsilon_{adj})$, specifying the minimum allowable cut size $\mathbf{s}_{min}$ and the permissible joint adjustment range J_{range} for absorbing cumulative residuals.

3.3 Task Compilation via IR Compiler

Given ElemRep $\mathcal{G}$ and AsmRep $\mathcal{S}$, the compiler deterministically computes a robot-executable **task specification** $\mathcal{T}$:

$$\mathcal{T} = (\mathcal{U}, \pi) \tag{3}$$

where $\mathcal{U} = \{u_i\}_{i=1}^{n}$ is **the set of component units** and $\pi = (i_1, \ldots, i_n)$ is a permutation of $\{1, \ldots, n\}$ that defines **the assembly sequence**. Each unit is defined as:

$$u_i = (\mathbf{p}_i \in SE(3),\ \mathbf{s}_i \in \mathbb{R}^3) \tag{4}$$

with 6D pose $\mathbf{p}_i$ and dimensions $\mathbf{s}_i$. All decisions follow fixed rules, so identical ElemRep and AsmRep $(\mathcal{G}, \mathcal{S})$ yield an identical task specification $\mathcal{T}$.

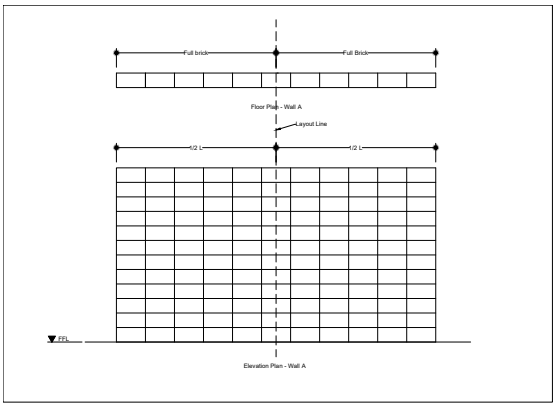
The IR compiler first maps the target element E and openings O from ElemRep $\mathcal{G}$ into a wall-local coordinate frame defined by the wall pose in E. All layout decisions are then made in the wall-local (x, z) plane, where x follows the wall direction and z corresponds to course height. Finally, each unit extent is lifted back to a global 6D pose in $SE(3)$ using the inverse wall transform, and an assembly sequence π is assigned using a deterministic ordering rule.

Step 1: Coordinate framing From the ElemRep $\mathcal{G}$, the compiler reads the global 3D pose and dimensions of the target element E and each opening $o \in O$, and transforms them into a common wall-local coordinate frame defined by the wall pose in E. In this wall-local frame, the compiler derives the wall bounds in the (x, z) domain, where x follows the wall direction and z corresponds to course height, and maps openings into the same domain.

Step 2: Layout line and course grid setup Using the layout term $L = (\lambda_{\text{align}}, \lambda_{\text{anchor}}, \delta, C_{\text{edge}})$ from the AsmRep $\mathcal{S}$, the compiler deterministically resolves a horizontal reference layout line x_{ref}. If $\lambda_{\text{align}} =$ *WALL_CENTER*, x_{ref} is obtained from the wall extents in E; if $\lambda_{\text{align}} =$ *OPENING_CENTER*, x_{ref} is obtained from the designated opening geometry in O; and if $\lambda_{\text{align}} =$ *STRUCTURE_FINISH_FACE*, x_{ref} is obtained from the referenced structure face and offset in R. Finally, λ_{anchor} selects the anchored unit feature (e.g., unit center or edge), which determines a unique grid origin x_0. The scalar offset δ then shifts x_{ref} to account for finish thickness or design intent.

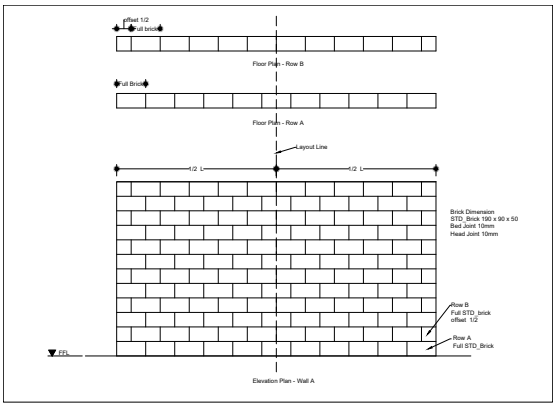
The compiler then defines the horizontal module $m_x = l_u + j_h$ from the unit length in B and head-joint thickness in P, and the vertical module $m_z = h_u + j_b$ from the unit height in B and bed-joint thickness in P. Vertically, courses are generated from the wall base upward at increments of m_z without vertical cutting.

Step 3: Pattern instantiation For each course, the bonding pattern $P = (\tau, \alpha, \mathbf{d}_{\text{joint}})$ deterministically defines a row-wise horizontal offset (e.g., alternating offsets for running bond). The compiler then instantiates nominal 1D unit spans along x, anchored at the grid origin x_0 with the course-dependent offset. Depending on λ_{align}, the compiler uses either *grid mode* for center-aligned reference lines (wall/opening center), where tiling is symmetric about x_{ref} and clipped to $[x_{\min}, x_{\max}]$, or *linear mode* for face-aligned reference lines (structure finish face), where tiling proceeds in a fixed direction from x_{ref} and is clipped to the same bounds. This step yields per-course nominal spans prior to applying the edge policy.



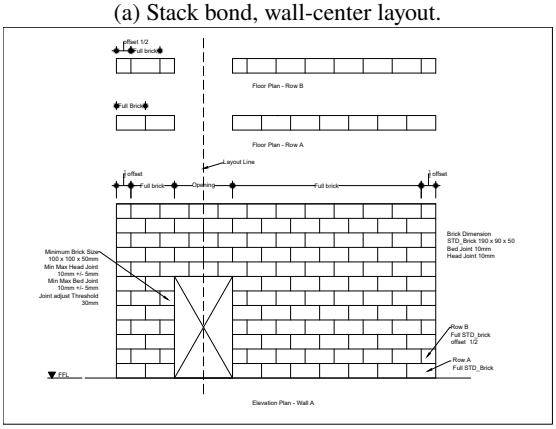
Step 4: Edge policy The compiler then applies the edge policy $C_{\text{edge}} = (\mathbf{s}_{\min}, J_{\text{range}}, \epsilon_{\text{adj}})$ to handle wall-end remainders ρ (remaining length after clipping, with head-joint thickness j_h from P): if $\rho \le \epsilon_{\text{adj}}$, the residual is absorbed by adjusting head joints within J_{range}; if $\rho \ge j_h + \mathbf{s}_{\min}$, a cut unit is appended; if neither condition holds (i.e., $\epsilon_{\text{adj}} < \rho < j_h + \mathbf{s}_{\min}$), the compiler redistributes the layout over the preceding k neighboring units to resolve the remainder. Here, k is chosen deterministically to remove ambiguity.

Step 5: Opening subtraction Openings O extracted from $\mathcal{G}$ are then subtracted from the generated spans: the compiler splits any course overlapping an opening at its boundaries and removes interior segments. Resulting fragments are checked against the minimum brick size $\mathbf{s}_{\min}$. Segments meeting this constraint are retained as cut units, while shorter ones are dropped.

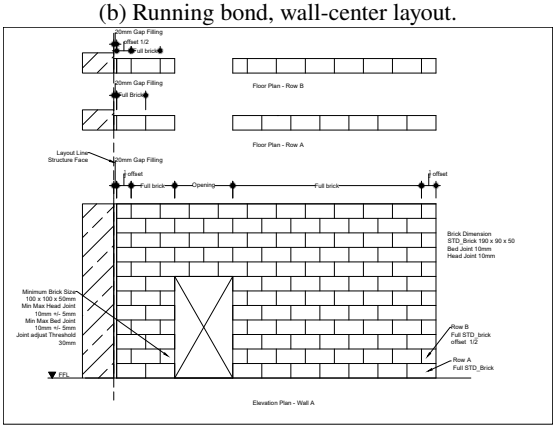


Step 6: Sequencing Finally, the compiler assigns an assembly sequence π: units are placed bottom-to-top by course index, and within each course, in increasing distance from the reference layout line. This places units near the reference line first, letting tolerances be absorbed at the boundaries instead of accumulating toward the layout line.

4 Experiments



We evaluate the proposed pipeline on controlled bricklaying scenarios to test our two-phase system. First, we measure whether a VLM foundation model can formalize assembly semantics in 2D drawings into an AsmRep, with emphasis on visually implied rules (e.g., layout line, anchor, and bond type). Second, we perform a compiler sensitivity study: We fix geometry (ElemRep) and vary assembly semantics (AsmRep) to see how assembly semantics affect the decomposition and sequencing of task specification.



(a) Stack bond, wall-center layout.

(b) Running bond, wall-center layout.

(c) Running bond with an opening and opening-center layout.

(d) Running bond with an opening and a finish-face layout.

4.1 Experiment 1: VLM AsmRep Extraction

4.1.1 Setup

We evaluate whether foundation VLM can reliably formalize drawing-encoded assembly semantics into the schema-constrained AsmRep. We compare Gemini 3 with GPT-4o under an identical schema and prompting setup. Both models were configured with temperature set to 0 and structured JSON output mode enforced via a Pydantic Schema that defines three field groups: brick definition, pattern logic, and wall mapping rule. Each model was executed 10 times independently. We report field-level extraction accuracy as the number of runs producing the correct value for each AsmRep field, evaluated against a manually defined ground truth per drawing. The full prompt specification is available in the git repository. [1]

We created four synthetic brickwork drawings (Figure 2) with progressively increasing semantic complexity to isolate specific extraction challenges: (a) stack bond with wall-center layout, containing only bond pattern and layout line without explicit numeric parameters; (b) running bond with wall-center layout, introducing offset logic and joint dimensions; (c) running bond with an opening and opening-center layout, adding opening detection and edge-policy parameters; and (d) running bond with an opening

[1] https://github.com/narchitect/assembly-seqeunce

and structure finish-face layout, further adding a reference entity and offset distance. This progression allows us to evaluate VLM reliability as drawing complexity and the number of extractable semantic fields increase.

4.1.2 Result

Table 1 reports field-level extraction accuracy across 10 independent runs per configuration. Gemini 3 achieved perfect extraction across all applicable fields and all four drawings. GPT-4o performed comparably on drawing (c) and (d) with running bonding, but failed on implicit visual conventions in the stack bonding drawing (a). It misidentified stack bond as running bond in all 10 runs and also returned null for offset distance in 3/10 runs, confirming that VLM outputs are not fully deterministic even at temperature 0. These results suggest that the primary bottleneck in extraction is not numeric recovery but the interpretation of visually encoded drafting conventions, such as bond type and offset logic.

4.2 Experiment 2: IR Compiler Task Compilation

4.2.1 Setup

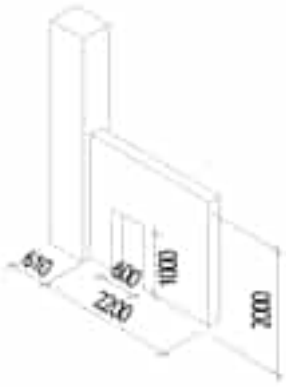

Figure 4. A sample design-stage 3D model for IR compilation experiment

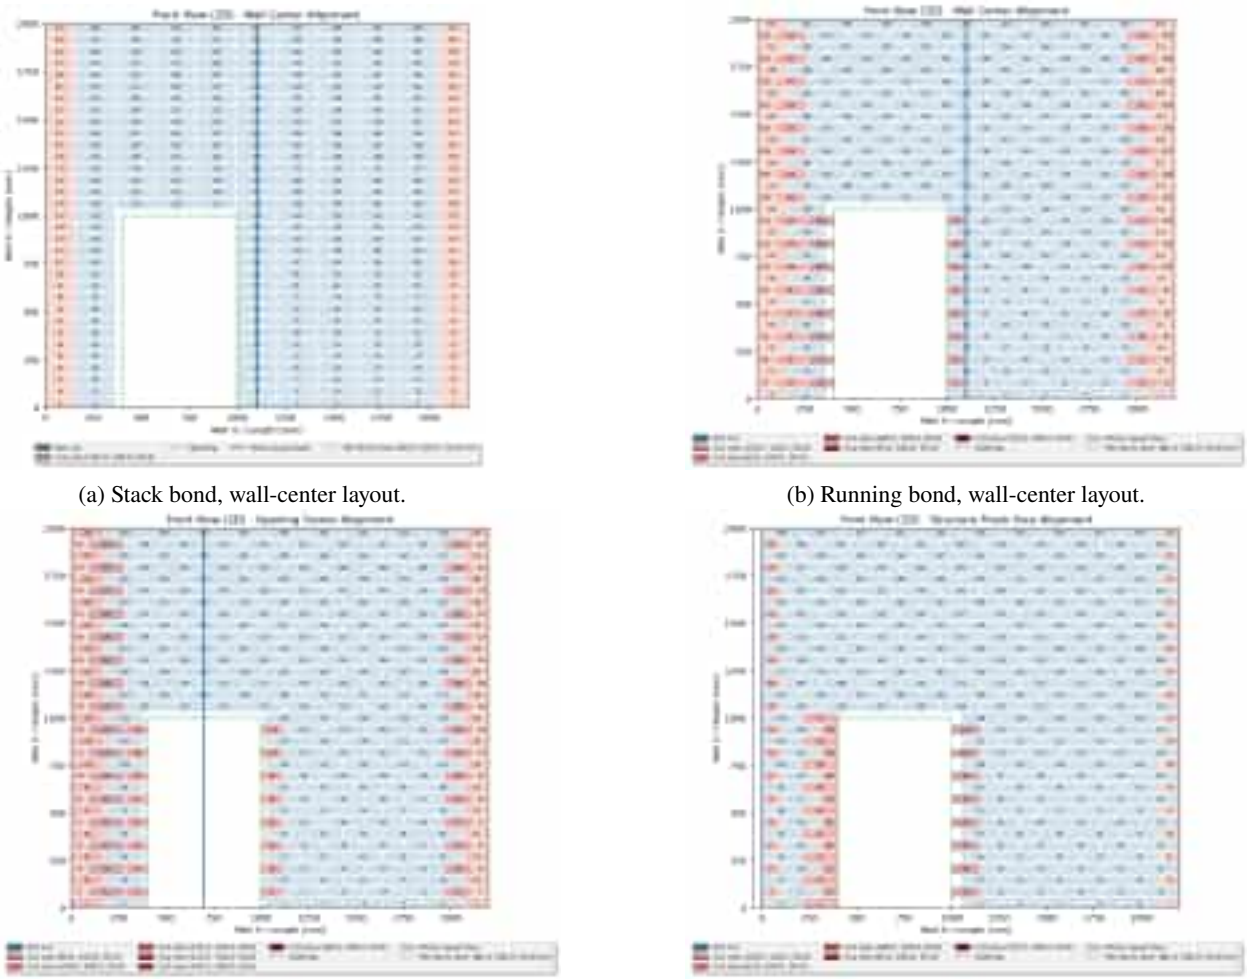
For task compilation, the IR compiler takes both an ElemRep and an AsmRep as inputs. We construct the ElemRep by exporting a design-stage 3D model to IFC (Figure 4) and parsing it with IfcOpenShell to extract the wall, a rectangular opening, and an adjacent reference structure, including their global 6D poses and dimensions. This ElemRep is reused across all runs.

We compile four AsmRep configurations against this identical geometry to examine how assembly semantics affect task specification generation. Configuration (a) and (b) differ in bond pattern (stack bond vs. running bond) under the same wall-center layout condition, allowing us to observe the effect of bond type on decomposition. Configurations (b), (c), and (d) share the same running bond but differ in layout line (wall center, opening center, and structure finish face), allowing us to isolate the effect of layout semantics under a fixed bond pattern.

4.2.2 Result

Figure 3 shows that, under an identical geometry (ElemRep), changing only the assembly semantics (bonding type and layoutline) term in the AsmRep produces different brick decompositions and assembly sequences.



Comparing configurations (a) and (b), the bond pattern changes the decomposition substantially. Stack bond (Figure 3a) maintains the same grid phase across courses and therefore produces more regular opening-adjacent fragmentation. In contrast, running bond (Figure 3b) introduces alternating row offsets that interact with opening boundaries, producing more varied cut-brick sizes and void patterns around jambs and lintels.

Within the running-bond configurations, Figures 3b, 3c, and 3d show that layout line alone also affects decomposition and sequencing. In the wall-center layout (Figures 3b), the overall pattern is symmetric with respect to the wall, but small fragments can appear near the opening boundaries. In the opening-center layout (Figure 3c), the bricks are arranged more symmetrically around the opening, although this often leads to uneven cuts at the wall ends. In the structure-finish-face layout (Figure 3d), the brick pattern is aligned with the referenced structure, and the remaining adjustment is shifted to the opposite side. These differences also appear in the generated sequence, because the bricks are placed in a fixed order by course and then by distance from the reference line.

4.3 Preliminary Simulation Validation

Figure 5. Compiled task specification executed in Isaac Sim: UR10e sequentially placing bricks according to the generated per-unit targets

(a) Stack bond, wall-center layout.

(b) Running bond, wall-center layout.

(c) Running bond, opening-center layout.

(d) Running bond, finish-face layout.

Figure 3. The results of experiment 2: Compiled task specifications for four different AsmRep configurations under identical ElemRep. red color: cut bricks; numbers: sequence IDs

To provide an execution-level validation of the compiled task specification, we integrated the generated output into a robot simulation environment. The simulation was set up in NVIDIA Isaac Sim with a UR10e manipulator and a Robotiq 2F-140 gripper. RMPflow was used for collision-aware motion generation. A finite-state pick-and-place controller sequentially executed the per-unit targets from the compiled task specification, following an approach $\rightarrow$ grasp $\rightarrow$ lift $\rightarrow$ move $\rightarrow$ place $\rightarrow$ release $\rightarrow$ retreat cycle. As shown in Figure 5, the robot can execute sequential brick placements at the compiled target poses in simulation. Although this does not yet constitute a full validation of autonomous bricklaying, it shows that the proposed task specification can be consumed by a downstream robotics execution layer.

5 Discussion

The experiments support our central premise that assembly semantics encoded in drawings affects component-level decomposition and sequencing even under identical BIM geometry. This motivates the proposed separation between semantic formalization and deterministic compilation: VLMs translate drawing conventions into a constrained AsmRep, while the IR compiler produces reproducible, verifiable per-unit task specifications by integrating the semantic IR with the geometric IR.

RQ1 (IR specification): The results (Figure 3) indicate that the combination of an ElemRep (element bounds, openings, and optional reference structures) and an AsmRep (layout line, anchor convention, bond pattern, and edge policy) is sufficient to generate component-level brick poses, dimensions, and assembly sequences, in the evalu-

ated cases.

RQ2 (VLM Task Formalization): The results of Experiment 1 (Table 1) show that both Gemini 3 and GPT-4o perform well overall under the evaluated drawing conditions, but GPT-4o is less consistent in extracting implicit visual assembly semantics. This suggests that the main bottleneck in VLM-based semantic extraction is not the recovery of explicit numeric or textual information, but the interpretation of visual conventions such as bond pattern, layout line, and anchor type. Although the current study is limited to synthetic drawings with controlled conventions, the results indicate that foundation VLMs already have practical potential to formalize construction-relevant drawing semantics without task-specific fine-tuning in this controlled setting.

RQ3 (Deterministic compilation): Experiment 2 (Figure 3) shows that, under an identical geometry (ElemRep), varying the assembly semantics (AsmRep) changes the resulting decomposition and assembly sequence in predictable ways. The comparison between stack bond and running bond shows that bond pattern alone affects row-phase behavior and opening-adjacent fragmentation. Within the running-bond cases, changing only the layout line further changes the grid phase relative to the opening, which leads to different cut-brick sizes, void patterns, and sequences under the same minimum cut-length rule. These results show that the compiler makes the effect of assembly semantics explicit and reproducible, rather than leaving it implicit in geometric modeling alone.

A preliminary robot simulation validation further showed that the compiled task specification can be integrated with a downstream robotics layer in simulation. The present study should be read as a controlled feasibility study rather than a robustness benchmark. Within the bricklaying domain, our results show that explicit modeling of assembly semantics and compilation logic enables structured and reproducible task specification generation across controlled layout variations and edge conditions. Future work should evaluate the framework on real drawings, more complex bricklaying cases, and different assembly tasks.

6 Conclusion

This paper presented a two-phase framework for component-level task planning in adaptive bricklaying by integrating design-stage 3D models with 2D shop drawings. The main contributions are two intermediate representations, ElemRep and AsmRep, and a deterministic IR compiler that combines them to generate per-unit brick poses, dimensions, and assembly sequences in a reproducible manner. The results show that foundation VLMs can formalize key assembly semantics from drawings, and that varying assembly semantics under identical geometry leads to different decompositions and sequences. A preliminary robot simulation further showed that the generated task specification can be integrated with a downstream robotics layer.

Abstract –

Engineering drawings remain a critical medium for conveying design intent in architectural and construction projects. Despite the increasing adoption of Building Information Modeling (BIM), two-dimensional drawings are still widely used in practice, particularly during early design stages and interdisciplinary coordination. The interpretation of such drawings largely relies on manual processes, which are time-consuming and prone to human error, especially when drawings contain dense graphical elements and complex textual annotations.

This study proposes an automated framework that integrates deep learning–based object detection and optical character recognition (OCR) to extract graphical symbols and textual information from architectural floor plans. A tile-based detection strategy combined with global non-maximum suppression (NMS) is employed to address large-format drawings and multi-scale objects. Detected text regions are further processed using an OCR module to extract text for subsequent analysis. Experimental results demonstrate the feasibility of the proposed pipeline and highlight key challenges related to complex layouts, rotated text, and domain-specific terminology. Overall, the proposed framework establishes a structured foundation for future semantic interpretation and intelligent engineering applications.

Engineering drawings, Floor plan recognition, Object detection, OCR, Semantic interpretation

1 Introduction

Engineering drawings remain a primary medium for conveying design intent in building projects. Despite the increasing adoption of Building Information Modeling (BIM), a substantial portion of design information is still generated and exchanged in two-dimensional floor plans. These drawings typically contain dense geometric components and domain-specific textual annotations, making automated interpretation particularly challenging.

Existing studies have explored object detection or text recognition in architectural drawings using deep learning techniques. However, most approaches focus on single-task recognition and lack an integrated framework capable of jointly extracting geometric objects and textual information from complex floor plans. This limitation restricts their applicability to downstream tasks such as information structuring and BIM model generation.

To address this gap, this study proposes a deep learning-based multi-task recognition framework for architectural floor plans. While the core components leverage established architectures like YOLO and OCR, the contribution of this work lies in integrating these components into a unified pipeline tailored to the characteristics of floor plans, including large-format images, dense layouts, mixed graphical-textual content, and Chinese annotations. This integrated design provides a practical basis for structured information extraction and subsequent engineering-oriented interpretation.

2 Literature Review

2.1 Automated Drawing Analysis

Early studies on automated engineering drawing analysis primarily relied on rule-based and traditional image processing techniques, including heuristic rules, line tracing, and template matching [1]. Due to significant variability in drawing styles, symbol conventions, and annotation density, these methods generally exhibited limited robustness and poor generalization [2], [3].

With advances in deep learning, convolutional neural networks (CNNs) have become the dominant approach for the analysis of engineering drawings. Architectures

such as U-Net, Mask R-CNN, and YOLO have demonstrated promising performance in detecting symbols and structural components in complex line-based drawings [4]-[6]. However, engineering drawings differ fundamentally from natural images, as they are characterized by dense geometric structures, high-contrast linework, scale variation, and the close interleaving of graphical and textual information, which continue to pose challenges for reliable automated recognition.

Within this category, compared with P&ID diagrams, architectural floor plans exhibit less standardized symbol libraries and higher layout variability.

2.2 Research Focus and Limitations of Existing Studies

A large body of existing research has focused on piping and instrumentation diagrams (P&ID), in which diagram structures and symbol libraries are relatively standardized, enabling high detection accuracy using deep learning–based methods [7]. In contrast, architectural floor plans have received comparatively limited attention.

Most current studies on architectural drawings address isolated tasks, such as object detection, room boundary extraction, or room type recognition [3], [5], [8]. Recent surveys classify automated floor plan analysis into room boundary detection, room type recognition, object detection, and text detection and recognition [9].

Nevertheless, most approaches remain single-task oriented, and few studies attempt to integrate multiple recognition tasks within a unified framework. As a result, many systems provide only low-level outputs, such as bounding boxes or masks, without cross-task integration or semantic interpretation.

2.3 Text Recognition in Engineering Drawings

Textual annotations in engineering drawings convey critical information, including dimensions, material specifications, and construction notes. Although recent studies have explored text detection and OCR in engineering diagrams [6], [10], recognition performance remains sensitive to text orientation, font variation, background noise, and image resolution.

These challenges are further amplified in drawings containing Chinese annotations. Chinese characters exhibit high visual complexity and lack explicit word boundaries, while engineering texts often involve domain-specific terminology and mixed-language expressions. Consequently, even when character-level recognition is achieved, the absence of contextual understanding frequently limits the interpretability of extracted text [11], [12] , rendering text recognition alone insufficient for downstream engineering applications.

2.4 Research Gap and Motivation

The reviewed literature reveals several limitations. Architectural floor plans remain underrepresented compared to P&ID diagrams, and most existing studies focus on single-task recognition with limited integration of graphical and textual information. Moreover, text recognition for Chinese engineering annotations remains insufficiently addressed, and few approaches link recognition outputs to higher-level engineering semantics or application-oriented representations.

These gaps motivate the development of an integrated framework that jointly considers object detection and text recognition. Accordingly, this study proposes a scalable detection–recognition pipeline for architectural floor plans, aiming to bridge the gap between visual extraction and intelligent engineering applications.

3 Proposed Framework

The proposed framework consists of four main stages: image tiling, object detection, result merging, and text recognition. The overall workflow is designed to accommodate high-resolution drawings and diverse annotation characteristics commonly found in engineering practice. The complete processing pipeline and the interactions between individual modules are illustrated in Figure 1.

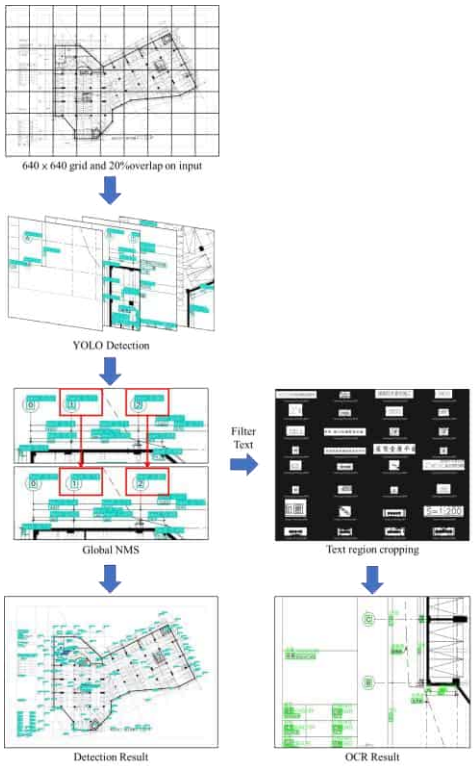

Figure 1. Overall framework

3.1 Image Tiling Strategy

Architectural floor plans are typically provided at high resolutions, which exceed the input size constraints of common deep learning models. To address this issue, a tile-based strategy is adopted, in which each input drawing is divided into fixed-size image patches (640 × 640 pixels). An overlap is introduced between adjacent tiles to mitigate boundary truncation effects and preserve contextual information for objects located near tile edges.

The selection of the tile size and overlap ratio was guided by a trade-off between detection accuracy and computational efficiency. Larger tiles preserve more contextual information but increase memory consumption, whereas smaller tiles may lead to object truncation and fragmented detections. An overlap between adjacent tiles was therefore introduced to mitigate boundary effects and reduce missed detections near tile edges.

3.2 Object Detection Using YOLO

A YOLO-based object detection model is employed to identify graphical symbols and text regions within each image tile. Detection is performed independently on each tile, producing bounding boxes, class labels, and confidence scores. The detected bounding boxes are then mapped back to the original image's coordinate system.

To eliminate redundant detections arising from overlapping tiles, a global non-maximum suppression (NMS) process is applied. This step retains the most representative bounding boxes based on confidence scores while removing highly overlapping predictions, thereby ensuring robust object localization across large-format drawings.

3.3 Text Region Filtering and Cropping

Among all detected objects, bounding boxes classified as text are selected for subsequent processing. Each text region is cropped from the original drawing, and padding is applied when necessary to ensure sufficient context. This selective filtering allows the OCR module to focus exclusively on candidate text regions, reducing computational cost and false recognition.

3.4 OCR-Based Text Recognition

The cropped text regions are processed by an OCR module to recognize text. The recognized text, confidence scores, and spatial information are recorded and associated with their corresponding bounding boxes. These outputs serve as intermediate results for future semantic interpretation and structured information extraction.

4 Dataset Construction

4.1 Data Sources

The dataset used in this study consists of 118 architectural floor plans collected from nine real-world building projects, including residential buildings, townhouses, educational facilities, and public infrastructure. The drawings exhibit substantial variation in scale, layout, annotation density, and visual style, reflecting realistic engineering conditions. Detailed statistics of the dataset, including project distribution, drawing characteristics, and data splits, are summarized in Table 1.

Table 1. Overview of the dataset

Item	Description
Number of projects	9
Number of floor plans	118
Drawing types	Residential and public buildings
Image resolution	3500–5000 px (short edge)
Annotation types	Symbols + text

As shown in Table 1, the dataset covers multiple building types and exhibits substantial variation in resolution and annotation density, which reflects realistic engineering drawing conditions rather than controlled benchmark datasets.

4.2 Annotation Strategy

Textual annotations are labeled on a line-by-line basis using horizontal rectangular bounding boxes. Blurred or partially occluded text is annotated as long as its textual nature can be reasonably identified. Graphical symbols are annotated separately to support multi-class object detection.

4.3 Dataset Generation Workflow

Annotated full-size drawings are divided into overlapping tiles following the image tiling strategy. Bounding boxes fully contained within a tile are retained, while partially truncated boxes are selectively preserved for specific classes, such as text. Tiles without annotations are discarded to reduce dataset imbalance. The resulting dataset is randomly split into training, validation, and testing sets using a 7:2:1 ratio.

5 Experimental Results

Preliminary experiments were conducted using multiple YOLO variants, including models from the YOLOv8 and YOLOv11 families. Performance was

evaluated using standard object detection metrics, including mean Average Precision (mAP) at IoU thresholds of 0.50 and 0.50–0.95, as well as bounding box precision. Quantitative detection performance for all evaluated models is reported in Table 2. Representative qualitative detection results under different drawing conditions are presented in Figure 2.

Table 2. Detection performance for all classes

Model	mAP@50	mAP@50–95
YOLOv8n	0.624	0.469
YOLOv8s	0.942	0.752
YOLOv8m	0.957	0.793
YOLOv8l	0.957	0.802
YOLOv8x	0.961	0.781
YOLOv11n	0.629	0.473
YOLOv11s	0.947	0.767
YOLOv11m	0.966	0.791
YOLOv11l	0.972	0.815
YOLOv11x	0.945	0.787

The results in Table 2 indicate an overall performance improvement with increasing model capacity up to a certain scale, particularly under the mAP@50–95 metric, suggesting enhanced robustness for multi-scale and densely distributed objects. This trend is especially relevant for architectural drawings, where object sizes and spatial distributions vary significantly within a single layout.

Compared with mAP@50, the mAP@50–95 metric provides a stricter evaluation of localization robustness, which is particularly relevant for architectural floor plans with dense and closely spaced elements. The observed performance gains of mid- to large-scale models suggest an enhanced ability to capture multi-scale contextual cues, albeit with increased computational cost, indicating that model selection should balance accuracy and practical deployment constraints.

Figure 2. Qualitative detection results

Figure 2 illustrates representative detection results under different drawing conditions, including dense annotation regions, overlapping symbols, and varying line thicknesses. While most objects are correctly localized, failure cases are mainly observed in regions with rotated text and severe overlap.

The results indicate that the tile-based detection strategy combined with global non-maximum NMS effectively improves detection coverage for large-format drawings. As summarized in Table 2 and illustrated in Figure 2, both textual regions and graphical symbols can be detected with acceptable accuracy across diverse drawing layouts. Nevertheless, several challenges remain, particularly in handling complex layouts and non-standard text orientations.

The OCR results demonstrate the feasibility of extracting textual content from detected regions using an off-the-shelf OCR model, although recognition accuracy varies with font style, text orientation, and background complexity. In practice, the OCR module performs reliably for short, horizontally aligned annotations with relatively clean backgrounds, while errors are more frequently observed for rotated or densely packed text. These observations suggest that OCR reliability is strongly influenced by detection quality, highlighting the importance of tighter integration between detection and recognition modules. Representative examples of Chinese text recognition results, illustrating typical successful recognition and failure cases, are shown in Figure 3.

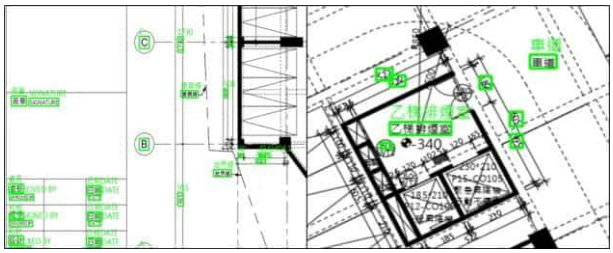

Figure 3. Examples of Traditional Chinese text recognition results on floor plans

To provide a more in-depth evaluation of the proposed framework, two supplementary analyses were conducted. First, an ablation study was performed to examine the effect of the tile-based strategy and overlap settings on object detection performance. Second, a quantitative OCR comparison was conducted to assess how different text extraction workflows influence the number of recognized text regions and the average OCR confidence. The corresponding results are summarized in Table 3 and Table 4, respectively.

Table 3. Ablation study on the effect of tiling and overlap ratio for YOLOv11l

Method	mAP@50	mAP@50–95
YOLOv11l without tiling	0.045	0.013
YOLOv11l tiling (no overlap)	0.882	0.699
YOLOv11l tiling (10% overlap)	0.972	0.815
YOLOv11l tiling (15% overlap)	0.992	0.858

As shown in Table 3, the tile-based strategy substantially improves detection performance compared with direct inference on the full-size drawing. Without tiling, YOLOv11l achieves only 0.045 mAP@50 and 0.013 mAP@50–95, indicating that large-format floor plans cannot be reliably processed in a single pass under the current model setting. Introducing tiling without overlap already leads to a significant improvement, while adding overlap further enhances detection robustness. Among the tested settings, a 15% overlap achieves the best performance, suggesting that overlap helps preserve contextual information near tile boundaries and reduces missed detections for objects located across adjacent patches.

Table 4. Quantitative comparison of text extraction workflows for OCR pre-processing

Method	Direct OCR on full drawings	OCR on tiled drawings	YOLO-based text detection + OCR
Number of detected boxes	153/241	173/241	233/241
Average OCR confidence	0.785	0.835	0.823

Table 4 presents a quantitative comparison of OCR performance under three text extraction workflows. Direct OCR applied to full drawings detects 153 out of 241 text instances, whereas OCR on tiled drawings improves the number of detected text regions to 173. The proposed YOLO-based text detection followed by OCR achieves the highest text coverage, with 233 out of 241 text regions successfully identified. Although the average OCR confidence of the tiled OCR approach is slightly higher than that of the YOLO-based pipeline, the latter provides substantially better text localization coverage. This result indicates that the main advantage of the proposed framework lies in improving text region recall before recognition, which is particularly important for engineering drawings containing dense and spatially distributed annotations.

6 Discussion

The experimental findings suggest that integrating object detection and OCR provides a viable approach for automated information extraction from engineering drawings. The tile-based strategy effectively addresses input size limitations while preserving detection performance across different drawing scales.

Nevertheless, the results also highlight inherent challenges associated with engineering drawings. Complex layouts, heterogeneous annotation styles, and domain-specific terminology pose difficulties for both detection and recognition models. These observations underscore the importance of domain-adaptive training strategies and robust post-processing mechanisms.

At the current stage, the proposed framework is not intended to achieve full automation. Instead, it aims to provide a structured basis upon which higher-level semantic interpretation and intelligent engineering applications can be developed.

From an application perspective, the current framework can serve as a front-end information extraction module for engineering workflows that require rapid access to drawing content. In particular, detected symbols and recognized annotations can be converted into structured records to support space inventory, drawing review, preliminary quantity takeoff, and BIM-assisted data entry. For example, text labels associated with rooms or components can be extracted together with their spatial locations, allowing practitioners to reduce the manual effort required for locating, transcribing, and organizing drawing information. While the full integration of these downstream applications remains outside the immediate scope of this paper, the current results demonstrate that the proposed pipeline can provide an operational basis for construction-specific decision support and further semantic interpretation. However, these use cases currently remain at the structured information extraction stage and have not yet been validated through deployment in a full production workflow.

7 Future Work

Future research will focus on several key directions:

1. OCR Model Fine-Tuning: Constructing a domain-specific Chinese annotation dataset with diverse fonts, sizes, orientations, and background noise to improve recognition robustness.

2. Hyperparameter Optimization: Systematically analysing the influence of detection-related hyperparameters, including input resolution, overlap ratio, confidence thresholds, and NMS strategies.
3. Extended Ablation and Sensitivity Analysis: Further examining the influence of model architectures, overlap ratios, confidence thresholds, and post-processing settings on detection and recognition performance across more diverse drawing conditions.
4. Semantic Interpretation: Integrating large language models to transform recognized graphical and textual information into structured engineering semantics for downstream applications such as quantity takeoff and cost estimation.

8 Conclusion

This study presents a compact and integrated deep learning framework for the joint recognition of geometric objects and textual information in architectural floor plans. By combining tile-based object detection with OCR-based text recognition, the proposed approach effectively addresses key challenges associated with large-format engineering drawings and heterogeneous annotations. While certain limitations remain, particularly in handling highly complex layouts and domain-specific textual variations, the proposed framework establishes a scalable and extensible foundation for future research on semantic interpretation and intelligent engineering drawing analysis.

Abstract –

Recent advances in three-dimensional (3D) generative Artificial Intelligence (AI) hold significant potential for automating architectural design. However, existing methods cannot effectively process Industry Foundation Classes (IFC) data due to its complex structure. There is a pressing need for a unified representation that preserves the object-level spatial information for generative tasks. This paper proposes an auto-decoder approach that converts IFC object geometry into a unified, generation-ready representation, enabling volumetric spatial reasoning. First, an IFC export strategy that retains each object in its original global coordinates frame is introduced. Second, a sampling method that pairs 3D points with their distance to the nearest surface is applied. Third, a neural network that jointly optimises per-object representation vectors and the decoder is presented, yielding unified representations for IFC objects. Finally, an octree-based decoding method that enables efficient geometry reconstruction is employed. Comparative experiments demonstrate that the proposed method significantly outperforms voxel-based baselines in reconstruction fidelity. Furthermore, these unified latent vectors successfully enable downstream AI models to utilise IFC spatial information for complex volumetric reasoning , achieving an overall accuracy of 96.8% in classifying multi-constraint spatial interactions. This is validated by evaluating the classification of multi-constraint spatial interactions between slab openings and door clearances, which achieved an overall accuracy of 96.8%. This method converts complex geometry data into a unified representation, thereby enabling the use of IFC in generative AI.

BIM, IFC, 3D geometry representation, signed distance function, generative AI

1 Introduction

Three-dimensional (3D) generative Artificial Intelligence (AI) has rapidly advanced in recent years, demonstrating a remarkable ability to learn from existing data and synthesise novel 3D models [1], [2]. Particularly, in digital entertainment, it has been applied to learn and create coherent virtual worlds that reflect real-world plausibility [3], [4]. This ability to learn spatial constraints and patterns is particularly valuable for the built environment. For example, architectural designs require content to be spatially coherent [5]. 3D generative AI, therefore, holds significant potential for automating aspects of architectural design. For instance, current generative studies in architectural design still focus on generating floor plans or façade images [6], [7].

However, establishing such an AI system requires access to high-quality architectural design data [8]. The Industry Foundation Classes (IFC) standard is a vendor-neutral, ISO standardised Building Information Modelling (BIM) schema that couples precise building geometry with rich semantic attributes [9]. After two decades of global adoption, extensive design data has accumulated in IFC format [10], [11]. The vast amount of data contained in IFC models has supported a range of AI-based studies, such as intelligent construction management, automated risk assessment, automated compliance checking, and autonomous construction robotics [12], [13]. Despite the promise, current 3D generative AI applications in BIM are rarely based on IFC, thereby overlooking the enriched 3D geometry data it offers. For example, Text2BIM [14] generated 3D models using design software operation commands from a large language model, while FloorDiffusion [15] created floor plans through training on a dedicated 2D residential floor plan dataset. Although IFC natively contains the same geometric and spatial information, both applications bypass the IFC model and instead

utilise other data sources.

The problem stems from the fact that 3D generative AI has difficulty processing IFC's complex geometry data directly [8]. IFC employs multiple paradigms for geometry representation, with each paradigm relying on distinct mathematical formulations and modelling procedures [9]. By contrast, 3D generative AI must satisfy data format requirements from two aspects. First, general AI learning requires a unified, fixed-dimensional data format [16]. Second, generative AI requires a data format that supports interpolation. Interpolation is the process of determining unknown values between two known values [17]. This mismatch constitutes a representation gap that prevents direct use of IFC data in 3D generative AI.

To bridge this gap, existing research in the Architecture, Engineering, Construction (AEC) domain has explored various approaches. Among the possible alternatives, 3D geometry embedding emerges as a promising solution. This method converts 3D geometry into unified, fixed-length vectors for AI use while preserving fine-grained geometric detail. Broadly, such methods can be grouped into explicit and implicit embeddings [18]. Explicit embeddings are effective for discriminative tasks such as classification, but do not emphasise generative aspects, whereas implicit embeddings achieve more substantial generative performance. In this study, we focus on signed distance function (SDF) based implicit embeddings, which describe a shape with points in space and its distance to the shape [19]. This method yields a unified, fixed-length 3D geometry representation that is suitable for generative tasks. However, existing SDF-based methods typically normalise the object's spatial information to facilitate shape learning [20]. In the built environment, maintaining spatial coherence requires careful preservation of fundamental object properties such as shape, size, location, and orientation [5]. Consequently, the loss of spatial information limits the applicability of existing SDF methods to generative tasks, such as automated architectural design.

To bridge the representation gap between IFC data and 3D generative AI, this study presents an auto-decoder approach that converts IFC object geometry into a unified, generation-ready representation while preserved spatial information. Our contributions include:

- Proposing an SDF-based auto-decoder that embeds IFC geometry into a unified representation for AI utilisation, preserving accurate spatial information and thereby enabling volumetric spatial reasoning.
- Developing a complete BIM-to-representation pipeline that automates data preparation, model training, and result visualisation, thereby enabling practical deployment.

2 Literature Review

3D geometry embedding is a method that turns 3D shapes into fixed-length vectors. These vectors allow AI models to process geometric data easily. Researchers group these methods into explicit and implicit categories. Each category has different strengths and weaknesses for building design tasks.

Explicit embedding methods encode the visible parts of an object. One common method is multi-view projection [21], [22]. It turns 3D elements into sets of 2D images. This approach uses simple data formats. However, it discards important volumetric and topological information. Another method uses point clouds [23], [24], [25]. Point cloud encoders capture a shape's global structure. But these encoders are sensitive to noise and uneven sampling. They also lack explicit connections between points. Voxel-grid methods divide 3D space into regular cubes [26], [27]. These grids work well with standard 3D neural networks. But they have low resolution because of high memory costs. Fine geometric details are often lost in voxel grids. Mesh encoders work directly with vertices and faces [28], [29], [30]. They keep high-quality surfaces and topology. However, their performance depends on the quality of the mesh triangulation. Generally, explicit methods are well-suited for tasks such as classification. Their reconstruction quality is usually limited by the resolution of the input data.

Implicit methods represent 3D objects as continuous fields in space. They use neural networks to approximate these fields. This produces compact codes that enable high-quality reconstruction. Signed Distance Function (SDF) methods are a popular choice [20], [31], [32]. They learn the distance from any point in space to the object's surface. This helps the model capture very small variations in shape. Neural Radiance Fields (NeRFs) generate realistic images from different viewpoints [33], [34]. But their geometry is hidden within density values. They do not align well with the specific parts of a building model. Occupancy networks decide if a point is inside or outside an object [35], [36]. They can handle a wide range of shapes and topologies.

A significant problem exists with current implicit methods. Most of these methods use a step called normalisation. They move every object to the centre of a small unit cube. This step helps the AI learn general shapes more easily. But it removes the building's real-world scale and position. Architectural design needs this spatial context. Designers must know the exact location of parts to check joints and assembly rules. Normalised methods cannot distinguish between different interfaces or adjacent components.

To address these critical limitations, it is essential to develop a representation that maintains spatial integrity while providing high-quality visual information to

support human judgment. This study utilises an SDF-based auto-decoder to overcome the deficiencies of existing implicit methods by preserving the original spatial setting and project coordinates of components. In addition to ensuring spatial accuracy, this approach enables high-fidelity 3D reconstruction for direct visual inspection. By delivering both precise coordinates and viewable geometry, the proposed method makes building data significantly more robust and intuitive for AI-driven design tasks.

3 Methodology

The methodology described in the sources presents a comprehensive pipeline for transforming Industry Foundation Classes (IFC) 3D geometric data into AI-compatible vector representations. This approach, implemented as a web-based tool, focuses on capturing the rich spatial and semantic context of architectural components to support downstream AI-driven design tasks. The pipeline consists of four integrated stages as in Figure 1: component extraction, spatial sampling, auto-decoder implementation, and geometric reconstruction. Unlike conventional computer vision methods that often strip away real-world metadata, this framework is specifically designed to operate within the original project coordinate frame, preserving scale, position, and orientation throughout the process.

The decision to bypass traditional unit cube normalisation is driven by the inherent position-dependent nature of architectural design. While standard normalisation facilitates shape learning in general computer vision, it discards the absolute elevation and relative topological relationships, such as the specific clearance between a door and a slab opening, that are fundamental to BIM. In large-scale models, maintaining geometric consistency across heterogeneous components is vital. If global coordinates are lost, downstream tasks like automated clash detection and volumetric spatial reasoning become mathematically impossible. Therefore, preserving the original project coordinate frame is a necessary design choice to ensure that the AI-driven reasoning reflects real-world construction constraints and spatial logic.

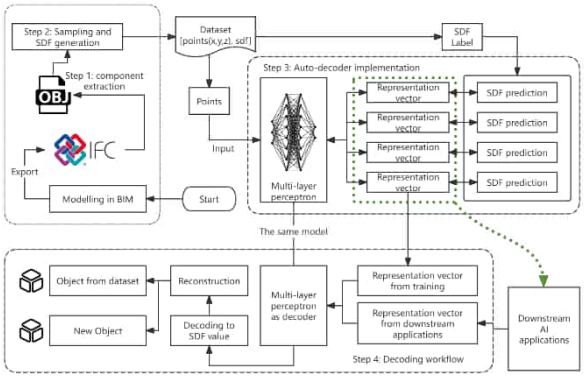

Figure 1. Overall architecture of the proposed method

The first stage, component extraction, involves isolating primary architectural entities—such as walls, columns, beams, slabs, doors, and windows—from the IFC model. Because neural representations based on SDFs require watertight, closed surfaces, the extracted geometry is converted to OBJ meshes and repaired where necessary. To handle the complexity of heterogeneous modelling practices, the workflow employs geometric proxy substitution. For instance, complex multi-part assemblies, such as windows and doors, are replaced with simplified cuboid proxies that preserve their functional volumes and spatial bounds. A critical aspect of this stage is the application of a 0.1 global scale factor, which serves as a linear unit change to ensure that coordinates and distance values remain within a stable numerical range for deep learning optimisation. Most importantly, the original coordinates and orientations are stored alongside these meshes, distinguishing this method from standard pipelines that normalise objects into an abstract unit cube and lose their real-world context.

Following extraction, the sampling and SDF generation phase converts the watertight meshes into training data. This process utilises a two-stage, surface-guided strategy to ensure the neural network learns both the precise shape of the component and the "free space" surrounding it. In the first stage, points are sampled uniformly across the object's surface to ensure total coverage. In the second stage, local jittering is applied around these surface points to create a dense cloud of near-field and far-field samples. Each sampled 3D point is paired with its SDF value, which represents the shortest distance to the component's surface; negative values indicate the interior, and positive values indicate the exterior. By sampling up to a 10-metre radius in real-world coordinates, the model is explicitly supervised to recognise that no geometry exists in the surrounding envelope, effectively preventing the AI from "hallucinating" surfaces in empty regions.

The core of the technical framework is the auto-decoder implementation. Unlike traditional encoder-decoder architectures that require an explicit network to generate features, the auto-decoder directly optimises object-specific representation vectors alongside the neural network weights during training. The architecture is based on a Multilayer Perceptron (MLP) with eight layers and 512 hidden units per layer. The network takes a 128-dimensional shape vector and a 3D spatial coordinate as input and predicts the corresponding SDF value. By sharing the same network weights across a family of similar architectural components, the model is forced to encode geometric variations, such as changes in window size or column thickness, within the latent vector space. This structured latent space enables the model to generalise across unseen architectural designs while maintaining the integrity of the spatial relationships learned from the training data.

The final stage is the reconstruction process, which identifies the zero-level set (the boundary where the SDF value is zero) to recover the explicit 3D surface from the learned vectors. Since searching a large spatial domain for these boundaries is computationally expensive, the methodology employs an adaptive octree refinement strategy. This hierarchical approach begins with a coarse grid and recursively subdivides space into smaller blocks only in regions near the predicted surface, reaching a maximum depth of five levels. Areas identified as "empty" or far from the surface are pruned to save memory and processing time. Finally, the Marching Cubes algorithm is applied to generate a triangulated mesh from the identified zero-crossing points. This bidirectional conversion ensures that the compact neural representations can be translated back into standard 3D formats for visual inspection and integration into conventional architectural modelling workflows. The following experiment validates the method using a common spatial coordination problem.

4 Experiment

4.1 Comparative Analysis with Voxel-based Representation

To justify the selection of the SDF-based auto-decoder, we conducted a comparative experiment against 3D-VAE, a representative voxel-based variational auto-encoder. A subset of 50 wall and slab components from the IFCNet dataset was utilised for evaluation. To ensure a fair comparison of representation capacity, both methods were tested under normalised conditions.

As summarised in Table 1, the proposed implicit representation achieves reconstruction errors approximately one order of magnitude lower than the voxel baseline across Chamfer distance, Hausdorff distance, and surface normal error. The qualitative comparison of these results is illustrated in Figure 2, which depicts representative reconstructions for wall and slab components.

Table 1. Reconstruction errors of the proposed method vs. 3D-VAE voxel baseline.

Scenario	Ours vs GT	3D-VAE vs GT
Chamfer Distance (mm, mean)	2.26	12.45
Hausdorff Distance (mm, mean)	8.17	54.87
Surface Normal Error (deg, mean)	7.65	19.54

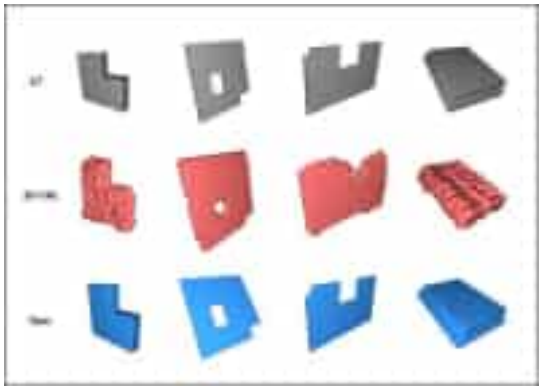

Figure 2. Qualitative comparison of per-object reconstructions. From top to bottom: ground-truth (GT), the 3D-VAE voxel baseline, and ours.

The visual evidence in Figure 2 demonstrates that the implicit representation better preserves sharp profiles and clean surfaces. By contrast, the voxel-based baseline exhibits significant aliasing and boundary artifacts due to its fixed resolution. These results indicate that while voxelization offers faster end-to-end processing, its sensitivity to resolution limits its use for high-fidelity IFC design checking. The proposed implicit representation yields smoother, more faithful surfaces, which is essential for preserving spatial integrity in BIM-to-AI workflows.

4.2 Downstream AI demonstration

To verify that the latent vectors produced by the proposed IFC-to-SDF pipeline can be used directly by downstream AI models, we designed a small demonstration experiment. The objective is to show that a simple neural network can learn implicit design rules solely from latent vectors and perform cross-component,

multi-constraint design checking. The test case is derived from a common architectural design scenario involving the coordination of building services and structural elements. Vertical service penetrations in the floor slab require specific openings, particularly for water pipes, which must be carefully positioned relative to nearby wall features. Potential conflicts arise when door swings overlap with these service openings and access routes. Furthermore, openings placed too close to the base of a wall can violate the minimum spatial clearances required for the structural integrity and precise installation of adjacent components. This scenario represents a typical cross-component, multi-constraint interaction, where traditional rule-based design checks often struggle to account for all possible spatial variations. By contrast, SDF-based latent vectors enable data-driven learning of these complex relationships, as they represent 3D objects as continuous fields that capture both the geometry and the surrounding "free space". This approach allows the neural network to identify spatial constraints without relying on handcrafted rules or explicit geometric coordinates.

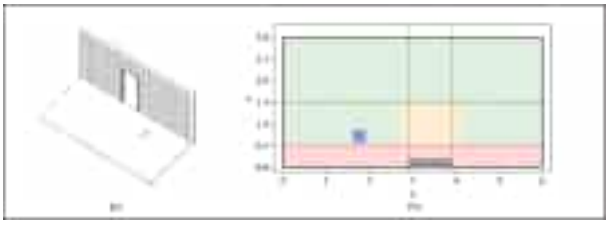

Figure 3. (a) Revit model of the slab–wall–door configuration used in the experiment. A rectangular vertical opening is placed on the slab surface. (b) Corresponding plan-view representation used for SDF-based rule classification. The red region marks the clash zone (objects with $y < 0.5$ m), the yellow region denotes the near-clearance band around the door in the mid-height range, and the green area represents the safe-far zone. The blue rectangle indicates the position of the opening sampled for this instance.

The illustrative geometry, shown in Figure 3(a), consists of a single slab, a single wall, and one door. We define three design rules for any given door position on the wall, as illustrated in Figure 3(b). In the global y direction, we measure the distance from the nearest edge of the floor opening to the wall. When the distance is less than 0.5 m, the configuration is labelled as a spatial clash case and shown in red. When the distance exceeds 1.5 m, the configuration is labelled as safe. For intermediate cases where the y-direction distance lies between 0.5 m and 1.5 m, an additional horizontal condition is applied. We check whether the horizontal projections of the door and opening overlap. We also measure their separation along the x direction. When the projections do not overlap, and their separation exceeds 0.2 m, the configuration is labelled as safe and shown in green. All remaining cases are labelled as attention required cases and shown in yellow. The yellow region indicates cases where the horizontal projections overlap, or the separation is less than or equal to 0.2 m. Such cases require additional design judgment.

The dataset for the experiment is generated procedurally. The door height is fixed at 2.1 m. The door width is sampled uniformly between 0.8 m and 1.2 m, yielding 50 distinct door variants with random positions along the wall. The floor opening size ranges from 0.2 m × 0.2 m to 0.6 m × 0.6 m. We sampled 50 distinct opening variants at random locations on the slab. All 50 door variants are combined with all 50 opening variants, yielding 2,500 unique door and opening configurations. Each configuration is labelled automatically according to the three design rules described above, producing three classes of outcomes: clash, near-clearance, and safe. The labelled dataset is then split into training, validation, and test subsets with a 0.7/0.15/0.15 ratio.

To test whether the latent vectors capture the relevant spatial relationships, we use a simple MLP classifier. The input consists only of the slab's latent codes, including its opening and the door. We adopt a two-tower architecture in which one MLP branch processes the door latent vector, and the other processes the slab latent vector. The outputs of the two branches are concatenated and passed through additional fully connected layers to predict the three design classes. After training, the classifier achieves high accuracy on the held-out test set. Representative quantitative results are reported in Table 2. Qualitative examples of correctly classified configurations are shown in Figure 4.

Table 2. Classification performance of the slab–door rule-learning classifier on the test set.

Label	Total sample	Correct predictions	Accuracy (%)
Safe	273	268	98.2
Near clearance	59	52	88.1
Clash	45	45	100.0
Overall	377	365	96.8

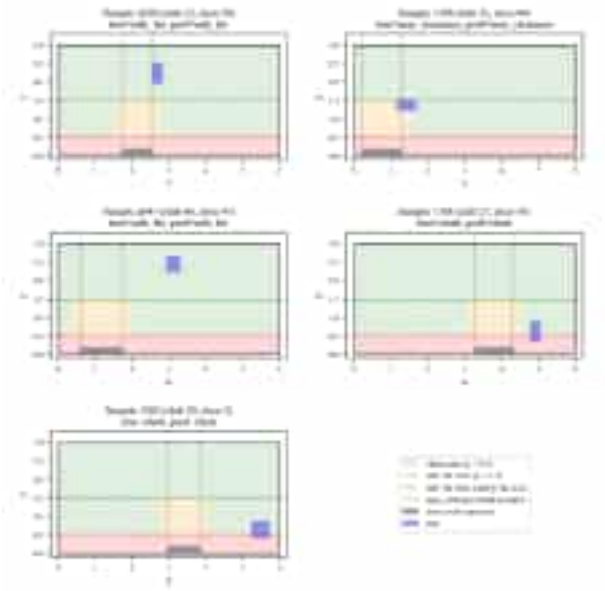

Figure 4. Representative plan-view samples from the slab–door dataset showing the rule-based labelling and MLP predictions. Each subplot depicts a slab with a vertical hole (blue) and a door segment along the wall (grey). The red band marks the clash zone ($y < 0.5$), the light green region marks the safe_far zone ($y > 1.5$), and the mid-height band is split into a near_clearance region (yellow) and a safe_far region when the door is sufficiently far in x. Vertical dashed lines indicate the x-gap thresholds used in the labelling rules. Titles report the sample index and slab/door IDs, together with the ground-truth label and the model prediction, illustrating that the classifier recovers the intended geometric rules for these examples.

The experimental results indicate that a downstream MLP can learn the spatial relationships encoded in the latent vectors. The model discovers the geometric correlation between door and slab opening positions without access to explicit geometric coordinates or handcrafted features. The model generalises well to unseen combinations of door and opening geometries and achieves high classification accuracy for new spatial configurations. In practical applications, similar pipelines can be used when as-built building projects are available as IFC models. The pipeline can encode building components and their penetrations into latent vectors and train AI models that learn from past adjustment decisions made to satisfy actual building construction. Such trained models could then provide data-driven feedback on new building designs, supporting designers with limited construction experience in checking clearances and avoiding cross-component conflicts.

5 Discussion: Pathways to Generative AI

The neural representation proposed in this study establishes a foundational framework that provides a technical bridge to Generative AI within the BIM domain. This application methodology follows a systematic pipeline that transforms irregular architectural data into a machine-learnable format. By mapping discrete IFC entities into a continuous feature space, the framework enables advanced generative architectures to interact effectively with complex structural information.

The first stage of this process involves standardising heterogeneous data through feature encoding to overcome the inherent irregularities of IFC geometries. Our approach utilises an auto-decoder architecture to compress diverse building entities into a series of fixed-length latent vectors. This transformation is essential because it converts complex symbolic data into a uniform format that mainstream machine learning models can process efficiently.

The coordinate-preserving nature of the resulting latent space serves as a critical enabler for various generative tasks. Since spatial positioning and geometric features are embedded directly within the vector distribution, generative models such as Diffusion Models or Generative Adversarial Networks can be trained to recognise underlying spatial assembly rules. These models operate directly within the latent space to predict optimal layouts or suggest design iterations while maintaining strict adherence to the global coordinate system.

Finally, the trained neural decoder functions as a restorative bridge back to the physical domain once a new latent vector is generated or predicted. The decoder interprets the synthesised vector and reconstructs it into a high-fidelity 3D geometric model. Because the latent space is conditioned on precise coordinate data, the reconstructed entities automatically maintain their intended spatial orientations and topological relationships. This closed-loop methodology ensures that AI-generated outputs remain fully compatible with standard BIM workflows and engineering requirements.

6 Conclusion

This study addresses the representation gap between complex IFC geometry and the data needs of AI-driven automated architectural design. The researchers developed an SDF-based auto-decoder that converts building components into compact latent vectors while preserving their original spatial context. Experiments show that the method is accurate enough for automated design coordination. Preserving real-world coordinates is essential, as standard normalisation results in significant accuracy loss. Additionally, the model supports the

generation of design variants through smooth interpolation of size, shape, and position. While the current experiment focuses on rectangular shapes and faces computational challenges for large projects, it successfully bridges the gap between IFC entities and neural representations. By isolating variables in a controlled setting, the study demonstrates the fundamental validity of coordinate preservation. Future research will focus on improving efficiency, conducting more robust evaluations on complex real-world scenarios, and creating new datasets to help AI learn complex assembly rules despite geometric noise.

Abstract –

Flooding can severely disrupt highway networks, causing substantial mobility loss and delayed recovery. Existing studies that quantify flood impacts on transportation networks primarily focus on structural or functional features, largely overlooking the role of socioeconomic vulnerability. Additionally, how socioeconomic vulnerability influences flood impacts and recovery prioritization across traffic-demand groups remains unknown. This study proposed a unified disaster impact index (DII) that integrates predicted traffic performance with surrounding socioeconomic vulnerability to assess flood impacts on highway networks. A graph neural network (GNN)-based model was employed to predict traffic flow and speed under flood conditions, enabling a performance-based evaluation of network disruption. Using Harris County during Hurricane Harvey as a case study, flood impacts on 18 major highways were quantified and compared across high-traffic-, medium-traffic-, and low-traffic-demand groups. Results showed that incorporating socio-economic features did not alter the identification of the most critical highways, but rather reshaped prioritization within the medium-traffic-demand highway group to emphasize highways that serve socially vulnerable communities.

Keywords –

Flood impacts; socioeconomic vulnerability; data analysis; GNN; highway networks

1 Introduction

Flooding is one of the most disruptive natural hazards affecting transportation systems, leading to extensive mobility loss, prolonged traffic delays, and significant socioeconomic consequences [1, 2]. Highway networks, as the backbone of urban mobility and emergency response, are particularly vulnerable when flood overwhelms surface drainage and inundate critical road segments [3]. During Hurricane Harvey, several major highway closures occurred due to flooding, severely constraining regional accessibility and delaying emergency operations [4]. These challenges underscore the growing need to quantify the impacts of disasters on highway networks and identify the most critical roads for effective restoration.

Existing research has examined the impact of flooding on transportation systems from both network structural and functional features. Studies focusing on network structural features typically employ graph-based metrics, such as network efficiency and centrality, to assess changes in connectivity and accessibility. Functional studies, on the other hand, focus on performance degradation such as reduced traffic flow, increased travel time, and loss of capacity to assess the severity of disruptions. However, most existing studies fail to consider the socioeconomic aspects of surrounding communities, limiting the practicality of disaster impacts on transportation networks' recovery.

Recent research has begun to incorporate socioeconomic vulnerability into disaster planning and assessment, recognizing that communities with higher vulnerability tend to face longer recovery times and weaker resilience [5]. These studies have assessed disaster impacts on different regions by AHP [6] and prioritized the recovery of small bridge and road networks considering socioeconomic vulnerability [7]. However, there are two main gaps. First, socioeconomic vulnerability is not integrated with actual functional performance, rendering it static and failing to quantify disaster impacts with a dynamic nature. Second, how socioeconomic vulnerability influences flood impacts and recovery prioritization across traffic-demand groups remains unknown.

To address the research gaps, this study quantified flood impacts integrating network structural, functional, and socioeconomic features on highway networks and explored how socioeconomic vulnerability influences the

restoration priorities of different traffic demand highway groups. We developed a disaster impact indicator (DII) that integrates predicted traffic performance from a graph neural network-multi-layer perceptron (GNN-MLP) model with socioeconomic vulnerability of surrounding communities. Using Harris County during Hurricane Harvey as the case study, we quantified flood impacts on 18 highways and examined how integrating social vulnerability can shift recovery priorities across high-traffic-, medium-traffic-, and low-traffic-demand highway groups. The contributions of this study are (1) developing a unified DII that captures network structural, functional, and socioeconomic features to assess flood impacts; (2) investigating how socioeconomic vulnerability influences recovery prioritization across traffic-demand groups.

The remainder of this paper is organized as follows. Section 2 reviews related work on disaster impact assessment for transportation networks. Section 3 introduces the methodology, including the construction of DII. Section 4 presents the case study, results, and discusses key findings. Section 5 concludes with implications for transportation disaster management.

2 Literature Review

This section introduces previous research on disaster impact assessment for transportation networks, focusing on the input features used in these studies (subsection 2.1). We then summarized their input features, strengths, and limitations in Table 1, and finally articulated research gaps and our research objectives (subsection 2.2).

2.1 Disaster Impact Assessment for Transportation Networks

Existing studies on the impacts of disasters on transportation networks have focused on the structural and functional features of these networks. Studies focusing on network structural features typically rely on network topology and connectivity. These studies have been applied to identify urban roads most affected by flash floods [8] and detect system-critical routes under terrorist attacks and volcanic eruptions [9]. However, these methods are simple and intuitive as they directly link the intensity of physical hazard to network vulnerability. Furthermore, they tend to have low fidelity as they ignore dynamic traffic conditions and fail to reflect the broader impact on surrounding communities.

Studies focusing on functional features typically use traffic speed [10], and traffic flow [11, 12] to quantify functional degradation of transportation networks under disaster conditions. These methods provide more quantitative and operationally meaningful estimates of network performance loss. However, they largely overlook the social aspects of transportation systems, treating road segments as isolated infrastructure elements without considering the vulnerable communities they serve.

A small number of studies have attempted to integrate network structural and functional features. They highlight network vulnerabilities across different hazard types and provide a more comprehensive view of operational disruptions [12]. Despite this progress, they still fail to incorporate the influence of socio-economic features from surrounding communities.

More recently, several studies have incorporated socioeconomic features into disaster assessment frameworks. One work has proposed a decision-making framework for transportation recovery planning that recognizes the importance of socioeconomic features [5]. Other studies have developed decision-support tools, such as an AHP-based framework [6], to assess regional earthquake risks considering socio-economic features. However, these studies fail to include real-time assessment, focusing on a macro-level regional risk assessment rather than the road-level assessment. Therefore, Merschman et al. [7] proposed a post-disaster bridge repair framework that incorporates social vulnerability to identify the most resilient recovery strategy. Although they have assessed the resilience for each bridge repair sequence, they did not explore how socio-economic features affect the impact of floods on roads with different travel demands.

Table 1 Representative studies on disaster impact assessments for transportation networks

Ref.	Input features	Strength	Limitation
[8]	Network structural features	Simple, intuitive; directly relates hazard intensity to risk	Low-fidelity; ignores dynamic traffic and impacts to surrounding communities
[10]	Functional features	Provides quantitative estimates of functional performance	Ignores impacts to surrounding communities
[12]	Network structural and functional features	Highlights structural vulnerabilities, applicable to various hazards	Ignores impacts on surrounding communities
[5]	Network structural, functional, and socio-economic features	Provide a decision-making framework for disaster recovery planning	There is no quantitative analysis of the influence of socio-economic

			features
[6]	Physical and socio-economic features	Provide a decision support tool for disaster assessing earthquake risk in different regions	There was no real-time assessment, nor was there an assessment at the road segment level
[7]	Network structural, functional, and socio-economic features	Propose a post-disaster bridge repair planning framework considering social vulnerablity	The selection process for the 8 social vulnerability factors used to construct SVI was subjective.
Our study	**Network structural features, functional features, and socio-economic features**	**Propose a unified disaster impact indicator that quantifies flood impacts**	**Since CDC statistics are collected once a year, social features are not dynamic**

2.2 Research Gaps and Objectives

In summary, there are two main research gaps. First, existing studies lack quantitative and real-time assessments of disaster impacts that integrate socio-economic and dynamic traffic performance. This limitation reduces the reliability of these methods for time-sensitive decision-making during emergency response and recovery planning. Second, although the importance of socioeconomic vulnerability has been increasingly recognized, its role in influencing flood impacts on transportation networks with different travel demand levels remains insufficiently explored. As a result, recovery strategies derived from existing methods may unintentionally fail to prioritize roads that are critical for socially vulnerable communities.

To fill these gaps, this study developed a unified indicator that integrates predicted traffic performance with surrounding socioeconomic vulnerability to assess the flood impacts and support recovery planning. Specifically, we developed a DII that integrates predicted traffic performance from a GNN-MLP model with socioeconomic vulnerability of surrounding communities to quantified flood impacts on 18 highways and examined how integrating social vulnerability can shift recovery priorities across highway groups with different travel demand.

3 Methodology

The workflow of the methodology was structured in three parts as shown in Figure 1: (1) data collection (subsection 3.1); (2) GNN-based model for traffic prediction (subsection 3.2); and (3) dynamic impact indicator for flood assessments (subsection 3.3).

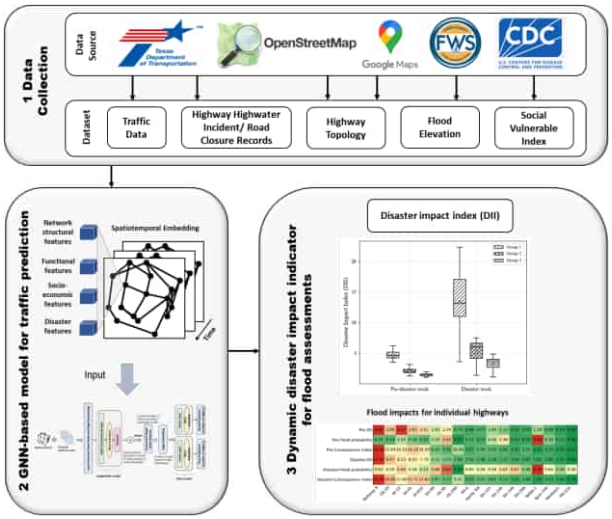

Figure 1. Workflow for flood impact assessment of highway networks

3.1 Data Collection

We collected four types of data: (1) network structural features, (2) functional features, (3) socio-economic features, and (4) disaster features. Table 2 introduces these data types, variables, and sources. flooding condition. Subsections 3.1.1-3.1.4 describe in detail the collection and processing of these four types of features. Section 3.1.5 introduces the road closures and network structure updates under the influence of floods.

Table 2 Input data types, variables, and sources

Date type	Variables	Data sources
Network structural features	Node degree centrality, node betweenness centrality, edge betweenness centrality	Texas Highway Freight Network [13]
Functional features	Traffic flow, traffic speed	Texas Department of Transportation [14], Houston TranStar [15]
Socio-economic features	Social vulnerability index	Centers for Disease Control and Prevention [16, 17]
Disaster features	Flood elevation,	Harris County Flood Warning System [18],

	flood probability	Texas Department of Transportation [14]

3.1.1 Network Structural Features

Network structural features capture the topological characteristics of the highway network, including node degree centrality, node betweenness centrality, and edge betweenness centrality. We collected the network structural features from the Texas Department of Transportation (TxDOT) and transformed them into a CSV format by manually identifying the node coordinates using Google Maps. We then constructed a directed graph $G = (V, E)$ with 546 nodes and 557 edges to encode the spatial topology of the highway network for subsequent spatiotemporal learning using GNN. Tensors $T_s \in \mathbb{R}^{J \times M_s}$ and $T_{ns} \in \mathbb{R}^{J \times N_s}$ represent the network structural features on the edges and nodes, respectively.

3.1.2 Functional Features

Functional features capture the functional performance of each highway segment, including traffic flow and speed. We collected the functional features from the TxDOT. Traffic flow data were later aggregated to characterize highway-level traffic demand and to support the classification of highways into different demand groups in the case study analysis. A speed value of zero can occur under two conditions: (1) a true zero, where a highway segment is closed, and no vehicle can pass; and (2) a false zero, where a highway segment is open, yet no vehicle travel through the segment during the recorded time. To reflect the actual condition, we kept the true zeros and used third-party speed data from Houston TranStar to supplement the false zeros. Tensor $T_f \in \mathbb{R}^{J \times M_f}$ represent the functional features on the edges.

3.1.3 Socio-economic Features

We used the social vulnerability index (SVI) to represent socio-economic features. The SVI data were collected from the Centers for Disease Control and Prevention (CDC) [17]. The SVI is the overall percentile rankings of 15 variables: below poverty, unemployed, income, no high school diploma, aged 65 or older, aged 17 or younger, civilian with a disability, single-parent households, minority, speak English "less than well," multi-unit structures, mobile homes, crowding, no vehicle, and group quarters. To integrate these data into the network, census-tract-level SVI values were mapped to graph nodes by assigning each node the SVI of the census tract in which it is located. This enables the representation of socio-economic vulnerability at the node level through the tensor $T_{sv} \in \mathbb{R}^{I \times N_{sv}}$.

3.1.4 Disaster Features

Disaster features used in this study were collected from the Harris County Warning System, including flood elevation and flood probability. The flood elevation is the water-surface elevation. Flood probability is an elevation threshold—when the water level reaches this height, it may cause flooding of surrounding roads. To map the disaster features on each highway segment, we first discretized the highway network into grids. Then, we mapped the flood elevation and flood probability from each monitoring station into these grids. Each highway segment was assigned the average value of the grids that it intersected. Tensors $T_d \in \mathbb{R}^{J \times M_d}$ represent the disaster features on the edges.

3.1.5 Road Closures and Network Structure Updates

We used the high-water incidents and road closures data provided by TxDOT to update the road network structure due to flooding. Each record contains the coordinates, detection time, and cleared time for each event. There are two flooding conditions of each grid: (1) flooded, with one or more flood or closure events; (2) unaffected, with no flood or closure event. Highway segments that intersected one or more flooding grids were marked as inundated. Accordingly, we updated the network structure based on the inundated segments.

3.2 GNN-Based Model for Traffic Prediction

We used a GNN model for generating node representations and a multi-layer perceptron (MLP) model for traffic prediction. We first conducted a rigorous hyperparameter selection to optimize six GNN-based variants and identify the most effective configuration based on root mean square error (RMSE), including GCN, STGCT, DCRNN, GAT, ChebNet and GraphSAGE. Then, we selected the GraphSAGE-MLP architecture for our case study, as shown in Figure 2.

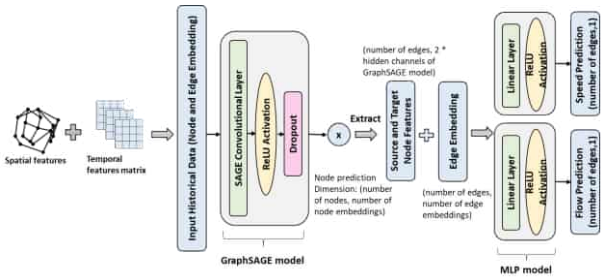

Figure 2 The architecture of the GraphSAGE-MLP case study model

Historical data, including node features (e.g., structural and social features) and edge features (e.g., disaster and functional features), is pre-processed as a

spatiotemporal matrix and used as model input. First, node features are iteratively updated through neighbourhood aggregation in SAGE convolutional layers, followed by nonlinear regularization using the Corrected Linear Unit (ReLU) activation function and dropout to obtain node prediction results. Next, we extract the embedding vectors of source and target nodes and concatenate them with edge-specific features to generate comprehensive edge embedding vectors. These embedding vectors are then fed into an MLP model, where independent linear layers predict traffic speed and flow, respectively.

3.3 Dynamic Disaster Impact Indicator for Flood Assessment

We proposed a disaster impact indicator (DII) to assess the impact of floods, which can identify the highway segments most severely affected by floods. The concept of DII was proposed by Zhang et al. [19], referring to the probability of disaster occurrence and the consequences of segment disruption. To incorporate the real functional performance and the social influence from the surrounding vulnerable communities, we extended Zhang et al.'s definition by integrating functional and socio-economic features. The DII for a highway segment e is formulated as:

$$DII(e) = DP(e) \times CI(e) \quad (1)$$

where $DP(e)$ represents the probability of a highway segment e is flooded, derived from the disaster tensor $T_d \in R^{J \times M_d}$. $CI(e)$ refers to the consequence index, which measures the degree of disruption caused by highway segment e being flooded. The $CI(e)$ is defined as:

$$CI(e) = \frac{(S_i + S_j)}{2} \times F(e) \quad (2)$$

where S_i and S_j capture the social vulnerability at the starting and ending nodes of highway segment e, respectively. Both values are derived from the socio-economic feature tensor $T_{sv} \in R^{I \times N_{sv}}$. Specifically, S_i and S_j correspond to the SVI of the census tracts where node i and j are located. The functional feature $F(e)$ quantifies function performance road segment e, and is derived from the functional feature tensor $T_f \in R^{J \times M_f}$. The functional feature $F(e)$ is calculated as:

$$F(e) = \alpha F_f(e) + \beta F_s(e) \quad (3)$$

where traffic flow $F_f(e)$ and speed $F_s(e)$ are commonly-used indicators for evaluating functional performance. $F_f(e)$ characterizes the traffic-carrying capability of a highway, while $F_s(e)$ indicates its service quality. We normalized $F_f(e)$ and $F_s(e)$ to the range [0,1] to eliminate scale-related bias. The weighting parameters α and β, each ranging from 0 to 1, specify the relative emphasis placed on flow versus speed and can be adjusted according to analytical needs.

4 Case Study

We applied the proposed DII to assess flood impacts on the Harris County highway network during Hurricane Harvey from August 25 -31, 2017. Figure 4 shows the 18 highways within the study area, each highlighted with a distinct colour. To facilitate comparative analysis, these highways were grouped by their traffic demand calculated as the total traffic flows during the study period.

- Group 1 (high-traffic-demand) highways: IH-10, Beltway 8, US-59, IH-45, IH-610, and US-290.
- Group 2 (medium-traffic-demand) highways: SH-99, SH-225, Hardy Toll Road, SH-146, SH-288, and SH-249.
- Group 3 (low-traffic-demand) highways: Spur-330, SH-6, US-90, NASA-1, Westpark Tollway, and FM-529.

Figure 4 18 highways within the study area

4.1 Data Collection

Network structural, functional, socio-economic, and disaster features were collected and processed as introduced in Section 3.1. The dataset spans the period from August 18 to 31, 2017, with a temporal resolution of 15 minutes. Specifically, data from the pre-disaster period (August 18–24) and the initial phase of the disaster (August 25–27) were used as inputs to predict traffic conditions and flood impacts during the subsequent four days (August 28–31). In addition, high-water incidents and road closures were used to update the highway network structure during the flood.

4.2 GNN-Based Model for Traffic Prediction

We used the GraphSAEG-MLP model introduced in

Section 3.2 to predict the traffic flow and traffic speed. The model was trained using historical data from Aug. 18–27 to predict traffic conditions during Aug. 28–31, with approximately 71% of the data used for training and 29% for testing. The model was optimized using the Adam optimizer with a learning rate of 0.0001. Hyperparameter tuning was conducted for key model components, including the number of epochs, GraphSAGE layers, hidden channels, and dropout rate. The final model configuration consisted of 25 training epochs, 1 GraphSAGE layer, 16 hidden channels, and a dropout rate of 0.3.

The RMSE values of traffic prediction for each model were presented by a pair of box plots, where speed was represented in blue and flow was represented in red (Figure 3). The lines inside the box plots mark the median RMSE, and the green triangles represent the mean values. The y-axis was capped at 1.7 to enhance readability by preventing GraphSAGE-LSTM-MLP's outliers (exceeding 2.4) from distorting the scale. We found that GraphSAGE-MLP exhibited the lowest RMSE values for both traffic speed and flow with a compact interquartile range, indicating both high accuracy and low variance.

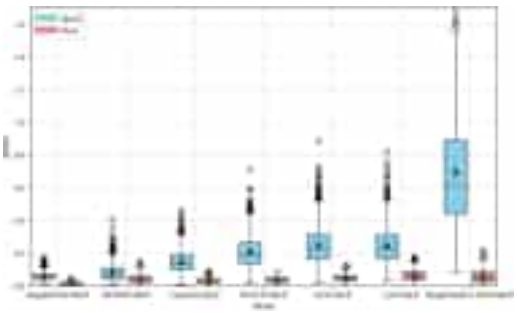

Figure 3 RMSE distribution for predicted speed and flow across models

4.3 Dynamic Disaster Impact Indicator for Flood Assessment

We calculated the DII for the pre-disaster week (August 18–24) using observed traffic data as a baseline. During the disaster week (August 25–31), observed data were used for the early disaster stages (August 25–27), while GNN-predicted traffic data were incorporated to assess flood impacts for subsequent periods (August 28–31).

First, we compared the DII across the three highway groups to evaluate how disaster impacts vary with traffic-demand levels. Second, we examined individual highways by their flood probability, consequence index, and DII to identify highways with high flooding probability, high disruption consequence, or both. Third, we explored how socioeconomic vulnerability affects flood impacts for highways with different traffic demand levels.

Figure 4 shows the boxplots of the DII across the three highway demand groups. Compared with the pre-disaster week, all groups experienced an expansion of the interquartile range (IQR) during the disaster week, indicating greater variability in impact severity among individual highway segments within the same group. Group 1 (high-traffic-demand) highways exhibited the largest DII values during the disaster, with a mean increase of 186.45%, indicating that suffered the most severe disruptions. This pattern aligns with most high-water events observed along these highways, highlighting the direct impact of flooding on them. In contrast, Group 3 (low-traffic-demand) highways showed the lowest DII values and the smallest relative increase from pre-disaster week (115.87%), implying relatively limited direct exposure to flooding. Examination of high-water records further indicates that the observed impacts on these highways were largely indirect, driven by suppressed travel demand in adjacent areas and reduced upstream network connectivity.

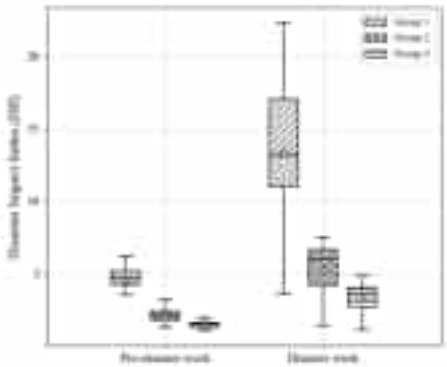

Figure 4 DII for pre-disaster week and disaster week by highway groups

We visualized the average flood probability, consequence index, and DII values of each highway during the pre-disaster and disaster weeks as a heatmap (Figure 5) to further examine the varying impacts of flood. These three indicators respectively capture a highway's exposure to flooding, its potential to disrupt network-wide mobility, and its overall disaster impact. As shown in Figure 5, highways are ranked in descending order of their DII values during the disaster week. Each row is colour-scaled independently—red indicating higher values and green indicating lower—to facilitate visual comparison.

The results revealed that highways such as Beltway 8, IH-10, and IH-45 already had high DIIs before the disaster, suggesting they are particularly vulnerable to potential impacts even before the flood. This is due to their locations in flood-prone (Beltway 8) or low-lying areas (IH-45) and their critical roles in regional traffic

(IH-10). This result highlights the need for flood prevention infrastructure and pre-disaster traffic management plans for these highways. Beltway 8, US-59, and IH-10 exhibited the highest DIIs during the disaster, indicating that these highways experience the most significant impacts during the flood. This underscores the need to prioritize these highways in disaster response and recovery, including timely road clearance and emergency access restoration to minimize cascading network disruptions.

Interestingly, despite having the lowest flood probability during the disaster (only 0.3), US-290 showed relatively high DII and consequence index values. This is likely because US-290's strategic location as a connector between high-traffic regions makes it vulnerable to network-level disruptions, even under minor local flooding. This result highlights that flood probability alone does not determine impact severity. Therefore, disaster preparedness and resilience planning should place greater emphasis on the potential consequences of disruptions.

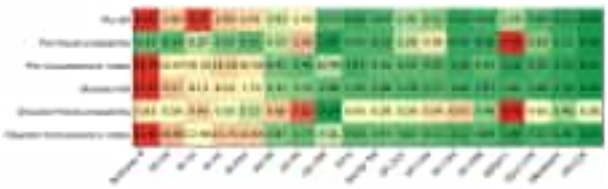

Figure 5 Average flood probability, consequence index, and DII for each highway during pre-disaster and disaster weeks

To quantify the influence of incorporating socio-economic vulnerable features, DII-based highway rankings during the disaster week were examined with and without the inclusion of SVI (Figure 6). The horizontal axis uses distinct font colours to denote highway demand groups, with blue, orange, and green representing Groups 1, 2, and 3, respectively. In both cases, Group 1 (high-traffic-demand) highways consistently had the highest DII, confirming the robustness of the overall priority. However, noticeable ranking shifts were observed among Group 2 (medium-traffic-demand) and Group 3 (low-traffic-demand) highways. Within Group 2, most highways experienced a decline in ranking after incorporating SVI, with only a few exceptions, such as SH-225 and SH-288, showing improvements. In contrast, Group 3 highways exhibited more pronounced heterogeneity. For instance, NASA-1 experienced a substantial drop in ranking, whereas US-90 and SH-6 rose by three positions, indicating that certain low-demand highways gained priority when socio-economic vulnerability was considered.

This pattern suggests that incorporating socio-economic vulnerability does not merely reshape rankings within individual demand groups but instead induces a cross-group reallocation of recovery priority. Specifically, priority shifts away from medium-demand highways toward low-demand highways that serve more socially vulnerable communities. This highlights that equity considerations can elevate the importance of otherwise lower-demand infrastructure when their surrounding populations are more vulnerable. From a broader perspective, these findings indicate that socio-economic features introduce a redistribution mechanism in recovery prioritization, moving beyond efficiency-driven decisions based solely on traffic demand. In practice, this implies that planners should pay attention to low-demand highways that may serve vulnerable communities, as they can become critical candidates for earlier intervention despite their lower functional prominence.

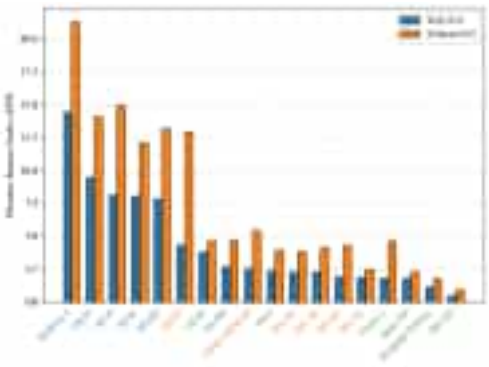

Figure 6 Highway DII rankings with and without SVI during the disaster week

5 Conclusions

This study proposed a DII that integrates predicted traffic performance with surrounding socioeconomic vulnerability to quantitatively assess the impacts of floods on highway networks. We first collected four types of features and then fed them into a GraphSAGE-MLP model for traffic prediction. Subsequently, the DII was calculated using the predicted traffic flow data. Using the flooding caused by Hurricane Harvey in Harris County as a case study, we quantified the impact of the flood on individual highways and demonstrated how socioeconomic vulnerability influences the flood impact on highway groups with different travel demands.

Several key findings emerge from this study. First, high-traffic-demand highways are more severely affected by floods. Second, assessing flood impact requires considering not only flood probability but also the consequences of the damage. Third, incorporating socio-economic features preserved the identification of critical highways while refining the prioritization of medium-traffic-demand highways to emphasize highways that

serve socially vulnerable communities.

The academic contributions of this study are (1) developing a unified DII that captures network structural, functional, and socioeconomic features to assess flood impacts; (2) investigating how socioeconomic vulnerability shapes recovery prioritization across traffic-demand groups. However, this study has some limitations. First, the analysis relies on data spanning only one week before and one week during the flood. Second, the SVI employed in this study is static and does not capture potential temporal variations in social conditions or behavioral responses throughout the disaster period. Future work could incorporate dynamic social indicators (e.g., mobility data) to better represent evolving population behavior and vulnerability during disaster events, thereby improving the realism of recovery prioritization.

Abstract -

Alignment between Building Information Models (BIM) and as-built representations is essential for automated construction progress monitoring. Existing pipelines that rely on images often require manual selection of correspondences or additional site instrumentation. Recent advances in differentiable scene representations, especially 3D Gaussian Splatting (3DGS), open new possibilities for automatic global BIM to as-built alignment through dense supervision from multi-view images. This paper presents *BIM-Align*, an automatic framework for global BIM to as-built alignment with multi-view imagery and 3DGS. The proposed framework initially estimates camera poses using Structure-from-Motion (SfM) and reconstructs a dense point cloud using multi-view stereo (MVS). Subsequently, the target building is extracted from the dense point cloud using DBSCAN clustering, and an initial BIM to as-built alignment is computed with classical geometric methods. The initial alignment is then refined with a coarse-to-fine strategy, where the coarse and fine stages each perform 3DGS optimization with a separate learnable Sim(3) transformation. Experimental results on construction site images show that the proposed approach achieves a mean reprojection RMSE within 2.13 pixels and a mean 3D alignment error within 9.18 cm of a manual baseline, demonstrating the feasibility of automatic BIM to as-built alignment from images with 3DGS.

3D Gaussian Splatting; Construction Site Monitoring; BIM to As-Built Alignment

1 Introduction

Timely and accurate construction progress monitoring is essential for project control and early detection of cost and schedule deviations. Conventional approaches rely on manual site inspections, photographs, and periodic reports, which require substantial labor and time. These limitations motivate automated methods that continuously capture the as-built state and perform comparisons with the as-planned BIM to quantify progress and identify deviations [1, 2, 3, 4, 5].

A common pipeline for automated construction progress monitoring consists of three stages: (i) data acquisition and as-built point cloud reconstruction, (ii) BIM to as-built alignment, and (iii) progress and deviation analysis. Since progress and deviation metrics are computed by comparing BIM and the as-built point cloud, accurate alignment is key to reliable progress monitoring. In practice, the quality and completeness of the as-built point cloud have a significant impact on alignment performance, motivating the selection of appropriate data acquisition modalities. For instance, terrestrial laser scanning and mobile LiDAR can directly capture dense point clouds with high accuracy and have been widely used in construction monitoring [2, 5, 6]. However, LiDAR-based methods require expensive sensors and specialized operation, which limits their practicality for frequent monitoring. In contrast, multi-view 3D reconstruction based on SfM and MVS recovers 3D geometry from standard RGB imagery captured by conventional cameras, which enables data capture at low cost and high frequency [7]. Early work by Golparvar-Fard *et al.* employed a custom implemented SfM pipeline to reconstruct sparse as-built point clouds from unordered construction site imagery for BIM to as-built alignment [8, 9, 10, 11]. The subsequent availability of robust, off-the-shelf SfM-MVS pipeline tools, such as VisualSFM [12], COLMAP [13], and Agisoft [14], has further lowered the barrier to acquiring as-built point clouds, enabling recent studies to generate dense as-built point clouds with improved geometric completeness for BIM to as-built alignment [2, 3, 15].

Despite the advancements in multi-view 3D reconstruction, accurate BIM to as-built alignment remains a major challenge for automated construction progress monitoring. Existing approaches can be categorized into local and global alignment methods, where local methods align individual building elements independently, whereas global methods estimate a unified transformation for the entire building. For local alignment, Omara *et al.* [16] proposed a rigid alignment strategy that aligns individual BIM elements with corresponding point cloud segments. The authors deployed 12 cameras to capture images of a specific region of a building to reconstruct an as-built point cloud. Subsets of the point cloud corresponding to specific structural components, such as reinforced concrete

columns, are independently aligned with predefined BIM geometries using rigid transformations with fixed scale. However, in complex building scenes with numerous structural elements, local alignment requires a large number of images for individual elements.

For global alignment, Golparvar-Fard *et al.* [8, 9, 10, 11] proposed a BIM to as-built alignment approach based on a sparse point cloud derived from SfM. In their methods, a set of correspondences between the sparse point cloud and the BIM is manually annotated. A Sim(3) transformation is then computed with the correspondences for BIM to as-built alignment. In practice, SfM-derived sparse point clouds often suffer from incomplete scene coverage. As a result, certain regions present in the BIM lack corresponding points in the sparse point cloud, reducing the reliability of manually selected point correspondences for alignment. To address this limitation, Chen *et al.* [3] employed a dense point cloud generated by MVS for global BIM to as-built alignment using manually selected correspondences. However, these point-picking methods require manual correspondence selection, which is time-consuming and may introduce human error.

Other approaches implicitly achieve global BIM to as-built alignment by enforcing metric consistency during photogrammetric reconstruction, rather than performing an explicit geometric alignment step. Mahami *et al.* [15] placed coded photogrammetric targets on a construction site to fix the datum and absolute scale of point clouds derived from MVS. An as-built mesh was then reconstructed in Autodesk Revit [18] from the scaled point cloud, after which building elements were manually traced. Subsequently, the as-built mesh was compared with a BIM for construction progress monitoring. Similarly, Tuttas *et al.* [19] incorporated photogrammetric ground control points into the bundle adjustment [7], thereby generating point clouds directly in the BIM coordinate system. Masood *et al.* [20] leveraged GPS-based georeferencing to obtain global BIM to as-built alignment by referencing both representations to a common Universal Transverse Mercator (UTM) coordinate system. However, while these approaches demonstrate the feasibility of global BIM to as-built alignment under varying levels of manual intervention during data acquisition, achieving global BIM to as-built alignment from multi-view images without manual correspondences, additional site instrumentation, or external georeferencing remains an open challenge in practical construction environments.

Recent advances in differentiable scene representations, particularly 3D Gaussian Splatting (3DGS) [21], provide a new opportunity to address automatic global BIM to as-built alignment by leveraging dense supervision from multi-view images. 3DGS achieves high quality novel view synthesis by optimizing a set of 3D Gaussians from multi-view images and camera poses with a photometric loss. The Gaussian mean positions are typically initialized from a point cloud obtained by SfM. When the Gaussian mean positions are frozen during 3DGS training, initialization misalignment leads to misalignment in rendered views and increased photometric loss. To mitigate this effect, correcting the initial misalignment during 3DGS training reduces the impact of initialization errors on the photometric loss. In the BIM to as-built alignment setting, we assume that the Gaussian mean positions are initialized from a point cloud sampled from the BIM, while the as-built point cloud defines the reference coordinate frame. Under this formulation, BIM to as-built alignment is equivalent to correcting the misalignment between BIM and the as-built point cloud during 3DGS training. Building on this observation, this study investigates the feasibility of using 3DGS for automatic global BIM to as-built alignment. To this end, we propose an automatic framework. The proposed framework first estimates camera poses and reconstructs a dense point cloud using SfM and MVS, respectively. Subsequently, the target building is extracted from the dense point cloud, serving as the as-built point cloud. An initial BIM to as-built alignment is then estimated using classical geometric registration methods. Afterward, the initial alignment is refined by training 3DGS models initialized from the BIM in a coarse-to-fine manner.

Our main contributions are:

- We propose *BIM-Align*, an automatic framework for global BIM to as-built alignment from multi-view imagery that combines geometric initialization with 3DGS-based refinement.
- We introduce a coarse-to-fine 3DGS optimization strategy, in which BIM to as-built alignment is refined through a global learnable Sim(3) transformation with frozen Gaussian mean positions.
- We provide an evaluation on collected aerial images of a construction site using alignment metrics in image and 3D domains, together with a manual baseline based on annotated correspondences.

2 Method

Given a set of N multi-view images $\mathcal{I} = \{I_i\}_{i=1}^{N}$ of a construction site and a BIM mesh B, our objective is to automatically estimate a Sim(3) transformation that aligns the BIM with the as-built scene reconstructed from the images. The proposed framework consists of three stages and is illustrated in Figure 1. Initially, we estimate the camera poses $\Pi = \{\pi_i\}_{i=1}^{N}$ of the images and reconstruct a dense point cloud of the construction site. Subsequently, an as-built point cloud is extracted from the dense point

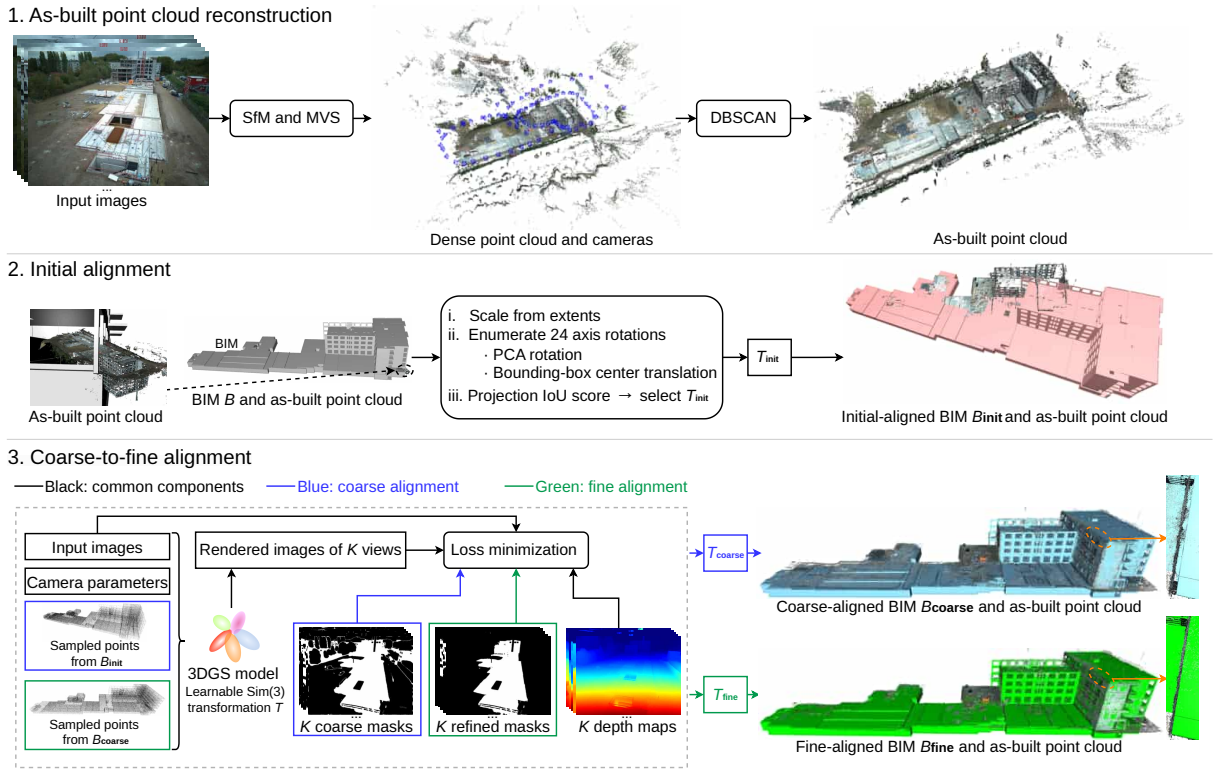

Figure 1. Overview of the proposed *BIM-Align* framework. (1) As-built point cloud reconstruction: SfM and MVS are used to estimate camera poses and reconstruct a dense point cloud, respectively. The as-built point cloud is extracted from the dense point cloud using DBSCAN clustering [17]. (2) Initial alignment: an initial Sim(3) transformation T_{init} is estimated using classical geometric alignment techniques. (3) Coarse-to-fine alignment: starting from the initial alignment, two separate 3DGS optimizations are performed. In the coarse stage, a learnable Sim(3) transform is optimized to estimate T_{coarse}. In the fine stage, the optimization is initialized from the coarse result and a separate Sim(3) transform is optimized to obtain T_{fine}. In addition, depth maps are used during 3DGS training in both phases. Specifically, coarse alignment employs coarse masks, the input point cloud sampled from B_{init}, and $K = 20$ views per iteration, whereas fine alignment employs refined masks, the input point cloud sampled from B_{coarse}, and $K = 1$ view per iteration. For visualization in stages (2) and (3), the as-built point cloud is cropped to retain only the building.

cloud. Next, an initial BIM to as-built alignment is computed using classical geometric alignment techniques, followed by a coarse-to-fine refinement using 3DGS [21].

2.1 Preliminary: 3D Gaussian Splatting

3D Gaussian Splatting (3DGS) [21] is an explicit scene representation proposed for novel view synthesis, which models a scene as a collection of anisotropic 3D Gaussians and supports efficient differentiable rendering. Each Gaussian is parameterized as $G = \{\mu, q, s, o, c, sh\}$. The mean position μ is initialized from an input point cloud and serves as the 3D anchor of each Gaussian. The rotation quaternion q defines the Gaussian orientation, s is a scaling vector that controls spatial extent, o represents opacity, c denotes color, and sh represents spherical harmonic coefficients encoding view-dependent appearance. A scene is represented by a set of Gaussians $\mathcal{G} = \{G_j\}_{j=1}^{H}$, where H denotes the number of Gaussians. Given the image set $\mathcal{I}$ and camera poses Π, the 3DGS model renders each view as $\hat{I}_i = \mathcal{R}(\mathcal{G}, \pi_i)$ using a differentiable renderer $\mathcal{R}(\cdot)$. Scene reconstruction is achieved by optimizing the Gaussian parameters by minimizing a photometric loss $\mathcal{L}$, leading to the following objective:

$$\min_{\mathcal{G}} \sum_{i=1}^{N} \mathcal{L}(\hat{I}_i, I_i) \, .$$

In our study, 3DGS is employed as an optimization backbone for global BIM to as-built alignment rather than for novel view synthesis.

2.2 As-built point cloud reconstruction

Given the image set $\mathcal{I}$, we employ a standard SfM-MVS pipeline implemented in COLMAP [13], where SfM is used to estimate the camera poses Π and reconstruct a sparse point cloud, and MVS is subsequently applied to generate a dense point cloud. Camera intrinsic parameters are estimated implicitly through COLMAP's built-in camera models and bundle adjustment. Subsequently, DBSCAN clustering [17] is applied to the dense point cloud to identify the building of interest. As the input images are captured with a focus on the building, the largest cluster is selected as the approximate as-built point cloud.

2.3 BIM to as-built initial alignment

An initial BIM to as-built alignment provides an appropriate initialization for subsequent refinement using 3DGS. Since the BIM and the COLMAP reconstruction differ in scale and coordinate frame, direct 3DGS optimization is unreliable. We therefore estimate an initial Sim(3) transformation T_{init}.

We first estimate the global scale $s_{\text{init}} \in \mathbb{R}^+$ by matching the overall spatial extents of the BIM and the as-built point cloud, and keep the scale fixed when estimating rotation and translation. To account for ambiguous BIM axis conventions [4], we enumerate 24 axis-aligned rotation hypotheses corresponding to the rotational symmetry group of a cube. For each hypothesis, rotation is further estimated by aligning the dominant principal directions of the BIM and the as-built point cloud using PCA [22]. Translation is computed by aligning their bounding-box centers. This yields a set of candidate Sim(3) transformations $\{T_{\text{init}}^k\}_{k=1}^{24}$.

To select the most plausible candidate, we evaluate each T_{init}^k using an overlap score based on orthographic projections. Specifically, we sample points from the transformed BIM mesh, project both the sampled points and the as-built point cloud onto the XY, XZ, and YZ planes, and rasterize the projections into binary footprint images. The consistency score is computed as the sum of the Intersection-over-Union (IoU) values of the three projection pairs, and the candidate with the highest score is selected as the final initial transformation T_{init}. The initially aligned BIM is denoted as $B_{\text{init}} = T_{\text{init}}(B)$.

2.4 BIM to as-built coarse alignment

We refine the initial BIM to as-built alignment with joint optimization of a BIM-initialized 3DGS model and a learnable global Sim(3) transformation T_{coarse}. Specifically, we uniformly sample P points from the initially aligned BIM B_{init} to construct an input point cloud $B_{\text{init}}^{\text{pcd}}$, which anchors the Gaussian mean positions in 3D space. To preserve the BIM-derived Gaussian structure, Gaussian densification and pruning are disabled throughout training. In addition, each sampled point is initialized with default spherical harmonic coefficients, resulting in a constant initial appearance.

The learnable Sim(3) transformation is parameterized as $T_{\text{coarse}} = (s_{\text{coarse}}, R_{\text{coarse}}, \mathbf{t}_{\text{coarse}})$, where $s_{\text{coarse}} \in \mathbb{R}^+$ denotes the scale factor, $R_{\text{coarse}} \in \text{SO}(3)$ is a rotation matrix, and $\mathbf{t}_{\text{coarse}} \in \mathbb{R}^3$ denotes the translation. To preserve the BIM-derived Gaussian structure, the mean position μ of each Gaussian initialized from $B_{\text{init}}^{\text{pcd}}$ is frozen during 3DGS training. The transformed mean position is obtained by applying the transformation T_{coarse} to the mean: $\mu' = s_{\text{coarse}} R_{\text{coarse}} \mu + \mathbf{t}_{\text{coarse}}$. Given the transformed Gaussian mean positions $\{\mu'\}$, the rendered image for view i is given by $\hat{I}_i = \mathcal{R}(\mathcal{G}(\{\mu'\}), \pi_i)$, where $\mathcal{G}(\{\mu'\})$ denotes the Gaussian set with updated mean positions, while all remaining parameters follow the standard 3DGS formulation [21]. Consequently, the BIM to as-built alignment is refined by jointly optimizing T_{coarse} and the remaining Gaussian parameters to enforce photometric consistency between rendered and observed images across all input views:

$$\min_{\mathcal{G},\, T_{\text{coarse}}} \sum_{i=1}^{N} \mathcal{L}(\mathcal{R}(\mathcal{G}(\{\mu'\}), \pi_i), I_i) .$$

To further regularize the optimization, we incorporate depth and mask supervision during 3DGS training. Depth supervision provides additional geometric constraints beyond photometric consistency, which can be ambiguous under weak texture, repetitive patterns, or occlusions. For each image, we predict a monocular inverse depth map using DepthAnything [23] and resolve the scale and shift ambiguity via per-image affine calibration to the SfM-derived point cloud using visible sparse 3D points. Views with abnormal calibration are discarded, and the calibrated inverse depth is used to supervise the rendered inverse depth. In addition, mask supervision suppresses the influence of non-building regions in the photometric loss, which is necessary since $B_{\text{init}}^{\text{pcd}}$ contains only building geometry. To generate masks, we use the prompt-based semantic segmentation model SAM3 [24]. In construction sites, buildings are often incomplete and only partially observed, especially at early stages where only structural slabs may be visible. As a result, extracting complete building masks using generic prompts such as *building* becomes unreliable. We therefore adopt an inverse strategy that segments typical background objects by querying SAM3 with the text prompts *dirt*, *bush*, *tree*, *car*, *sky*, *crane*, *container*, *road*, *fence*, and *metal*. A building mask is obtained by taking the complement of all segmented background regions. As a result, a set of coarse building masks $\mathcal{M}^0 = \{M_i^0\}_{i=1}^N$ for the N input images is created.

The optimization objective for a viewpoint π_i in our

3DGS training is a weighted combination of RGB and depth losses [21]:

$$\mathcal{L}^i = \lambda_{\text{rgb}} \left(\mathcal{L}^i_{\text{rgb}} \odot M^0_i \right) + \lambda_{\text{depth}} \left(\mathcal{L}^i_{\text{depth}} \odot M^0_i \right). \quad (1)$$

Here, the RGB loss $\mathcal{L}^i_{\text{rgb}}$ is a weighted combination of ℓ_1 loss and D-SSIM [25] loss, given by

$$\mathcal{L}^i_{\text{rgb}} = (1 - \lambda_{\text{D-SSIM}})\, \mathcal{L}^i_1 + \lambda_{\text{D-SSIM}}\, \mathcal{L}^i_{\text{D-SSIM}}, \quad (2)$$

where $\mathcal{L}^i_1 = \|\hat{I}_i - I_i\|_1$ and $\mathcal{L}^i_{\text{D-SSIM}} = 1 - \text{SSIM}(\hat{I}_i, I_i)$. The depth loss $\mathcal{L}^i_{\text{depth}}$ is defined as the absolute difference between the rendered and calibrated inverse depth maps. The operator $\odot$ denotes element-wise multiplication. Moreover, the weights λ_{rgb}, λ_{depth}, and $\lambda_{\text{D-SSIM}}$ control the weight of each component.

During coarse alignment, large initial misalignment causes the photometric objective to be dominated by mismatched pixels and incorrect visibilities, resulting in high variance and ambiguous gradients. As a result, single-view supervision is prone to 3DGS training failure. To stabilize the optimization, we compute the mean loss over multiple training views at each iteration. Specifically, we randomly sample $K \geq 1$ distinct indices from the training view index set $\{1, \ldots, N\}$, denoted as $\mathcal{S}$, where $\mathcal{S} \subset \{1, \ldots, N\}$ and $|\mathcal{S}| = K$. Thus, the total loss is given by

$$\mathcal{L}_{\text{all}} = \frac{1}{K} \sum_{i \in \mathcal{S}} \mathcal{L}^i. \quad (3)$$

As a result, the coarse alignment phase yields an optimized transformation T_{coarse} and a coarsely aligned BIM $B_{\text{coarse}} = T_{\text{coarse}}(B_{\text{init}})$.

Despite the segmentation capability of SAM3, the coarse building masks still contain non-building regions, providing insufficient constraints for fine-grained refinement at the coarse phase. We therefore introduce a fine alignment phase.

2.5 BIM to as-built fine alignment

The fine alignment phase leverages refined building masks to further suppress the impact of non-building regions during optimization. Based on the coarse alignment results, a geometric prior for the building region in each image is obtained by back-projecting the coarsely aligned BIM B_{coarse} into each input view, yielding BIM-projected masks $\mathcal{M}^1 = \{M^1_i\}_{i=1}^N$. However, residual misalignment can distort the projected building boundaries, causing boundary erosion and the loss of thin structures in the mask. To address this issue, we refine $\mathcal{M}^1$ using instance masks predicted by SAM3 on the input images. For each input image I_i, let $O_i = \{O^v_i\}_{v=1}^{V_i}$ denote the set of instance masks, where V_i is the number of instances segmented in I_i. We retain an instance mask O^v_i if the fraction of its pixels that lie inside M^1_i exceeds a threshold β. Subsequently, the retained instance masks are merged and combined with the BIM-projected mask M^1_i with set union to produce an intermediate refined mask M^2_i:

$$M^2_i = \left(\bigcup_m O^m_i \right) \cup M^1_i, \quad (4)$$

where O^m_i denotes the m-th retained instance mask in image I_i after overlap filtering. Despite this refinement, M^2_i may still contain clutter tightly adjacent to the building due to residual misalignment. To remove such clutter, we further refine M^2_i by intersecting it with the semantic segmentation mask M^0_i, yielding the final refined mask:

$$M^3_i = M^2_i \cap M^0_i. \quad (5)$$

The set of final refined masks is denoted as $\mathcal{M}^3 = \{M^3_i\}_{i=1}^N$.

In the fine alignment phase, we mostly follow the same optimization procedure as in coarse alignment. In contrast to the coarse phase, we initialize Gaussians using a point cloud sampled from B_{coarse} and compute the loss using the refined masks $\mathcal{M}^3$. Moreover, we calculate the loss using a single randomly sampled view per iteration, with $K = 1$. The fine alignment phase yields a refined Sim(3) transformation T_{fine} and a finely aligned BIM $B_{\text{fine}} = T_{\text{fine}}(B_{\text{coarse}})$.

3 Experiments

3.1 Dataset

We collected a dataset of aerial photographs of a construction site. The dataset contains 87 RGB images (960×720) captured from multiple viewpoints, yielding $N = 87$ input images in our experiments. In addition to the image data, we provide a corresponding as-planned BIM. To ensure consistency between the BIM and the as-built scene for alignment, we incorporate construction progress information and remove all unbuilt elements from the as-planned BIM. The resulting BIM B therefore represents the actual construction state at the time of image acquisition and serves as the BIM input to the subsequent automatic alignment framework in all experiments in our study.

We evaluate BIM to as-built alignment accuracy using reprojection error. For each image, we manually annotate a set of 2D points at distinctive geometric features and select the corresponding 3D reference points from the BIM at the same structural locations to form annotated 2D-3D correspondences. In total, we use 419 correspondence pairs across 87 images for evaluation, with a varying number of correspondences per image.

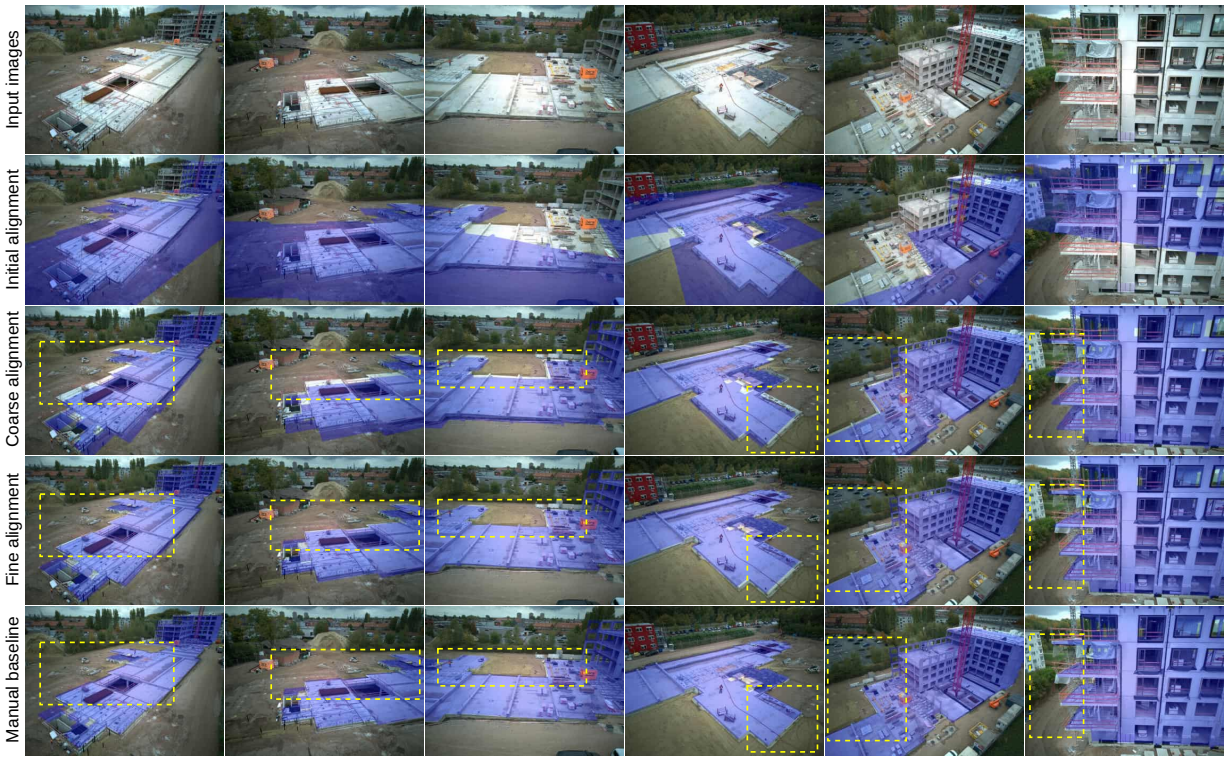

Figure 2. Qualitative comparison of BIM to as-built alignment at different stages. The aligned BIMs are back-projected into input images using the estimated camera poses. The projected BIM geometry is overlaid in blue in the visualized images. From top to bottom, the figure shows input images, initial alignment, coarse alignment, fine alignment, and the manual baseline. For visualization, BIM elements corresponding to an underground parking garage, which are not observable in the input images, are removed prior to projection.

3.2 Metrics

Alignment accuracy is evaluated in both image space and 3D space. Given an annotated 2D point p in image I_i with corresponding 3D point q on the BIM B, let T denote the estimated transformation at a given alignment stage. For the initial, coarse, and fine stages, T is defined as T_{init}, $T_{\text{coarse}}T_{\text{init}}$, and $T_{\text{fine}}T_{\text{coarse}}T_{\text{init}}$, respectively. In image space, q is transformed by T and projected onto I_i using camera pose π_i, yielding a 2D point p'. The 2D alignment error is defined as the Euclidean distance between the annotated point p and the projected point p'. In 3D space, the annotated point p is backprojected into the coordinate frame of BIM B, yielding a 3D point q''. The 3D alignment error is defined as the Euclidean distance between the corresponding BIM point q and the backprojected point q''. Since the BIM coordinate system is not expressed in physical units, the 3D distance is converted to centimeters using a scale ratio α. For each image, point-wise errors are aggregated using RMSE, and the overall performance across all images is reported using the mean ($\text{RMSE}_{\text{mean}}$), median ($\text{RMSE}_{\text{med}}$), and 95th percentile ($\text{RMSE}_{\text{p95}}$).

3.3 Implementation

In both the coarse and fine alignment phases, we uniformly sample $P = 500{,}000$ points from B_{init} and B_{coarse}, respectively, to construct the input point clouds for 3DGS training. The learnable Sim(3) transformation is optimized in a continuous parameter space. To ensure positivity, the scale is optimized in log-space and the rotation is parameterized and optimized as a unit quaternion during training. During the coarse alignment phase, the learning rates for the transformation parameters are initialized to 10^{-1} and exponentially decayed to 10^{-2} over 500 iterations [21]. The number of views used for loss computation per iteration is set to $K = 20$, balancing training stability and GPU memory constraints. In the fine alignment phase, the overlap threshold β for refined building mask generation is set to 0.9. The learning rates for the transformation parameters are initialized to 10^{-3} and exponentially decayed to 10^{-4} over 30,000 iterations. During fine alignment, a single view is used to compute the photometric loss per iteration, with $K = 1$. For metric evaluation in 3D space, we use a scale ratio of $\alpha = 99.36$ to convert

distances in the BIM B coordinate system to centimeters.

3.4 Manual baseline

We compare our method against a manual point picking baseline. Specifically, we manually annotate 30 corresponding points distributed over the BIM B and the as-built point cloud, and compute the Sim(3) transformation using [26].

3.5 Results

Table 1 reports a quantitative comparison of different alignment stages using 2D reprojection error in pixel units and 3D reprojection error in metric units (cm). For evaluation, the coarse alignment is run five times. Each coarse result is then used to initialize one corresponding fine-alignment run, yielding five paired coarse-to-fine trials. We report the mean and standard deviation over these five trials.

Table 1. Quantitative results of different alignment methods measured by 2D reprojection error (px) and 3D reprojection error (cm). Lower values indicate better performance.

Method	2D reprojection error (px)			3D reprojection error (cm)		
	$\text{RMSE}_{\text{mean}} \downarrow$	$\text{RMSE}_{\text{med}} \downarrow$	$\text{RMSE}_{\text{p95}} \downarrow$	$\text{RMSE}_{\text{mean}} \downarrow$	$\text{RMSE}_{\text{med}} \downarrow$	$\text{RMSE}_{\text{p95}} \downarrow$
Ours (initial alignment)	332.52	272.46	824.43	1275.61	1131.08	2829.79
Ours (coarse alignment)	21.22 ± 3.75	18.97 ± 3.02	39.62 ± 7.03	77.85 ± 13.53	77.40 ± 13.00	138.23 ± 28.02
Ours (fine alignment)	7.11 ± 0.72	6.46 ± 0.76	15.23 ± 1.27	28.61 ± 2.83	21.16 ± 2.44	62.67 ± 5.08
Manual baseline	**4.98**	**4.46**	**10.08**	**19.43**	**15.69**	**38.37**

As shown in Table 1, the initial alignment shows severe global misalignment. Nevertheless, it provides a feasible starting point for subsequent refinement with 3DGS. From the initial to the coarse and fine stages, both the 2D and 3D reprojection errors consistently decrease, demonstrating the effectiveness of the proposed framework in progressively minimizing misalignment. Compared with the manual baseline, the fine alignment achieves competitive performance in both 2D and 3D metrics. In particular, the fine alignment reaches a 2D $\text{RMSE}_{\text{mean}}$ of 7.11 px, which is 2.13 px higher than the manual baseline, and a 3D $\text{RMSE}_{\text{mean}}$ of 28.61 cm, which is 9.18 cm higher than the manual baseline. The larger difference in 3D RMSE_{p95} suggests that the 3D metric is more sensitive to residual misalignment, where small 2D deviations can lead to larger spatial errors after backprojection. These quantitative results demonstrate the feasibility of using 3DGS-based coarse-to-fine refinement for global BIM to as-built alignment, as evidenced by the consistent reduction in both 2D and 3D errors and the small gap to the manual baseline.

Qualitative results are shown in Figure 2, where aligned BIMs are back-projected into input images using the estimated camera poses. For visualization, we show the qualitative results of the paired trial that achieved the lowest mean reprojection error after fine alignment. A clear coarse-to-fine improvement is observed, and the fine alignment produces projections that closely approach the manual baseline. These visualizations further show that the proposed framework produces visually consistent projections across viewpoints, indicating the effectiveness of 3DGS for global BIM to as-built alignment.

3.6 Ablation study

We conducted ablation studies to analyze the impact of key design parameters in our method and report the average performance over five runs for each experiment. In this section, only 2D reprojection error in pixel units is reported.

Table 2. Ablation study on the number of views K used to compute the photometric loss during the coarse alignment stage, evaluated using 2D reprojection error in pixel units only. Results for $K = 5$ are reported as N/A due to training failure.

K	$\text{RMSE}_{\text{mean}} \downarrow$	$\text{RMSE}_{\text{med}} \downarrow$	$\text{RMSE}_{\text{p95}} \downarrow$
5	N/A	N/A	N/A
10	30.51	28.44	55.71
20	**21.22**	**18.97**	**39.62**

Effect of the number of views in coarse alignment. Table 2 evaluates the impact of the number of views K used to compute the photometric loss during the coarse alignment stage, evaluated using 2D reprojection error in pixel units. When $K = 5$, the combination of large initial misalignment and insufficient multi-view constraints leads to 3DGS training failure. This setting is therefore reported as N/A. Increasing K improves both 3DGS training stability and alignment accuracy, as more views provide more robust multi-view photometric constraints. In particular, K is evaluated up to 20 due to GPU memory constraints, with $K = 20$ achieving the lowest errors across all metrics.

Table 3. Ablation study on the mask type used in the fine alignment stage, evaluated using 2D reprojection error in pixel units only. $\mathcal{M}^1$: BIM-projected masks; $\mathcal{M}^3$: refined masks. Fine alignment is initialized from the best coarse-alignment run with $K = 20$.

Masks	$\text{RMSE}_{\text{mean}} \downarrow$	$\text{RMSE}_{\text{med}} \downarrow$	$\text{RMSE}_{\text{p95}} \downarrow$
$\mathcal{M}^1$	13.87	13.50	25.68
$\mathcal{M}^3$	**6.68**	**6.21**	**14.27**

Effect of mask quality in fine alignment. Among five coarse-alignment runs with $K = 20$, the run with the lowest $\text{RMSE}_{\text{mean}}$ is used to initialize the fine alignment in this ablation study. Table 3 studies the impact of different mask types in the fine alignment stage using 2D reprojection error in pixel units. Using BIM-projected masks $\mathcal{M}^1$ yields limited improvement due to residual misalignment. The proposed refined masks $\mathcal{M}^3$, obtained by further refining $\mathcal{M}^1$ with instance segmentation masks and semantic segmentation masks, improve performance further and

achieve the lowest mean, median, and tail errors. These results highlight the importance of accurate masks for fine alignment.

4 Limitations

The proposed framework has several limitations. First, the coarse-to-fine refinement depends on a sufficiently accurate initial alignment, particularly in orientation. The initialization may become unreliable when DBSCAN extracts only a partial building point cloud or when the target building exhibits strong geometric symmetry. Future work may improve this stage using unmanned aerial vehicle (UAV) GPS priors or semantic structural cues. Second, the refinement stage assumes relatively clean and visible building surfaces. Scaffolding, safety nets, and other temporary structures may introduce mismatches between the images and the BIM geometry, which can affect the optimization. Third, the proposed framework assumes as input a BIM that is already consistent with the observed construction state. Thus, the automation applies to the alignment process under this input condition, and extending the method to operate directly on complete BIMs remains future work. Finally, the current evaluation is limited to a single construction site, a specific construction stage, and UAV imagery. Accordingly, the robustness and transferability of the framework across different construction completion levels, capture strategies, and site layouts remain to be evaluated.

5 Conclusion

This study investigated the feasibility of using 3DGS for automatic global BIM to as-built alignment from multi-view imagery, given a BIM that is consistent with the observed construction state. The proposed *BIM-Align* framework combines classical geometric initialization with coarse-to-fine 3DGS refinement under the supervision of refined building masks. Experimental results show that our method achieves satisfactory alignment and approaches a manual baseline in a fully automatic manner, indicating the effectiveness of 3DGS for global BIM to as-built alignment. Further validation under more diverse and challenging construction scenarios is needed in future work.

6 Acknowledgment

This work was financially supported by the VLAIO COOCK-project 'AIDA' (HBC.2024.0591), a collaboration between imec, Buildwise, and Embuild. We gratefully acknowledge all project partners for their valuable contributions to technical discussions and data collection. We also thank the ibens project team of the Hoboken site for granting access to the construction project and for their practical support during data acquisition. In addition, this research received partial funding from the Flemish Government under the 'Onderzoeksprogramma Artificiele Intelligentie (AI) Vlaanderen' program.

Abstract –

Underground working environments are inherently hazardous, with explosion risks posing a persistent threat. Traditional static risk assessments struggle with dynamic conditions. This paper presents a novel real-time explosion risk prediction framework integrating Internet of Things (IoT) sensor data, Long Short-Term Memory (LSTM) networks, and Bayesian Networks (BNs). The system monitors critical indicators (e.g., methane, wind speed) via IoT. The LSTM captures temporal patterns via online learning, and its outputs feed into a BN, which combines predictions with expert knowledge for interpretable risk levels. A case study on a real underground coal mine demonstrated accurate methane concentration forecasting (R^2 = 0.93), with errors decreasing over time. The BN assessment dynamically reflected increased explosion risk upon introduction of an ignition source. This integrated approach offers real-time, interpretable support for explosion risk mitigation.

Explosion Risk Prediction; Dynamic Risk Assessment; Process Safety; Internet of Things; Long Short-Term Memory; Bayesian Networks

1 Introduction

Developing and operating underground spaces poses unique hazards characterized by spatial opacity, geological uncertainty, and dynamic environmental fluctuations such as gas emissions and seismic activity [1]. These risks, exemplified by fatal gas explosions, endanger workers and infrastructure, causing substantial economic losses [2]. Traditional static risk analysis methods, assuming stable environments, fail to incorporate time-dependent fluctuations [3]. Consequently, there is a pressing need for dynamic, real-time risk monitoring and prediction systems that can adapt to the evolving conditions characteristic of underground industrial settings.

Recent technological advancements offer promising avenues to address these challenges. The proliferation of the Internet of Things (IoT) enables continuous, real-time data collection on critical environmental indicators through wireless sensor networks. However, current monitoring systems primarily visualize data, leaving it untapped for deeper risk insights [4]. Furthermore, compatibility issues among data sources and the complexity of analyzing multivariate sensor streams hinder generalization [5]. Simultaneously, data-driven models, particularly deep learning architectures like Long Short-Term Memory (LSTM) networks, have demonstrated superior capability in capturing complex temporal patterns in time-series data. However, these models often operate as "black boxes," providing limited interpretability and failing to integrate crucial domain expertise [6]. On the other hand, knowledge-driven probabilistic models like Bayesian Networks (BNs) excel in representing expert knowledge and facilitating transparent, causal reasoning but may lack the adaptive learning capacity required for highly dynamic environments [7].

This paper addresses these limitations by introducing a novel dynamic risk prediction system that integrates IoT sensors, LSTM networks, and BNs into a unified, real-time framework. The technical novelty of this framework lies in an automated, real-time pipeline coupling continuous online LSTM learning (updating weights per time-step) with instantaneous Bayesian probabilistic inference via an Application Programming Interface (API), providing dynamic adaptability and interpretability for high-risk mining environments.

2 Literature Review

This section surveys the current state of research and technological applications in underground risk management.

2.1 Risk Management in Underground Settings

Traditional risk analysis in underground domain employs both qualitative techniques, such as safety checklists and the Delphi method, and quantitative techniques, including event tree analysis, fault tree analysis, and neural networks [8]. Typically, these methods rely on expert knowledge, historical data, and static models that assume stable conditions, thereby failing to capture the rapid environmental shifts common underground.

This limitation has prompted a shift towards dynamic modeling. For instance, Wu, et al. [9] proposed a quantitative risk assessment method for coal mine gas explosions based on BNs and Computational Fluid Dynamics (CFD), emphasizing that a dynamic model integrating real-time conditions could enhance production safety. Furthermore, the interconnected nature of underground systems leads to cascading hazards. Bai, et al. [10] developed an energy-based coupling risk assessment model for utility tunnels, identifying multiple cascading accident scenarios and stressing the need for stronger preventive actions. Hai, et al. [11] noted that existing methods often perform static analysis on individual risks while overlooking dynamic interactions, recommending the development of better risk indicator systems and the incorporation of interdependencies among risk factors.

2.2 IoT Applications in Monitoring Underground Hazards

The adoption of IoT technology has significantly advanced the monitoring of factors such as gas, dust, temperature, humidity, airflow, and seismic activity in underground mining. IoT devices enable swift data transmission, facilitating a dynamic approach to risk assessment. Onifade, et al. [12] highlighted how IoT enables smart ventilation systems that deliver precise amounts of fresh air to specific areas, using sensor networks to transmit real-time data to control rooms for immediate alerts and automated adjustments. Wu, et al. [13] developed a dynamic information platform for underground coal mine safety using IoT, integrating data acquisition, transmission, analysis, and application layers to collect and analyze vast amounts of operational data. Despite these advancements, a significant challenge remains. Ślęzak, et al. [4] pinpointed that the big data collected is typically used for raw data visualization and monitoring, with deeper analytical potential largely untapped. Applying intelligent forecasting models and data analytics to this data could predict near-future conditions and substantially enhance decision support systems.

2.3 Bayesian Risk Assessment in Underground Environments

BNs have become a crucial tool in underground risk management due to their probabilistic nature and ability to handle complex, uncertain relationships. Their applications range from accident cause analysis to dynamic risk modeling. Xuecai, et al. [14] developed a data-driven BN model for analyzing coal and gas outburst accidents, learning its structure and parameters from a comprehensive dataset of real-world incidents. In scenarios with insufficient data, expert knowledge is integrated. Tong, et al. [15] constructed a BN for mine gas explosions using expert knowledge and the Delphi method to establish conditional probabilities, featuring multi-scale nodes with dynamic probability updates. Mousavi, et al. [16] introduced an IoT and BN framework for online safety risk management, emphasizing the need for accurate BN structures and comprehensive sensor data. However, large and diverse data streams can challenge BN accuracy and computational efficiency. Moradi, et al. [17] noted that relying solely on BNs for complex assessments with numerous sensors and heterogeneous data becomes impractical, underscoring the importance of integrating BNs with data-driven prediction engines for proactive, dynamic risk monitoring.

2.4 Data-Driven Risk Prediction in Underground Spaces

Data-driven models, particularly LSTM networks, have emerged as powerful tools for uncovering complex patterns in time-series data from underground environments. Their application focuses on predicting critical parameters to provide early warnings. Kumari, et al. [18] proposed a UMAP and LSTM model for predicting fire and explosibility risks in sealed-off areas of coal mines, using historical and real-time gas sensor data to forecast concentrations and calculate fire ratios. Dey, et al. [19] implemented a hybrid CNN-LSTM model with IoT sensors to predict miner health quality and gas concentration levels, achieving high prediction accuracy.

Despite these strides, significant concerns remain. A primary issue is the black-box nature of these deep learning models, which fail to deliver context-specific insights or support interactive what-if scenario analysis, limiting customized decision-making guidance [20]. This lack of interpretability challenges trust in the algorithms, necessitating careful integration with engineering knowledge [21]. Furthermore, a notable gap in the literature is the absence of online learning frameworks specifically tailored for underground spaces. Online learning, which involves continuously training a model on newly arriving data streams [22], is essential for real-time adaptability in dynamic environments but has not

been extensively explored. This gap highlights the need for methodologies that seamlessly integrate deep learning with online learning to ensure predictive models can evolve continuously in response to changing underground conditions [23].

3 Research Methodology

The proposed IoT-LSTM-Bayesian system, as illustrated in Figure 1, operates through three modules, with static segments occurring pre-operation and dynamic segments occurring periodically during operation. The first module involves IoT deployment for real-time data acquisition and preprocessing. The second module updates an LSTM model with real-time data and predicts future values. The third module evaluates target risks using a pre-developed BN and the LSTM predictions, reporting risk evolution to users.

3.1 Data Specifications and Preparation

Data is derived from IoT sensors (e.g., for methane, wind speed, temperature, dust) deployed in critical locations like work fronts and ventilation corridors. Data is recorded at intervals from minutes to hours and transmitted via technologies like Wi-Fi. The real-time nature is crucial for adapting to dynamic conditions but requires robustness against sensor failures.

Data preparation involves three key tasks. First, missing values are imputed using forward fill to maintain temporal order. Second, anomalies, such as test-induced sensor readings, are identified via domain knowledge and replaced with the last known correct value. Third, the sliding window technique segments input data into overlapping fixed-length windows to capture temporal dependencies for the LSTM.

3.2 Online LSTM Learning and Prediction

LSTM networks are chosen for their ability to model long-term temporal dependencies in sequential data, such as methane concentration patterns. This memory mechanism is particularly critical in underground environments where gas accumulation and dispersion exhibit complex, time-lagged trends that simpler models fail to capture. An LSTM cell contains forget, input, and output gates that regulate information flow via sigmoid and hyperbolic tangent functions [24].

The model undergoes online learning, updating itself with each new data sample at every time step. This enables adaptation to evolving trends. Model performance is evaluated at each step using Mean Squared Error (MSE), Mean Absolute Error (MAE), and

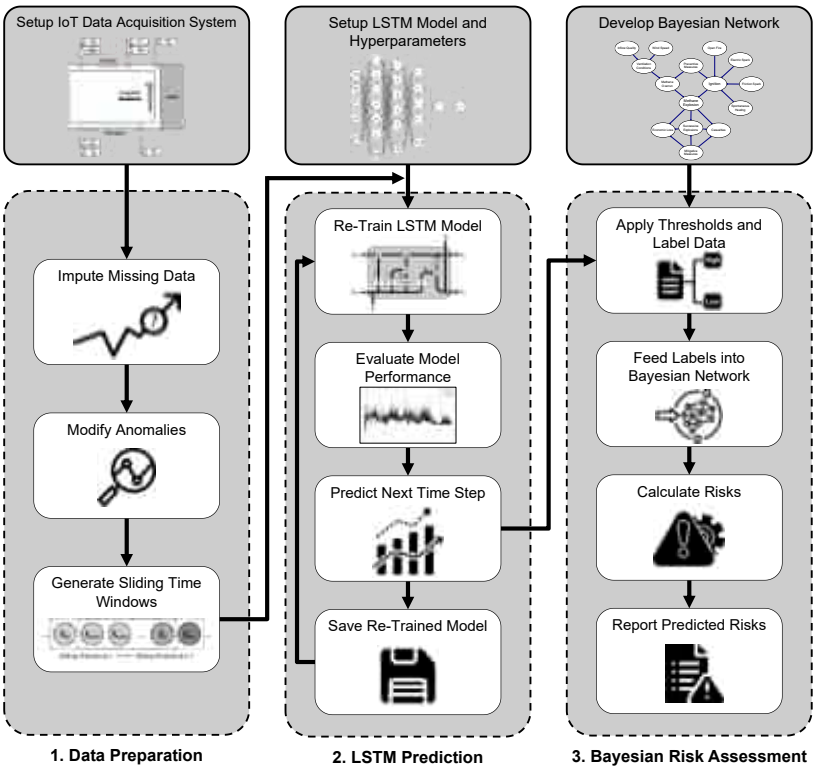

Figure 1. Overview of the proposed IoT-LSTM-Bayesian risk prediction system.

the Coefficient of Determination (R^2). Lower MSE/MAE and an R^2 closer to 1 indicate better performance. The trained model then predicts the next step's values. This model is saved and reused for subsequent retraining.

3.3 Bayesian Risk Assessment

BNs are chosen for their ability to integrate data-driven insights with expert knowledge into a transparent, interpretable probabilistic framework. A BN is a directed acyclic graph where nodes represent variables and edges represent conditional dependencies, quantified via Conditional Probability Tables (CPTs) [25]. The joint probability distribution is calculated using Eq. (1). Inference, updating probabilities given new evidence, is performed using Bayes' theorem (Eq. 2).

$$P(U) = P(X_1, \dots, X_n) = \prod_{i=1}^{n} P(X_i | Parent(X_i)) \quad (1)$$

$$P(Parent(X_i)|X_i) = \frac{P(Parent(X_i))P(X_i|Parent(X_i))}{P(X_i)} \quad (2)$$

In the dynamic system, predicted environmental indicators from the LSTM are discretized using predefined thresholds (e.g., methane concentration labeled as negligible or serious) and fed as evidence into specific BN nodes. The BN then updates probabilities throughout the network, providing real-time, interpretable risk insights.

4 Case Study on Underground Coal Mine

Methane explosions, resulting from methane concentrations reaching 5-15% in the presence of an ignition source, are among the most severe hazards in underground coal mining [26]. Concentrations exceeding 1% are typically considered hazardous, triggering safety protocols that halt production and incur significant financial losses [13]. This case study evaluates the proposed system using environmental monitoring data from a real longwall underground coal mine in China, focusing on methane concentration prediction and explosion risk assessment.

4.1 Data Characteristics and Preparation

Data was collected from eight sensors deployed at the mine's working face: five methane concentration sensors (T0-T4), one temperature sensor (TP1), one wind speed sensor (WS1), and one dust concentration sensor (D1). Figure 2 shows the spatial distribution of the sensors used in this study. Data spanned 3 January 2022 to 12 May 2023 (494 days) at one-minute intervals, yielding 710,367 samples. Table 1 presents the data characteristics. The raw dataset contained missing values and outliers. Missing values were imputed using forward fill, replacing them with the last recorded value to preserve temporal order. Outliers, primarily caused by controlled sensor calibration tests that artificially raised methane levels above 1%, were identified using domain knowledge from mine experts and replaced with the last known valid reading. Data from all eight sensors formed a six-step sliding window to capture multivariate spatial-temporal dynamics, targeting the critically located T0 sensor for prediction.

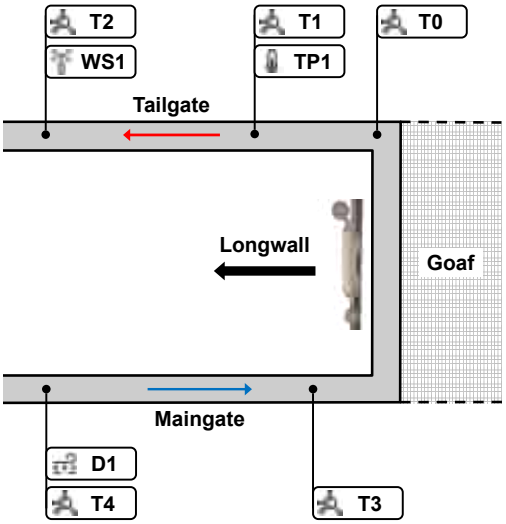

Figure 2. Deployment layout of the environmental sensors within the coal mine.

4.2 Online LSTM Learning and Prediction

A predictive LSTM model, whose architecture is shown in Figure 3, was constructed with two LSTM layers (256 and 128 units, respectively) followed by two dense layers (32 and 1 unit). The Rectified Linear Unit (ReLU) activation function was used, and the model was compiled with the Adam optimizer having a learning rate of 0.001. The hyperparameter selection, including the six-step window length, was based on domain knowledge and empirical testing related to gas dynamics in mines. The model was trained using online learning; at each one-minute time step, a single data sample (the current sliding window) was used to update the model weights via the *train_on_batch* function in *Keras*. Subsequently, the *predict_on_batch* function was used to forecast the T0 methane concentration for the next immediate time step.

Table 1. An overview of the characteristics of the sensor readings.

Variable	Unit	Sensor Code	Min	Max	Mean	SD
Methane Concentration	% CH4	T0	0.000	0.985	0.121	0.083
		T1	0.000	0.995	0.146	0.084
		T2	0.000	0.995	0.184	0.093
		T3	0.000	1.000	0.064	0.042
		T4	0.000	0.947	0.052	0.032
Wind Speed	m/s	WS1	0.003	6.345	1.193	0.525
Temperature	°C	TP1	9.400	20.700	15.315	2.600
Dust Concentration	ppm	D1	0.000	238.067	1.250	5.796

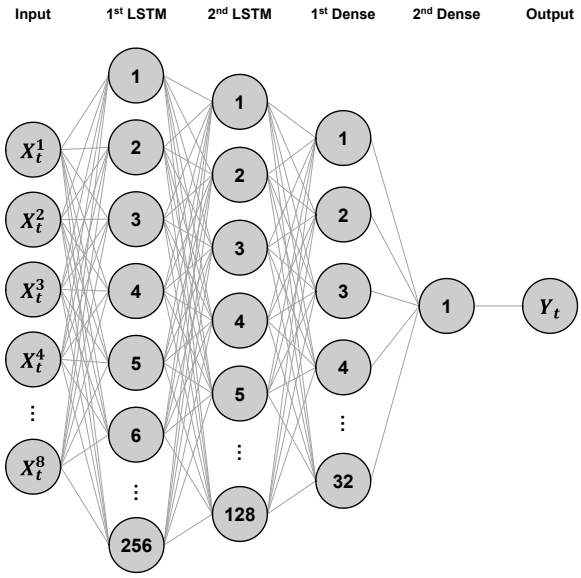

Figure 3. Architecture of the developed LSTM network.

Figure 4 compares the actual methane concentrations measured by sensor T0 and those predicted by the developed LSTM model. The model's performance evolved significantly over time as it engaged in continuous online learning, updating its weights incrementally with each new minute of data using the *train_on_batch* function. Initially, with scant training data, predictions displayed considerable deviation from actual readings; this early phase underscores the importance of expert oversight before deploying model outputs for operational decisions. However, as sequential processing continued, the model rapidly adapted to fluctuations and, aided by spatially distributed multivariate inputs, demonstrated strong responsiveness to sudden spikes. The prediction error, evaluated cumulatively using MAE and MSE, decreased sharply within the first 250 time steps and then plateaued at a low, stable level, indicating successful convergence. Over the entire dataset, the final MAE reached 0.01, MSE reached 0.0005, and the R^2 achieved 0.93. This high R^2 value reflects a strong explanatory power and indicates a high level of predictive accuracy for methane concentration, validating the LSTM's suitability for real-time hazard forecasting in dynamic underground environments.

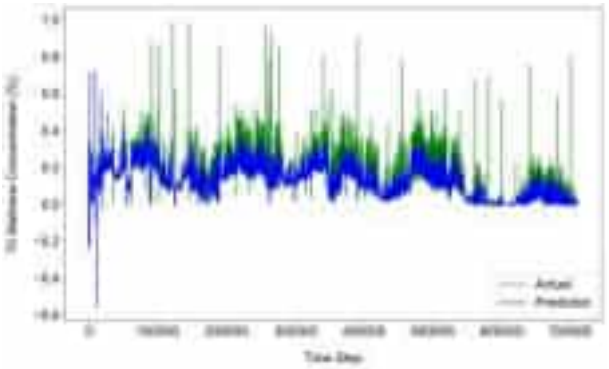

Figure 4. Comparison of the predicted and actual values over time.

4.3 Methane Explosion Bayesian Network

Due to a lack of comprehensive historical data on methane explosions, the BN was constructed using a knowledge-driven methodology. An initial network structure was drafted from literature, identifying causal and consequential variables related to ignition sources, gas accumulation, ventilation, safety interventions, and explosion consequences. This structure builds upon the authors' previous work [27]. This structure was refined through three rounds of expert consultation involving academic specialists and a senior mine ventilation officer. Based on expert feedback, variables like atmospheric pressure and oxygen concentration were removed for being redundant or constant, while practical proxies like wind speed (for airflow) and inflow methane quality were

added. Various methane sources were aggregated into a single "methane overrun" node, as sensors measure cumulative concentration.

The final BN, as shown in Figure 5, comprised 15 discrete nodes organized into five groups: (1) Causes: ignition sources like friction spark, open fire; (2) Environmental Conditions: methane overrun, wind speed, inflow quality, ventilation conditions; (3) Accident Trigger: methane explosion; (4) Consequences: casualties, economic loss, successive explosions; and (5) Control Actions: preventive and mitigative measures. Nodes were defined as binary or ordinal states (e.g., negligible/serious, none/slight/severe). CPTs were populated via a structured expert elicitation process, which is fully detailed and validated in [16]. The structure allowed certain nodes (e.g., methane overrun) to receive direct sensor input, while others (e.g., ignition sources) could be set manually for scenario analysis.

Figure 5. Refined BN for methane explosion in underground coal mines.

4.4 LSTM-Bayesian Risk Assessment

Figure 6 displays the architecture of the LSTM-Bayesian fusion system. The system integrated the prediction and assessment layers. At each time step, the continuous methane concentration predicted by the LSTM for sensor T0 was discretized using a 1.0% threshold; values above were labeled serious, others negligible. This step converted the numerical prediction into a format compatible with the BN's categorical reasoning framework. This labeled evidence was then input into the "methane overrun" node of the BN via *SMILE Engine* [28], the API of *GeNIe Modeler*. The BN performed automatic probabilistic inference to update the risk levels of all dependent nodes, including the "methane explosion" node.

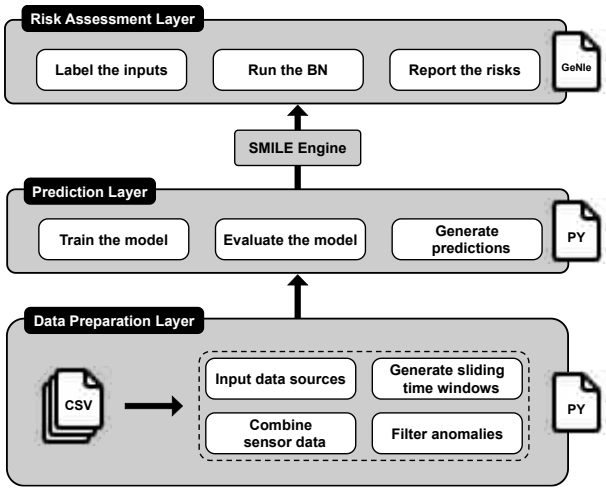

Figure 6. Architecture of the LSTM-Bayesian risk assessment system.

The system's performance was examined under two evidential scenarios. In Scenario 1, representing normal operations, only the predicted methane concentration was used as evidence, while ignition source nodes retained their prior low probabilities. The BN calculated a stable explosion risk probability of approximately 3.5% throughout the period. In Scenario 2, simulating a localized open flame near T0 for three hours, the "open fire" node was set to 1 during this interval. This nearly doubled the explosion risk to 6.8%. Given methane consistently remained below 1% during the study, low absolute probabilities are expected. In practice, operators utilize these relative risk spikes to trigger tiered advisory interventions before deterministic alarms mandate shutdowns.

4.5 Discussion and Implications

The case study validates the framework's core functionalities. The LSTM component demonstrated effective online learning, with predictive accuracy for methane concentration improving to a high level (R^2=0.93) as it adapted to the mine's dynamic environment. The integration with the BN provided a crucial interpretative layer. It translates predicted gas levels into contextualized probabilistic risks, enabling automated safety protocols (e.g., machinery power-offs) within the 1-minute forecast window. Unlike reactive 1% alarms that mandate costly complete operational shutdowns, the system detects ascending trends early. This grants operators crucial lead time to proactively intensify ventilation or slow production, preventing catastrophic financial losses and fatal explosive states. This hybrid approach bridges data-driven prediction and explainable reasoning to support critical decision-making.

5 Conclusions

An innovative system for dynamic risk management in underground environments was introduced, integrating IoT, LSTM, and BNs. A case study in a Chinese coal mine demonstrated its capability to accurately predict methane concentrations and assess explosion risks in real time. The LSTM model achieved high accuracy (R^2=0.93), and the BN provided interpretable, scenario-sensitive risk updates. This integration addresses limitations of purely data-driven or knowledge-driven methods, enhancing safety and operational efficiency.

While the extensive 494-day dataset establishes a robust proof-of-concept, relying on a single mine limits generalizability. Ongoing future work will conduct cross-site validation, benchmark against baseline models, develop 5-10 minute multi-step forecasts for human intervention, apply cost-sensitive learning, and explore digital twin integration.

Abstract

Recent construction sites increasingly employ real-time safety monitoring systems that apply rule-based logic to frame-level object detections. However, because such approaches rely on isolated detections and manually defined rules, they provide limited evidence for how workers, PPE, actions, locations, and hazards jointly constitute safety risk, and their predictions often fluctuate over time, leading to false alarms and missed detections. To address these limitations, we propose an interpretable framework for streaming construction safety monitoring based on video–text retrieval, which captures spatiotemporal context and provides explicit textual explanations. The proposed method evaluates short video segments by retrieving relevant evidence from a structured safety text bank and estimating risk from the retrieved results, while also presenting representative evidence sentences for operator verification. Experiments on representative scaffold safety scenarios demonstrated strong risk classification performance, with accuracy of up to 97.6%, while the retrieved evidence consistently outperformed captioning baselines in explanatory quality, achieving top-1 BERTScore-F1 values of 0.925–0.943 and top-1 SPICE values of 0.618–0.727. The system also achieved a mean end-to-end latency of 210.8 ms on a single GPU, supporting real-time operation. These findings indicate that video–text retrieval offers a practical and interpretable approach to spatiotemporally informed construction safety monitoring without site-specific retraining.

Keywords

construction safety, real-time monitoring, interpretability, video–text retrieval

1 Introduction

Computer-vision (CV)-based real-time safety monitoring has become a central approach for detecting hazardous situations in construction sites, where visual data are continuously analysed to identify workers, equipment, and site conditions. However, construction sites remain highly dynamic environments: construction phases, spatial layouts, and equipment placements change frequently, while viewpoint and illumination changes, occlusions, and motion blur caused by worker movements continuously alter the visual conditions under which CV models operate.

Consequently, the visibility and appearance of target entities can vary substantially from frame to frame, causing detection outputs to fluctuate even within the same ongoing situation. This temporal instability in detections often results in intermittent misses and spurious detections over time, i.e., temporal inconsistency. Because frame-wise decision-making treats each frame independently, it cannot effectively use adjacent temporal evidence to stabilize predictions, which in turn increases false positives and false negatives and undermines the reliability of hazard detection[1].

Moreover, construction-site hazards are not determined solely by the presence of a particular object in an isolated frame, but by how multiple risk cues, such as workers, personal protective equipment (PPE) compliance, actions, objects, and locations, interact and evolve in spatiotemporal context[2]. Consequently, reliance on frame-level detections alone can either miss hazardous events or incorrectly classify normal operations as dangerous[3]. These observations motivate moving beyond frame-wise detection toward video-based safety monitoring that incorporates temporal context and supports more reliable interpretation of how risk cues jointly indicate hazardous situations.

In response to these challenges, prior studies have explored several video-based approaches for safety monitoring. Temporal modelling methods, such as RNN/LSTM-based approaches, aggregate information across consecutive frames to reduce prediction fluctuations and improve temporal consistency [4], while video anomaly detection methods learn normal patterns from videos and assign anomaly scores to clips that deviate from them[5]. However, both approaches mainly produce scores, labels, or detections, providing limited explicit evidence about why a situation is risky or how specific risk cues contribute to the assessment. Video

captioning methods improve interpretability by describing scenes in natural language[6]. However, generated descriptions can vary across similar scenes and may omit or overstate critical evidence, while repeated clip-wise decoding also increases computational cost and end-to-end latency in real-time deployment.

Thus, existing approaches remain limited in two practical respects for construction safety monitoring: explicit interpretability and real-time suitability. To address these limitations, we propose a framework for real-time construction safety monitoring that constructs a structured text bank encoding relationships among risk cues from safety regulations and real-world site data, and applies video–text retrieval to provide interpretable evidence for streaming inputs.

2 Related Work

2.1 Computer Vision-based construction safety monitoring

Construction safety monitoring has evolved toward detecting workers, equipment, and site conditions from vision data (e.g., CCTV/UAV videos) and issuing alarms by rule-based assessment of PPE compliance or hazardous states. Recently, pipelines have been proposed that first detect objects using real-time single-stage detectors and then integrate knowledge-based (ontology-driven) reasoning as post-processing to determine violations or hazardous situations[7]. In addition, PPE monitoring has progressed beyond a binary "worn/not worn" decision, with attempts to combine instance segmentation and tracking to associate PPE with individual workers and to refine compliance states at a finer granularity[8].

Nevertheless, frame-level, detection-based risk judgment is highly susceptible to occlusions, viewpoint/illumination changes, and motion blur, causing predictions to fluctuate and making errors accumulate as false positives and false negatives over time. To mitigate this, prior work has proposed aggregating decisions over a temporal window to reduce false alarms, or enhancing spatial reasoning with depth information [1][9]. However, such temporal and spatial augmentations primarily aim to stabilize alarm outputs, and they remain limited in explaining why a scene is judged as hazardous—i.e., which relationships among PPE, actions, locations, and hazard factors constitute the basis for the decision.

2.2 Unsupervised/Self-supervised Video Anomaly Detection (VAD)

To overcome the limitations of frame-based decision-making, a growing body of work has explored applying unsupervised/self-supervised video anomaly detection (VAD) to safety monitoring. In general, VAD learns normal patterns from videos and then assigns anomaly scores or detects abnormal segments by identifying sequences that deviate from the learned normal distribution. In construction safety monitoring, a study combined unsupervised GAN-based learning with pseudo-anomaly synthesis and introduced the WeTeam22 dataset to detect unsafe worker behaviors[10].

However, because VAD typically outputs anomaly scores or abnormal intervals, it is difficult to directly translate the results into concrete risk cues that operators can readily understand and act upon. Recently, benchmarks have been proposed that encourage models to go beyond mere anomaly detection and explain what happened, why it occurred, and what evidence supports the risk judgment[11]. This trend suggests that producing such explanations generally requires additional annotations and/or a separate language reasoning module. Moreover, construction sites exhibit substantial distribution shifts due to changes in phases, spatial configurations, and camera conditions, which induces drift in the normal-data distribution and imposes considerable burdens in collecting, curating, maintaining, and re-adapting normal data for unsupervised learning.

2.3 Video Captioning-based construction safety monitoring

Video captioning aims to complement situation understanding by describing video scenes in natural language. Vision-language models (VLMs), such as Qwen2.5, SmolVLM, and InternVL, process video or multi-frame inputs to perform clip-level scene understanding and generate textual descriptions accordingly[12][13][14]. In another high-risk domain, transportation, research has continued toward explainable video understanding—for example, domain-specific captioning approaches such as TrafficVLM, which describe incidents in a stepwise manner and incorporate output control mechanisms[15].

In contrast, within the construction domain, captioning has been used primarily for recording and documentation, while it has received limited attention as a real-time interpretation mechanism for safety monitoring[16]. This is partly because scene distributions vary substantially across sites, making it difficult to build training data, and because accurately reflecting regulatory semantics—such as PPE compliance or proximity to hazardous zones—often requires vocabulary standardization. Moreover, when deployed in streaming settings, clip-wise text decoding must be repeatedly executed, which can increase computational cost and end-to-end latency.

Overall, prior approaches have advanced either

toward stabilizing alarms or toward providing natural-language descriptions, but mechanisms that consistently present explanations of streaming scenes while accounting for temporal context remain limited. To address this gap, we propose a low-latency framework that combines a structured text bank encoding relationships among key risk factors in construction site with video–text retrieval, thereby achieving both temporal consistency and interpretability in real-time monitoring.

3 Method

This study proposes a real-time monitoring framework that interprets construction-site videos via similarity-based retrieval against a text bank and simultaneously provides a risk score and evidence-grounded explanations. After aligning text and video in a shared embedding space, the framework retrieves text entries most similar to each segment embedding to form an evidence set, and then aggregates unsafe evidence to compute a risk score. Figure 1 illustrates the overall workflow of the proposed framework. The workflow begins with constructing a structured text bank from safety knowledge and indexing its text embeddings in the joint embedding space. During real-time inference, the input video stream is segmented, each segment is encoded into a video embedding, and top-K similar text entries are retrieved by similarity search. The retrieved texts are then used to compute the risk score RS(t), and the results are rendered as real-time overlay outputs.

3.1 Text Bank Construction in a Joint Embedding Space

To provide evidence for risk assessment in terms of relationships among key risk cues, we construct a text bank that describes the work subject, PPE state, action, location, and hazard factor. Safety risk is not determined solely by the presence of a single object; rather, it emerges from combinations of who (SUBJECT) performs what action (ACTION) under which protective condition (SUBJECT_STATE), at which location (LOCATION), and with which associated hazard factor (RISK). This formulation is aligned with semantic scene representations used in computer vision and multimodal scene understanding, while explicitly extending them to construction-safety attributes such as PPE condition and hazard relevance[17]. In construction safety, PPE compliance and work location are particularly decisive determinants of risk, and prior studies have emphasized the importance of entity interactions and contextual information[18]. Accordingly, texts structured around subject, PPE state, action, location, and risk provide an appropriate basis for composing evidence cues.

Each text entry c_i is encoded by the text encoder $f_T(\cdot)$ of a pretrained video–text dual encoder, producing a text embedding $e_T(i) \in \mathbb{R}^d$, which is stored in the bank. The collection of these embeddings forms a joint embedding space $\mathbb{R}^d$ that enables similarity-based interpretation of streaming scenes. To enable low-latency retrieval, all text embeddings are pre-indexed in an offline stage, allowing efficient text search under real-time monitoring constraints.

3.2 Streaming Video Segmentation

In our framework, the input stream is processed by grouping frames into fixed-length segments. Because a segment comprises consecutive frames over a short time interval rather than a single frame, it is less sensitive to instantaneous noise and can capture both motion dynamics and scene cues[1].

Concretely, we partition the input stream into segments V_t of duration t seconds and apply a sliding window with stride S seconds to generate temporally

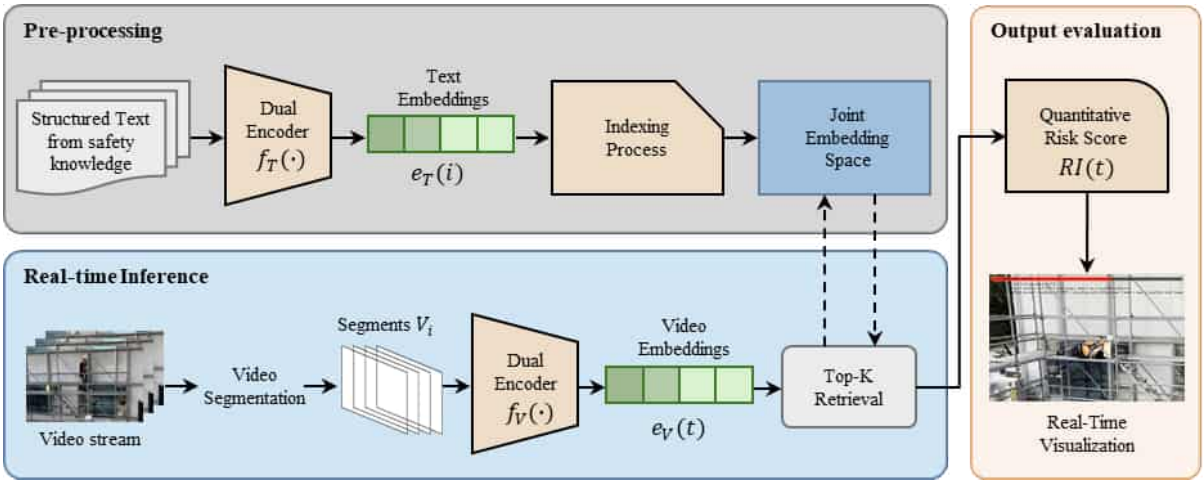

Figure 1. Research framework

overlapping segments along the timeline. All subsequent steps—embedding extraction, evidence retrieval, risk score computation, and visualization—are performed at the segment level.

3.3 Video Embedding Extraction

Each segment V_t is encoded into a video embedding $e_V(t) \in \mathbb{R}^d$ using the video encoder $f_V(\cdot)$ of the same dual-encoder model. Given the consecutive frames that constitute the segment, the video encoder summarizes the scene information over the corresponding time interval into a single fixed-length vector. The resulting video embedding is represented in the same joint embedding space $\mathbb{R}^d$ as the text embeddings and is subsequently used to select evidence texts via similarity-based retrieval.

3.4 Similarity-Based Retrieval of Evidence Texts

Given the video embedding $e_V(t)$ at time t, we retrieve the top-K texts from the text-bank embedding set $\{e_T(i)\}$ with the highest cosine similarity to form an evidence set $E_K(t)$. The video–text matching score is defined as the cosine similarity $\mathrm{sim}(\cdot)$, computed as the inner product after applying ℓ_2-normalization to all embeddings:

$$E_K(t) = \mathrm{TopK}_i(\mathrm{sim}(e_V(t), e_T(i))). \quad (1)$$

Here, $E_K(t)$ denotes the candidate set of evidence texts that describe the scene observed at time t.

3.5 Evidence-Grounded Risk Score

Based on the retrieved evidence set $E_K(t)$, we compute a segment-level Risk Score $RS(t)$. Our formulation relies on two assumptions: (i) in hazardous scenes, the proportion of unsafe evidence among the retrieved texts increases, and (ii) evidence with higher retrieval scores (similarities) provides more direct explanatory power for risk assessment.

Each text c is assigned a binary label $u(c) \in \{0,1\}$ indicating whether it constitutes unsafe evidence. In this study, texts that contain explicit worker-centered risk cues—such as missing PPE and proximity to missing guardrails/openings—are labeled as $u(c) = 1$ (unsafe), whereas texts describing normal working conditions are labeled as $u(c) = 0$ (safe). These labels are assigned consistently using a rule-based procedure grounded in the OSHA guide A Guide to Scaffold Use in the Construction Industry and the AI-Hub real-time video dataset for work-at-height scenarios [19]. For each evidence text $c \in E_K(t)$, its weight $w(c)$ is set to the cosine similarity returned by the retrieval step.

With these definitions, the risk score is computed as the weighted proportion of unsafe evidence among the retrieved top-K texts and normalized to the range $[0, 100]$:

$$RS(t) = 100 \cdot \frac{\sum_{c \in E_K(t)} w(c)\, u(c)}{\sum_{c \in E_K(t)} w(c)} \quad (2)$$

Accordingly, $RS(t)$ increases when a larger number of highly similar evidence texts are labeled as unsafe.

3.6 Real-Time Visualization with Evidence Captions

The proposed framework outputs a segment-level risk score $RS(t)$ sequentially over time for streaming inputs, while simultaneously presenting a subset of the retrieved evidence texts (top-N) as evidence captions. This enables operators to inspect both the current risk level and the textual evidence underlying the risk assessment. For real-time monitoring, the final outputs are continuously rendered as an overlay on the video frames.

4 Experiments and Results

4.1 Safety Text Bank Construction and Indexing

In this study, we built a text bank to interpret real-time monitoring scenes in terms of relationships among key risk factors. Each text is structured into five fields—SUBJECT / SUBJECT_STATE / ACTION / LOCATION / RISK—and the vocabulary for each field was defined by extracting and organizing terms from the OSHA guide and the AI-Hub dataset. The numbers of tokens per field are 3 for SUBJECT, 6 for SUBJECT_STATE, 44 for ACTION, 37 for LOCATION, and 19 for RISK, yielding a total of 151,296 texts through combinatorial generation. In addition, each text entry c_i is assigned a binary label $u(c_i) \in \{0,1\}$ indicating whether it constitutes unsafe evidence.

To compare the text bank and video segments within the same embedding space, we employ a pretrained video–text dual encoder, Perception Encoder (PE-Core). PE-Core maps video and text representations into a shared embedding space via contrastive vision–language alignment learned from large-scale data. In our experiments, the embedding dimension is $d = 1024$[20]. For real-time top-K retrieval over the large-scale text bank, we pre-index the text embeddings offline using a FAISS IVF-PQ (IndexIVFPQ) approximate nearest neighbor (ANN) index.

4.2 Streaming Inference Settings

We partition the real-time streaming video into segments of length $t = 2.0$s and apply a sliding window

with stride $S = 0.5$ s to continuously update the risk signal. For each segment, we uniformly sample 16 frames as input to the video encoder to produce a segment embedding $e_V(t)$. In the online stage, we retrieve $K = 10$ texts to construct $E_K(t)$, and in the visualization stage, we select the top $N = 2$ entries as evidence captions and render them as an overlay on the video stream. All streaming experiments were conducted on a single NVIDIA GeForce RTX 5070 Ti (16GB) GPU with Driver 591.44 and CUDA 13.1.

4.3 Dataset and Ground Truth Annotation

To assess field deployability, we recorded three staged video clips in a scaffold environment at Building 208, Chung-Ang University, Seoul, Republic of Korea. The clips correspond to three hazard scenarios: Vertical (1 min 50 s), referring to vertically overlapping work; Mobile (1 min 11 s), referring to mobile-scaffold movement with a worker riding on the scaffold; and Fall (48 s), referring to falling events. For evaluation, we manually assigned segment-level binary ground-truth labels (unsafe = 1, safe = 0) for all clips. Notably, the unsafe label was defined to cover not only the hazardous moment itself, but also the precursor interval immediately before the event and the recovery interval afterward when applicable. In addition, we manually wrote detailed descriptive captions for each segment, which were used to evaluate the interpretability of the retrieved evidence texts.

For baseline comparison, the same segmented clips were additionally evaluated using three open-source vision-language models: Qwen2.5-VL, SmolVLM2-2.2B, and InternVL2.5-2B. Each model was prompted to generate a one-sentence neutral description of the visible construction scene and to classify the scene as safe or unsafe based only on visible evidence. To ensure a consistent output format across models, we used a fixed instruction requiring the response to contain exactly two fields, caption: and scene_safety:.

4.4 Interpretability of Evidence Captions

Table 1 presents a scenario-wise comparison (Vertical, Mobile, and Fall) of how well the descriptions generated or retrieved by each model support the ground-truth (GT) explanatory captions for each segment. The evaluation was conducted using BERTScore-F_1, which measures sentence-level semantic similarity, and SPICE, which reflects structural semantic alignment in terms of objects, actions, and relations. The baseline models (Intern, Qwen, and Smol) generate a single final caption for each segment; therefore, their performance was evaluated using the top-1 F_1 score of that single output. In contrast, the proposed method (Ours) retrieves a set of evidence texts ranked by similarity, and thus reports not only top-1 performance but also the maximum score within the top- K retrieved set (max F_1@5 and max F_1@10).

Table 1. BERTScore Between Evidence Captions and Ground-Truth Text

Scenario	Model	Metric	Top-1 F_1	Max F_1@5	Max F_1@10
Vertical	Intern	BERT	0.888	-	-
Vertical	Qwen	BERT	0.886	-	-
Vertical	Smol	BERT	0.876	-	-
Vertical	Ours	BERT	0.925	0.938	0.941
Mobile	Intern	BERT	0.888	-	-
Mobile	Qwen	BERT	0.891	-	-
Mobile	Smol	BERT	0.879	-	-
Mobile	Ours	BERT	0.925	0.933	0.934
Fall	Intern	BERT	0.893	-	-
Fall	Qwen	BERT	0.891	-	-
Fall	Smol	BERT	0.890	-	-
Fall	Ours	BERT	0.943	0.948	0.950

Overall, the proposed method achieved the highest caption alignment across all scenarios. In terms of BERTScore-F_1, the top-1 F_1 of Ours was 0.925 for Vertical, 0.925 for Mobile, and 0.943 for Fall, while the corresponding max F_1@5 scores increased to 0.938, 0.933, and 0.948, and the max F_1@10 scores further increased to 0.941, 0.934, and 0.950. In contrast, the top-1 BERTScore-F_1 values of the baseline models remained within 0.876-0.888 for Vertical, 0.879-0.891 for Mobile, and 0.890-0.893 for Fall. This indicates that the evidence retrieved by the proposed method maintains a higher degree of semantic consistency with the GT descriptions.

In Table 2 the difference becomes even more pronounced in SPICE. The top-1 SPICE of Ours was 0.618 for Vertical, 0.647 for Mobile, and 0.727 for Fall, while the corresponding max F_1@5 scores increased to 0.679, 0.720, and 0.767, and the max F_1@10 scores further improved to 0.715, 0.734, and 0.779. In contrast, the top-1 SPICE scores of the baseline models were limited to 0.119-0.193 for Vertical, 0.183-0.225 for Mobile, and 0.144-0.190 for Fall. These results suggest that the baseline models fail to sufficiently capture the objects, actions, and spatial relations that constitute the actual scene.

Table 2. SPICE score Between Evidence Captions and Ground-Truth Text

Scenario	Model	Metric	Top-1 F_1	Max F_1@5	Max F_1@10
Vertical	Intern	SPICE	0.193		
Vertical	Qwen	SPICE	0.128		
Vertical	Smol	SPICE	0.119		
Vertical	Ours	SPICE	0.618	0.679	0.715
Mobile	Intern	SPICE	0.225		
Mobile	Qwen	SPICE	0.183		
Mobile	Smol	SPICE	0.208		
Mobile	Ours	SPICE	0.647	0.720	0.734
Fall	Intern	SPICE	0.190		
Fall	Qwen	SPICE	0.144		
Fall	Smol	SPICE	0.178		
Fall	Ours	SPICE	0.727	0.767	0.779

In other words, although the captions produced by existing generative models may appear linguistically natural, they may still fail to accurately describe the key evidence underlying hazardous situations. Therefore, such single generated captions are difficult to rely on directly as interpretable outputs or as a basis for safety judgment. In contrast, the proposed method not only shows high semantic similarity to the GT descriptions but also achieves a substantial advantage in SPICE, confirming that it provides evidence that more accurately reflects the structural meaning of the scene.

In addition, the proposed method consistently maintained strong performance across all three scenarios: Vertical, Mobile, and Fall. This suggests that its descriptive capability is not limited to a particular scenario type, but can robustly reflect both semantic and structural information across diverse work situations and risk contexts. The substantial margin observed in SPICE across all scenarios further indicates that the proposed method more robustly captures scene-level objects, actions, and spatial relations, and therefore can provide highly interpretable evidence under a wider range of site conditions.

4.5 Risk Score Performance

Risk-score performance was evaluated by applying multiple thresholds (0.1-0.9) to the proposed Risk Score, classifying each segment as unsafe if its score exceeded the given threshold and as safe otherwise, and then comparing the resulting predictions with the segment-level ground-truth labels. Table 3 summarizes the segment-level classification performance under each threshold. As the threshold increased from 0.1 to 0.7, Accuracy steadily improved from 88.5% to 97.6%, while Recall remained at 1.00 throughout this range. F1 also increased consistently from 0.936 to 0.985. In contrast, when the threshold was further increased to 0.8 and 0.9, Accuracy remained high at 97.5% and 96.1%, respectively, but Recall decreased to 0.983 and 0.957, and F_1 was 0.985 and 0.977.

Table 3. Risk Score Performance Across Thresholds (Acc. = Accuracy)

Threshold	Acc(%)	Recall	F_1
0.1	88.5	1	0.936
0.2	88.7	1	0.937
0.3	88.7	1	0.937
0.4	90.0	1	0.944
0.5	92.8	1	0.959
0.6	94.9	1	0.970
0.7	97.6	1	0.985
0.8	97.5	0.983	0.985
0.9	96.1	0.957	0.977

These results indicate that gradually increasing the threshold improves classification reliability, but excessively high thresholds may cause some hazardous segments to be missed. In particular, a threshold of 0.7 can be regarded as the most balanced operating point overall, as it achieved the highest Accuracy (97.6%) while simultaneously maintaining Recall of 1.00 and the highest F_1 score (0.985). Therefore, in this study, 0.7 was selected as the representative threshold for the subsequent analysis of temporal variation patterns.

Figure 2 shows the temporal evolution of $RS(t)$ under this representative threshold in the streaming setting ($t = 2.0$s $S = 0.5$s) across three hazard scenarios. In the graph, the risk score rises distinctly during the annotated hazardous intervals and is generally well aligned with the shaded GT-unsafe regions. This suggests that the proposed Risk Score appropriately reflects the timing of hazardous events across different hazard situations, including Vertical, Mobile, and Fall.

Overall, the proposed Risk Score enabled the identification of a stable operating point through threshold analysis, and under this threshold, it showed high segment-level classification performance and favorable temporal alignment across all three hazard scenarios. These results support that, even in a streaming-based safety monitoring environment, the proposed method can achieve both strong detection performance and stable operational behavior.

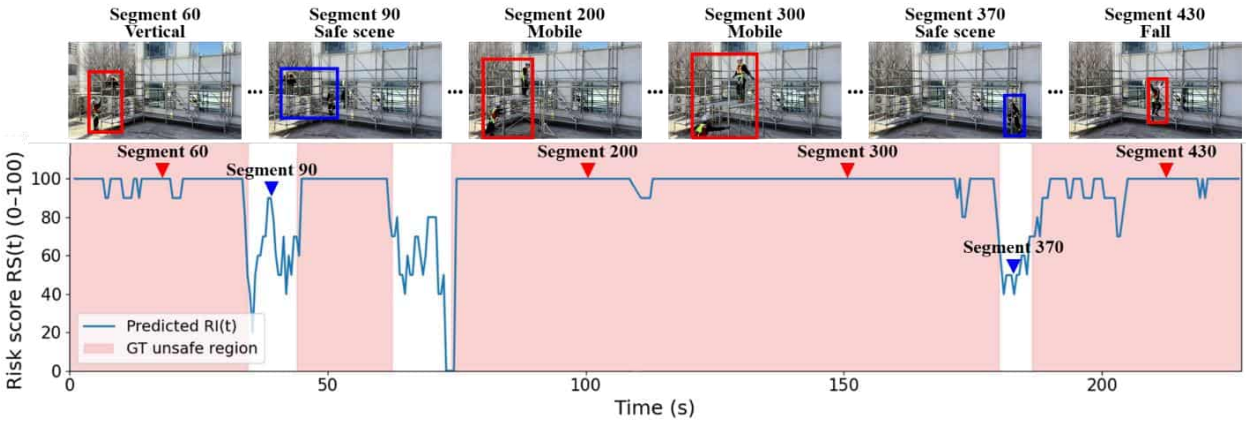

Figure 2. Risk Score Align with Unsafe Events in Streaming Video

4.6 End-to-End Streaming Feasibility

Table 4 reports the end-to-end per-segment processing latency of each model under the streaming stride setting ($S = 0.5$s) to verify whether the system satisfies the real-time condition $L \leq S$.

Table 4. Comparison for Real-Time Operation

Model	Stride	Latency	Realtime
Intern	500.0 ms	1274.3ms	✗
Qwen	500.0 ms	1663.8ms	✗
Smol	500.0 ms	3748.6ms	✗
Ours	500.0 ms	210.8 ms	✓

In this study, real-time capability is defined in terms of timeliness, that is, whether the system can update its output without delay as an event unfolds. Because the streaming pipeline updates its output every 0.5s, real-time operation is considered feasible only when the mean per-segment processing latency L does not exceed the stride S. As shown in Table 3, the proposed method achieved a mean latency of 210.8 ms, which is substantially smaller than the stride of 500.0 ms and therefore satisfies the real-time condition. In contrast, the baseline models, InternVL2.5-2B, Qwen2.5-VL, and SmolVLM2-2.2B, showed mean latencies of 1274.3 ms, 1663.8 ms, and 3748.6 ms, respectively, all of which exceed the stride. This indicates that real-time online operation is difficult for these models under the same setting. These results show that only the proposed method can provide timely segment-level updates within the required streaming interval. Therefore, the proposed framework not only demonstrates effective hazard interpretation performance, but also secures a processing speed that is practically applicable to real-time safety monitoring even in a single-GPU environment.

5 Conclusion

This study proposed a real-time construction safety monitoring framework that interprets streaming site videos through text-bank-based retrieval and provides both a segment-level risk score $RS(t)$, and supporting evidence texts. The framework constructs a structured text bank, aligns video and text in a shared embedding space, and retrieves top-K evidence texts for each segment to compute and visualize risk without site-specific retraining.

Experimental results showed that the proposed Risk Score achieved stable classification performance across threshold settings, with 0.7 identified as the most balanced operating point (Accuracy = 97.6%, Recall = 1.00, and F_1 = 0.985). Under this threshold, the temporal response of the risk score was generally well aligned with the GT-unsafe intervals across the three hazard scenarios: Vertical, Mobile, and Fall. In addition, the proposed method consistently outperformed the generative baseline models in interpretability, showing stronger semantic and structural alignment with the GT explanatory captions.

The proposed framework also demonstrated practical real-time capability. Under the streaming setting of $S = 0.5$ s, the mean end-to-end latency was 210.8 ms, satisfying the condition $L \leq S$, whereas the baseline VLMs exceeded the allowable interval. These results suggest that the proposed method can support low-latency safety monitoring in streaming environments.

This study has several limitations. Validation was conducted on a limited set of hazard scenarios and a single experimental setting, so generalization under more diverse conditions remains to be verified. Future work will extend the framework through broader evaluation, expansion of the hazard taxonomy and text bank, and adaptive alarm strategies based on temporal accumulation, smoothing, and dynamic thresholds.

Abstract –
Representation learning for 3D scenes in the architecture, engineering and construction domains is becoming important, as it facilitates Scan-to-BIM, 3D perception and robotic deployment in built environments. This study presents NUS3D, a dataset that consolidates BIM-synthetic, mobile-scan and terrestrial laser scan (TLS) point clouds for building interiors. Originated in 2022, we attempted to integrate heterogeneous data sources to capture the spectrum of 3D data characteristics including structural and M&E (mechanical and electrical) components. BIM-synthetic point clouds provide noise-free geometry that serves as a design-intent reference, mobile-scan contributes dynamic observations collected in real-world conditions, TLS offers high-precision and dense measurements of as-built scenes. Such mixed-source composition enables training and evaluation of algorithms for representation learning, allowing models to acquire generalizable spatial and geometric features that are transferable across synthetic and real, static and dynamic, as well as design and as-built domains. This paper includes a semantic segmentation test using several BIM and TLS M&E point clouds. Experiment demonstrates the potential of NUS3D for advancing future research on 3D scene understanding, Scan-to-BIM, and robotic perception in the built environment.

Keywords –
Point Cloud; 3D Scene Understanding; Scan-to-BIM; Robotic Perception.

1 Introduction

Robots are increasingly integrated into built environments [13], yet autonomous perception in these settings remains highly challenging. Such environments range from unstructured construction sites, where layouts change over time, to semi-structured spaces with known geometry but movable elements like furniture, equipment and human activity present. Unlike controlled conditions, these spaces are in constant flux such as clutter, moving obstacles, and human presence alter scene geometry, complicating environment perception.

Point cloud semantic segmentation serves as a key enabler for 3D scene understanding. In practice, 3D point clouds can be obtained through passive reconstruction or active sensing. Passive reconstruction typically relies on cameras to infer geometric information. This includes monocular approaches that estimate depth from a single image, often supported by deep learning techniques [7]. Stereo or multi-view approaches exploit disparity or multi-view geometry (structure-from-motion, multi-view stereo) to generate point clouds [25]. In contrast, active sensing relies on external sensors to directly acquire geometry of the object. For ground-based measurements, LiDAR (Light Detection and Ranging) is more capable of producing dense point clouds in large-scale environments. Among these systems, terrestrial laser scanners (TLS) are particularly effective, offering superior accuracy and measurement range. However, TLS does not support real-time point loud registration that are usually required in scanning complex, occluded environments where the sensor should move around the built environment [13].

As such, researchers are looking into mobile scanning (MLS) in which LiDAR are leveraged with robot to improve the mobility of 3D scanning [13,28]. In this regard, Simultaneous Localization and Mapping (SLAM) has gained increasing attention. SLAM enables robots to determine their position within an environment while simultaneously generating a 3D map of that environment. It allows real-time tracking of the scanning system while reconstructing the 3D scene [10,14]. This approach enhances the efficiency of mobile LiDAR mapping and point cloud acquisition, particularly in indoor building and construction environments where cluttered and occluded spaces are commonly encountered.

In recent years, several 3D point cloud datasets have been released (see **Table 1**). Notably, ModelNet [26] is one of the earliest collections, comprising CAD models primarily intended for 3D object classification,

recognition and shape analysis. Semantic3D [12] provides a benchmark for outdoor semantic segmentation, featuring extensive terrestrial laser scans of streets, buildings, vegetation, and other urban structures. For autonomous driving and navigation, KITTI [11] remains a widely used dataset, containing road scenes captured with LiDAR and stereo cameras for benchmarking 3D detection and SLAM. Extending this effort, nuScenes [4] incorporates a rich set of LiDAR, camera, and radar recordings across urban traffic environments.

The TUM RGB-D dataset [23] focuses on visual SLAM evaluation, offering indoor RGB-D sequences with ground truth trajectories, and has become a de facto standard for benchmarking SLAM. Meanwhile, ScanNet [6] introduces richly annotated RGB-D indoor scans, including reconstructed meshes and semantic labels, which have since become a foundation for indoor scene parsing tasks. Similarly, the Stanford Large-Scale 3D Indoor Spaces (S3DIS) dataset [2] offers labeled point clouds of complex building interiors. Both the ScanNet and S3DIS were employed in Scan-to-BIM studies.

Table 1. Representative 3D datasets used in computer vision, robotics and built environment research

Dataset		Description	Reference
ModelNet	CAD (indoor objects)	CAD models for object classification, recognition, and shape analysis.	[26]
Semantic 3D	Outdoor urban scenes	Large-scale outdoor laser point cloud dataset including streets, buildings, churches, and vegetation.	[12]
KITTI	Urban scenes	Classic dataset for autonomous driving with LiDAR, GPS/IMU for 3D detection.	[11]
nuScenes	Urban scenes	Dataset covering roads, including LiDAR, cameras, and radars.	[4]
TUM RGB-D SLAM	Indoor SLAM	RGB-D sequences with ground-truth trajectories.	[23]
ScanNet	Indoor scenes (RGB-D scans)	Real indoor scene with RGB-D sequences, reconstructed meshes, and annotations.	[6]
S3DIS	Indoor large building spaces	Point clouds of large-scale indoor buildings with semantic labels.	[2]

Despite the breadth of existing resources, several limitations remain when applying these datasets. Built environments, particularly indoor spaces and building-street interfaces with indoor-outdoor transitions, are characterized by clutter, occlusions, narrow passages, mixed lighting, and weakly textured surfaces, posing substantial challenges that differ from existing datasets. Particularly, such environments often contain dense mechanical, electrical and plumbing components and spatial relationships with structural components.

Figure 1. Prospect for built environment 3D dataset

Another limitation lies in the method used to generate these datasets. The type and quality of point cloud data available from passive and active sensing, as well as static or dynamic mobile approaches involve different trade-offs in terms of accuracy, completeness, noise and operational efficiency. Looking ahead, built environment datasets should include multiple data sources such as BIM-synthetic point clouds, which represent noise-free design intent; mobile scans that capture dynamic observations under real-world conditions; and TLS data, which offer dense, high-precision ground truth. This mixed-source composition supports robust training and evaluation of 3D representation learning models with improved generalization. Specifically, there is growing momentum toward robotic data acquisition (see **Figure 1**). Integrating mobile robotic LiDAR mapping with

BIM-synthetic and TLS data enables a holistic dataset for BIM-to-Scan and Scan-to-BIM verification, supporting reliable structural semantic segmentation, surface-level feature extraction, and enhances 3D scene understanding.

This paper presents our ongoing efforts to develop NUS3D, a hybrid dataset that consolidates BIM-synthetic, mobile-scan, and high-precision TLS point clouds to capture the diverse characteristics of 3D data in built environments, particularly with indoor and indoor-outdoor transitional spaces that are characterized by clutter, occlusions, semi-structured layouts and weakly textured surfaces. This composition supports the development and evaluation of geometric representation learning pipelines, enabling them to acquire generalizable geometric features transferable across synthetic and real data as well as design-intent and as-built domains. Such capabilities are expected to advance scene understanding for environment perception, robotic deployment and Scan-to-BIM research.

2 Related Work

2.1 Data Acquisition for Indoor Environments

In cluttered changing environment, conventional static terrestrial laser scanning remains accurate but it is often time-consuming and limited in flexibility for large or continuously evolving spaces. There is a growing deployment of mobile robots in clutter, unstructured environments, such as scanning building geometry with UAV-UGV [14] and automated mobile robot navigation to produce survey-quality 3D point clouds of construction sites.

Ibrahim, Golparvar-Fard and El-Rayes [17] introduced metrics and methods for assessing the quality of reality capture, particularly in scenarios where unmanned ground rovers are deployed for construction monitoring and inspection. Cheng et al. [5] proposed an improved coverage planning that optimizes waypoint ordering and sequences for robotic data acquisition. Such integration opens the possibility of quality-assurance-driven scanning, where robots adapt their movement trajectories to optimize coverage and improve point cloud quality.

2.2 Point Cloud Quality Assessment

Research has been undertaken to explore how errors affect scene understanding, including those arising from SLAM drift, LiDAR occlusions, and inaccuracies in BIM models. Esfahani et al. [9] provide groundwork by conducting a quantitative investigation into how levels of automation and modeler training affect Scan-to-BIM accuracy, offering predictive models of geometric uncertainty under various workflows.

The establishment of point cloud quality metrics, such as density, coverage and spatial distribution, remains important for defining minimum data requirements for Scan-to-BIM outcomes. Liu et al. [20] contributes toward this goal by introducing BIMNet, an IFC-based large-scale dataset and corresponding benchmark focused on as-built BIM reconstruction from. Furthermore, the deviation analysis method proposed by Anil et al. [1] demonstrates how geometric deviations between point clouds and BIMs can be systematically analysed to locate, characterize, and diagnose errors in as-built models.

2.3 Representation Learning

Another research avenue lies in the evaluation of representation learning and scene understanding, including transformer-based architecture, contrastive learning, and recent 3D Gaussian splatting approaches. For instance, Perez-Perez et al. [22] proposed a learning-based pipeline combining semantic labels and geometric descriptors, leveraging classifiers (SVM, AdaBoost) and Markov Random Field optimization, to segment point clouds for automated 3D model fitting. Semantic-geometric pipeline was demonstrated in industrial contexts enriching RGB-point clouds with instance segmentation for geometry fitting to yield structural and M&E models [21]. Another study [18] proposes an instance-level clustering method for road markings from mobile LiDAR, robust to occlusion and complex geometric conditions across 28 datasets. Complementing these, Hu and Brilakis [16] introduced instance segmentation anchored in design-intent via matching IFC models to as-built scenes using PROSAC-based detection and DBSCAN clustering, which achieves high precision in cluttered, occluded scans.

Another promising direction is the development of geometry-aware AI, in which BIM-derived priors, such as the verticality of walls or the planarity of slabs, are incorporated to regularize predictions in real-world scans. New representation learning pipelines can leverage BIM-synthetic point clouds as training data, combined with domain adaptation to bridge discrepancies between synthetic and real scans [15]. These approaches can be extended to zero- or few-shot scenarios by applying large vision-language models (e.g., OpenMaskDINO3D, SegPoint, Reason3D).

Beyond data capture and representation learning, geometric synchronization is another direction where point cloud data streams are continuously used for geometric updates. Bosché et al. [3] have combined Scan-to-BIM and Scan-vs-BIM techniques in a unified approach for automated comparison of as-built and as-planned M&E works. Future work seeks to explore automatic as-built model updating, where deviations between reality capture and the design model are detected

and translated into structured updates, enabling self-correcting digital representations. Erişen et al. [8] proposed a multi-task domain-adapted deep learning framework capable of generating semantically annotated 3D reconstructions directly from a single RGB image, delivering mesh accuracy and semantic fidelity.

These developments indicate a research trajectory that integrates sensor-agnostic reconstruction (especially mobile scans) with 4D spatiotemporal geometric updates. Together, the research paves the way toward enriched and adaptable 3D scene understanding that evolves with real-world environments.

3 Developing NUS3D Dataset

The proposed NUS3D dataset aims to integrate multiple sources of 3D point clouds to support the testing and verification of scene understanding and environment perception. It comprises three subsets shown in **Table 2**.

BIM-synthetic point clouds are derived from BIM by sampling geometric primitives and surfaces directly from building elements, producing noise-free and complete synthetic representations. Mobile-scan point clouds are captured using active or passive 3D scene reconstruction systems supported by SLAM algorithms. TLS point clouds are obtained through high-resolution time-of-flight laser scanning from ground-based stations, providing dense and accurate data. It includes structural and mechanical and electrical (M&E) components.

Table 2. Structure of NUS3D dataset

Subset	Method	Description
BIM-Synthetic Point Clouds	BIM 3D model	This subset comprises synthetic 3D point clouds generated from BIM providing complete and noise-free geometric representations of building elements.
Mobile-Scan Point Clouds	Handheld or robotic scans with SLAM	This subset comprises real-world 3D point clouds using handheld or robotic scan (e.g., RealSense L515 or SHARE SLAM S20), capturing practical variations in density and noise.
TLS Point Clouds	Terrestrial laser scanner	This subset comprises high-density 3D point clouds using terrestrial laser scanners (e.g., FARO®), providing accurate as-built geometry while reflecting challenges such as occlusion in real environments.

Note: As different sensing devices exhibit varying levels of accuracy, density, and noise characteristics, this paper does not differentiate such sensor-specific variations at a finer level.

3.1 BIM-Synthetic Point Clouds

BIM-synthetic point clouds are synthetic datasets produced by sampling geometric primitives and surfaces directly from building elements within a BIM model. This process ensures that representations are both noise-free and comprehensive, providing ideal ground truth for downstream learning. A notable application of this subset is its use in BIM-to-scan semantic segmentation, where synthetic point clouds serve as training data to overcome the domain gap between as-designed and as-built data. For example, a domain adaptation network, DawNet, augments segmentation performance by combining hybrid attention mechanisms with feature whitening, significantly enhancing accuracy when adapting to noisy real-world scans [15].

3.2 Mobile-Scan Point Clouds

Figure 2 illustrates mobile-scan point clouds conducted since 2022. The environments present dense furniture, narrow corridors, reflective surfaces and severe occlusions, combined with semi-structured layouts and transitions between indoor and outdoor domains.

Handheld active or passive 3D scene reconstruction systems are deployed for data acquisition with the aid of robots for some scenes. The 3D scene reconstruction are undertaken with SLAM to support real-time mobile 3D mapping under real-world conditions. The workflow begins with data capture, as investigated in previous studies [14,24]. LiDAR measures depth by emitting laser pulses and calculating distances based on time-of-flight, generating depth maps with spatial geometry. Then, the data captured are matched via SLAM to incrementally reconstruct dense colorized 3D point clouds along the robot or handheld sensor trajectory.

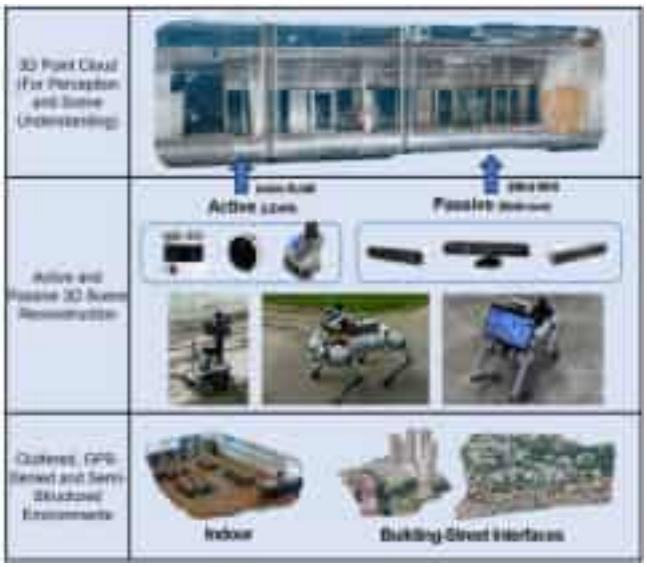

Figure 2. Mobile-scan point cloud acquisition

3.3 TLS Point Clouds

TLS point clouds are generated using high-resolution time-of-flight laser ranging, which captures dense and highly accurate 3D point clouds from ground-based scanning stations. Each point encodes a precise spatial coordinate, enabling faithful reconstructions of architectural and structural elements such as walls, floors, ceilings, columns, and detailed furnishings, including desks, chairs, and equipment. This results in a comprehensive and true-to-life digital representation that supports tasks ranging from spatial measurement and geometric analysis to the built facilities.

Compared with mobile-scan or BIM-synthetic point clouds, TLS exhibits higher density and accuracy, but their quality can still be influenced by environmental conditions. Variations in lighting, weakly textured surfaces and reflective materials across indoor and outdoor environments can introduce challenges in point cloud registration.

4 Cross-Domain Point Cloud Semantic Segmentation and Evaluation

4.1 Semantic Segmentation

In this paper, a segmentation experiment is undertaken as an illustrative example to demonstrate the potential benefit of NUS3D dataset. The evaluation focuses on augmenting TLS data with BIM-synthetic point clouds to explore cross-domain learning. The comparison evaluates TLS-only as well as TLS and BIM-synthetic training, using M&E components. In this study, ResPointNet++ [27] is adopted as a representative backbone for controlled evaluation, while broader benchmarking across additional architectures and tasks will be investigated in future work.

Semantic segmentation aims to assign each point a meaningful interpretation, either in the form of a semantic category or an object-level instance label. Classical geometry-based approaches typically utilize local surface descriptors, such as normals, curvature, and smoothness, to group points with similar differential properties, while model-fitting techniques identify structural primitives (e.g., planes, cylinders) through parametric estimation and consensus-based optimization [3]. In contrast, learning-based methods leverage neural architectures designed for irregular point sets to learn hierarchical feature representations and perform dense, point-wise classification under supervised or weakly supervised settings. The network is trained for 200 epochs on an NVIDIA RTX 4090 GPU.

The experiments are conducted on four real TLS scan M&E scenes (P1-P4) [19] together with four BIM-synthetic scenes (V1-V4). The synthetic point clouds are generated by exporting BIM models to OBJ format and importing them into CloudCompare, where virtual scanner positions are placed to mimic realistic acquisition effects such as occlusion and view-dependent incompleteness. The training and testing scenes are shown in **Figure 3**. To assess the impact of synthetic data, two training regimes are examined under identical hyperparameter settings: (i) a model trained solely on real TLS scans, and (ii) a model trained on the combined set of real TLS scans and BIM-synthetic point clouds as shown in **Figure 4**. This experimental design allows for a controlled evaluation of how synthetic augmentation contributes to segmentation performance across different M&E component types.

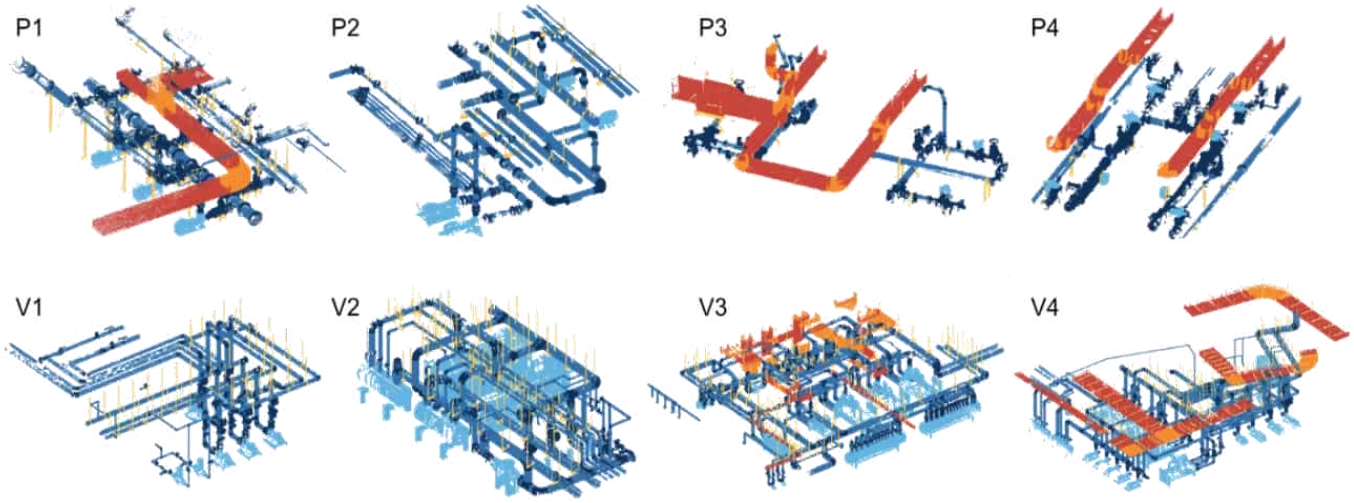

Figure 3. Dataset visualization: training – P1, P2; testing (real) – P3, P4; testing (hybrid) – P3, P4, V1-V4

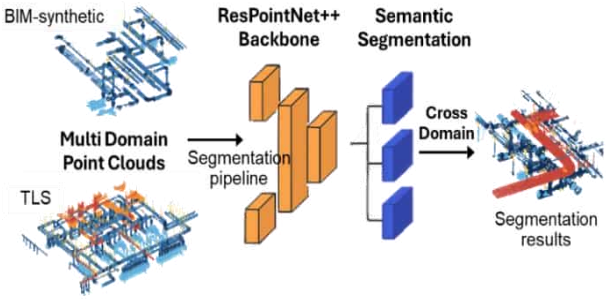

Figure 4. Cross-domain semantic segmentation method

The semantic segmentation output can be refined through a series of post-processing operations, including noise suppression, structural connectivity analysis, and primitive-based geometric fitting. These steps enforce topological consistency, preserve object boundaries, and improve robustness in dense or cluttered environments.

4.2 Evaluation of Segmentation Performance

Evaluation of point cloud segmentation quantitatively assesses the agreement between predicted labels and ground truth. Class-wise performance is typically measured using Intersection over Union (IoU), which evaluates the overlap between the predicted point set and the ground-truth point set of each semantic category. For a given class c, IoU is defined as:

$$\mathrm{IoU}_c = \frac{|\mathcal{P}_c \cap \mathcal{G}_c|}{|\mathcal{P}_c \cup \mathcal{G}_c|} \tag{1}$$

where $\mathcal{P}_c$ and $\mathcal{G}_c$ denote the sets of points predicted and annotated as class c, respectively. The mean Intersection over Union (mIoU), obtained by averaging IoU over all C classes, provides a class-balanced indicator:

$$\mathrm{mIoU} = \frac{1}{C}\sum_{c=1}^{C} \mathrm{IoU}_c \tag{2}$$

Additional metrics include Overall Accuracy (OA):

$$\mathrm{OA} = \frac{\sum_{c=1}^{C} |\mathcal{P}_c \cap \mathcal{G}_c|}{N} \tag{3}$$

where N is the total number of points. OA measures the proportion of correctly classified points across all categories. Furthermore, per-class accuracy is reported to reveal the model's behavior on individual component types, which is particularly important under class imbalance or when different M&E components exhibit varying geometric complexity.

5 Results and Discussion

Table 3 presents the segmentation performance. The segmentation results are also visualized in **Figure 5**. Incorporating synthetic scenes into the training set yields substantial performance gains across nearly all M&E categories. The model trained solely on real scans exhibits limited generalization, particularly for components that are sparse or absent in the real dataset. This leads to extremely low IoU values for Duct fittings (8.93%), Hangers (32.70%), and Machinery (0.17%), while even common classes such as Ducts and Pipes remain suboptimal. In contrast, the hybrid training regime significantly boosts per-class performance: Machinery (+34.27%), Hangers (+27.32%), and Duct fittings (+24.37%) show the largest increases, and even major categories such as Ducts and Pipes improve by 15.00% and 8.27%, respectively. Overall, mIoU increases from 35.37% to 54.86% (+19.49%), and OA improves by more than 11%.

These results highlight the value of supplementing TLS real scans with BIM-synthetic point clouds. The BIM-synthetic data broadens the geometric and structural variability of component instances, enabling the network to better recognize rare, small, or partially occluded elements in real evaluations. The experimental results further demonstrate the potential of the NUS3D hybrid dataset to support the training and improvement of 3D

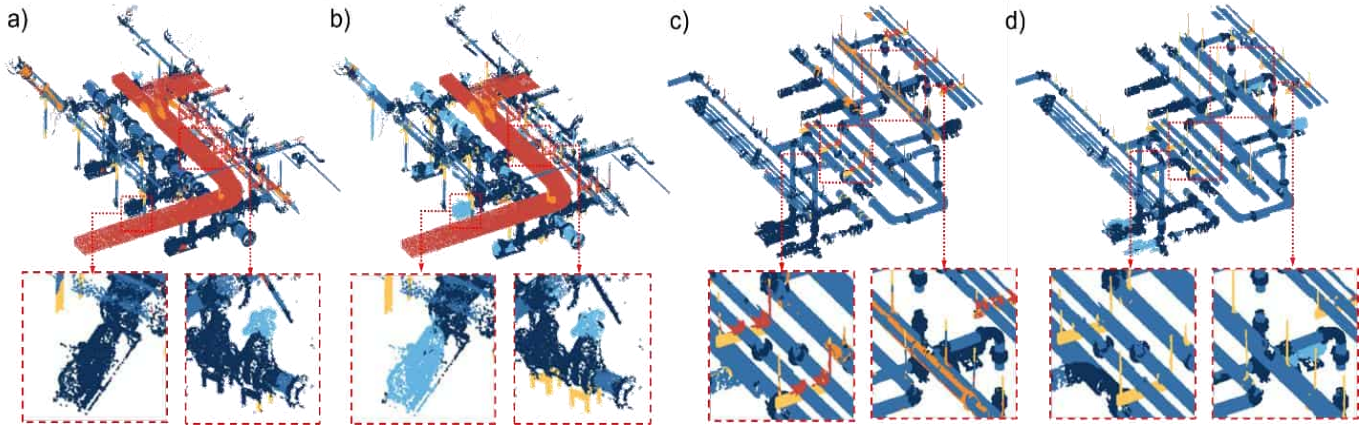

Figure 5. Semantic segmentation results: a) Real – P1; b) Hybrid – P1; c) Real – P2; d) Hybrid – P2

representation learning models. By jointly leveraging BIM-synthetic and TLS data, the dataset improves generalization across design and as-built domains.

Table 3. Segmentation accuracy

Category	TLS	TLS + BIM	Improve-ment
Duct	56.38	71.37	+15.00
Duct fitting	8.93	33.31	+24.37
Hanger	32.70	60.02	+27.32
Machinery	0.17	34.44	+34.27
Pipe	69.21	77.48	+8.27
Pipe fitting	44.85	52.55	+7.70
mIoU	35.37	54.86	+19.49
OA	66.84	77.96	+11.12

6 Conclusions

This study presents ongoing efforts for developing a hybrid dataset that integrates BIM-synthetic, mobile-scan and TLS point clouds to capture the diverse geometric characteristics of the built environment. NUS3D bridges the gap between design-intent and as-built representations, providing a unified foundation for 3D representation learning and scene understanding for scan-to-BIM and robotic perception. The dataset enables evaluation of algorithms for semantic segmentation, geometric reconstruction, and cross-domain transfer between synthetic and real, static and dynamic, as well as design and as-built domains. Demonstrations on BIM-synthetic and TLS-acquired M&E scenes further illustrate its capability.

Looking ahead, our research will be extended to incorporate mobile-scan point clouds, further enriching the dataset diversity. A cross-domain representation learning pipeline focused on mobile 3D scanning with BIM and TLS point clouds will be investigated with applications to robotic perception, construction progress monitoring and scan-to-BIM and BIM-to-scan verification. These capabilities will support research on point cloud representation learning and generalizable 3D scene understanding.

Abstract

Modular construction offers significant efficiency benefits over traditional methods, yet its production systems remain vulnerable to workflow variability caused by product customization and manual operations. While buffering is a standard strategy to mitigate such variability, the unique constraints of modular factories (e.g., specifically the large physical footprint of modules and high labor costs) often render traditional inventory and capacity buffers impractical. This study proposes a novel time buffer allocation methodology to absorb process variability and protect throughput in space-constrained modular production lines. Adopting a simulation-optimization approach, the study integrates Discrete-Event Simulation (DES) with the Covariance Matrix Adaptation Evolution Strategy (CMA-ES) algorithm to determine optimal project-specific time slacks. The framework is evaluated through a case study of a prefabricated timber wall assembly line in Edmonton, Canada. The results demonstrate that the optimized time buffer strategy reduces the workload at the bottleneck loading station by approximately 20% compared to a continuous flow scenario, effectively preventing starvation. Crucially, the optimized approach avoids the upstream blocking and excessive Work-in-Progress (WIP) accumulation observed under uniform buffering policies. The findings provide factory managers with a practical, data-driven method for scheduling releases that harmonizes upstream production efficiency with downstream logistics constraints.

Keywords –
Modular Construction; Simulation-Optimization; Buffer Allocation; Discrete-Event Simulation; Time Buffers

1 Introduction

Modular construction offers significant advantages over traditional methods, including reduced project schedules and improved quality control [1]. However, the operational reality of modular factories is characterized by substantial variability. The make-to-order nature of the industry necessitates extensive customization in component geometry, structural details, and finishing requirements, which introduces heterogeneous processing times at individual workstations [2,3]. This inherent variability, compounded by manufacturing tolerances and material handling uncertainties, frequently leads to production imbalances, bottleneck formation, and reduced overall efficiency [4,5].

To mitigate such variability, manufacturing systems typically employ inventory, capacity, or time buffers [6]. While effective in high-volume manufacturing, standard buffering strategies face unique hurdles in modular construction. Inventory buffers are often impractical because the large physical footprint of wall panels and volumetric modules severely restricts the available floor space between workstations [7–9]. Similarly, capacity buffering, maintaining excess labor or equipment, is constrained by the high costs of skilled labor, union restrictions, and crew specialization [10–12].

Given physical and economic constraints, time

buffers emerge as the most operationally feasible mechanism for absorbing process variability, utilizing temporal slack to protect critical workstations without requiring the additional space or redundant resources associated with inventory or capacity buffers [13,14]. This approach is well supported by the literature. Building on the foundational concept of strategic temporal protection for release-based scheduling introduced by Gao [15], subsequent work has shown that time buffers can be used to approximate the Buffer Allocation Problem by reformulating traditional integer programming models into more tractable linear formulations [16]. Furthermore, this approach was validated in the construction domain through the development of a stochastic optimization model integrating Monte Carlo simulation with critical chain techniques, which achieved a 37% reduction in project delays and a substantial improvement in schedule reliability [17].

However, existing research on time buffering remains predominantly grounded in Critical Chain Project Management (CCPM), prioritizing project-level schedule protection over the station-to-station flow control required for manufacturing contexts [18,19]. While CCPM methodologies have introduced advanced sizing techniques, including network decomposition [14] and entropy-based methods [20], they do not adequately address the dynamics of flow lines, an area where buffer allocation research has traditionally focused on inventory rather than time [21,22]. Consequently, there is a distinct lack of methodologies tailored to the stochastic dynamics of modular production lines. The unique combination of high process variability, space constraints, and make-to-order production in modular construction creates specific buffering challenges that necessitate station-level stabilization—a gap currently unaddressed by existing optimization frameworks.

This study addresses this gap through a Design-Science approach by developing and evaluating a prescriptive simulation-optimization decision-support artifact for time-buffer allocation in modular prefabrication. By integrating discrete-event simulation [23] with evolutionary optimization techniques [24], the proposed framework identifies project-specific buffer times that mitigate downstream starvation while avoiding excessive upstream blocking, thereby improving overall production performance under space constraints. The artifact is demonstrated and evaluated through an industrial case study at a prefabricated timber construction factory in Edmonton, Canada, providing actionable, data-driven guidance for planners in space-constrained manufacturing environments [25].

2 Methodology

This study adopts a Design Science Research (DSR) methodology [26], which emphasizes the development and evaluation of prescriptive solutions to real-world operational problems. The DSR artifact developed in this paper is a simulation-optimization decision-support framework for project-specific time-buffer allocation in space-constrained modular construction factories. The framework is implemented through a simulation-based optimization engine that recommends release slacks for downstream loading activities. Consistent with DSR, the study is structured around three stages: (i) problem identification and motivation, where spatial limitations and stochastic variability restrict the use of conventional inventory and capacity buffers; (ii) framework design and implementation, where the discrete-event simulation model and the optimization mechanism are developed; and (iii) evaluation, where the proposed framework is assessed in an industrial case study and benchmarked against baseline buffering policies.

2.1 Framework Design: Simulation-Optimization Approach

The proposed framework is designed using a simulation-optimization approach in which the Discrete-Event Simulation (DES) model functions as a black-box objective function [27]. In this framework, the optimizer treats the simulation as an evaluative function f(x) that accepts candidate time buffer allocations as inputs and returns performance metrics as outputs, without requiring explicit mathematical formulation of system dynamics [28]. This black-box approach is particularly suitable for modular construction environments where stochastic variability, customization-induced heterogeneity, and spatial constraints create complexities that resist traditional mathematical optimization methods [6]. The optimizer iteratively explores the buffer allocation space, executing the simulation for each candidate configuration and refining the solution toward optimal configurations based on performance feedback [29].

2.1.1 Discrete-Event Simulation Model Development

The discrete-event simulation model captures the stochastic dynamics of modular construction production lines by representing the system as a sequence of discrete events, such as job arrivals, station completions, and transfers between workstations, each causing a change in system state [30]. Jobs are characterized by distinct types reflecting different product configurations and customization requirements. Processing times at each workstation are sampled from job-specific probability distributions to represent production variability [31]. Blocking and starving are explicitly modelled through

limited intermediate buffers, such that a station may be starved by insufficient upstream supply or blocked by saturated downstream capacity. The primary performance metric is Workload Time, defined as the total active processing time required for a segment to complete its assigned jobs.

2.1.2 Optimization Framework

The optimization framework addresses a constrained single-objective minimization problem. The decision variables are the time-buffer parameters assigned to entities (jobs, tasks, or production batches) within a defined two-stage production line segment.

Let $\mathbf{s} = (s_1, s_2, \dots, s_n)$ denote the vector of time-buffer parameters, where each $s_i \in [s_{\min}, s_{\max}]$ represents the time slack assigned to entity i.

The optimizer treats the simulation as a black-box stochastic function [32]. For each stochastic simulation replication k with random inputs ω_k, the simulation returns:

$W_{\text{up}}(\mathbf{s}, \omega_k)$: The total active processing time accumulated by the upstream stage.

$W_{\text{down}}(\mathbf{s}, \omega_k)$: The total active processing time accumulated by the downstream stage.

The optimization objective is to minimize the expected total workload of the coupled two-stage segment:

$$\min_{\mathbf{s}\in[s_{\min},s_{\max}]^n} \mathbb{E}_\omega\left[W_{\text{up}}(\mathbf{s}, \omega) + W_{\text{down}}(\mathbf{s}, \omega)\right] \quad (1)$$

Since the true expected value is intractable, a Monte Carlo approximation is employed over K simulation replications with independent random seeds $\{\omega_k\}_{k=1}^K$:

$$\hat{J}(\mathbf{s}) = \frac{1}{K}\sum_{k=1}^{K}\left[W_{\text{up}}(\mathbf{s}, \omega_k) + W_{\text{down}}(\mathbf{s}, \omega_k)\right] \quad (2)$$

The problem is subject to simple box constraints:

$$s_{\min} \le s_i \le s_{\max}, i = 1, \dots, n. \quad (3)$$

Operational constraints (resource limits, blocking/starving rules) are enforced internally within the simulation logic.

2.1.3 Optimization Algorithm

Because the objective is evaluated through a discrete-event simulation treated as a black-box stochastic function, and its expectation is approximated via Monte Carlo replications, analytic gradients are unavailable and finite-difference gradients are unreliable due to simulation noise and non-smooth event logic. Therefore, a derivative-free stochastic optimization algorithm is used to iteratively propose candidate buffer vectors *S* and refine the search. In this study, the Covariance Matrix Adaptation Evolution Strategy (CMA-ES) is employed due to its effectiveness in handling continuous bounded domains and stochastic objective functions [33].

CMA-ES adapts its search distribution based on the history of evaluated solutions, making it well-suited for expensive black-box optimization. Depending on problem dimensionality and computational budget, alternative metaheuristic approaches such as particle swarm optimization, simulated annealing, or surrogate-assisted methods may also be suitable [34].

2.2 Evaluation Design

The framework is evaluated using an industrial case study of a modular wall-panel production line under space-constrained conditions. Performance is assessed by comparing the optimized time-buffer policy against baseline buffering strategies (e.g., zero buffering and a uniform buffering rule) under identical production scenarios. All candidate policies are evaluated through multiple Monte Carlo replications to account for stochastic variability and to ensure fair comparison of expected workload outcomes for the coupled upstream–downstream segment. The case-study implementation and benchmarking results are presented in the section 3, which operationalizes the framework in an industrial setting and reports the comparative evaluation outcomes.

3 Framework Evaluation

3.1 Case Study Overview

This section presents the implementation of the proposed framework in the wall assembly line of a prefabricated timber factory in Edmonton, Alberta, producing components for residential modular buildings. The factory operates two adjacent plants manufacturing walls, roofs, floors, stairs, decks, and finishing elements. The wall line was selected because it reflects the main characteristics of the target production environment: hybrid automation-manual operations, severely constrained intermediate buffers, and high product variety driven by customization. Together, these features create heterogeneous workstations and specification-dependent processing-time variability. Figure 1 shows the wall assembly line and overall production flow.

The line consists of six interconnected sections: Framing, Sheeting, CNC Nailing, Packaging, Doors and Windows (DW) Installation, and Loading. Framing uses one CNC machine and one crew to assemble multiwall (MW) panel frames, which move through limited-capacity buffers to Sheeting, CNC Nailing, and Packaging. After Packaging, interior panels are routed to storage, while the remaining panels proceed to four parallel DW lanes for finishing before being transferred

by cart to the Loading buffer. At Loading, two crews use a loading cart to place panels onto delivery trailers.

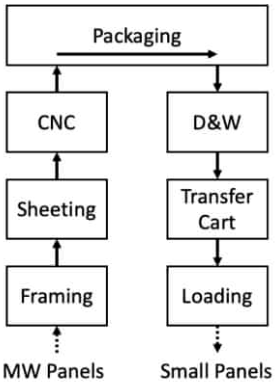

Figure 1: Schematic Layout of the Wall Assembly Line.

3.2 Simulation Model Development

Processing time data were collected through field observation and sampled production records, including panel durations and job specifications (e.g., interior/exterior classification and installation requirements). This provided a practical basis for model parameterization in a data-limited industrial setting, although the input assembly process remained partially manual. A sample of panel records per station was obtained, capturing both quantitative processing times and contextual factors influencing variability. Triangular distributions were selected for modeling processing times due to practical advantages in data-limited environments [35,36]. Parameters were derived from empirical data and validated with shopfloor experts.

The simulation model was developed in Python using SimPy to capture the stochastic dynamics of the wall assembly line. The model represents process flow, resource contention, and buffer limitations using capacity-limited SimPy Store objects enforcing first-in, first-out (FIFO) discipline. Single-capacity stores represent transfer elements; multi-capacity stores model buffers (e.g., DW: 4 lanes × 4 panels = 16 panels capacity; Loading: 6 lanes × 4 panels = 24 panels capacity). Blocking and starving arise naturally from resource constraints. Routing logic dynamically assigns panels at Packaging based on panel type and queue lengths, replicating observed load-balancing behavior.

Model validation against real production data (84 MW panels, 135 small panels) demonstrated acceptable accuracy: Framing ($R^2 = 0.95$), DW ($R^2 = 0.89$), Loading ($R^2 = 0.88$), with mean absolute percentage errors of 16–18% (acceptable for complex construction simulations) [36].

3.3 Optimization Specification

This study focuses on optimizing the time buffer between the upstream production segment (Framing through DW Installation) and the Loading station. Loading, constrained by external trailer logistics, can load a maximum of three projects per day, regardless of project size or upstream production rate. This external constraint positions Loading as a system bottleneck regarding project throughput. Furthermore, the transfer cart section, identified as the internal bottleneck based on panels' expected processing times, feeds directly into the constrained Loading buffer.

Currently, plant management decouples Loading from upstream stations using an average one-day time buffer. However, this uniform buffer policy does not account for project-specific variability or system dynamics. Given the severely limited inventory buffer capacity (24 panels total across six lanes), excessive time buffers cause WIP accumulation that blocks or slows upstream production, while insufficient buffers lead to Loading starving and underutilization [37]. This segment therefore represents an excellent case for testing the effectiveness of the proposed time buffer optimization technique, where the goal is to determine project-specific loading slacks that balance upstream production flow with downstream logistics constraints.

Projects flow through the upstream production segment (Framing through DW Installation), generating production workload W_{prod}. The time buffer s decouples this from the constrained Loading station (workload W_{load}), as illustrated in Figure 2. The optimization objective is to determine per-project buffer allocations that minimize the combined workload $W_{\text{prod}} + W_{\text{load}}$.

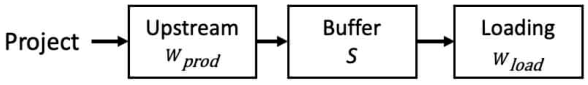

Figure 2: Schematic representation of the proposed time buffer allocation approach.

The selected test schedule comprises 14 projects of varying sizes, mimicking a one-week workload of the production line. For each project i, the decision variable s_i represents the time slack (loading buffer in hours) between when project i reaches the Loading buffer from upstream stations and when it is released to the Loading station. The bounds on s_i are determined by project-specific delivery deadlines: $s_i \in [0, d_i]$, where d_i is the maximum allowable slack for project i based on its deadline. For the plant's operations, typical deadlines following the loading date are within 2–3 days; thus, bounds reflect this practical constraint.

The production workload $W_{\text{prod}}(\mathbf{s}, \omega)$ represents the

total active processing time required by the upstream (i.e., Framing, Sheeting, CNC Nailing, Packaging, DW Installation, and transfer cart stages) to complete all 14 projects, while the loading workload $W_{\text{load}}(\mathbf{s}, \omega)$ measures the Loading station's active processing time for the same project set. The optimization objective is to minimize the expected total workload of the coupled production-Loading system:

$$\min_{\mathbf{s}\in[0,d_1]\times\cdots\times[0,d_{14}]} \mathbb{E}_{\omega}\left[W_{\text{prod}}(\mathbf{s}, \omega) + W_{\text{load}}(\mathbf{s}, \omega)\right] \quad (4)$$

With an effective buffering strategy, the total makespan for finishing the 14-project set is expected to remain relatively constant; however, strategic time buffer allocation changes the distribution of workload and utilization patterns between the production segment and Loading. By decoupling the upstream production from the constrained Loading station through optimized project-specific slacks, the buffer creates a more consistent arrival flow at Loading, smoothing demand variability and reducing starving events. This workload redistribution improves Loading station utilization while preventing upstream blocking, thereby enhancing overall system efficiency [37].

The CMA-ES algorithm was configured with population size proportional to the 14-dimensional decision space and standard initial step size. Monte Carlo estimation used $K = 50$ simulation replications during candidate evaluation and final validation of the best solution, ensuring reliable stochastic objective function approximation [38].

3.4 Results

Three scenarios were simulated to evaluate the proposed time-buffer optimization framework: (1) continuous production with no buffer slack, representing uninterrupted flow; (2) uniform buffering with an 8-hour slack for all projects, reflecting current plant practice; and (3) optimized buffering with project-specific slacks determined by the optimization model. The test schedule included 14 projects of varying sizes released over a four-day horizon. Figure 3 compares the execution timelines of the upstream production segment and the Loading station under the three scenarios.

In the continuous production scenario, the upstream segment completed its work in 31.77 hours, consistent with the four-day production window, but the Loading station required 21.92 hours and extended to a fifth day because of the three-project-per-day trailer logistics constraint. This indicates poor decoupling, with the Loading station frequently starved despite uninterrupted upstream flow.

Under the uniform 8-hour buffer policy, Loading workload decreased to 16.71 hours, indicating fewer starving events and more stable downstream operation. However, upstream workload increased to 37.12 hours, exceeding the four-day window and requiring substantial overtime. This occurred because the uniform slack caused excessive WIP accumulation in the space-constrained buffer, which increased upstream blocking and reduced throughput.

The optimized buffer scenario achieved a better balance between upstream and downstream performance. Loading workload was reduced to 17.11 hours, close to the uniform-buffer case, while upstream workload remained at 31.83 hours, comparable to the continuous-flow scenario and still within the four-day production window. This shows that project-specific slacks can effectively decouple Loading from upstream variability, improving downstream utilization without causing upstream blocking or significant overtime. Although Loading still required five days because of the external logistics constraint, its workload was about 20% lower than in the continuous scenario, creating opportunities to reassign the Loading crew to other value-adding tasks.

The results highlight the critical importance of strategic time buffer allocation in production systems with coupled internal and external bottlenecks. While a uniform buffer policy improves downstream efficiency, it negatively impacts upstream production due to physical space constraints. The proposed optimization framework effectively addresses this challenge by determining project-specific slacks that absorb variability without overwhelming buffer capacity. The optimized solution achieves the best of both scenarios: it maintains upstream production efficiency comparable to a continuous flow model while achieving downstream workload reductions similar to a large uniform buffer, thereby maximizing overall system efficiency and labor productivity. These findings provide a validated foundation for implementing dynamic, data-driven buffering strategies in modular construction factories.

Overall, the results demonstrate that strategic time-buffer allocation is critical in systems with coupled internal and external bottlenecks. A uniform buffer improves downstream stability but degrades upstream performance under space constraints. In contrast, the proposed framework identifies project-specific slacks that absorb variability without overwhelming buffer capacity. As a result, it preserves upstream efficiency while achieving downstream workload reductions similar to the uniform-buffer case. From an implementation perspective, the optimized slacks can be directly incorporated into production schedules as project-specific release delays from upstream production to the Loading buffer, providing managers with simple and actionable scheduling guidance.

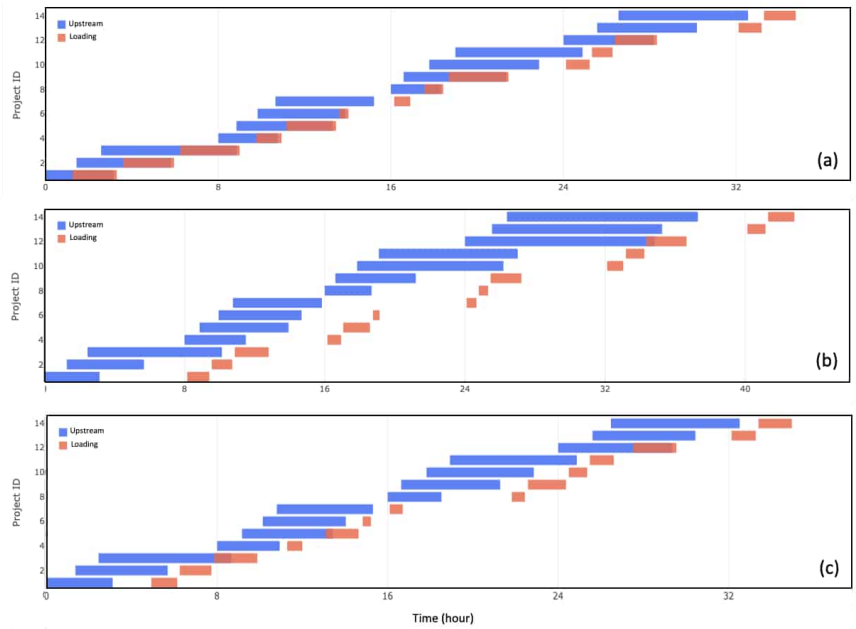

Figure 3: Project execution timelines for upstream segment and loading station under three buffering scenarios: (a) no buffer, (b) uniform 8-hour buffer, and (c) optimized project-specific buffers.

3.5 Practical Implementation

The proposed framework is intended to operate as a decision-support layer on top of the factory's existing planning process rather than as a stand-alone tool that production planners must model manually. In practice, the required inputs are already generated during routine weekly or monthly planning, including the project list, project sequence, target release dates, and station-level production assumptions. These data can be transferred from the plant's scheduling spreadsheets or production management system into the simulation-optimization engine with limited preprocessing.

From an implementation perspective, the main technical requirement is not that every planner or manager possess simulation expertise, but that the organization have access to an industrial engineer, analyst, or digital-production specialist capable of maintaining the simulation model and periodically updating its input parameters. Once this model is established, end users interact only with the results, which can be delivered as a lookup table or simple scheduling rule: for each project in the weekly schedule, apply the recommended loading slack before releasing it to the Loading buffer. In this way, the complex stochastic behavior captured by the DES-CMA-ES framework is translated into concrete release times that are directly usable in operational planning.

This implementation logic minimizes disruption to current manual or semi-automated scheduling practices while still enabling data-driven decision-making. The operational value of the approach lies in converting simulation outputs into actionable project-level dispatch adjustments that reduce Loading crew overtime, improve labor utilization, and maintain upstream production within the expected four-day window. Nevertheless, wider deployment at industrial scale would benefit from a user-friendly interface and automated data exchange between the scheduling platform and the optimization engine, which remains an important direction for future development.

4 Conclusion

This study addressed production variability in modular construction factories where space constraints limit the use of inventory buffers and labor costs restrict capacity buffering. Following a Design Science Research (DSR) methodology, it developed a simulation-optimization framework that combines discrete-event simulation with CMA-ES to allocate project-specific time buffers without requiring additional space or redundant resources. The framework was evaluated on a prefabricated timber wall production line in Edmonton, Canada, as a real-world demonstration case under space-constrained modular production conditions. The optimized time-buffer policy outperformed both zero-buffer (continuous) operation and the plant's uniform buffering practice, reducing bottleneck Loading workload by approximately 20% while preventing downstream starvation. Unlike uniform buffering—which stabilizes the downstream station by blocking upstream work and extending lead times—the optimized

solution maintained upstream efficiency within the targeted four-day window. Overall, the results indicate that time buffers can provide a practical alternative to inventory buffers in space-constrained off-site construction. From a managerial perspective, the framework translates complex stochastic system behavior into simple project-specific scheduling rules that can improve labor utilization and throughput reliability.

While the findings are promising, the present study should be interpreted as a preliminary industrial evaluation with several limitations. First, the framework was assessed using a single demonstration case on one prefabricated timber wall production line, which limits immediate generalizability to other factory layouts, product mixes, and operating conditions. Second, as with any simulation-based study, the analysis depends on modelling assumptions regarding workflow logic, variability representation, and system constraints that may differ across industrial settings. Third, the DES input data in this study were assembled from field observations and sampled production records, which was practical for the case-study context but still required partial manual preprocessing.

Future research should therefore validate the framework across additional production lines, broader project portfolios, and alternative buffering scenarios. It should also extend the method to more complex factory environments, such as multi-line and multi-product systems with interacting bottlenecks. In addition, more systematic data acquisition should be explored through integration with digital production reporting systems, shop-floor sensing, and digital-twin-oriented data pipelines, enabling more automated model updating and more scalable industrial implementation.

Abstract

Reinforcement detailing quality in reinforced concrete structures is directly associated with structural safety and project costs. However, manually cross-checking structural construction drawings against rebar schedules remains inefficient and highly susceptible to human error. Although demand for digital transformation in construction has become increasingly urgent, achieving high-precision automated information extraction continues to be challenging owing to the ultra-high-resolution of engineering drawings and the semantic complexity of domain-specific annotations. To address these issues, this paper proposes a staged visual semantic parsing framework tailored to structural construction drawings and rebar schedules. The proposed approach incorporates an overlapping tiling strategy to preserve local contextual information within large-scale drawings and constructs an end-to-end pipeline that integrates YOLOv11-based text detection with TrOCR-based sequence recognition, enabling accurate dense rebar annotation and tabular data extraction. Experimental results from real-world engineering datasets demonstrate that the proposed method exhibits strong robustness under high-density text conditions and complex background interference, achieving a Character Accuracy of 90.93% (CER = 0.0907) on the held-out test set, outperforming the best baseline by approximately 37.2 percentage points. These findings validate the feasibility and accuracy of leveraging deep-learning techniques for automatic structured information reconstruction from two-dimensional engineering documents, establishing a technical foundation for advancing automated quantity take off, intelligent code-compliance assessment, and digital quality management in the construction industry.

Keywords –

Structural Drawings; Rebar Schedule; Optical Character Recognition; Text Recognition

1 Introduction

The construction quality of reinforced concrete (RC) structures is a fundamental determinant of the lifecycle safety performance and service durability of infrastructure systems [1]. As a core element in ensuring structural load-bearing capacity and long-term durability, reinforcement detailing accuracy not only forms the cornerstone of quality control but also represents a critical variable in project cost management and quantity surveying [2]. Previous statistical studies have indicated that reinforcement costs account for approximately 30% of the total project cost in conventional RC structures [1]. Reinforcement deviations and the resulting rework pose substantial risks to effective cost control [3]. Consequently, in modern engineering projects characterized by a large number of components and highly complex specification systems, project managers are required to rigorously verify and document key parameters, such as reinforcement quantity, diameter, spacing, and layout patterns, as presented in structural construction drawings and rebar schedules, to ensure compliance between construction deliverables and design specifications [2,4].

However, in the digital transformation of the construction industry, automated structural data acquisition poses fundamental challenges. Although building information modeling (BIM) and computer-aided design (CAD) technologies have been widely adopted, 2D rasterized drawings, such as PDF files or scanned documents, remain the legally authoritative single source of truth in critical processes, including multi-party coordination, construction approval, and contractual delivery [4]. While CAD-to-BIM conversion theoretically provides an alternative pathway for data acquisition, its applicability is severely constrained by its strong dependence on strict drafting standards and layer conventions [5]. In complex engineering practice, heterogeneity in design habits, software version

incompatibility, and non-standardized layer management frequently result in significant semantic ambiguity when directly parsing geometric primitives [4,5]. By contrast, computer-vision-based approaches aim to emulate the cognitive processes of human engineers by interpreting information through visual features rather than file attributes [6]. Therefore, developing a generic parsing method that does not rely on specific design software or layer standards and that can deconstruct drawing content directly from the visual domain is essential for achieving true automation and robustness [7].

Although computer-vision techniques have made notable progress in general domains such as document analysis and legal contract review [8,9], their application to structural engineering drawings remains hindered by unresolved technical barriers. Existing general-purpose optical character recognition (OCR) systems are primarily designed for documents with well-aligned layouts and homogeneous backgrounds [7], whereas structural drawings exhibit distinctive characteristics, including high information density, large spatial scale, and weak semantic explicitness [10]. First, structural drawings typically possess extremely high resolutions, often exceeding 4K, and direct input into generic detection models frequently leads to graphic memory overflow or loss of small object features [11]. Second, reinforcement annotations commonly employ highly compressed domain specific syntax, such as "Φ8@200," and are often subject to severe visual overlap with dimension lines, grid lines, and background noise [1,10]. This complex spatial topology and specialized symbolic semantics combination renders generic document-processing techniques insufficient for practical accuracy in engineering scenarios [7].

To address the challenges posed by high-resolution, dense annotations, and compressed semantics in structural construction drawings, this paper proposes a staged visual semantic parsing approach that decomposes the task into text region detection and semantic recognition. In the detection stage, an adaptive overlapping tiling strategy is introduced to preserve local contextual information and reduce misdetections caused by small-scale text fragmentation [12]. Based on this strategy, a YOLOv11-based detection network was employed to achieve stable and accurate text region localization. For semantic recognition, a Transformer-based sequence recognition model was adopted to enhance intercharacter dependency modeling and improve robustness under complex background conditions [13]. By integrating YOLOv11 and TrOCR, an end-to-end parsing framework was constructed, enabling coordinated detection and recognition optimization. Experimental results confirmed the robustness and generalization capability of the proposed method in complex structural drawing scenarios.

2 Related Work

Early studies on text parsing in engineering drawings primarily relied on traditional image-processing techniques and handcrafted feature design methods such as morphological operations and connected component analysis[14]. Using this class of approaches, Ahmed et al. [15] achieved text and symbol extraction from engineering drawings, demonstrating relatively high accuracy under conditions in which drawing formats were fixed and background noise was minimal. Moreno-García et al. [14] combined rule-based reasoning with clustering algorithms to classify symbols and connection relationships in piping and instrumentation diagrams, thereby validating the feasibility of such methods in controlled environments [14,15]. However, these approaches are highly sensitive to environmental conditions, as variations in the scanning resolution, noise interference, symbol overlap, and background clutter can lead to substantial performance degradation. In practical engineering archives, in which drawing quality varies significantly, traditional methods relying on handcrafted features struggle to maintain a stable and robust parsing performance [7].

In recent years, deep-learning approaches, particularly those based on convolutional neural networks (CNNs), have been widely recognized and validated for visual analysis tasks in construction engineering [16]. Compared with traditional image-processing techniques, these methods are more effective in handling complex scenes while simultaneously improving accuracy and robustness, thereby providing strong technical support for construction informatization and intelligent decision-making [2,4]. In the context of the automatic engineering drawing parsing, previous studies commonly modeled text extraction as a two-stage pipeline consisting of text detection followed by text recognition. For example, Ravagli et al. [17] reformulated drawing text extraction as a two-stage task and employed the CTPN along with Tesseract to extract information from architectural floor plans. However, this approach exhibits limited effectiveness when dealing with non-horizontal text. To improve practical performance, Saba et al. [18] integrated an EAST detector with a CRNN-based EasyOCR module and achieved improved performance in terms of handling rotated and inclined text. Similarly, Schönfelder et al. [7] developed a recognition pipeline combining YOLOv7 and PARSeq, covering multiple types of drawing annotations and providing valuable methodological references for subsequent research.

To achieve deeper feature representation and stronger global context modeling, Zhang and He [8] introduced a method based on YOLOv10 and LORE for parsing complex engineering tables, demonstrating that deep-learning models significantly outperform traditional

approaches in terms of handling structured data. Khallouli et al. [9] further demonstrated the advantages of Transformer-based architectures, specifically TrOCR, in processing engineering drawings containing multi-lingual content and complex fonts, with a performance clearly surpassing that of conventional CNN-based baselines. However, within the specific context of RC structural drawings, previous studies have largely been limited to relatively simple tasks, such as text classification or geometric element extraction. For instance, Ma et al. [1] attempted to separate geometric and non-geometric content to extract reinforcement shapes; however, but approach remains insufficient for handling highly compressed composite semantic annotations such as "Φ8@200." Furthermore, existing general-purpose models often overlook the information loss caused by tiling large-format drawings during pre-processing and lack systematic investigation tailored to the joint interpretation of reinforcement schedules and structural drawings.

3 Material and Methods

3.1 Data collection

The dataset used in this study was collected from 31 real engineering projects, all involving the aboveground structural systems of apartment buildings across multiple provinces and cities in China. Each project comprises one structural construction drawing and one corresponding rebar schedule, yielding a total of 62 high-resolution engineering images (31 matched pairs). These projects originate from multiple design firms, encompassing a range of drafting styles and drawing conventions, thereby ensuring a degree of diversity in page layout, font style, and annotation practice within the dataset. The structural component types covered include beams, columns, walls, and foundations. The image resolution ranged from 7560 × 5174 to 15000 × 5914 pixels, reflecting the large-scale and high-information-density characteristics of structural engineering drawings.

As illustrated in Fig. 1(a), structural construction drawings are primarily used to represent the spatial arrangement of structural components and their corresponding identification labels, such as component names denoted by codes such as GBZ1. Fig. 1(b) shows the corresponding rebar schedules, which systematically describe the internal rebar configuration of each component, including the component name, elevation information, quantity and specification of longitudinal reinforcement (e.g., number of bars and diameter), type and spacing of stirrups or ties, and, in certain cases, cross-sectional details illustrating the spatial arrangement of reinforcement.

In addition to rebar-related content, the original structural drawings contained auxiliary textual information, including contractor details, client information, and general project notes. To protect project privacy and prevent irrelevant information from affecting model learning, the auxiliary regions were anonymized using mosaic processing prior to annotation. Text regions were manually annotated using the PPOCRLabel tool. A category-based annotation strategy was adopted: rebar-related semantic elements (component name, elevation, longitudinal reinforcement quantity and specification, stirrup or tie type and spacing) were annotated using green bounding boxes and served as exclusive targets for model training; auxiliary textual information was annotated using blue bounding boxes and selectively retained or excluded according to task requirements.

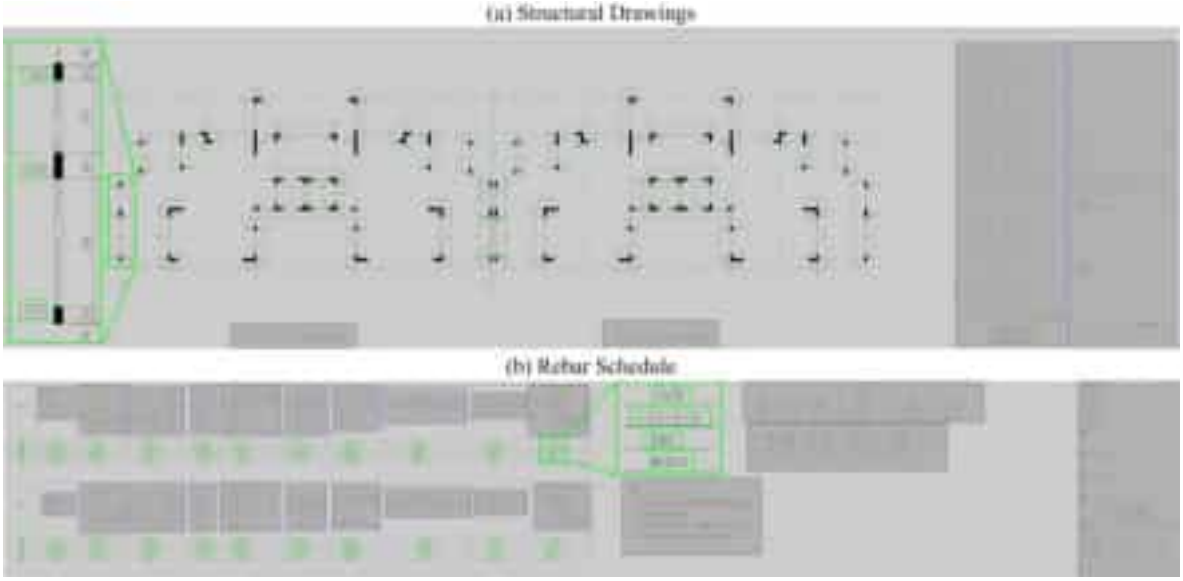

Figure 1. Example of structural engineering drawings: (a) structural construction drawing; (b) rebar detail schedule

Although cross-sectional detail drawings are graphical rather than textual in nature, their positions were also annotated and retained separately, given their potential value for downstream structural information association. To ensure consistency between the annotation data and recognition output, symbols representing different reinforcement grades were normalized to Φ during annotation, thereby reducing recognition noise caused by symbol variation and scanning inconsistencies.

3.2 Data Preprocessing Strategy

Owing to the ultra-high-resolution characteristics of the original structural construction drawings, directly feeding the entire image into a deep-learning model often results in excessive GPU memory consumption and degrades the recognition performance for dense small-scale text targets. To address this issue, as illustrated in Fig. 2, an overlap tiling strategy was introduced during the data pre-processing stage to decompose large-scale engineering drawings into manageable units [12].

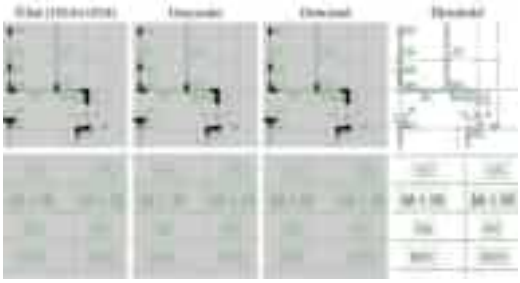

Figure 2. Example of data preprocessing.

Specifically, each original image was cropped into sub-images with a fixed size of 1024 × 1024 pixels. An overlap region of 200–300 pixels was applied between adjacent tiles to prevent text elements from being fragmented, while simultaneously reducing the risk of disrupting tabular structures or splitting component identifiers across tiles. For regions located at image boundaries where the cropped area was smaller than 1024 × 1024 pixels, white background padding was applied to achieve a uniform input size, thereby ensuring consistency during the model inference stage. Through this tiling procedure, 3510 valid cropped samples were generated from original 62 drawings.

Following spatial tiling, additional pre-processing operations tailored for text recognition tasks were applied to the cropped images, including grayscale conversion, noise suppression, and threshold-based segmentation. These steps enhance the contrast of the text regions while attenuating background interference. The described pre-processing pipeline preserves the integrity of the rebar-related semantic information and provides stable and standardized input data for subsequent text detection and Transformer-based sequence recognition models.

3.3 Hybrid Pipeline Architecture

This study proposes a staged hybrid OCR parsing architecture for structural construction drawings in which reinforcement semantic parsing is decomposed into two sequential stages: text-region detection and character-sequence recognition. This separation reduces learning complexity and enables independent optimization of each stage [17].

As shown in Fig. 3, after tiling and pre-processing, the drawings were first processed during the detection stage to localize reinforcement-related text regions and output bounding boxes. The detected regions were then cropped and forwarded to the recognition stage to generate the corresponding character sequences. This staged design effectively addresses the coexistence of dense text distributions and highly compressed semantic expressions typical of structural construction drawings.

3.3.1 Detection Stage

The detection stage employs the YOLOv11 Small model to localize text regions in structural drawings [19]. Model parameters were initialized using yolo11s.pt weights pre-trained on the COCO dataset. As a single-stage detection architecture, YOLOv11 maintains

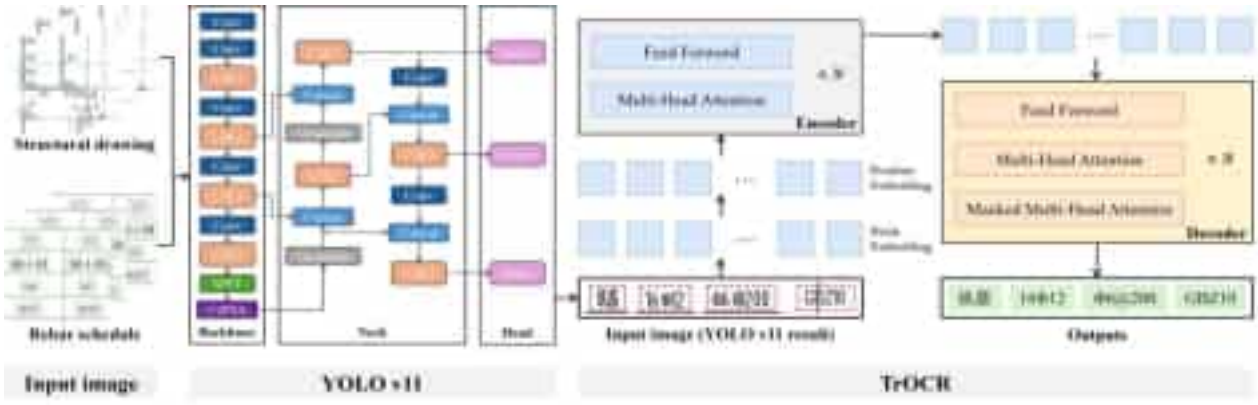

Figure 3. Hybrid Pipeline Architecture for Drawing OCR Analysis

reliable localization performance for small-scale and densely distributed text targets, making it suitable for engineering drawing scenarios. Text detection was formulated as a single-class object-detection task, allowing training to focus on spatial localization accuracy without category-level ambiguity.

3.3.2 Recognition Stage

In the recognition stage, a Transformer-based TrOCR model is adopted to perform character sequence modeling of the text regions produced by the detection stage. By constraining the recognition task to pre-detected text regions, the proposed framework substantially reduces the interference of background structures on character modelling.

The TrOCR model is initialized using a hybrid strategy [13]. The visual encoder is loaded from pre-trained Microsoft/trocr-base-printed weights, providing visual feature representations with a strong generalization capability. By contrast, the text decoder is initialized from scratch using a lightweight transformer architecture specifically adapted to the highly regularized and syntactically compact reinforcement annotations in structural drawings. This design leverages pre-trained visual representations while avoiding the modelling redundancy of general-purpose language model decoders in domain-specific scenarios.

3.4 Experimental Strategy

All experiments were conducted on a Windows 11 Pro platform using Python 3.9 and PyTorch 2.8.0. The hardware configuration consisted of an NVIDIA GeForce RTX 5080 GPU and an AMD Ryzen 9 9950X processor. Separate datasets and training strategies were designed for the detection and recognition stages to reflect their distinct task characteristics.

3.4.1 Detection Model Training

The text-detection model was trained using a dataset generated through the tiling procedure, which contains 3510 cropped engineering drawing images. The dataset was divided into training, validation, and test sets in a ratio of 8:1:1 to ensure sufficient training data while enabling independent performance monitoring and final evaluation. The model was trained for up to 100 epochs using an early stopping strategy based on the validation performance. Training was terminated if no improvement was observed for 20 consecutive epochs to mitigate overfitting under limited-sample conditions. Owing to the GPU memory constraints associated with the 1024 × 1024-pixel inputs, the batch size was set to eight. The default YOLO optimization configuration was adopted, including built-in learning-rate warm-up and decay mechanisms, to facilitate stable transfer-learning adaptation to the text-localization task [19].

The detection performance was evaluated using the mean average precision (mAP), including mAP50 and mAP50:95. [6]mAP50 corresponds to an intersection over union (IoU) threshold of 0.50, whereas mAP50:95 represents the average precision computed over IoU thresholds ranging from 0.50 to 0.95 with a step size of 0.05 [10]. IoU is defined as

$$IoU = \frac{Area\left(B_{pred} \cap B_{gt}\right)}{Area\left(B_{pred} \cup B_{gt}\right)} \tag{1}$$

where B_{pred} and B_{gt} denote the predicted and ground-truth bounding boxes, respectively. The detection was considered correct when the IoU exceeded a given threshold. AP is defined as the area under the precision–recall curve, as follows:

$$AP = \int_0^1 p(r)dr \tag{2}$$

As text detection was formulated as a single-class detection task in this study, the mAP was equivalent to the AP of this class under the corresponding IoU threshold.

3.4.2 Recognition Model Training

The training data for the text-recognition model were generated by cropping the text region output from the detection stage, yielding 11427 character-level annotated samples. The dataset was divided into training, validation, and test sets in the same 8:1:1 ratio. The recognition model was trained for 50 epochs by using a staged training strategy. During the first 10 epochs, the visual encoder was frozen and only the decoder was trained. Subsequently, the higher encoder layers were partially unfrozen, and the learning rate was reduced to one-fifth of its initial value to enhance domain adaptation while preserving the pre-trained visual features.

The training employed the AdamW optimizer with an initial learning rate of 1×10^{-4} and a batch size of 32. Weight decay and label smoothing were applied, and early stopping based on the validation set character error rate (CER) was used, with training terminated after 10 consecutive epochs without improvement.

Recognition performance was evaluated using the CER and character accuracy (CA), respectively defined as

$$CER = \frac{S + D + I}{N} \tag{3}$$

$$CA = 1 - \frac{S + D}{N} \tag{4}$$

where *S*, *D*, and *I* denote the number of substitutions, deletions, and insertions, respectively, and *N* is the total number of characters in the ground-truth text.

4 Results

4.1 Text Detection Results

The training process was systematically analyzed to evaluate the convergence behavior and localization performance of the text-detection model. Training was terminated early at epoch 61 on the basis of validation performance. As illustrated in Fig. 4, the box loss and DFL loss for both the training and validation sets decreased steadily throughout the optimization process, with no observable divergence between the two curves, confirming the stability of convergence. The detection model surpassed an mAP of 0.95 at IoU = 0.50 within the early training epochs, and the stricter mAP50:95 metric reached approximately 0.636 toward the final stage, indicating that the model attains reliable performance in both coarse localization and precise boundary regression.

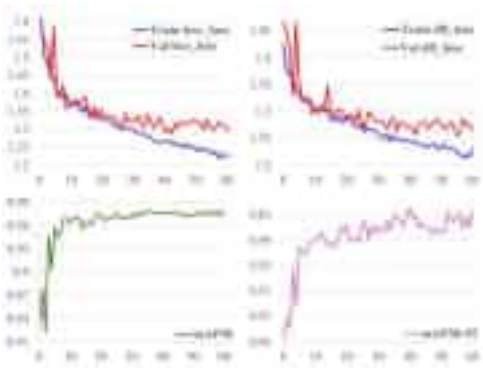

Figure 4. Training curves of the detection model

Fig. 5 presents representative detection results on the test set. The predicted bounding boxes exhibit a high degree of spatial overlap with the ground truth annotations, with no notable false positives or missed detections observed, confirming the effectiveness of the adopted detection strategy in the context of engineering drawings and providing a reliable input foundation for the subsequent text recognition stage.

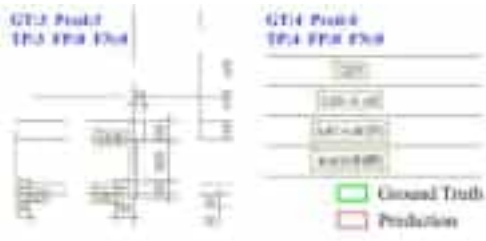

Figure 5. Typical examples of detection test results

4.2 Text Recognition Results

The performance of the text-recognition module is analyzed following the introduction of enhanced regularization strategies. As shown in Fig. 6, the training process converged stably, with the training loss and validation loss decreasing in parallel while maintaining a narrow gap. The validation CER reached its optimal value of 0.0281 (CA = 97.19%) at epoch 7. After unfreezing the top two encoder layers at epoch 11, no appreciable performance degradation was observed. Training was terminated early at epoch 17 based on validation performance, indicating that the model achieves favorable convergence and generalization under the combined regularization and staged unfreezing strategy.

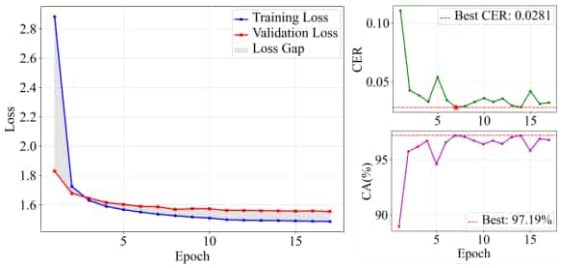

Figure 6. Training curves of the text recognition

To evaluate the effectiveness of the proposed pipeline, three representative open-source OCR methods (docTR, EasyOCR, and Tesseract) were employed as baselines for comparative experiments. None of the baseline methods incorporated a dedicated object detection module; instead, they applied the same sliding window strategy to segment the original engineering images into patches for direct recognition. The results are summarized in Table 1. Among the three baselines, EasyOCR achieved the best performance, yet its CER remained as high as 0.4622 (CA = 53.78%), with a precision of only 0.196, indicating that patch-based recognition using fixed windows can improve text recall but still introduces substantial background noise and redundant detections in the absence of semantic-level text localization, falling short of the high-accuracy recognition demands of engineering drawings. The proposed YOLOv11 + TrOCR pipeline, through a staged detect-then-recognize strategy, achieved a CA of 90.93% (CER = 0.0907) on the held-out test set, representing an improvement of approximately 37.2 percentage points over the best baseline EasyOCR (CA = 53.78%), fully demonstrating the necessity and effectiveness of incorporating a semantic-level dedicated detection module for structural drawing recognition.

Table 1. Comparison with Baseline OCR Model

Model	Tesseract	docTR	EasyOCR	**Ours**
CER	0.9341	0.6791	0.4622	**0.0907**
CA	6.59	32.09	53.78	**90.93**

Table 2 presents representative recognition results on the test set along with their corresponding error types. For standard structural annotation texts that appear frequently in engineering drawings, such as rebar diameter notations 18Φ14, component identifiers GBZ4, and stirrup spacing expressions Φ8@200, the model achieved zero-character error rate, indicating stable and reliable recognition capability for conventional annotation text.

Table 2. Typical examples of text recognition test results

Image	GT	Pred	CER	Error Type
	18Φ14	18Φ14	0	-
	编号	编号	0	-
	GBZ4	GBZ4	0	-
	Φ8@200	Φ8@200	0	-
	8.700~ 52.200	8.700~ 2.200	0.154	Digit Missing
	2Φ12+ 6 Φ14 (实心)	2Φ12+ 6 Φ14 (实必)	0.188	Char Confusion
	-2.520	-25.20	0.333	Decimal Shift

To further identify directions for model optimization, a character-level error decomposition was conducted on the 131 non-exact-match samples. It should be noted that the majority of these samples contained only one-to-two-character deviations, and the overall CER remained at a low level. Among a total of 304 edit operations, Digit Missing accounted for the highest proportion (148 occurrences, 48.7%), primarily manifesting as the omission of individual digits by the model and affecting 15.9% of all test samples. Decimal Shift ranked second (52 occurrences, 17.1%, affecting 8.7%), mainly attributable to the high visual similarity between elevation values and dimensional annotations, which makes it difficult for the model to distinguish between the two based solely on local image features. Char Confusion and special symbol errors together accounted for only 10.5% of all edit operations, occurring infrequently yet carrying relatively notable impact at the semantic level. Other errors (72 occurrences, 23.7%) were predominantly caused by missing or extraneous spaces and did not affect practical semantic parsing. The above analysis indicates that the residual recognition deviations of the current model are primarily concentrated in numerically dense short texts, and performance can be further improved through the introduction of structured numerical constraints or domain-adaptive post-processing strategies.

5 Conclusions

This study proposed a staged visual semantic parsing framework for 2D rasterized structural construction drawings, targeting the automated extraction of reinforcement information from structural construction drawings and rebar schedules. A high-resolution engineering drawing dataset comprising 62 drawings, was constructed, and an overlap tiling strategy was employed to process large-format images, effectively alleviating GPU memory constraints and text fragmentation.

From a methodological perspective, a hybrid OCR pipeline integrating YOLOv11 and TrOCR was developed in which reinforcement semantic parsing was decomposed into text-detection and -recognition stages. Experimental results demonstrate that the text-detection model can stably localize dense text regions under complex structural drawing backgrounds, thereby providing reliable inputs for the recognition stage. The text recognition model achieves a CA of 90.93% (CER = 0.0907) on the held-out test set, representing an improvement of approximately 37.2 percentage points over the best baseline method EasyOCR (CA = 53.78%) under the same sliding window strategy. Analysis of representative samples showed that the model accurately recognized high-frequency structural annotations, including reinforcement diameters, component identifiers, and spacing expressions, whereas recognition errors were primarily concentrated in complex text instances characterized by dense numerical content or highly compressed semantics.

Despite achieving stable recognition performance, several limitations remain. This study normalized different reinforcement grades using the symbol Φ to ensure recognition consistency, without performing fine-grained differentiation among different grade symbols. Furthermore, the current scope is confined to character-level text detection and recognition, and does not yet encompass the reconstruction of structured engineering semantics or the cross-drawing information association between structural construction drawings and rebar schedules. To bridge this gap, future research will proceed along four stages: (1) structured information reconstruction, parsing raw OCR output into structured fields (component name, rebar diameter, spacing, and quantity) based on domain-specific grammatical rules (e.g., the KS D 3504 reinforcement notation standard) and regular expressions; (2) component-level entity matching, using recognized component identifiers (e.g., GBZ1) as indices to establish one-to-one or one-to-many cross-drawing mapping relationships with corresponding rebar schedule entries; (3) compliance verification, automatically comparing matched structural information against design codes to verify mandatory requirements such as minimum rebar spacing and concrete cover

thickness; and (4) automated quantity extraction, calculating the reinforcement quantity for each component to support quantity surveying and cost management. Future work will also expand the fine-grained recognition of reinforcement-grade symbols and validate the generalization capability of the model across a broader range of engineering project types and drafting standards.

Abstract –

Occurrences of blockages in stormwater drainages could be a significant issue, especially in urban areas, due to various challenges for infrastructure operation and maintenance. Predicting blockage occurrences is a complex problem that involves numerous parameters and an adequate understanding of their impacts, interactions and the nonlinear behaviours of certain parameters. This research study aims to develop a data-driven predictive model-based framework for potential urban stormwater drainage blockages. The framework would be using selective explainable machine learning methods with a focus on improving model transparency. This paper presents an interim summary of employing some machine learning models, such as K-nearest neighbours, logistic regression, random forest, artificial neural networks, and XGBoost. The prototype framework discussed in this paper has been developed and evaluated using a set of practical datasets obtained from historical maintenance records of a local city council in Victoria state of Australia, along with some climatic, environmental, socio-economic and asset-related datasets compiled from various sources. In the pilot testing of models of prototype framework, XGBoost demonstrated the best predictive performance, showing a strong ability to capture non-linear relationships in the data. The SHAP global feature importance analysis was used to explore the importance of chosen model parameters, which revealed that specific rainfall and vegetation cover in the catchment zones are the key influencing parameters for predicting potential occurrences of blockages in stormwater drainage systems. Hopefully, the study outcomes at the outset would demonstrate that explainable machine learning can support the development of a smart stormwater drainage asset management digital twin infrastructure.

Keywords – Stormwater infrastructure, Blockage Prediction, Machine Learning, Explainable AI, Predictive Maintenance, Asset Management

1 Introduction

Urban stormwater drainage systems are essential components of modern cities, providing protection against flooding, safeguarding public health, and supporting other operational urban activities. However, these systems face significant challenges due to ageing infrastructure, climate change, growing urbanisation, and expanding cities[1]. Under these conditions, drainage blockages have become a major operational challenge, which reduces the drainage capacity and significantly increases the likelihood of urban flooding[2]. Stormwater blockages are caused by tree root intrusion, sediment deposition, debris and litter accumulation[3, 4]. Therefore, managing these challenges requires effective maintenance strategies that can support informed decision-making in stormwater asset management.

Current stormwater maintenance, such as manual inspections and CCTV inspections, is mostly reactive or schedule-based, where inspections and cleaning activities are driven by public complaints, costly and time-consuming[5, 6]. Consequently, researchers and local councils have increasingly focused on developing proactive approaches that can identify potential blockage issues before failures occur. Such approaches can help enhance system efficiency, prioritise high-risk assets, and reduce the likelihood of unexpected blockage-related failures.

Recent advances in machine learning have led to the development of data-driven prediction models for urban drainage systems. Using historical maintenance data, these models can predict drainage issues at the asset level, enabling proactive maintenance planning [7]. Machine learning techniques are well-suited to capture complex and non-linear relationships between input and output variables, which helps in understanding how key

influencing factors contribute to drainage blockage occurrence[8]. According to [9], Predictive models can achieve substantial cost savings, including reductions of up to 60% in preventive maintenance costs through a 39% decrease in preventive maintenance frequency. Despite their strong predictive performance, one of the main challenges of these models is the lack of transparency, as many high-performing machine learning models are often treated as "black boxes"[10]. Explainable artificial intelligence (XAI) helps transform black-box machine learning models into transparent models by explaining how factors and their contributions affect the final output. This transparency enables decision makers to trust predictions, justify maintenance priorities and allocate resources effectively across infrastructure like drainage networks [11].

Therefore, this study uses classical machine learning models, together with explainable AI methods, to predict and interpret the occurrence of drainage blockages. Historical maintenance data and environmental and climatic variables are used to develop an explainable prediction framework. The study aims to assess model performance, improve understanding of model behaviour, and show how the results can support proactive and risk-based asset management. In future applications, the developed models can be integrated into proactive drainage management frameworks, including digital twin systems, where explainable predictions can support monitoring, maintenance prioritisation, and informed decision-making.

2 Background of Research

Blockage formation in urban drainage systems is a complex process governed by the interaction of physical, environmental, climatic, operational, and socio-economic factors. This complexity limits the effectiveness of traditional analytics approaches, such as statistical approaches to capture nonlinear relations between factors and blockage formation. For example, Statistical models for predicting blockages in drainage systems have several limitations, particularly related to data availability and model assumptions. These models are highly dependent on the quality and resolution of input data, and inaccurate or incomplete records can significantly reduce prediction reliability. For example, Markov chain models require large and consistent datasets describing pipe condition and blockage history, which are often unavailable in municipal records, leading to reduced prediction accuracy [12]. While Log Gaussian Cox models are capable of representing spatio-temporal patterns, they are computationally intensive and require a long simulation time [13]. Similarly, Cox proportional hazards models rely on assumptions that may not adequately represent the nonlinear behaviour. As a result, the applicability of these models remains limited in practical drainage management contexts.

A wide range of machine learning (ML) and deep learning (DL) models have been applied in previous studies to diagnose and predict failures within urban sewer systems. Classical ML approaches, including decision trees, random forests, logistic regression, and support vector machines, have demonstrated strong predictive capability for blockage prediction trained on historical asset and inspection data [14-16]. More recently, deep learning models, such as neural networks, graph-based neural networks, and autoencoder-based frameworks, have enabled the integration of spatiotemporal data and large feature sets to predict deposit accumulation, siltation severity, and cleaning requirements with improved accuracy [17-20]. Despite these advances, most existing predictive models focus on wastewater or combined sewer systems, with limited attention given to stormwater drainage systems. Tran [21], developed a neural network model to assess serviceability conditions of stormwater drainage, but predictive modelling for stormwater-specific blockage behaviour remains underdeveloped.

Many existing studies use a limited set of input variables, mainly focusing on pipe attributes such as diameter, length, age, material, depth, and soil type, as well as population and property density. Although these inputs are commonly used, environmental and catchment-related factors such as land use, vegetation cover (e.g., NDVI), impervious area, and the number of dry days preceding a blockage event are employed in only a limited number of studies. These factors strongly influence runoff, debris movement, and sediment build-up in stormwater systems. Their effects on stormwater blockages are still not well studied, highlighting a clear research gap in stormwater blockage prediction. Moreover, some of these studies try to understand important features from feature importance, but systematic use of model explainability to interpret predictions is also limited in existing literature. This study incorporates stormwater-specific variables into blockage prediction, which have been rarely considered in previous studies. In addition, it introduces the use of explainable machine learning in drainage infrastructure blockage prediction to improve model interpretability. SHAP-based analysis is applied to provide transparent and interpretable insights into how different variables influence blockage formation, supporting more informed maintenance decision-making.

3 Methodology

This section describes the methodology adopted to develop an explainable machine learning framework for predicting stormwater drainage blockages. The overall workflow includes dataset preparation, model development and the use of explainable machine learning for interpreting model outputs. Each component of the methodology is described as shown in Figure 1.

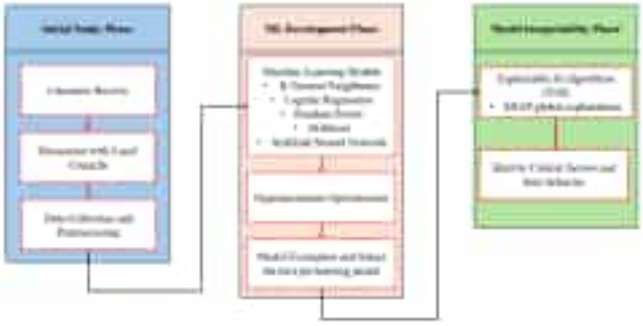

Figure 1. Research Methodology

3.1 Dataset and Variables

The dataset used in this study was provided by the Frankston council in Victoria, Australia. It comprises historical stormwater maintenance records collected between 2019 and 2025, totalling 4407 records. The stormwater drainage network includes 40,083 pipes, totalling about 1,059 km, culverts, and open drains, connected by around 41,003 stormwater pits. Pipe diameters range from 150 mm to 3,300 mm, representing both local collection pipes and larger downstream conveyance pipes. A key limitation of the dataset is that blockage information is primarily recorded at the pit level, which limits the direct use of detailed pipe attributes, such as diameter, length, and slope, as input parameters.

The factors considered in this study were identified through a comprehensive review of existing literature and experts' discussions with the local council based on their operational experience and practical knowledge of stormwater drainage management. The input factors used in this study, along with their corresponding data sources, are summarised in Table 1.

Table 1. Factors Considered in this Study

Input factor	Unit	Description
Rainfall	mm	Rainfall amount before the blockage event
Number of dry days	Days	Days without rainfall before the blockage event
Land Use	%	Impervious land use in the catchment
Number of Connections	-	Number of pipes connected to pits
NDVI	-	Vegetation cover across the area
Network density	(km/km^2)	Drainage network length per area
Population density	(Persons/km^2)	Population per unit area

Rainfall is the cumulative rainfall before a blockage event as an indicator of stormwater runoff. The number of dry days was defined as the consecutive days with rainfall less than 1 mm before a blockage, representing dry-weather periods that influence debris accumulation [22]. Some variables, such as land use and population density, were assumed to remain constant throughout the year due to the lack of high-frequency temporal data. Vegetation cover (NDVI) was derived from Sentinel-2 satellite imagery, providing spatial information on vegetation conditions across the study area.

3.2 Model Development

3.2.1 Types of Models

Classical machine learning models, including K-Nearest Neighbours (KNN), Logistic Regression, Random Forest (RF), XGBoost, and an Artificial Neural Network (ANN), were developed to predict the occurrence of stormwater blockages using the prepared dataset. These models were selected because they have been widely applied in previous studies for prediction and classification problems [23, 24]. Thus, their predictive accuracy and reliability have been well-suited for drainage infrastructure and asset management problems.

3.2.2 Training and Optimization

Model training was performed using historical data, with the dataset divided into training and testing subsets. The dataset consists of 1669 blockage records (37.9% of total records) and 2738 non-blockage records (62.1% of total records). Given this relatively moderate class distribution, no specific class imbalance handling

techniques were applied in this study. Hyperparameter tuning was conducted using a grid search (GS) approach to optimise model performance and prevent overfitting. Five-fold cross-validation (5-fold CV) was applied during training to ensure model robustness and generalisation across different data samples. The optimal model configuration was selected based on consistent performance across validation folds. Additionally, a simple baseline model (logistic regression) was trained without hyperparameters to assess the performance gains of hyper parameterized models. Table 2 shows the optimized hyperparameters used for each model.

Table 2. Optimized hyperparameters of each model

Model	Hyperparameters	Optimum
XGBoost	Max depth	6
	Estimators	400
	Learning rate	0.1
RF	Estimators	400
	Max depth	20
	Minimum sample split	5
KNN	Weights	Distance
	Neighbours	15
	Metric	Manhattan
LR	C	0.7
	Penalty	L1
ANN	Number of hidden layers	2
	Number of neurons per layer	(64,32)

3.2.3 Model Evaluation

The performance of the trained models was evaluated using multiple evaluation metrics obtained from testing data split to assess prediction accuracy (see equations 1-5).

$$Accuracy = \frac{(TP + TN)}{(TP + TN + FP + FN)} \quad (1)$$

$$Precision = \frac{TP}{(TP+FP)} \quad (2)$$

$$Recall = \frac{TP}{(TP+FN)} \quad (3)$$

$$F1score = \frac{(2 \times Precision \times Recall)}{(Precision+Recall)} \quad (4)$$

$$ROC - AUC = Area\ under\ the\ ROC\ curve \quad (5)$$

Where TP is true positives, and FP are false positives. TN is true negatives, and FN are false negatives. The evaluation metrics were obtained using a 70/30 training and testing data split for each model to identify the most accurate model performance. A comparative analysis was conducted across all models, and the best-performing model was subsequently selected for further analysis.

3.3 Explainable AI

To address the black-box nature of machine learning models, explainable artificial intelligence (XAI) techniques were incorporated. SHAP-based global interpretation analyses were used to provide how environmental, climatic, and asset-related factors influence stormwater blockage occurrence. This interpretability enhances confidence in the model predictions and supports transparent, data-driven decision-making for drainage asset management.

4 Results

4.1 Model Performance Evaluation

The trained machine learning models were systematically evaluated to assess their predictive capability. This evaluation is critical to ensure (a) the ability of the proposed machine learning framework to capture complex and non-linear relationships among climatic, environmental, and related other factors under limited data availability, and (b) the robustness of the trained models in accurately predicting blockage occurrence for previously unseen (test) data. Following model training and hyperparameter optimization, performance was assessed using an independent test dataset, as shown in the table 3 below. Table 3 presents a comparative evaluation of the five classification models using Accuracy, F1-score, and ROC–AUC on the test dataset.

Table 3. Results and Model Comparison

Model	Accuracy	F_1 Score	ROC-AUC
XGBoost	0.81	0.74	0.88
RF	0.80	0.74	0.87
KNN	0.77	0.71	0.85
ANN	0.72	0.56	0.76
LR (With hyperparameters)	0.61	0.55	0.66
LR (Baseline model)	0.66	0.35	0.65

According to Table 3, among all models, XGBoost achieved the best overall performance, with an accuracy of 0.81, an F1-score of 0.74, and the highest ROC–AUC value of 0.88. Random Forest showed comparable performance (accuracy = 0.80, ROC–AUC = 0.87), indicating that ensemble tree-based models are also

effective for capturing the complex and non-linear relationships governing stormwater drainage blockages. KNN demonstrated moderate predictive capability (accuracy = 0.77, F_1 = 0.71, ROC–AUC = 0.85), while Logistic Regression (F_1 = 0.55, ROC–AUC = 0.66) and ANN (F_1 = 0.56, ROC–AUC = 0.76) showed comparatively lower performance, especially in terms of F1-score and ROC–AUC. ANN models typically require larger datasets to effectively capture complex patterns and avoid overfitting. In contrast, classical machine learning algorithms such as Random Forest and boosting models (e.g., XGBoost) often perform better with less training data and require less extensive hyperparameter tuning [25]. Moreover, a baseline Logistic Regression model without hyperparameter tuning was implemented to provide a simple benchmark for comparison of optimized models over traditional ML models. The baseline model produced performance (accuracy = 0.66, F1 = 0.35, ROC–AUC = 0.65). In terms of accuracy, it has a slight accuracy improvement over the Logistic Regression with hyperparameters, but overall performances of optimized models outperforming traditional ML models. Figure 2 shows ROC–AUC curves for the tested models, illustrating their classification performance on the test dataset.

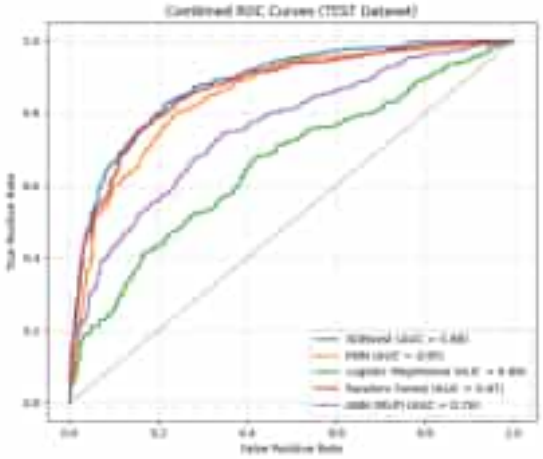

Figure 2. ROC-AUC Curves for each model

In addition to standard evaluation metrics, the confusion matrix for the best-performing model was analysed to better understand the model's misclassification patterns, as shown in Figure 3. The presence of false positives indicates that some non-blockage cases were predicted as blockages, which may lead to unnecessary inspections or preventive maintenance actions. Conversely, false negatives are cases in which actual blockages were predicted as non-blockages, potentially leading to undetected issues in the drainage network.

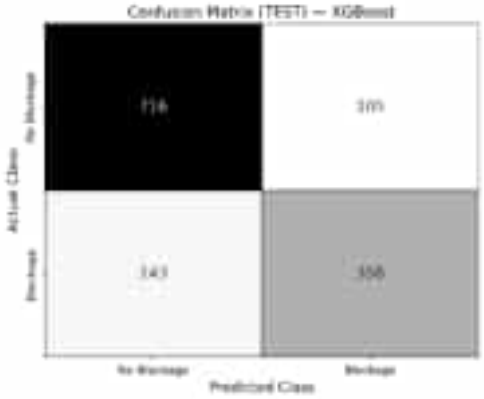

Figure 3. Confusion Matrix for test data set for XGBoost model

According to the figure, most samples are correctly classified compared to misclassified cases, indicating that the model performs well in distinguishing blockage and non-blockage events.

4.2 SHAP Explanation

To interpret the best-performing model, SHAP-based explainable AI analysis was applied to the XGBoost classifier. The explanation is shown in Figure 3.

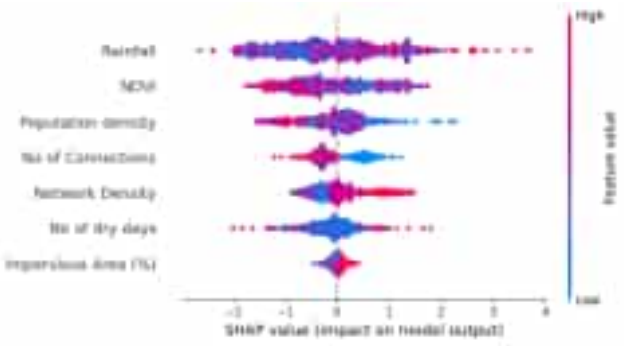

Figure 4. SHAP Summary plot

The SHAP summary plot reveals that rainfall is the most influential predictor of blockage occurrence, followed by NDVI, population density, and the number of connections. Higher rainfall values generally increase the likelihood of blockages because rainfall generates higher runoff that carries debris and sediment into pits and pipes. The SHAP results for NDVI indicate that higher and mean NDVI values are associated with an increased likelihood of blockage, likely due to greater vegetation coverage, which contributes organic debris to the drainage system. Although higher population density generally increases blockage likelihood, the SHAP plot

shows that low population density can also contribute to higher blockage risk in certain cases. This occurs when low-density areas may interact with other dominant factors, such as high rainfall, NDVI, etc. Network characteristics (e.g., network density and number of connections) also exhibit significant contributions, highlighting the influence of infrastructure complexity on blockage formation. Higher values of antecedent dry days and impervious area percentage increase blockage risk, but their influence is relatively smaller. These results not only enhance model transparency but also provide physically and operationally meaningful insights to support decision-making.

5 Conclusions and Future Works

This paper developed and evaluated a data-driven predictive framework for the occurrence of stormwater drainage blockages, focusing on model performance and interpretability. Among the machine learning approaches, the XGBoost model achieved the best predictive performance, capturing complex, non-linear relationships between drainage blockages and external influencing factors. The use of explainable artificial intelligence helped address the black-box nature of the model by clearly identifying the key factors influencing blockage predictions. The results show that rainfall and vegetation indicators (NDVI) are the dominant factors, and other environmental factors have a strong influence on blockage occurrence. The outputs of this study can be integrated with decision-support systems such as multi-criteria decision-making (MCDM) methods to support inspection prioritization, maintenance scheduling, and resource allocation. For instance, explainable blockage risk factors can be translated into criteria weights or constraint rules within MCDM frameworks, enabling transparent ranking of assets that require priority maintenance or inspection. Moreover, the direct effect of pipe attributes is limited in this study; they are still useful when combined with environmental and climatic factors. The main reason for this is that maintenance data are recorded at the pit level rather than for individual pipes. Therefore, methods such as pit–pipe mapping link each pit to its connected pipe segments based on the network topology, allowing pipe attributes such as diameter, length, slope, and material to be incorporated indirectly into the model and could improve predictive performance up to a certain level in future versions. Overall, these findings demonstrate both the strengths and limitations of the proposed approach and support its use as a data-driven tool for risk-based stormwater drainage asset management.

Future work focuses on extending the proposed predictive framework to improve interpretability, robustness, and practical applicability. This includes incorporating local explanations and feature dependency analysis using explainable AI to better understand how blockages vary across individual cases and operating conditions. The model can be integrated with additional input variables, such as traffic intensity, soil type, humidity, and temperature, which influence debris accumulation, sediment transport, and moisture conditions within the drainage network. In addition, the current occurrence-based prediction will be extended towards a risk-based formulation by incorporating blockage frequency and severity to predict the blockage risk for a better understanding of critical drainage assets. Also, future studies could extend the current model by incorporating graph-based or hybrid deep learning approaches, such as Graph Neural Networks (GNNs), which can explicitly capture spatial dependencies, network connectivity, and upstream–downstream interactions within urban drainage systems, since the input variables in the current model are treated independently and do not explicitly represent network relationships.

The framework will also be extended to incorporate real-time sensor data, including water level and flow measurements, to enable early blockage detection and warning alerts. In addition, coupling the predictive model with hydraulic modelling will enable scenario-based assessment of system performance under different rainfall and blockage conditions. By integrating real-time sensor data with physics-based hydraulic models, this model can be improved as a data analytics layer of a digital twin environment of stormwater drainage systems. Furthermore, 3D BIM visualisation will be used for asset condition monitoring to represent critical drainage assets under various predicted blockage risks to enhance visualisation capabilities.

Abstract – Electrical system modeling in BIM environments still relies heavily on manual interpretation of 2D CAD drawings, which can propagate circuit and panelboard assignment errors and increase rework. This paper presents an AI-driven, a parametric CAD–BIM workflow that automates outlet-to-circuit assignment and circuit-to-panelboard connections while maintaining semantic traceability. CAD plan views are captured as images and processed with a multimodal large-language model (Microsoft Copilot). Through iterative prompt engineering, the system extracts outlet identifiers, associated distribution board, and element counts, and exports a structured Excel dataset for downstream automation. Autodesk Dynamo and Python then ingest the dataset, match it to Revit parametric families, and execute rule-based logic to generate circuits and connect them to the target panelboard. The approach was validated on five real case studies from a data-center project by comparing a conventional manual Revit procedure against the automated workflow using execution time and review-stage errors as performance metrics. For 42 outlets, the manual procedure took 31.5 minutes and produced six misassignments, whereas the automated routine completed in 0.033 seconds with zero errors; for 24 outlets, the manual procedure took 12 minutes with two errors, while the automated routine took 0.025 seconds with zero errors.

1 Introduction

The increasing scale and technical complexity of contemporary construction projects have intensified the demand for accurate, consistent, and interoperable information management across the design and execution stages [1]. In this context, electrical system planning remains heavily dependent on two-dimensional CAD documentation, in which circuit layouts, outlet distributions, and panel assignments are commonly interpreted manually, introducing coordination risks and propagating errors into downstream BIM processes [2]. Although Building Information Modeling has enhanced multidisciplinary coordination and centralized data, its application to electrical design workflows is often constrained by fragmented information transfer between CAD drawings and BIM environments [3]. These limitations become particularly critical when repetitive components, standardized electrical conventions, and regulatory requirements must be maintained consistently across multiple project iterations [4]. Deficiencies in early-stage electrical data integration can lead to misaligned circuit assignments, inconsistent schedules, and increased rework during construction, directly affecting project cost, time, and model reliability. Current digital practices, including spreadsheet-based coordination and rule-based verification, provide partial support but continue to rely heavily on manual intervention. As a result, recent research has increasingly explored artificial intelligence and parametric programming as enabling technologies for interpreting structured graphical information and implementing automated logic within BIM workflows [5]. By combining AI-assisted extraction of graphical inputs with parametric scripts that support semantic matching and rule-driven classification, it becomes feasible to bridge the persistent gap between CAD-based electrical plans and BIM models [6]. This integration supports automated outlet identification, circuit correspondence, and panel allocation while preserving consistency between design documentation and digital representations. In this setting, the convergence of CAD inputs, AI-driven data structuring, and parametric automation within BIM platforms emerges as a promising pathway to enhance reliability, reduce human error, and improve efficiency in electrical system modeling [7].

The accelerated adoption of artificial intelligence across industrial domains has reshaped how technical information is processed, interpreted, and operationalized, particularly in environments with large volumes of graphical data and repetitive decision rules [8]. In construction-related workflows, AI-driven solutions have progressively enabled automated drawing interpretation, data structuring, and rule-based decision support, offering new opportunities to reduce manual

effort and improve consistency in digital models [9]. Within BIM-centered processes, these technologies have been applied to scheduling, coordination, and analytical tasks, providing near-real-time feedback that was previously unattainable with conventional tools. At the same time, advances in machine learning and generative systems have enabled the transformation of unstructured visual inputs into structured datasets that parametric environments can directly consume. This capability is especially relevant in electrical design processes, where information embedded in CAD drawings must be accurately translated into BIM elements while preserving naming conventions, circuit logic, and panel relationships. Despite these advances, adoption remains uneven due to organizational inertia, limited standardization, and the technical complexity of integrating AI outputs into interoperable BIM workflows [10]. Lightweight, task-oriented AI tools have recently emerged as a practical entry point for embedding intelligence into traditional manual processes, enabling incremental experimentation with lower implementation barriers [11]. However, a clear methodological gap persists in integrating AI-based graphical extraction, intermediate data processing, and parametric automation into a coherent end-to-end workflow. Addressing this gap is essential to move from isolated AI applications toward reliable automation strategies that support data-driven decision-making and consistent model generation in BIM-based electrical system design [12].

Although prior research has extensively examined the application of artificial intelligence and automation within BIM-based environments, most contributions have focused on isolated tasks or domain-specific use cases, leaving unresolved questions about their systematic integration into end-to-end design workflows [6]. Existing studies have explored AI-driven methods for graphical information extraction [13], parametric modeling strategies, and interoperability solutions between CAD and BIM platforms [14], demonstrating measurable improvements in efficiency and data consistency. However, these approaches are often implemented independently, without a unified methodological structure that integrates graphical interpretation, intermediate data processing, and automated model generation within a single workflow. Limited attention has been paid to electrical design processes, in which circuit logic, outlet distribution, and panel assignment rely heavily on manual interpretation of CAD drawings and on repetitive decision rules. The lack of integrated solutions to automate these tasks contributes to inconsistencies between design documentation and BIM models, increasing coordination effort and the propagation of errors. In response to this gap, this research aims to propose an AI-driven, parametric workflow that systematically links CAD-based electrical drawings, automated graphical information extraction, structured data processing, and BIM model generation through programming-based automation. The proposed approach enables the automated identification and assignment of electrical outlets and circuits while preserving semantic coherence [illegible]

parametric programming, and CAD–BIM interoperability within a unified framework, this study advances a reproducible, scalable methodology that addresses critical limitations identified in the current literature and supports more reliable digital modeling of electrical systems.

2 Literature Background

The growing complexity of construction projects and the increasing reliance on digital workflows have reinforced Building Information Modeling (BIM) as a central platform for managing geometric and semantic information throughout the project lifecycle [15,16]. Although BIM has demonstrated significant benefits in coordination and information integration, its effectiveness is often constrained by continued reliance on two-dimensional CAD-based documentation, which requires manual interpretation and limits automation potential [2]. Recent research has therefore shifted toward incorporating computational and data-driven approaches to enhance the transformation of graphical information into structured BIM environments [17]. Advances in artificial intelligence, parametric programming, and interoperability strategies have enabled new methods for extracting, processing, and reusing design data with reduced human intervention [18]. Studies indicate that integrating image-based analysis, rule-based logic, and visual programming can improve consistency, traceability, and scalability in BIM workflows, especially in disciplines characterized by repetitive elements and strict design conventions [19]. Despite these developments, the literature remains fragmented regarding how these approaches are jointly implemented within coherent methodological frameworks. This fragmentation highlights the need for a structured review of existing contributions addressing AI-based graphical information extraction, parametric automation in BIM, and CAD–BIM interoperability, as foundational components for advancing automated and reliable digital modeling processes.

Recent academic contributions reveal a growing focus on integrating artificial intelligence, parametric automation, and interoperability within BIM-based workflows, driven by the need to reduce manual modeling and improve semantic consistency across digital construction processes. Montas-Laracuente et al. [20] presented a systematic examination of AI-driven Scan-to-BIM strategies, highlighting the dominance of deep learning approaches for semantic segmentation of point clouds and images, while exposing limitations in end-to-end automation and BIM interoperability. Kutá et al. [21] offered a comprehensive overview of AI adoption throughout BIM-enabled project lifecycles, demonstrating advances in automation, generative processes, and digital twins. However, their analysis underscored the dependence on structured data and expert validation. Araya-Aliaga et al. [22] introduced an integrated AI–BIM framework to automate the generation and validation of geometric and semantic information, reporting higher model coherence, reduced manual effort, and improved data traceability. Harle [23]

extracting visual and geometric data within BIM environments, reporting enhanced element recognition alongside unresolved challenges related to model generalization and platform interoperability. Taken together, these studies reflect steady progress in AI-assisted BIM workflows, yet they consistently point to fragmented implementations across disciplines and project stages.

Building on these developments, further research has advanced AI–BIM integration to support safety monitoring, parametric reconstruction, and performance-driven analysis. Wang et al. [24] demonstrated the feasibility of computer vision–based systems for identifying construction activities and unsafe behaviors from site imagery, achieving high accuracy in real-time safety monitoring. Salmi et al. [25] proposed a BIM-based parametric modeling strategy for generating Mine Information Models from heterogeneous spatial datasets, showing that algorithmic rules and parametric objects enable accurate reconstruction with limited human intervention. Semjén et al. [26] synthesized existing knowledge on parametric and generative design within BIM workflows, revealing optimization gains during early design phases while noting persistent issues related to standardization and lifecycle integration. Kamel et al. [3] analyzed BIM–BEM interoperability processes, identifying semantic inconsistencies and data loss during information exchange. Su et al. [27] developed a BIM–machine learning framework for automated property valuation that combines IFC data with optimized regression models, achieving higher accuracy than traditional methods. Zhang et al. [28] integrated BIM for building energy efficiency, highlighting its role in energy prediction and lifecycle assessment, but noted that interoperability issues and costs limit adoption. Collectively, the literature depicts a landscape in which AI, parametric automation, and interoperability are treated as partially isolated components. In response to this gap, the present paper advances an integrated methodology that connects CAD-based electrical drawings, AI-assisted graphical information extraction, and parametric automation in Dynamo to automate the assignment and connection of electrical outlets in BIM models. This contribution introduces a structured, end-to-end workflow that enhances consistency, reduces errors, and improves efficiency in electrical modeling processes, directly addressing limitations identified in prior studies.

3 Research Method

3.1 Image-Based Data Extraction Process

The methodological workflow began by formalizing a procedure for extracting information from CAD-derived images of electrical layouts, with a focus on outlet tags and distribution boards, as shown in plan views. A multimodal large language interface (Microsoft Copilot) was then utilized to identify and parse the visual attributes embedded in the CAD imagery. To ensure reliable extraction, a structured prompt engineering process was conducted through iterative refinement, ambiguity in label detection, color-based classification, and record structuring. After approximately 20 iterations, a stable prompt specification was established, enabling the automated identification of three key variables for downstream automation: the outlet identifier, the associated panelboard, and the count of outlets in the drawing segment.

The extracted information was exported into a structured Microsoft Excel file, which served as the standardized input dataset for the subsequent parametric assignment of outlets to panels and circuits within Autodesk Revit. Prompt calibration was conducted using three representative CAD images. Simultaneously, two professionals with extensive experience in interpreting CAD electrical drawings independently reviewed the same images and generated reference reports, which served as a baseline for comparison. The final prompt achieved complete agreement with the expert-derived outputs on the calibration set, confirming its reliability as a preprocessing mechanism for transforming unstructured plan-image content into machine-readable data for BIM-based automation. **Error! Reference source not found.** shows the instructions for generating the prompt for data extraction.

Table 1. Prompt used in data extraction.

Id	Actions	Instructions
1	Label identification	- Extract all visible labels in the image. - Each label follows the format BaseText-#Number. - Read and process the image from top to bottom. - If the first element is blue, classify it as Secondary (S) and the next as Primary (P), alternating thereafter. - If the first element is red, classify it as Primary (P) and the next as Secondary (S), alternating thereafter.
2	Base-text cleaning	- Remove the suffix -#Number and keep only the base text (e.g., RPPBB112-#1 → RPPBB112).
3	Table generation	- The table must contain three columns: a) Type: P or S b) Base label: the base text without the suffix c) Count: a consecutive index starting at 1 and ending at the total number of elements.

Although the prompt reached full agreement with the expert-generated outputs for the calibration images, the AI extraction stage should be interpreted as a calibrated preprocessing component rather than as a universally deterministic procedure. Because multimodal large language models may exhibit non-deterministic behavior, the reproducibility of the extraction depends on maintaining the same prompt structure, image preparation criteria, and review protocol. The extraction is also sensitive to variations in drawing legibility, annotation density, color conventions, and screenshot quality, which may affect robustness when different CAD standards are used. For this reason, the workflow incorporates expert validation during calibration and fixes the final prompt before evaluation. In addition, the present study assessed the extraction process only with Microsoft Copilot; therefore, the transferability of the results to other AI tools remains a relevant limitation that should be examined in future research.

3.2 Development of an Automated Tool in a BIM Environment

The BIM tool that automates the assignment of electrical outlets to distribution boards, leveraging the structured dataset produced by the Microsoft Copilot–based analysis, was implemented using Autodesk Dynamo as the primary development environment. As a prerequisite, a dedicated library of parametric families was created in Autodesk Revit to represent outlets and distribution board, encoding the key attributes required for identification, matching, and subsequent parameter assignment. These families were designed to conform to the labeling logic and graphical conventions observed in the CAD drawings analyzed by the AI component, thereby ensuring semantic alignment among the source documentation, the extracted Excel dataset, and the target BIM model. The Dynamo algorithm was structured into three main modules: (1) an input-processing module responsible for reading, parsing, and validating the Excel file generated by the AI pipeline; (2) a matching module that compares outlet identifiers obtained from the spreadsheet with the corresponding identifiers embedded in the Revit family instances, incorporating basic normalization rules to reduce mismatches due to formatting differences; and (3) an assignment module that programmatically links each matched outlet instance to its corresponding panelboard within the BIM model by writing the appropriate parameter values. In this third module, once a valid name-based correspondence is detected, the algorithm automatically populates the outlet instance with the associated board information, enabling consistent model-wide traceability of outlet-to-board relationships. An initial prototype was subjected to desktop-based functional tests to verify correct behavior under the expected input conditions and with the developed parametric families. Following calibration of the matching and assignment logic, a first compiled version of the Dynamo workflow was produced as the baseline implementation for subsequent evaluation and refinement.

3.3 Validation and Calibration

Building on the procedures outlined in Sections 3.1 and 3.2, the validation and calibration processes were designed to test the proposed workflow under realistic modeling conditions and to evaluate its operational performance against a conventional manual baseline. This assessment compared the standard Revit-based circuit assignment process, which relied on direct interpretation of CAD electrical documentation, with the automated implementations using Dynamo and Python. The primary performance indicators for this comparison were execution time and the number of misassignments identified during the review stage. A unified set of five real-world case studies from a data center project was selected, featuring outlet rows with varying densities and configurations. This selection aims to assess the workflow's stability across different input conditions. For each case study, a reference assignment was generated from the CAD documentation and used as a benchmark circuit-to-panelboard relationships.

Calibration was conducted before validation by performing desktop-based functional tests on an initial prototype. This was done to verify that the developed parametric families operated correctly with the expected input structure. Refinements focused on consolidating the matching and assignment logic to create a stable baseline workflow. Subsequently, the parameters were fixed to prevent any adjustments during the evaluation runs. To ensure comparability, manual timing excluded file preparation overhead and captured only the assignment activity, while automated timing measured the end-to-end script runtime. Accuracy was assessed by counting discrepancies identified during the review stage and comparing them with the reference assignment list. This approach enabled consistent reporting across cases and facilitated replication of the evaluation protocol.

4 Results

4.1 Proposed framework

Figure 1 presents the proposed framework for automating outlet-to-circuit assignment and circuit-to-panel connection in a BIM environment, based on information extracted from CAD drawings with AI assistance. The workflow starts by compiling the project’s technical documentation, generating screenshots from the AutoCAD plan views, selecting rows or groups of outlets, and verifying the legibility of electrical symbols and annotations. This step is repeated until a consolidated image is obtained with sufficient resolution and the largest possible number of clearly identifiable elements. The consolidated image is then processed in Microsoft Copilot using structured prompts that guide the interpretation of annotations and symbols, enabling the identification of outlets and the extraction of the required attributes, outlet identifier, circuit, and panel, which are organized into a dataset exported in Excel format. In the automation stage, the Excel file is imported into Dynamo to locate the corresponding outlets in the Revit model, retrieve their spatial coordinates (X, Y, and Z), establish spatial ordering, and execute Python scripts that generate circuits and connect each outlet to its corresponding distribution board. The outcome is an updated BIM model in which the electrical assignment consistently reflects the information specified in the CAD drawings, reducing manual effort during circuiting and panel configuration.

4.2 Evaluation framework and algorithmic workflow

To rigorously evaluate the performance of the Python-based automated workflow for assigning electrical outlets to circuits in BIM environments, five real-world case studies from a data center project were defined. The evaluation compared the traditional manual procedure in Revit, which relies on direct interpretation of electrical CAD drawings, with the proposed automated solution. Execution time and the number of errors detected during the review stage were selected as

in the literature as critical factors influencing BIM model reliability and efficiency in MEP disciplines. Figure 2 shows a representative row of outlets requiring circuit assignment, highlighting the high level of geometric and functional repetition that characterizes this configuration and that, under manual workflows, increases the likelihood of inconsistencies. This operational context is particularly relevant, as previous studies on BIM automation emphasize that the greatest efficiency gains occur in repetitive, rule-governed tasks driven by structured graphical information.

Algorithmic architecture comprises four clearly defined stages, as shown in Figure 2**Error! Reference source not found.**. In the first stage, the system automatically identifies outlet families within the BIM model and extracts their spatial coordinates (X, Y, Z). The second stage processes the Y-coordinate exclusively, which is critical in this case study, given the vertical arrangement of the outlets. Sorting these values in descending order establishes a spatial hierarchy consistent with the logic embedded in the original electrical drawings. Subsequently, a Python-based node filters secondary outlets, recognizing that they appear in paired configurations with primary outlets and that the study focuses only on assigning primary elements. The third stage automatically generates electrical circuits in Revit, associating each primary outlet with its corresponding circuit. In contrast, the fourth stage performs the bulk connection of all generated circuits to the selected panelboard, completing the workflow without manual intervention (see Figure 2). This sequential structure ensures traceability between extracted geometric data and electrical assignment decisions, directly addressing limitations reported in prior CAD–BIM interoperability solutions.

4.3 Case study analysis and critical performance assessment.

The validation of automated BIM workflows requires empirical evidence that goes beyond proof-of-concept demonstrations and explicitly examines their behavior under realistic modeling conditions. In this context, the proposed AI-driven parametric workflow was evaluated through a unified set of five real case studies derived from a data center project, each representing rows of electrical outlets with varying densities, configurations, and operational constraints. The assessment compares the conventional manual circuit-assignment process in Revit, guided by CAD-based electrical documentation, with the automated solution implemented through Python scripts and Dynamo integration. Execution time and assignment accuracy were adopted as the primary performance indicators, since both metrics directly affect modeling efficiency, coordination reliability, and the quality of subsequent construction documentation (Table 22. Impact of AI-driven parametric automation on efficiency and accuracy in CAD–BIM electrical workflows.). The reported time corresponds exclusively to the circuit-assignment stage: manual assignment time in Revit versus the algorithm execution time once the input is available. The preparation of that input file, generated by the AI component after the extraction process, was not included in the measurement because prompt refinement represents a one-time, non-recurring calibration cost, while CAD image capture was also excluded because it is independent of the assignment process under analysis. The results reveal a consistent and substantial reduction in execution time when automation is applied, with gains increasing proportionally to the number of outlets involved. This behavior suggests that the algorithm exhibits favorable scalability characteristics, particularly in environments dominated by repetitive elements and a strict sequencing logic. In large outlet rows with more than 40 elements, the automated workflow effectively mitigates the cumulative delays inherent to manual selection, verification, and circuit creation, a limitation frequently reported in BIM-based electrical coordination studies.

In terms of accuracy and model reliability, the automated workflow performed consistently across all evaluated cases, although a slight discrepancy in Case 3 (48 outlets) indicates that minor variations may still occur under specific conditions. By contrast, the manual approach showed increasing inconsistencies as task repetition and dataset size grew, mainly due to incorrect circuit–panel associations, misinterpretation of CAD references, and omissions in repetitive assignments. Supported by geometric filtering, rule-based ordering, and parametric control, the deterministic algorithm produced consistent and reproducible outcomes that reduced human-induced variability. Although time savings were evident even in small-scale scenarios, the advantage of automation became more pronounced in larger datasets, where manual execution led to disproportionate increases in time and error risk. Unlike prior AI-assisted BIM approaches focused on isolated tasks, the proposed workflow integrates graphical

interpretation, data processing, and circuit assignment into a unified pipeline, strengthening model consistency and supporting scalable electrical system modeling in complex BIM environments. Table 2 summarizes the case studies, comparing manual and automated methods by execution time and errors.

Table 22. Impact of AI-driven parametric automation on efficiency and accuracy in CAD–BIM electrical workflows.

Case Studies	# Outlets	Manual method		Automated method	
		Time (min)	Errors	Time (min)	Errors
Case 1	42	31.50	6	0.03	0
Case 2	24	12.20	2	0.02	0
Case 3	48	72.50	10	0.01	1
Case 4	12	8.32	1	0.02	0
Case 5	6	4.33	0	0.02	0

4.4 Comparative impact on efficiency, accuracy, and model reliability

Beyond improvements in execution time and error reduction, the comparative evaluation reveals structural limitations in prevailing electrical modeling automation approaches. Prior studies often focus on partial automation or decision-support systems that accelerate isolated tasks while maintaining manual interpretation during critical CAD–BIM translation stages. In contrast, the proposed workflow demonstrates that substantial performance gains arise when rule definition, geometric filtering, and assignment logic are fully formalized within a unified algorithmic process. This approach effectively decouples modeling effort from the number of elements, overcoming the efficiency decline commonly observed in manual and semi-automated BIM practices as task repetition increases.

From an accuracy perspective, the findings indicate an epistemic shift rather than a minor technical improvement. Manual workflows depend on continuous cognitive validation, introducing variability, fatigue-related errors, and inconsistencies that scale with repetition. While previous studies mitigate these issues through visual checks or post-processing validation, the proposed method embeds decision rules directly into the execution logic, eliminating interpretative ambiguity at its source. The results therefore challenge the assumption that human oversight is essential for correctness in complex electrical assignments, showing that deterministic, geometry-driven logic can outperform manual reasoning in highly repetitive and regulated design contexts.

The workflow also improves BIM model reliability compared with fragmented automation strategies reported in prior research. Whereas many studies automate extraction or classification without resolving downstream connectivity, the proposed approach ensures consistent outlet-to-circuit and circuit-to-panel relationships, producing a more stable, auditable, and reusable model for coordination, simulation, and operation. Overall, the results support viewing AI-driven and parametric CAD–BIM automation not merely as a productivity enhancement, but as a structural mechanism for enforcing design logic and reducing systemic uncertainty.

Conclusions

This study provides three main theoretical contributions. First, it proposes an end-to-end CAD-to-BIM automation workflow for electrical outlet assignment by integrating graphical capture, AI-assisted information extraction, structured data processing, and BIM-based parametric execution. Second, it defines the role of AI as a mechanism for converting unstructured electrical CAD information into structured datasets that support rule-based BIM automation while reducing manual interpretation. Finally, it introduces a reproducible rule-driven logic for outlet-to-circuit and circuit-to-panelboard assignment, demonstrating how repetitive MEP tasks can be formalized into deterministic BIM workflows that improve semantic consistency in model authoring.

The theoretical contributions of this study have practical applications in industry workflows. The proposed method integrates AI-based data structuring with Dynamo and Python scripting in Revit, significantly reducing the time for outlet and circuit assignments while enhancing consistency during model reviews. Validation through five case studies highlighted two representative tests: in the first, manual assignment of 42 outlets took 31.5 minutes with six errors, while the automated workflow completed it in 0.033 seconds without mistakes. In the second, the manual process for 24 outlets took 12 minutes with two errors, and the automated method finished in 0.025 seconds error-free. These results demonstrate a shift from expert-dependent processes prone to human error to a rule-based, structured input workflow, reducing rework and improving model reliability, especially in projects with repetitive electrical configurations.

Despite the contributions of this study, several limitations remain. The empirical assessment was based on two data center case studies with high geometric repetition and a spatial layout that enabled classification mainly along a single coordinate, which may restrict the generalizability of the findings to projects with more heterogeneous designs, multiple distribution logics, or different outlet-matching patterns. In addition, the

proposed workflow depends on consistent outlet family identification and naming across CAD documentation, the AI-assisted structured dataset, and BIM parameters, so variations in drafting standards, screenshot quality, or prompt sensitivity may affect its robustness. The system also does not explicitly verify compliance with electrical engineering regulations, including circuit load capacity, load balancing, or conformity with applicable codes, as these were treated as predefined input conditions. Future research should therefore validate the approach across a wider range of building typologies and electrical design conventions, explore direct data extraction from CAD sources instead of image captures, incorporate automated checks for electrical rules and model consistency, and examine adoption-related aspects, including setup effort, script maintainability, and input governance at the organizational scale.

Abstract -

Automated point cloud understanding is critical for modern digital construction workflows, yet existing datasets focus predominantly on architectural elements, leaving complex mechanical, electrical, and plumbing (MEP) systems severely underrepresented. This paper introduces Industrial3D, the first large-scale, high-fidelity dataset specifically designed for industrial MEP scene understanding. Industrial3D comprises over 610 million expertly labeled points across 13 water treatment facilities, captured at 6mm terrestrial LiDAR resolution with 12 specialized MEP and structural classes, representing 4× the scale of existing construction datasets. The dataset exhibits extreme class imbalance (215:1 ratio) and geometric ambiguity where over 86% of tail-class points share cylindrical primitives with the dominant pipe class, creating systematic challenges absent in architectural benchmarks. We evaluate representative methods across learning paradigms, including fully-supervised approaches (KPConv, ResPointNet++, PosPool, and a class-balanced variant) and unsupervised methods (GrowSP). Our evaluation reveals that current state-of-the-art methods face significant limitations in specialized industrial domains, particularly for small, functionally critical components such as valves, strainers, and reducers. Fully-supervised methods achieve approximately 53–54% mIoU, while unsupervised GrowSP reaches only 11.7% mIoU and fails completely on most tail classes. These results point to research opportunities in long-tailed learning and geometry-aware segmentation for industrial scenes. Industrial3D provides a resource for advancing automated construction verification and Scan-to-BIM workflows. Dataset and code will be publicly available at: `https://github.com/pointcloudyc/Industrial3D`.

Point Cloud Dataset; MEP Systems; Semantic Segmentation; Benchmark; Terrestrial Laser Scanning; Industrial Scene Understanding

1 Introduction

Automated point cloud understanding is essential for modern digital construction workflows, including as-built verification, progress monitoring, and automated Building Information Model (BIM) generation [1, 2]. Terrestrial laser scanning (TLS) has become the standard for rapid, high-fidelity 3D data acquisition, capturing billions of geometric measurements of complex mechanical, electrical, and plumbing (MEP) systems. However, a critical bottleneck persists: transforming raw point clouds into actionable semantic understanding remains challenging, particularly for complex industrial environments where MEP systems exhibit intricate geometric relationships, extreme scale variations, and severe occlusion.

Consider a typical water treatment facility: pipes with identical cylindrical geometry serve different functions, small components like valves are embedded within larger structural systems, and dense equipment arrangements create challenging visibility conditions. Current point cloud understanding methods achieve strong results on architectural datasets like S3DIS [3] and ScanNet [4], but struggle with the specialized demands of industrial MEP environments. Existing datasets exhibit three fundamental limitations: (1) *domain mismatch*, focusing on furniture and architectural elements rather than MEP systems; (2) *insufficient scale*, with inadequate point density and scene complexity for fine-grained industrial analysis; and (3) *limited class diversity*, lacking specialized MEP components critical for construction applications.

To address these limitations, we introduce Industrial3D, the first large-scale, high-fidelity dataset specifically designed for industrial MEP scene understanding. Industrial3D comprises over 610 million expertly labeled points across 13 water treatment facilities, captured at 6mm TLS resolution with 12 specialized MEP and structural classes. We also evaluate representative methods across learning paradigms, including fully-supervised approaches (KPConv [5], ResPointNet++ [6], PosPool [7], and a class-

balanced variant using CB loss [8]) and the unsupervised method GrowSP [9], providing baseline performance metrics and analysis of domain-specific challenges.

2 Related Work

2.1 Point Cloud Datasets

Large-scale annotated datasets have driven progress in point cloud understanding. S3DIS [3] provides 273 million points across 271 rooms with 13 classes focused on architectural elements and furniture. ScanNet [4] expands to 1,500 indoor scans with 20 classes but maintains similar architectural bias. Semantic3D [10] offers outdoor scenes with 4 billion points but limited class diversity. Construction-specific datasets remain scarce: CLOI [11] includes industrial objects but has limited public availability, while PSNet5 [6] provides a medium-scale MEP-specific publicly available dataset with 80 million points across 5 classes, yet remains limited in scale and class diversity. Table 1 summarizes the comparison.

These datasets share critical limitations for MEP understanding: domain mismatch (architectural focus versus MEP complexity), insufficient resolution for fine-grained components, and absence of specialized classes like valves, flanges, and pumps. Industrial3D addresses these gaps as the first large-scale public dataset targeting MEP understanding, with 610M+ points at 6mm resolution across 12 specialized classes—4× the scale of existing construction datasets.

Table 1. Comparison of Industrial3D with existing point cloud datasets. M = million, B = billion. * indicates limited public availability.

Dataset	Type	Points	Classes	Imbal.
S3DIS	Indoor	273M	13	62:1
ScanNet	Indoor	242M	20	~25:1
Semantic3D	Outdoor	4B	8	75:1
CLOI*	Industrial	140M	10	–
PSNet5	Industrial	80M	5	~50:1
Industrial3D	**Industrial**	**610M**	**12**	**215:1**

2.2 Point Cloud Semantic Segmentation

Deep learning has driven significant progress in point cloud semantic segmentation [12]. PointNet [13] pioneered neural architectures for 3D point clouds, while PointNet++ [14] extended this with hierarchical feature learning. Recent advances include kernel-based convolutions (KPConv [5]), efficient random sampling strategies (RandLA-Net [15]), and local aggregation operators (PosPool [7]).

Construction-specific applications have further explored these architectures. Our prior work ResPointNet++ [6] integrated residual learning into PointNet++ for industrial MEP segmentation with 5 classes on the PSNet5 dataset, and SE-PseudoGrid [16] introduced squeeze-and-excitation attention for piping component classification. Beyond supervised learning, unsupervised methods like GrowSP [9] learn semantic groupings without labels through primitive clustering and superpoint growing. Industrial3D enables systematic evaluation of these representative methods on real-world industrial MEP scenes with 12 classes.

3 Industrial3D Dataset

3.1 Data Acquisition and Annotation

The Industrial3D dataset was captured from 13 large-scale rooms within operational water treatment facilities in Hong Kong. These scenes were selected for their diverse and complex arrangements of MEP and structural components. The total scanned area covers approximately 20,000 m^2, encompassing over 2.3 billion raw 3D points. Table 2 provides statistics of seven representative scenes.

Table 2. Statistics of seven representative scenes in Industrial3D, showing the scale and diversity of industrial environments captured.

Scene	Length (m)	Width (m)	Area (m^2)
Chiller	45.1	19.2	865.92
OGB	86.2	42.5	3,663.50
OSCG	15.3	38.2	584.46
PBF2_1	58.0	22.0	1,276.00
PBF2_2	68.4	38.2	2,612.88
SPH	36.1	26.9	971.09
WRT2	53.3	23.7	1,263.21
Total	-	-	**11,237.06**

High-fidelity point cloud data was acquired using a Leica BLK360 terrestrial laser scanner [17], as shown in Figure 1. This instrument captures 360,000 points per second with 6mm accuracy at 10-meter range, which is critical for capturing small MEP components. Multiple scans were performed within each room from different locations to ensure comprehensive coverage. Raw scan data was processed using Autodesk ReCap software for registration and format conversion.

The annotation process required approximately 754 person-hours to complete, with five domain experts labeling over 610 million points. We defined 12 semantic classes encompassing MEP and structural elements, as detailed in Table 3. Using CloudCompare [18], annotators followed a systematic pipeline: tiling large scenes into manageable chunks, extracting point clusters for each class, merging results, and refining boundaries with outlier removal. Figure 2 illustrates representative instances of each semantic category. Notably, the geometric similarity among pipe-related classes (pipe, elbow, tee, reducer) creates significant geometric ambiguity, where over 86%

Figure 1. Data acquisition setup for Industrial3D (source from [6]). (a) Partial view of the WRT2 scene showing complex industrial piping systems. (b) Leica BLK360 terrestrial laser scanner during data acquisition with iPad controller for scan registration and preview.

Figure 2. Representative instances of each semantic category in Industrial3D, visualized as synthetic point clouds sampled from BIM models. Note: these are idealized representations; actual LiDAR scans exhibit significant occlusion, noise, and incomplete coverage due to terrestrial scanning geometry.

of tail-class points share cylindrical primitives with the dominant pipe class.

Table 3. The 12 semantic classes in Industrial3D, grouped by frequency. Head classes account for 77% of total points; tail classes each represent less than 3%.

Class	Description
Head classes (77% of points)	
Pipe	Cylindrical conduits for fluid transport
RectangularBeam	Rectangular structural support members
Duct	Rectangular air handling conduits
Common classes	
Ibeam	I-shaped structural steel beams
Tank	Large storage vessels
Tail classes (<3% each)	
Flange	Circular connecting components
Valve	Flow control devices
Pump	Mechanical fluid movement devices
Strainer	Filtration devices in pipe systems
Elbow	Angular pipe connectors
Tee	T-shaped pipe junction fittings
Reducer	Pipe diameter transition fittings

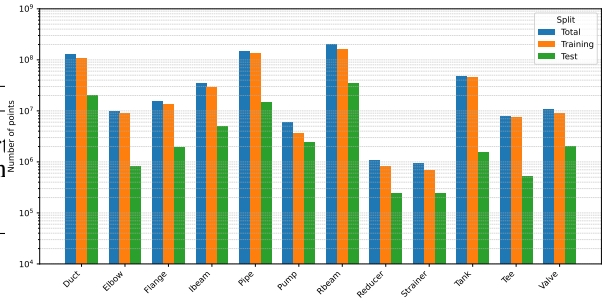

Figure 3. Category-wise point distribution in Industrial3D (logarithmic scale). The severe class imbalance (215:1 ratio) between head classes (Pipe, RectangularBeam, Duct) and tail classes (Reducer, Strainer, Tee) is characteristic of real-world industrial environments.

3.2 Dataset Statistics and Visualization

The final dataset comprises over 610 million expertly labeled points. Each point includes 3D coordinates (X, Y, Z), intensity, and RGB color values. The dataset exhibits significant class imbalance with a 215:1 ratio between the most and least frequent classes—3.5× more severe than S3DIS (62:1). Figure 3 shows the category-wise point distribution on a logarithmic scale. Figure 4 presents the distribution of semantic categories across different industrial areas. Figure 5 provides qualitative visualizations of two representative scenes.

3.3 Dataset Characteristics

Industrial3D differs from existing datasets in several ways: (1) **Scale**, 4× larger than existing industrial datasets with 610M+ labeled points; (2) **Public availability**, as the first large-scale publicly available industrial MEP dataset; (3) **Class diversity**, with 12 specialized MEP and structural classes absent from architectural benchmarks; and (4) **Challenge severity**, the most extreme class imbalance (215:1) among comparable benchmarks, combined with geometric ambiguity where functionally different components share similar cylindrical shapes.

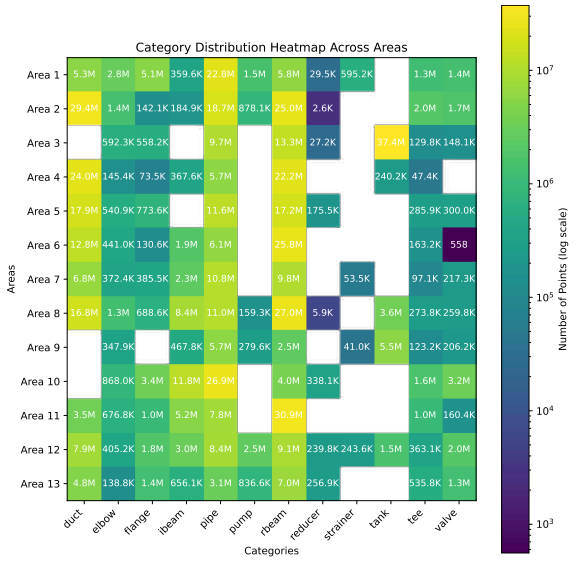

Figure 4. Heatmap showing distribution of semantic categories across industrial areas in Industrial3D. Values are displayed in millions (M) or thousands (K) of points. Structural elements are distributed across all areas, while specialized functional components are concentrated in operation-specific zones.

4 Benchmark Experiments

4.1 Experimental Setup

We partition Industrial3D into a test set (Area 6 and Area 12) and a training set (remaining areas), following the S3DIS area-based evaluation protocol [3]. Area 6 (PBF2_2, Primary Biological Filter) and Area 12 (SPH, Sludge Press House) were selected as test sets because they represent spatially separated facilities with distinct operational characteristics: Area 6 features dense piping arrangements typical of biological filtration systems, while Area 12 contains all diverse mechanical equipment including presses and pumps. This split ensures evaluation on unseen facility types, testing generalization capability across different industrial environments. We evaluate representative methods across two learning paradigms: (1) fully-supervised approaches including ResPointNet++ [6], KPConv [5], PosPool [7], and ResPointNet++ with class-balanced (CB) loss [8]; and (2) the unsupervised method GrowSP [9]. We report overall accuracy (OA), mean Intersection-over-Union (mIoU), and per-class IoU as evaluation metrics.

4.2 Fully-Supervised Results

Table 4 presents benchmark results for fully-supervised methods. All methods achieve similar overall performance (mIoU $\approx$ 53–54%) but exhibit substantial gaps on tail classes. ResPointNet++ achieves 53.31% mIoU

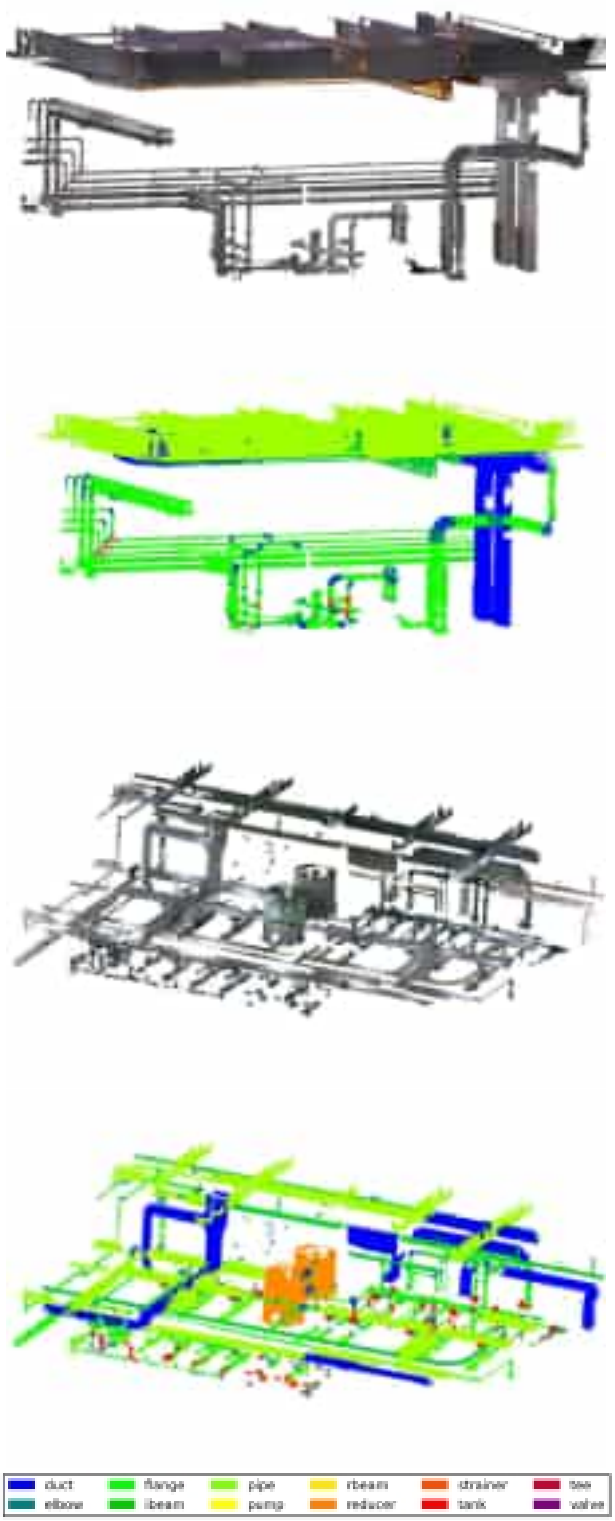

Figure 5. Qualitative visualization of two representative scenes from Industrial3D. Each scene shows: (1) raw point cloud data with RGB color; (2) semantic annotations with class-specific coloring. Rows from top to bottom: Area 6-1 (dense piping region) raw data and annotated data, and Area 12 (Sludge Press House - SPH scene) raw data and annotated

with strong performance on head classes (Duct: 91.36%, Ibeam: 99.41%, RectBeam: 95.19%) but struggles with rare components (Reducer: 0.00%, Strainer: 0.00%). KPConv shows similar patterns with 53.65% mIoU. PosPool achieves non-zero performance on Reducer (34.48%) but comparable overall mIoU at 53.18%. The class-balanced variant (ResPointNet++ w. CB) improves Reducer performance to 14.92% and achieves the highest mIoU at 54.05%, demonstrating that addressing class imbalance provides modest gains.

The results reveal a "dual crisis" in industrial point cloud segmentation: statistical rarity combined with geometric ambiguity. Critical functional components (valves, pumps, strainers) achieve significantly lower IoU than structural elements. The complete failure on Strainer (0.00% for all methods) results from multiple factors: (1) insufficient training samples (Strainer represents only 0.6% of training points), (2) geometric similarity to pipes (both are cylindrical), and (3) small physical size making these components difficult to distinguish from surrounding clutter. For Reducer and Tee, geometric ambiguity is the primary issue, these components share cylindrical primitives with pipes, causing systematic confusion. The class-balanced variant shows modest improvement on Reducer (14.92% IoU versus 0.00%), confirming that frequency-based re-weighting helps but cannot fully resolve geometric ambiguity. For an in-depth treatment including proposed solutions, we refer readers to our long-tailed learning methods paper [19].

4.3 Unsupervised Results

Table 5 presents results for GrowSP [9], which learns semantic groupings through unsupervised primitive clustering and superpoint growing. We evaluate three stages of the GrowSP pipeline: initial primitive extraction, superpoint formation, and final primitive merging to understand performance at each processing level.

GrowSP achieves 84.57% OA and 42.06% mIoU at the superpoint stage, demonstrating reasonable performance on geometrically distinct classes such as Tank (90.61%), RectBeam (86.23%), and Pipe (73.46%). However, performance degrades substantially for fine-grained MEP components: Elbow (4.19%), Reducer (0.00%), and Strainer (0.00%) are nearly or completely unrecognized. The primitive merging stage leads to severe performance collapse (mIoU drops to 11.73%), indicating that the merging heuristics fail to preserve semantic boundaries in complex industrial scenes.

These results demonstrate that while GrowSP can capture coarse geometric structure without supervision, it fundamentally struggles with the fine-grained distinctions required for MEP components. The 11-point mIoU gap between GrowSP (42.06%) and supervised methods (∼54%) indicates that domain-specific supervision remains essential for accurate industrial scene understanding.

5 Conclusion and Future Work

We introduced Industrial3D, the first large-scale, high-fidelity point cloud dataset for industrial MEP scene understanding. With over 610 million labeled points across 12 specialized classes from 13 water treatment facilities, Industrial3D provides 4× the scale of existing construction datasets while exhibiting authentic industrial challenges: severe class imbalance (215:1), geometric ambiguity where 86% of tail-class points share primitives with head classes, and complex occlusion patterns. Our benchmark evaluation reveals that fully-supervised methods achieve approximately 53–54% mIoU but struggle significantly with tail classes. The unsupervised GrowSP method achieves only 11.7% mIoU and fails completely on multiple tail classes (Reducer, Strainer, Tee at the merged stage). These results point to fundamental research gaps in handling geometrically ambiguous and statistically rare components.

Addressing these challenges requires multi-faceted approaches. For extreme class imbalance, techniques such as class-balanced loss functions [8], re-sampling strategies, and two-stage training can help models learn from tail classes. However, as our class-balanced experiments show (Reducer improving from 0.00% to 14.92% IoU), re-weighting alone is insufficient due to geometric ambiguity. Effectively distinguishing functionally different but geometrically similar components (e.g., pipes versus reducers) requires geometry-aware segmentation that leverages topological relationships, cylindrical primitive fitting, and multi-modal feature fusion combining geometric (XYZ), appearance (RGB), and intensity information. Industrial3D provides the testbed for developing such specialized approaches.

Future work will expand benchmarking to include weakly-supervised methods (SQN [20], CPCM [21], and WSSS-ST [22]), self-supervised approaches (PointContrast [23], OcCo [24]), and foundation models (Point-SAM [25], Reason3D [26]) to evaluate their effectiveness under sparse supervision and zero-shot settings. Beyond semantic segmentation, Industrial3D enables research in instance segmentation, geometric primitive fitting, and topological relationship inference, critical steps toward fully automated Scan-to-BIM workflows. We will release Industrial3D publicly to support research in automated construction verification and digital twin generation.

Abstract

Construction robotics has significant potential to improve the efficiency, quality, and safety of structural assembly, yet its practical deployment is constrained by the limited availability of online task sequence optimization methods. This study focuses on gantry robots performing connection tasks in floor frame assembly under limited nail magazine capacity. To improve operational efficiency, the sequencing problem is formulated as a split-delivery vehicle routing problem (SDVRP). An attention-based deep reinforcement learning (DRL) model is employed to learn routing policies, and its performance is compared against an exact solver (Gurobi), a genetic algorithm (GA), and a nearest-neighbor (NN) heuristic. Experiment results show that the DRL policy achieves solutions within 2.1% of the optimal benchmark while requiring only 0.1s per instance. Additional tests across different nail capacities demonstrate robustness to distribution shifts. Overall, the results highlight the potential of attention-based DRL for fast and high-quality task sequence optimization, representing the first application of this approach to robotic structural assembly connection operations.

Deep Reinforcement Learning; Optimization; Construction Robot; Task Sequence; Structural Assembly Connection

1 Introduction

The construction sector continues to face sustained challenges from skilled labour shortages, worker health and safety concerns, and modest growth in productivity [1]. Within this context, structural assembly constitutes a fundamental construction activity in which discrete components are connected to form larger systems such as walls, floors, and roofs [2,3]. These operations are particularly well suited to partial or full automation using robotic systems owing to their repetitive and physically demanding nature [4].

With recent advances in robotics, gantry robots have been adopted across diverse applications such as timber prefabrication [5], rebar tying [6], furniture manufacturing [7], and shipbuilding [8], owing to their ability to transport materials efficiently across large workspaces. These robotic systems are increasingly regarded as promising platforms for automating structural assembly tasks. An example of an overhead gantry robot performing floor-frame connection operations is illustrated in Figure 1.

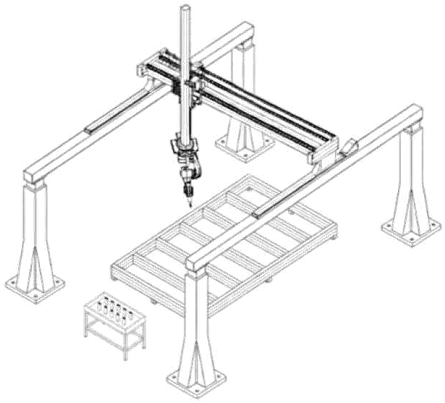

Figure 1. Example of a gantry robot performing connection tasks in timber floor-frame assembly

In practical construction settings, human workers naturally plan and adapt their own task sequences, whereas robots rely on explicitly specified task sequences to operate efficiently [9]. When gantry robots are used for connection tasks in structural assembly, their productivity depends critically on the quality of task sequence planning.

This study addresses this challenge by formulating task sequence optimization for robotic connection operations as a split-delivery vehicle routing problem (SDVRP) and solving it using an attention-based deep reinforcement learning (DRL) model. The performance of the trained policy is compared against heuristic methods and an exact solver, and its generalization capability is evaluated across varying problem settings. This proposed method achieves solutions within 2.1% of

the optimal benchmark while requiring only 0.1s per instance, and maintains competitive performance when nail capacities remain close to the training dataset range.

2 Literature Review

2.1 Gantry Robot Applications in Structural Assembly

Gantry systems have long been used in the construction industry, with early applications appearing in the 1980s. During this period, gantry platforms were installed in temporary site factories on top of buildings under construction and were progressively raised as each floor was completed [10]. With continued advancements, gantry robots have been increasingly adopted for assembly operations. In industry practice, IronBot (for rebar lifting and placement) and TyBot (for rebar tying) developed by Advanced Construction Robotics are notable examples. They exhibit a high level of autonomy, including automated rebar grasping, placement, intersection detection, and tying execution [5].

In the research domain, Chai et al. presented an integrated timber construction platform incorporating a gantry-based multi-robot system, sensing, control, and a timber machining center to enable multifunctional prefabrication of timber components [6]. Wenna et al. developed a digital-twin framework for 3D path planning of a large-span curved-arm gantry robot for automated wooden-furniture production, enabling the generation of collision-free and efficient trajectories [7]. Other studies have focused on gantry robots for connection operations. For example, Saleem et al. designed a six-degree-of-freedom gantry welding robot through mathematical modelling and mechanical design [11]. Similarly, an improved RRT* algorithm was proposed for gantry-mounted welding robots to enhance planning efficiency and reliability in complex environments [8].

The majority of prior research focuses on path planning and control methods to ensure safe and efficient operation. However, few studies address task sequencing optimization, despite its importance for assembly efficiency. This gap motivates the present study on gantry robotic connection operations in structural assembly.

2.2 Task Sequencing in Robotic Structural Assembly

Although task sequencing has been studied only rarely for gantry robotic structural assembly, research on a broader range of robotic systems, including aerial robots and robotic arms, provides useful insights.

In multi-robot structural assembly, Muñoz et al. integrate a constraint-based vehicle routing problem (VRP) solver with a hierarchical task network (HTN) planner [12]. Assembly tasks are abstracted into a VRP formulation, where the VRP solver provides an initial task allocation and coarse sequencing. The HTN planner subsequently expands these assignments into executable schedules. The two planners operate in a closed feedback loop, and the method is validated through simulations of aerial robots assembling a truss-like structure. The VRP solver part relies on heuristic search strategies rather than exact optimization.

Yang et al. address assembly sequence planning for timber wall framing using a robotic arm [13]. Their method jointly considers stud placement and fastening operations while incorporating task precedence constraints. A modified A* algorithm is used to identify an executable assembly sequence, where the accumulated end-effector travel distance forms the actual cost, and the remaining cost is estimated using a minimum spanning tree (MST)-based heuristic. This approach highlights the role of domain-specific heuristics in navigating the assembly sequence planning.

You et al. explored the use of large language models (LLMs) for structural assembly task sequencing [14]. Their system, RoboGPT, leverages ChatGPT's reasoning capabilities to autonomously generate and adapt task sequences. The approach is validated using a single robotic arm executing assembly tasks, demonstrating the feasibility of LLM-driven task planning through direct application programming interface (API) integration.

To the best of the authors' knowledge, no existing studies on robotic structural assembly have employed DRL for task sequence planning. Among the various optimization methods, attention-based DRL has shown strong potential for tackling combinatorial optimization problems, in some cases outperforming traditional metaheuristic algorithms [15], and has already been explored in related manufacturing applications [16]. A further advantage of DRL is its fast inference: once trained, the policy produces near-instantaneous solutions without a repeated optimization process, enabling online adaptation to robotic structural assembly.

In summary, task sequencing research for gantry robotic structural assembly remains limited, and DRL-based optimization in structural assembly is still lacking. This study addresses these gaps by applying an attention-based DRL model [17] to an SDVRP formulation of gantry robot connection tasks in structural assembly.

3 Methodology

3.1 Problem Formulation and Abstraction

This study investigates a common application scenario of gantry robots in structural assembly, in which a robot equipped with a nailing end-effector executes

floor frame connections. The robot must periodically return to a storage location for refilling after a certain number of nailing operations because the nailing end-effector has a limited magazine capacity. Consequently, the execution sequence of the nailing tasks directly determines the robot's total travel distance and, in turn, the assembly efficiency.

During assembly, the gantry robot operates within a predefined workspace free of internal obstacles, enabling collision-free motion of the end-effector. In this study, the robot is assumed to first travel in the horizontal plane from the storage location to a point vertically above the target nailing position, and then perform a vertical approach to the connection plane to execute the nailing operation. Since this vertical motion contributes a constant and negligible portion of the overall travel effort, the travel cost between the storage and each nailing task is approximated by the two-dimensional Euclidean distance in the horizontal plane.

Based on the abstraction, the robotic nailing process is modeled as an SDVRP. The SDVRP is a variant of the classical VRP defined on a set of customer nodes and a depot, in which each customer has a demand, vehicles have limited capacity, and demands may be fulfilled through multiple vehicle visits. The goal is to determine a set of routes originating from and returning to the depot that minimizes the total travel cost while satisfying vehicle capacity constraints.

In the robotic structural assembly nailing setting, the storage location is treated as the depot, the capacity of the nailing end-effector as the vehicle capacity, and each connection task as a customer node with a corresponding demand. The objective is to determine a sequence of nailing operations that minimizes the total travel distance while satisfying the capacity constraint.

Among the available methods for solving the SDVRP, attention-based DRL offers fast inference, strong combinatorial optimization capability, and promising potential for complex construction scenarios [15,17–19]. Accordingly, this study adopts an attention-based DRL framework for the formulated SDVRP.

3.2 Optimization Framework

The Transformer is an encoder–decoder architecture built around the attention mechanism, enabling highly parallelizable sequence modeling through self-attention blocks [20]. Building on the Transformer architecture, attention-based models can effectively capture global dependencies and combinatorial structure, making them well-suited to sequential decision-making under constraints. Accordingly, routing problems such as the SDVRP can be formulated as sequence generation: instance features (e.g., locations, demands, and capacity) are embedded and encoded by an attention-based encoder [21], and a decoder then sequentially selects the next node to construct one or more feasible tours [17].

While Transformers in natural language processing are typically trained in a supervised, next-token-prediction manner using large text corpora, deep models for routing problems are often trained without access to optimal solutions. Instead, these models are commonly optimized using reinforcement learning, where the policy interacts with an environment, receives a scalar reward reflecting solution quality (e.g., total route length or cost), and is updated via policy-gradient methods [15,17,22].

This study employs the attention-based transformer model proposed by Kool et al. [17] to solve the SDVRP. Since its introduction in 2019, this model has become a milestone in attention-based DRL for combinatorial optimization and has been widely applied to routing problems, such as the traveling salesman problem (TSP), the orienteering problem (OP), the capacitated vehicle routing problem (CVRP), SDVRP and the prize-collecting TSP (PCTSP). In this framework, the routing problem is formulated as a sequential decision-making process, in which a parameterized stochastic policy is learned to construct feasible solutions. The policy is implemented using an attention-based encoder–decoder neural network and optimized with the REINFORCE algorithm [23] with a deterministic greedy rollout baseline.

The following subsections describe the proposed optimization framework in detail, including the Markov decision process (MDP) formulation, policy definition, neural network architecture, and DRL training procedure in the context of the SDVRP.

3.2.1 MDP Formulation and Policy Definition

The SDVRP is formulated as a finite-horizon Markov decision process (MDP), where the agent sequentially constructs a feasible routing solution. At each decision step t, the state s_t captures the problem instance and the current routing status, including the current location, remaining vehicle capacity, and the remaining demand of each task. An action a_t corresponds to selecting the next node to visit, subject to feasibility constraints enforced by action masking. An episode terminates when all tasks are fully served, and the solution quality is evaluated by a terminal cost corresponding to the total travel distance.

Based on this MDP formulation, a stochastic policy $p_\theta(\pi|x)$ is learned to construct a complete routing solution for a given problem instance x. A feasible solution is represented by an ordered sequence of node indices $\pi = (\pi_1, \dots, \pi_n)$, where π_t denotes the node selected at decision step t. The objective of the policy is to generate a complete sequence that satisfies all problem constraints while minimizing the overall travel cost.

The attention-based model defines this policy in an autoregressive manner. Specifically, the conditional

probability of generating a complete solution sequence π is factorized as (1).

$$p_\theta(\pi|x) = \prod_{t=1}^{n} p_\theta(\pi_t \mid x, \pi_{1:t-1}) \quad (1)$$

Here, $\pi_{1:t-1}$ denotes the partial sequence constructed up to step $t-1$, and θ represents the parameters of the neural network.

3.2.2 Neural Network Architecture

The neural network adopts the standard attention-based encoder-decoder architecture proposed by [17]. The encoder consists of three stacked attention layers, each comprising a multi-head self-attention sublayer followed by a node-wise feed-forward sublayer. Skip-connections and batch normalization are applied in each sublayer to stabilize training.

Each input node is represented by its spatial coordinates and associated attributes (e.g., demand), which are first projected into a shared embedding space. Through self-attention, the encoder aggregates information across all nodes, producing context-aware embeddings that capture the global structure of the routing instance.

The decoder constructs a solution in an autoregressive manner. At each decision step, it attends to the encoder embeddings and incorporates information from the partial solution constructed so far. A masking mechanism is applied to exclude infeasible actions, such as selecting already visited nodes or actions that would violate capacity feasibility. The decoder then outputs a probability distribution over all admissible nodes, from which the next node is selected.

3.2.3 DRL Training with REINFORCE

With the policy parameterized by the neural network architecture described above, the policy parameters θ are trained using the REINFORCE algorithm [23] by minimizing the expected cost of solutions sampled from the stochastic policy. For a given problem instance x, the training objective $\mathcal{L}(\theta|x)$ is defined as (2).

$$\mathcal{L}(\theta|x) = E_{p_\theta(\pi|x)}[L(\pi)] \quad (2)$$

$L(\pi)$ is a scalar cost function that evaluates the quality of a solution π. The training objective is optimized using gradient descent, which is calculated with the REINFORCE gradient estimator with a baseline in (3).

$$\nabla\mathcal{L}(\theta|x) = E_{p_\theta(\pi|x)}\big[\big(L(\pi) - b(x)\big)\nabla \log p_\theta(\pi|x)\big] \quad (3)$$

$b(x)$ is a baseline that depends only on the instance x and is used to reduce the variance of the gradient estimate. In this study, $b(x)$ is given by the cost of a deterministic greedy rollout of the current policy.

When the sampled solution π achieves a lower cost than the baseline, the term $L(\pi) - b(x)$ becomes negative, and the gradient update increases the log-probability $\log p_\theta(\pi|x)$ of the selected actions. Conversely, if the sampled solution is worse than the baseline, the update decreases this probability. This formulation supports end-to-end learning without optimal solutions or stepwise supervision.

All experiments were run on a workstation with an Intel Core Ultra 9 185H CPU and an NVIDIA GeForce RTX 4070 Laptop GPU. The DRL model was trained using a fixed set of hyperparameters throughout the study, and the main training settings are summarized in Table 1.

Table 1. Training hyperparameters of the attention-based DRL model

Hyperparameter	Value
Dataset size	1 million instances per epoch
Number of epochs	100
Learning rate	$1e^{-5}$
Batch size	512
Optimizer	Adam
Training duration	Approximately 100 minutes

4 Case Study

4.1 Application Scenario

This study applies an attention-based DRL approach to a representative floor-frame nailing task in structural assembly, with the aim of demonstrating both its effectiveness and practical advantages in structural assembly settings.

Figure 1 in Section 1 illustrates the overall gantry robot system considered in this study. The gantry structure provides overhead motion and defines the robot's operational workspace. A nailing end-effector, integrating both a nail gun and a nail magazine, is mounted on the moving carriage to enable autonomous connection operations. The target floor frame structure to be assembled is on the floor, while the nail storage area, where nail magazines are refilled, is near the boundary of the gantry system. During operation, the robot travels within the gantry workspace to access each connection location and periodically returns to the storage area when the magazine capacity is exhausted.

Figure 2 presents a plan view of the gantry robot workspace and the corresponding floor frame nailing tasks. The dashed boundary indicates the reachable workspace of the gantry system. The floor frame consists of two pairs of horizontal header joists at the top and bottom, connected by 9 vertical cross joists. Nailing demand is intentionally defined as non-uniform across

the joints to reflect realistic fastening requirements. Specifically, the four corner joints between the header joists and outermost cross joists, along with the two midspan joints on the top and bottom headers, are designated as strengthened connections requiring twice as many nails as standard joints.

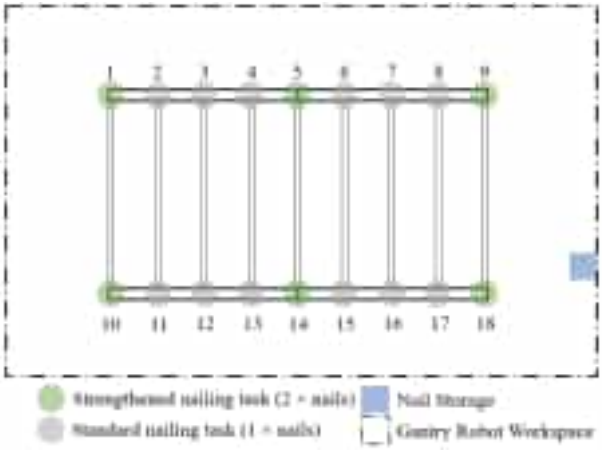

Figure 2. Plan view of the gantry robot workspace and floor-frame assembly

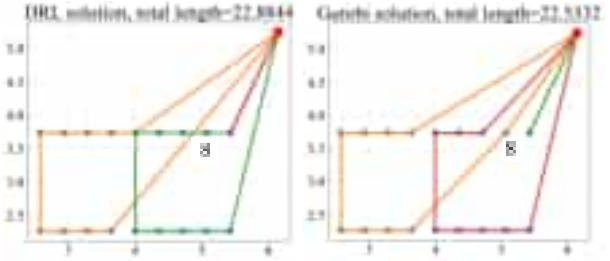
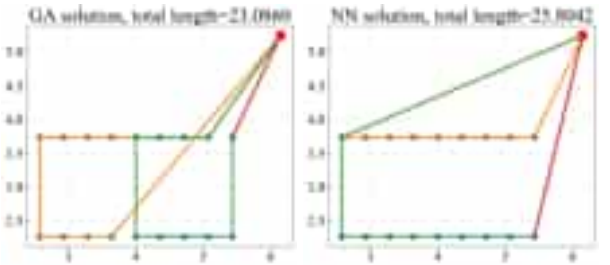
The training instances in this study are generated using a set of predefined rules with a fixed seed. The floor-frame to be assembled is first placed within a 4 m × 2 m rectangular region, with the length of the vertical cross joists sampled uniformly between 1 m and 2 m. The 9 vertical joists are then positioned with center-to-center spacings drawn from a uniform range of 0.3-0.5 m, yielding overall frame dimensions between 2.4 m × 1 m and 4 m × 2 m. The reachable workspace of the gantry system is defined by sampling its plan dimensions between 4 m × 2 m and 8 m × 6 m. The nail storage location is selected along the boundary of this workspace such that it always lies outside the range of the assembled floor frame. For each instance, the nail demand at a standard nailing task is drawn uniformly from 5-11 nails, while the demand at a strengthened nailing task is set to twice this value. The magazine capacity of the nailing end-effector is fixed at 100 nails for all experiments.



4.2 Results

4.2.1 Comparison of DRL with Exact and Heuristic Solvers

With all instances generated using a fixed random seed (seed = 123), 100 problem instances were created under this setting, and the solutions produced by the trained DRL model were compared against those obtained by Gurobi [24], Genetic Algorithm (GA) [25], and Nearest Neighbour (NN) baselines.



Gurobi was used as the optimal benchmark solver. It can obtain globally optimal solutions for small- to medium-scale routing problems within reasonable time, but its computational cost grows rapidly with problem size due to NP-hardness. For large-scale instances (e.g., over 100 connection tasks), solving can take hours or even days, making exact optimization impractical under limited time constraints [24,26].

Figure 3 illustrates the routing solutions obtained by different optimization methods for the first instance generated under seed=123. In this instance, each standard connection task requires 9 nails, while each strengthened connection task requires 18 nails. Overall, both the DRL and GA approaches produce solutions that are close to the optimal routes generated by Gurobi, whereas NN exhibits substantially greater deviation from optimality. Specifically, the primary discrepancy between the DRL result and the Gurobi solution occurs at Connection Task 8: in the Gurobi solution, this task is completed during the return segment of Route 1, thereby reducing the total travel distance.

DRL solution:
Route 1: 13,12,11,10,1,2,3,4,5
Route 2: 18,17,16,15,14,5,6,7,8,9
Route 3: 9

Gurobi solution:
Route 1: 4,3,2,1,10,11,12,13,8
Route 2: 9
Route 3: 7, 6, 5, 14, 15, 16, 17, 18

GA solution:
Route 1: 13,12,11,10,1,2,3,4,6,8
Route 2: 8,7,5,14,15,16,17,18,9
Route 3: 9

NN solution:
Route 1: 9,8,7,6,5,4,3,2,1
Route 2: 1,10,11,12,13,14,15,16,17,18
Route3: 18

Figure 3. Comparison of routing solutions obtained by DRL, Gurobi (optimal), GA and NN for a representative problem instance (1st instance with seed=123)

To mitigate the effects of randomness and robustly evaluate the effectiveness of the DRL approach, all methods were evaluated across the full set of 100 generated instances. The average total travel distance,

percentage gap to the optimal solution, and average computation time are summarized in Table 2. In addition to a deterministic greedy rollout, a stochastic DRL variant based on top-p (nucleus) Monte Carlo sampling was also evaluated, generating 128 candidate routes per instance and selecting the best-performing solution [27].

The results show that both DRL methods (greedy and sampling) achieve solutions within approximately 2.1% of the optimal benchmark, similar to the performance of GA. In contrast, NN exhibits the largest degradation from optimality, with an average gap of 9.6%. In terms of computational efficiency, the DRL inference time for both greedy and sampling remains low (around 0.1s), making it suitable for near-real-time applications. While NN provides the fastest solutions (approximately 0.001s), this advantage is negligible in practical construction planning contexts. GA requires significantly more computation time (over 9s), whereas Gurobi solves each instance in over 1s.

Table 2. Average solution and computation time over 100 generated instances (seed=123)

Solver	Distance (m)	Gap to Best	Time (s)
Gurobi	20.0429	0.00%	1.374
DRL (Greedy)	20.4682	2.12%	0.078
DRL (Sampling)	20.4518	2.04%	0.102
GA	20.4631	2.10%	9.100
NN	21.9632	9.58%	0.001

4.2.2 Generalization Performance under Varying Nail Capacities

The proposed DRL policy is trained on problem instances with a fixed nail capacity of 100. Ideally, such a policy should not only perform well on the training distribution, but also generalize to related problems with different nail capacities. To assess this generalization capability, an out-of-distribution evaluation is conducted on 100 instances generated with seed 123 by varying the nail capacity from 50 to 150 at intervals of 10.

Table 3 reports the average total travel distance obtained by Gurobi and DRL for each capacity level, along with the percentage gap between the DRL solution and the optimal Gurobi solution. When the nail capacity lies between 80 and 150, the DRL policy maintains a reasonably stable performance, with the gap to the optimum remaining below 7%. This indicates that the learned policy can adapt to moderate changes in capacity without substantial degradation in solution quality. However, as the capacity is reduced to 70 and below, the gap increases sharply, reaching 22.2% at capacity 70 and exceeding 40% at capacity 60, with the poorest performance observed at capacity 50 (66.9% gap).

Overall, these results suggest that the DRL policy exhibits satisfactory generalization for capacities within the vicinity of the training setting but deteriorates when applied to substantially different settings characterized by lower capacities. The underlying reasons are further discussed in Section 5.1.

Table 3. Generalization performance of the trained DRL policy under varying nail capacities, compared with Gurobi over 100 generated instances (seed = 123)

Nail Capacity	Gurobi Results (m)	DRL (Greedy) Results (m)	Gap to Best
150	15.6065	16.5800	6.24%
140	16.1545	16.9771	5.09%
130	16.9889	17.9866	5.87%
120	17.2348	18.4647	7.14%
110	18.9855	19.5970	3.22%
100(Trained)	20.0429	20.4682	2.12%
90	21.0676	21.8989	3.95%
80	22.8803	24.2583	6.02%
70	25.1728	30.7637	22.21%
60	27.2099	38.5350	41.62%
50	31.5817	52.7125	66.91%

5 Discussion

5.1 Interpretation of Results

Section 4.2.1 evaluates the trained attention-based DRL policy on randomly generated instances drawn from the same distribution as the training data and compares it against Gurobi, GA, and NN. The DRL policy attains solutions with an average gap of about 2.1% to the optimal benchmark, while requiring around 0.1s per instance. This runtime is compatible with online task sequence planning in structural assembly connection operations, yet still delivers high-quality routes. As problem complexity increases (e.g., to instances with 100 tasks), the constant-time inference property of the DRL policy suggests that sub-second runtimes can still be maintained, while the computational burden of Gurobi and GA is expected to grow substantially. For larger-scale or more constrained instances, Gurobi will experience a sharp increase in computational effort, with solution time extending to hours or longer. Taken together, these comparisons illustrate that the DRL approach occupies a favorable position in the speed-quality trade-off spectrum: sufficiently accurate for near-optimal planning and sufficiently fast for on-site deployment.

Section 4.2.2 examines the generalization of the trained policy to datasets with modified nail capacities. In the application scenario considered, the total nail demand ranges from 120 to 252 nails. When the capacity

is between 90 and 120, the gantry robot typically needs two to three tours to complete all connection tasks, which is consistent with the training instances. In this setting, the policy produces routes that remain close to optimal. For capacities between 130 and 150, some instances can be completed in a single tour, but most still require two tours; the policy continues to perform reasonably well when chaining more connection tasks into each tour. However, when the capacity drops to 80 or below, the robot must undertake many more tours (up to five tours at capacity 60 and six at capacity 50), a condition that never occurred during training. As a result, performance degrades noticeably.

To enhance robustness in such low-capacity settings, future training could expand the training distribution so that the policy encounters a wider range of demand-capacity ratios and more multi-tour scenarios. In the present study, the training instances were designed to reflect the practical application setting, where the nail magazine capacity is 100, and the nail demand per connection task ranges from 5 to 11. Although this setting is realistic for the target scenario, it limits the diversity of tour structures seen during training. Future work could therefore broaden the nail demand range during training, for example, from 2 to 20 nails per connection task, so that the model is exposed to more varied routing patterns and may generalize better to low-capacity cases.

5.2 Limitations and Future Research

Despite the encouraging results, this study has several limitations that point to important directions for future research.

First, the experimental scenarios considered in this study involve a relatively small number of connection tasks (18 tasks). Although the current results demonstrate the feasibility and promise of the proposed method, its computational advantage is expected to become more evident in larger and more complex problem instances. Future studies should therefore consider larger-scale cases and compare the proposed method with exact solvers such as Gurobi and heuristic methods in terms of inference time and solution quality under practical time constraints.

Second, the current formulation assumes a two-dimensional workspace without obstacles, and travel cost is approximated using Euclidean distance. The proposed approach therefore focuses on high-level task sequencing and routing, rather than low-level motion planning. In more realistic construction settings, the resulting task sequence could be combined with lower-level path planning methods, such as RRT* or Dijkstra-based algorithms, so that travel cost is estimated from feasible collision-free trajectories. Extending the framework in this direction remains an important future task. Third, the current framework assumes static task settings and does not account for replanning. In practical construction environments, robots may need to adapt their plans in response to unexpected events, such as delays, partial task completion, or human-robot interactions. Incorporating online replanning mechanisms and dynamic task updates constitutes an important extension of this work.

Finally, the present study evaluates the proposed approach at the algorithmic level only. Future work will focus on validating the method in laboratory-based robotic experiments, which is a necessary step towards real-world deployment in construction settings.

6 Conclusion

This study presented an attention-based DRL framework for task sequence optimization in gantry robotic connection tasks. By formulating the nailing operation as an SDVRP, the proposed method enables systematic optimization of both routing and refilling behavior under nail magazine capacity constraints. Benchmark comparisons with Gurobi, GA, and NN show that the trained DRL policy achieves a favorable balance between solution quality and computational efficiency: solutions remain within 2.1% of the optimal benchmark while requiring only 0.1s of inference time per instance. This constant-time inference property underscores the suitability of the DRL approach for online planning in construction robotics scenarios.

Generalization experiments show that the policy performs reliably for nail capacities close to the training setting but deteriorates when applied to substantially different conditions that require many additional tours. These findings suggest that robustness could be enhanced by training on a broader range of nail magazine capacities and by incorporating greater variability in nail demand across tasks.

Several limitations point to directions for future research. The experiments were conducted on relatively small problem instances in obstacle-free environments, so extending the method to larger assemblies is an important next step. The current framework also assumes static task settings and does not support replanning, which is crucial for handling disruptions in real construction operations. In addition, the approach has been evaluated only at the algorithmic level; laboratory-based robotic experiments are needed to assess practical feasibility. Overall, the results highlight the potential of attention-based DRL task sequence optimization to enable more efficient robotic connection operations.

Abstract -

Semantic understanding of indoor building environments is essential for digitalization, facility management, robotics, and human–computer interaction. However, existing workflows typically decouple data acquisition, semantic interpretation, and 3D reconstruction into offline processes, limiting on-site verification and interaction. This paper presents an extended reality assisted framework for semantic understanding and digitalization of indoor scenes by integrating on-device artificial intelligence based semantic segmentation with photogrammetric reconstruction. Image frames captured using a mixed reality headset are processed in near real time using a lightweight YOLOv11-seg model to obtain object-level detections and segmentation masks. The same image data are subsequently used for Structure-from-Motion reconstruction, where 2D semantic information is spatially propagated into a 3D point cloud and mesh, yielding semantically enriched 3D scene models. These models are visualized and interactively validated by the user within the extended reality environment, enabling immediate assessment of digitalization completeness. The proposed framework demonstrates how extended reality can function as an active tool for near real-time semantic perception, 3D modeling, and user-guided scene digitalization.

1 Introduction

The semantic understanding of indoor building environments is a fundamental requirement for a wide range of applications, including building documentation, facility management, digital twins, robotics, and human–computer interaction [1, 2]. Accurately identifying and localizing building elements and objects within interior spaces enables more efficient digitalization workflows and supports downstream tasks such as asset inventory, spatial analysis, and interaction-aware planning [3]. Despite recent advances in computer vision, most existing semantic understanding approaches rely on offline image processing pipelines, where data are collected on site and analyzed afterward on external computing platforms [4]. This separation between data acquisition and semantic interpretation limits responsiveness, hinders on-site verification, and often requires repeated visits when additional information is needed or errors are discovered during post-processing.

Recent progress in artificial intelligence (AI), particularly deep learning–based semantic and instance segmentation, has significantly improved the automated recognition of objects and scene elements from images [5, 6]. These methods have demonstrated strong performance in both outdoor and indoor environments, enabling pixel-level delineation of semantic classes and supporting dense scene understanding [7]. However, most AI-driven semantic segmentation workflows remain inherently two-dimensional, operating on individual images or image sequences without explicit spatial grounding [8]. As a result, semantic information is often disconnected from the three-dimensional (3D) structure of the environment, limiting its interpretability and usefulness for spatial reasoning, digital modeling, and interactive applications [9].

In parallel, photogrammetric reconstruction techniques such as Structure-from-Motion (SfM) have become well established for generating accurate 3D representations of indoor scenes from image collections [10, 11]. While these methods provide detailed geometric models, they typically lack semantic richness, producing unstructured point clouds or meshes that require additional processing to identify meaningful objects or building elements [12, 13]. Bridging the gap between 2D semantic perception and 3D geometric reconstruction remains a key challenge, particularly in scenarios where rapid feedback, validation, and interaction with the reconstructed scene are required [14, 15].

Extended Reality (XR) technologies—including augmented, virtual, and mixed reality—offer a unique opportunity to address these challenges by tightly coupling perception, computation, and visualization within a single interactive platform [16, 17]. XR head-mounted devices

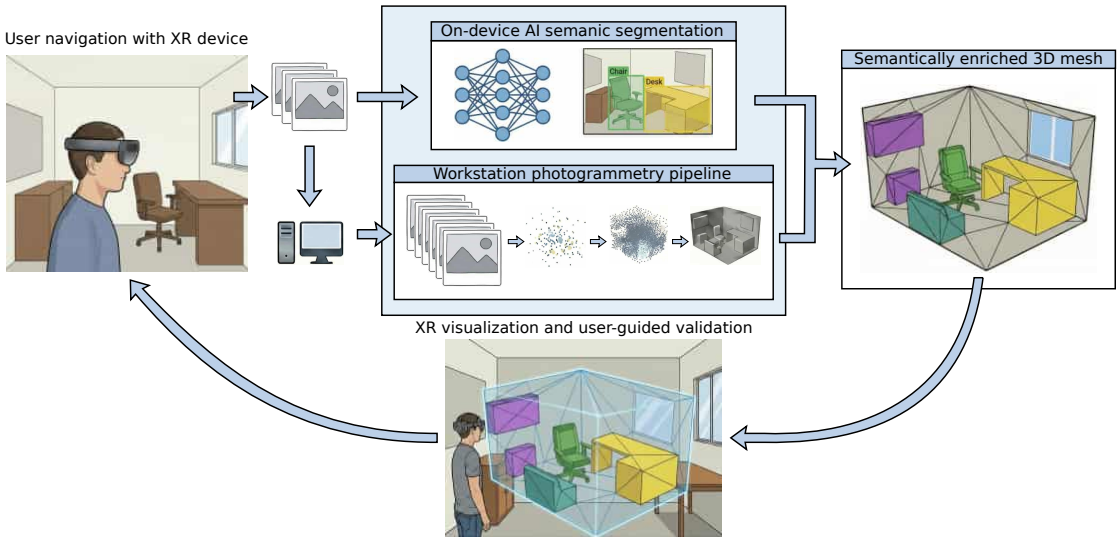

Figure 1. Closed-loop XR-assisted pipeline for semantic scene understanding. On-device semantic segmentation is performed on image frames acquired with a mixed reality headset, while photogrammetric reconstruction is executed on an external workstation. Semantic information is propagated into a 3D reconstruction and visualized in XR for interactive validation.

enable hands-free, spatially aware interaction with both physical and digital content, allowing users to observe, verify, and contextualize AI-generated information directly within the environment being analyzed [18]. Compared to conventional mobile devices or laptops, XR systems provide an immersive interface that supports near real-time understanding of spatial relationships, immediate validation of captured data, and intuitive exploration of semantic and geometric representations [19]. These capabilities are particularly beneficial for indoor scene digitalization, where occlusions, clutter, and complex layouts make purely image-based verification difficult.

Despite these advantages, current XR-based applications for semantic scene understanding remain limited. Many systems focus primarily on visualization, while AI-based semantic interpretation is performed offline or relies on cloud-based processing, introducing latency and restricting near real-time interaction [20, 21]. Furthermore, semantic outputs are often displayed in 2D overlays without enforcing spatial consistency across views or integrating semantic labels into a coherent 3D scene representation [22]. This limits the ability to verify semantic accuracy on site and reduces the usefulness of XR as an active tool for scene digitalization rather than a passive visualization interface.

To address these limitations, this paper proposes an XR-assisted framework for semantic understanding of indoor building scenes that integrates AI-based segmentation with photogrammetric reconstruction. In the proposed approach, images acquired using a mixed reality (MR) headset are processed using a deep learning–based segmentation model to identify semantic elements within the scene. The same image set is then used for SfM reconstruction to generate a 3D representation of the environment. By associating 2D semantic predictions with the reconstructed geometry, semantic information is spatially propagated into the 3D scene, enabling the creation of semantically enriched 3D models. These models are subsequently visualized and explored within the XR environment, allowing users to inspect, validate, and interact with semantic scene representations directly on site.

The contributions of this work are threefold:

- An XR-assisted pipeline for indoor semantic scene understanding, combining AI-based image segmentation and photogrammetric reconstruction within a unified workflow.
- A method for spatially consistent projection of 2D semantic information into 3D reconstructed scenes, enabling semantically enriched models of indoor environments.
- An interactive XR visualization framework that supports near real-time verification and exploration of semantic 3D scenes, facilitating immediate validation of digitalization results.

By shifting XR from a passive visualization tool to an active component of semantic scene understanding and digitalization, this work demonstrates the potential of XR-enabled AI systems to support more efficient, reliable, and interactive indoor environment modeling. Given the scope of this paper, the emphasis is placed on demonstrating the feasibility and end-to-end integration of the proposed workflow rather than on a comprehensive quantitative benchmarking of its components. The proposed frame-

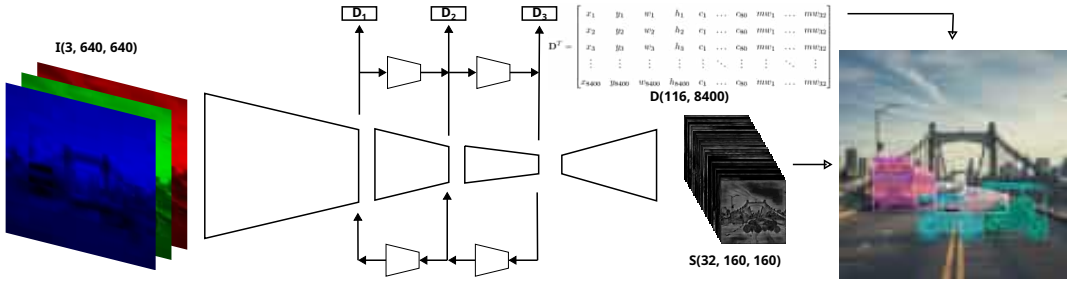

Figure 2. Overview of the YOLOv11-seg architecture used for on-device semantic perception, illustrating the processing pipeline from RGB image input to joint object detection and instance-level segmentation outputs.

work lays the groundwork for future extensions toward native 3D semantic segmentation, language-grounded scene queries, and tighter integration with building information models and digital twins.

2 Methodology

This work proposes an XR-assisted framework for semantic understanding and digitalization of indoor building scenes by integrating on-device AI-based semantic segmentation with photogrammetric reconstruction. The methodology is designed to enable near real-time semantic perception together with spatially consistent 3D modeling and on-site verification through XR. Building upon previous research integrating XR and AI for real-time infrastructure inspection [18], this work extends the approach from damage assessment to semantic scene understanding and 3D digitalization of indoor environments.

The overall pipeline is illustrated conceptually in Figure 1 and follows a closed-loop workflow. While the user navigates an indoor environment wearing an XR device (in this work, a Microsoft HoloLens 2 MR headset), image frames are continuously acquired and processed in near real time using an embedded deep learning model for semantic segmentation. In parallel, selected image frames are stored and transmitted to an external workstation, where a SfM pipeline is executed offline to reconstruct a three-dimensional representation of the scene. Semantic information extracted from the 2D images is subsequently associated with the reconstructed geometry, enabling the generation of a semantically enriched 3D model. This model is then transferred back to the XR device and visualized within the XR environment, allowing the user to interact with, inspect, and validate the reconstructed scene.

2.1 System overview

The proposed framework consists of three tightly coupled components:

1. XR-based semantic perception: A MR headset is used as both an image acquisition and visualization device. Image frames captured by the headset's RGB camera are processed on-device using a lightweight AI model based on the YOLOv11-seg architecture, pre-trained on the COCO dataset for semantic and instance-level object segmentation. During operation, the model performs near real-time inference, generating bounding boxes and segmentation masks for common indoor objects such as furniture and equipment. These predictions are visualized directly in the XR environment through spatially aligned 3D text labels, bounding boxes, and image-aligned planes that overlay segmented regions onto the physical scene.
2. Photogrammetric reconstruction and semantic mapping: In parallel with near real-time XR perception, image data are transmitted to an external computer, where a SfM pipeline is executed to reconstruct a 3D representation of the environment in the form of a point cloud or mesh. Point feature correspondences used during the SfM process are exploited to establish spatial relationships between 2D image pixels and 3D points. By leveraging the semantic segmentation masks generated during inference, semantic labels are propagated from the image domain into the reconstructed geometry, enabling object-level segmentation of the 3D scene.
3. XR-based visualization and validation of semantic 3D models: Once the reconstruction and semantic mapping are completed, the semantically enriched 3D model is transferred back to the XR device. The model is then visualized within the XR environment, where users can manipulate, inspect, and validate both geometry and semantic labels. This enables immediate assessment of digitalization completeness and semantic correctness. If inconsistencies or missing regions are identified, additional images can be acquired on site, closing the loop between perception, reconstruction, and validation.

A key feature of the proposed methodology is its iterative and user-in-the-loop nature. Rather than treating digitalization as an offline, post-processing task, the frame-

work is intended to allow users to continuously assess reconstruction quality and semantic coverage during acquisition. This reduces the risk of incomplete or erroneous models and minimizes the need for repeated site visits. Once a scene is considered satisfactorily digitazed, the workflow could be extended to adjacent rooms or spaces, supporting scalable indoor environment digitalization.

2.2 XR-based image acquisition and on-device semantic segmentation

Near real-time image acquisition and semantic perception are performed directly on a MR headset, which serves as both the sensing and visualization platform. During operation, the headset's RGB camera continuously captures image frames from the user's viewpoint as they navigate the indoor environment. These frames are processed on-device to enable near real-time semantic understanding of the scene without reliance on cloud-based computation. Performing inference directly on the device enables immediate feedback during acquisition, avoids dependency on network connectivity, and supports interactive, user-guided data collection within the XR environment.

Semantic perception is achieved using the YOLOv11-seg architecture (Figure 2), which performs joint object detection and instance-level segmentation in a single inference pass. In this work, a pre-trained YOLOv11-seg model trained on the COCO dataset is employed without additional fine-tuning. The COCO dataset provides a diverse set of common object categories typically found in indoor environments, such as chairs, desks, monitors, and other furniture or equipment, making it suitable for demonstrating semantic scene understanding in building interiors. By relying on a pre-trained model, the focus of this study is placed on system integration and spatial semantic mapping rather than model development or training.

For each processed image frame, the model outputs a set of object detections represented by bounding boxes, class labels, confidence scores, and corresponding pixel-wise segmentation masks. These outputs are generated in the 2D image domain but are immediately translated into spatially aligned visual elements within the XR environment. Bounding boxes are rendered as three-dimensional wireframe overlays aligned with the camera view, while object class labels are displayed as 3D text annotations positioned relative to the detected objects (Figure 3). This enables users to directly perceive semantic information in context, without interrupting their interaction with the physical environment.

In addition to bounding boxes and labels, segmentation results can be visualized through image-aligned 3D planes instantiated in the XR scene (Figure 4). Each plane is textured with the corresponding image frame, where segmented object regions are highlighted according to their predicted classes. These planes are spatially aligned with the real-world background, creating the perception that the segmentation results are embedded within the physical scene. This visualization strategy allows users to observe semantic boundaries while preserving spatial context.

Figure 3. YOLOv11-seg detection outputs visualized in the XR environment.

Figure 4. YOLOv11-seg segmentation results visualized as 3D textured planes in XR.

To avoid visual clutter and maintain usability, segmentation planes are not instantiated continuously for every processed frame. Instead, their creation is triggered explicitly by the user, enabling selective visualization of segmentation results when needed. Multiple planes corresponding to different viewpoints can be instantiated sequentially, supporting inspection of semantic predictions from multiple perspectives. This interaction-driven visualization approach leverages the strengths of XR by combining near real-time perception with user-controlled exploration of semantic information.

2.3 Photogrammetric reconstruction and semantic mapping

Photogrammetric reconstruction is employed to generate a three-dimensional representation of the indoor environment using the image data acquired during XR-based operation. Image frames captured by the MR device are transmitted to an external workstation, where, using Mesh-

room [11], a SfM pipeline executed to estimate camera poses and reconstruct the scene geometry in the form of a sparse point cloud, followed by a dense point cloud and surface mesh. The reconstructed geometry provides a spatial backbone onto which semantic information extracted from 2D images can be mapped.

A key aspect of the proposed framework is the association of 2D semantic segmentation results with the reconstructed 3D scene. During the SfM process, distinctive point features are detected and matched across multiple images to establish correspondences and triangulate 3D points. Because these features originate from known pixel locations in the input images, their projections can be directly related to the semantic segmentation masks generated during on-device inference. For each reconstructed 3D point, its originating 2D feature locations are checked against the corresponding segmentation masks to determine whether the point belongs to a specific semantic object class.

Using this association, semantic labels are propagated from the image domain into the 3D reconstruction. Points whose corresponding 2D features fall within segmented object regions are assigned the semantic class of that object. This results in a semantically labeled point cloud (Figure 5), where each point carries both geometric and semantic information. When multiple image observations are available for a given 3D point, semantic labels are aggregated to improve robustness and reduce the impact of occasional misclassifications.

Figure 5. Semantically segmented 3D point cloud generated from 2D YOLOv11-seg predictions.

To generate a semantically segmented surface representation, the labeled point cloud is further linked to the reconstructed mesh. For each mesh vertex, nearby reconstructed points are queried to determine its most likely semantic class. Mesh triangles whose vertices are consistently associated with the same semantic label are then identified and highlighted as belonging to a specific object or scene element (Figure 6). This process yields a semantic mesh in which object-level regions are explicitly delineated, enabling clear visualization and interaction at the surface level rather than only at sparse point locations.

Figure 6. Semantically segmented 3D mesh derived from the segmented point cloud.

The resulting semantically enriched 3D model preserves both, geometry and object-level semantic structure, providing a coherent representation suitable for visualization, interaction, and validation in XR environment. This representation is subsequently transferred back to the Hololens device, where it can be inspected and manipulated by the user, closing the loop between perception, reconstruction, and semantic scene understanding. Note that this semantic propagation from 2D observations to 3D geometry builds upon well-established approaches (e.g., SemanticFusion [8]), and is here adopted as a component within the proposed workflow rather than introduced as a novel contribution.

2.4 XR visualization and user-guided validation of semantic 3D models

After photogrammetric reconstruction and semantic mapping are completed, the semantically enriched 3D model is transferred back to the MR device. The model is then loaded and visualized within the XR environment, allowing the user to inspect the reconstructed scene directly in situ (Figure 7). This visualization step enables the seamless integration of geometry and semantic information within the physical context of the building interior.

Within the XR environment, the reconstructed model is rendered as an interactive 3D object. Semantic information is displayed through color-coded surfaces corresponding to different object classes, enabling intuitive identification of scene elements. Users can freely manipulate the model—such as rotating, translating, or scaling it—to examine its geometry and semantic segmented objects. This interaction facilitates rapid assessment of reconstruction completeness and semantic correctness.

A central feature of the proposed framework is its user-guided validation loop. By visualizing the semantic 3D

Figure 7. Semantically enriched 3D mesh visualized in the XR environment.

model immediately after reconstruction, users can identify missing regions, insufficient coverage, or incorrect semantic assignments while still on site. If deficiencies are observed, additional image data can be acquired using the XR device and incorporated into the reconstruction process, improving both geometric fidelity and semantic completeness. This iterative process reduces the likelihood of incomplete digitalization and minimizes the need for repeated site visits.

Once the user is satisfied with the reconstructed and semantically labeled scene, the workflow can be extended to additional rooms or adjacent spaces, supporting scalable indoor environment digitalization. By enabling immediate feedback and validation, the XR-based visualization closes the loop between data acquisition, AI-driven semantic perception, and 3D reconstruction, transforming digitalization from an offline post-processing task into an interactive, near real-time process.

3 Conclusions

This paper presented an XR-assisted framework for semantic understanding and digitalization of indoor building scenes by integrating on-device AI-based segmentation with photogrammetric reconstruction. By combining near real-time semantic perception, SfM–based 3D modeling, and immersive visualization within a single workflow, the proposed approach enables users to capture, verify, and interact with semantically enriched 3D scene representations directly on site.

Unlike conventional pipelines that decouple data acquisition, semantic interpretation, and reconstruction into separate offline stages, the proposed framework tightly couples these processes through XR. On-device semantic segmentation provides immediate contextual understanding of the environment, while photogrammetric reconstruction and semantic mapping allow this information to be propagated into a spatially consistent 3D representation. The XR-based visualization and user-guided validation loop further support immediate assessment of digitalization completeness and semantic correctness, reducing the risk of incomplete models and minimizing the need for repeated site visits.

Despite these advantages, several limitations remain. MR headsets offer limited computational resources compared to desktop or cloud-based platforms, making the deployment of large-scale spaces or large deep learning models challenging. As a result, lightweight segmentation models are required, which may limit achievable accuracy compared to offline processing. In addition, current XR hardware still presents ergonomic constraints, including device weight and comfort during prolonged use, as well as limited battery life that restricts continuous operation time. Environmental factors also affect usability; in particular, high ambient lighting conditions—common in construction sites—can reduce hologram visibility and impact the clarity of XR visualizations. Addressing these hardware limitations is largely dependent on future advances in XR device design and is beyond the scope of this work. This study focuses on demonstrating the feasibility of the proposed integrated workflow and therefore does not include a comprehensive quantitative evaluation, including an assessment of the effectiveness of the user-guided validation loop within the XR environment. Finally, photogrammetric reconstruction and semantic 3D mapping stages are performed offline on an external workstation and depend on the selected pipeline and available computing resources.

While the present study employs a pre-trained model based on the COCO dataset to demonstrate semantic scene understanding, the proposed framework is model-agnostic and can be readily adapted to other segmentation models trained on domain-specific datasets. This flexibility enables extension to a broad range of construction-related applications, including semantic segmentation of structural elements, condition assessment and monitoring of construction activities. Future work will explore native 3D semantic segmentation, tighter integration between reconstruction and inference pipelines, and language-grounded models as interaction mechanisms that allow users to query and manipulate semantic content directly within the XR environment. Additionally, it will include a systematic evaluation of the proposed framework. This will involve assessing 2D segmentation performance, evaluating 3D semantic consistency and reconstruction completeness, and measuring end-to-end latency of the pipeline. In addition, a user study will be conducted to quantify the impact of the XR-based validation loop on usability and data acquisition efficiency. Together, these directions highlight the potential of XR as an active tool for near real-time scene understanding, digitalization, and decision support in the built environment.

Abstract - Reliable and timely construction progress monitoring remains challenging due to the dynamic, spatially complex, and visually cluttered nature of jobsite environments, where conventional inspection- and report-based approaches often yield subjective and intermittent assessments. This paper maps the adoption of artificial intelligence and computer vision for construction progress monitoring through a bibliometric and thematic review of 103 publications spanning 2005–2026. Using performance analysis and science mapping in Bibliometrix, the study characterizes scientific production, leading contributors, thematic structures, and topic evolution. Results indicate a marked growth and concentration of research output, led by the United States (61 publications) and China (43), followed by the United Kingdom (19), Germany (14), Australia (13), and South Korea (13). The thematic map reveals four interrelated research fronts: (1) computer vision as a transversal methodological core (e.g., machine learning, activity recognition, image processing, real-time monitoring), (2) construction progress monitoring as the primary application theme (strongly associated with deep learning, point clouds, object detection, and semantic segmentation), (3) photogrammetry and reality-capture pipelines as mature enabling technologies, and (4) BIM as an integration layer connecting field inference to planning and control. Trend analysis suggests a transition from early recognition and as-built modeling toward deep learning–driven, 3D-centric, and increasingly operational workflows. The findings provide an evidence-based agenda to strengthen benchmarking, generalize across sites, and tighten the coupling between vision outputs and project control systems.

Keywords – Artificial Intelligence; Computer Vision; Construction Progress Monitoring; Bibliometric Analysis; Trend Analysis

1 Introduction

The growing pressure to deliver construction projects within constrained schedules and budgets has heightened the need for reliable, objective, and continuous mechanisms to assess construction progress [1]. Conventional progress-monitoring practices, often reliant on manual inspections, periodic reports, and visual judgment, struggle to capture the dynamic and spatial complexity of construction activities [2]. As construction sites increasingly generate large volumes of visual data from fixed cameras, mobile devices, and aerial platforms, artificial intelligence and computer vision have gained prominence as technologies that transform visual information into structured indicators of project advancement [3]. Recent advances in deep learning and visual recognition enable automated detection of construction elements, activity states, and temporal changes directly from images and videos. These capabilities allow near-real-time progress evaluation, reduce subjectivity in reporting, and support more consistent performance tracking across project phases [4]. Furthermore, vision-based outputs can be aligned with planning and scheduling systems to provide data-driven insights into deviations between planned and actual progress. Despite the rapid expansion of technical solutions, research contributions remain dispersed across methods, application scenarios, and evaluation criteria, limiting the consolidation of knowledge in this field. A comprehensive understanding of how artificial intelligence and computer vision have been applied to construction progress monitoring, how research themes have evolved over time, and where methodological gaps persist is therefore essential. In this context, bibliometric and thematic analyses offer a systematic means to map scientific production, identify influential research streams, and highlight emerging directions in AI-enabled construction progress monitoring [5].

The rapid evolution of artificial intelligence and computer vision has significantly altered how construction processes are observed, measured, and analyzed, particularly in contexts marked by high visual complexity and continuous physical transformation. Vision-based technologies enable automated interpretation of site imagery, facilitating identification of construction elements, activity states,

and temporal changes that are difficult to capture through conventional monitoring approaches [6,7]. Within construction management research, these developments have supported the transition from subjective, report-based progress assessments to data-driven, repeatable evaluation mechanisms. Deep learning architectures applied to images and videos have demonstrated the ability to track work execution, detect deviations from planned schedules, and provide quantitative indicators of progress with increasing accuracy [8]. At the same time, integrating visual outputs with planning, scheduling, and digital modeling environments has expanded the analytical capabilities of progress-monitoring systems. The advancement of Artificial Intelligence (AI) applied to construction progress monitoring is closely connected to the development of automation and robotics. Specifically, robotic inspection systems and autonomous monitoring platforms are increasingly playing a vital role in boosting efficiency and accuracy at construction sites. In recent years, automation has evolved from emerging technology to a key component of progress monitoring, especially through robotic inspection systems. Progress in this field enables the integration of AI for hazard prediction, real-time surveillance, and autonomous decision-making, leading to substantial improvements in tracking construction activities and reducing risk-related delays. Despite these advances, research remains fragmented across algorithms, data sources, and application contexts, often emphasizing technical performance without systematically relating findings to broader research trends. Furthermore, differences in evaluation metrics, validation strategies, and reporting practices hinder comparative assessment across studies. As a result, the absence of a consolidated view of how artificial intelligence and computer vision have been applied to construction progress monitoring limits the identification of dominant research streams and emerging thematic directions [9]. Addressing this limitation requires a structured synthesis of scientific production that captures methodological evolution, thematic concentration, and research gaps over time. In this regard, bibliometric and thematic analyses provide a robust framework for organizing existing knowledge and supporting the strategic development of AI-enabled research on progress monitoring.

Despite the increasing number of studies on artificial intelligence and computer vision in construction, the literature remains fragmented across methodologies, application scales, and analytical objectives, limiting a comprehensive understanding of the field's evolution [10–13]. Previous studies have developed algorithms for activity recognition, object detection, and progress estimation using images, videos, and sensor-based data [14–16], often demonstrating strong technical performance under controlled conditions. However, most research prioritizes algorithm development without systematically examining the evolution of research themes, evaluation methods, and application contexts over time. Consequently, it remains unclear which technological paradigms have driven the field, how dominant research streams have emerged, and where persistent gaps hinder practical implementation. To address these limitations, this study conducts a bibliometric and thematic review of publications from 2005 to 2026 on artificial intelligence and computer vision for construction progress monitoring. By integrating performance analysis, scientific mapping, and thematic evolution assessment, the study identifies influential contributions, dominant research clusters, and emerging thematic trends shaping the field's intellectual structure. Beyond descriptive analysis, the review highlights conceptual imbalances, methodological gaps, and underexplored connections between algorithmic development and real-world deployment in construction environments, providing a foundation for future research and the development of scalable, reliable, and data-driven progress-monitoring solutions.

2 Literature Background

The growing demand for objective, continuous assessment has positioned progress monitoring as a key area in digital construction. Conventional practices based on site visits and subjective reporting offer limited capacity to capture evolving spatial and temporal conditions [14,15]. The availability of visual data from cameras, UAVs, and mobile devices has driven adoption of AI and computer vision for automated evaluation [11]. Recent studies show that deep learning enables systematic interpretation of site imagery, identifying elements, activity states, and execution stages with reduced reliance on manual judgment [16,17]. These advances shift monitoring toward data-oriented paradigms, where measurable indicators replace qualitative descriptions. Yet diversity in analytical approaches, acquisition strategies, and validation procedures reveals fragmented trajectories, complicating knowledge consolidation.

A substantial body of work has developed vision methods to detect activities and estimate progress from images and videos. Early studies focused on object recognition and feature-based techniques, while recent contributions employ deep neural networks to capture complex spatial–temporal relation [18]. Several works report strong performance in recognizing work states and quantifying progress under controlled conditions [19]. Others link visual outputs with scheduling to detect deviations between planned and executed work [20]. Persistent challenges include limited transferability, sensitivity to environmental variability, reliance on context-specific datasets, and inconsistent evaluation metrics, which constrain comparability and generalization.

Beyond algorithms, attention has turned to how AI and computer vision research has evolved as a domain. While individual studies provide technical insights,

fewer examine publication dynamics, thematic concentrations, and intellectual structures [10,21–23]. Addressing this gap requires approaches tracing evolution across methods and applications. Bibliometric and thematic analyses systematically identify influential publications, dominant streams, and emerging topics. By reviewing output from 2005–2026, this study offers a comprehensive view of the maturation of AI and computer vision in progress monitoring, highlighting enduring challenges, methodological shifts, and opportunities for scalable, reliable, data-driven solutions.

3 Research Method

3.1 Methodological rationale and scope definition

Research on AI and computer vision for construction progress monitoring has expanded rapidly, producing a heterogeneous and methodologically dispersed body of literature. Contributions differ in data types, analytical pipelines, validation strategies, and monitoring objectives, complicating the identification of dominant trajectories and consolidated paradigms. In this context, bibliometric analysis offers a reproducible framework to examine scientific production collectively, revealing structural patterns, thematic concentrations, and temporal dynamics beyond narrative or technology-centered reviews.

This study adopts a bibliometric and thematic review of peer-reviewed publications from 2005 to 2026, spanning early visual inspection and object recognition to recent advances in deep learning, 3D sensing, and data-intensive workflows. Three objectives guide the analysis: (1) evaluate the evolution and performance of scientific output, (2) characterize the intellectual and thematic structure, and (3) identify dominant and emerging trends shaping AI-enabled progress monitoring. These objectives provide a coherent foundation for interpreting methodological evolution and research priorities over time.

3.2 Selection of bibliometric techniques

The bibliometric methodology was designed to align directly with the research objectives, ensuring consistency between the analytical procedures and the evidence generated. Performance analysis was used to characterize the development of the field by examining publication growth, citation patterns, and the geographical distribution of scientific output, thereby identifying the countries, institutions, and research contributions that have shaped the evolution of artificial intelligence and computer vision applications for construction progress monitoring. To complement this assessment, citation-based indicators and collaboration networks were analyzed to evaluate scientific influence and knowledge exchange within the domain, revealing the central role of leading institutions, authors, and technological paradigms. In particular, the prominence of terms such as machine learning and deep learning among highly cited publications reflects the growing importance of data-driven approaches for automation and real-time monitoring in construction environments. The conceptual structure of the literature was examined through science-mapping techniques, including co-word analysis and thematic mapping, which enabled the identification of recurrent concepts, thematic relationships, and the relative maturity and relevance of different research streams. Finally, temporal trend analysis provided insight into the evolution of the field, highlighting a transition from early recognition-based and as-built modeling approaches toward deep learning-enabled, three-dimensional, and increasingly operational frameworks for construction progress monitoring.

Data collection and filtering process

Scientific data were collected from Scopus, chosen for its broad coverage of peer-reviewed journals in engineering, construction, and computer science, and its robust indexing standards. A structured search strategy was refined iteratively, combining preliminary inspection with team input. Keywords on artificial intelligence, computer vision, and progress monitoring were combined with Boolean operators to balance sensitivity and specificity.

The final search equation — [("construction progress" OR "progress monitoring" OR "progress tracking") AND ("computer vision" OR "image-based" OR "video-based" OR photogrammetry OR "visual inspection")] — targeted publications on visual data analysis, automated monitoring, and progress assessment. Records were refined through multi-stage filtering to ensure relevance and quality. Temporal limits (2005–2026) captured long-term evolution. Filters retained journal articles and reviews, excluding conference and editorial material, and focused on engineering, construction, and computer science. Titles, abstracts, and keywords were reviewed independently, with full-text checks for ambiguous cases. Inclusion required explicit use of AI or computer vision in construction progress monitoring and sufficient metadata for bibliometric analysis. In this study, conference proceedings were excluded from the bibliometric analysis mainly because they usually present preliminary results. While conferences offer valuable information and advancements, they tend to highlight initial findings that often lack the depth needed for a thorough analysis. By focusing on articles from scientific journals, the goal is to ensure a more consistent and comprehensive examination of the field's impact and emerging trends, leading to a more reliable assessment of the research landscape. This systematic process resulted in a curated corpus that supports reliable, reproducible bibliometric analysis.

3.3 Execution of bibliometric and thematic analysis

The bibliometric analysis was conducted in three stages: performance analysis, scientific mapping, and trend analysis. Performance indicators were computed using the Bibliometrix package in RStudio, enabling systematic assessment of annual publication output, citation trajectories, and country-level contributions. These metrics reveal how scientific activity has intensified and become more geographically distributed over time. The scientific mapping stage used author-provided keywords to construct co-occurrence networks that reflect the field's conceptual organization. To enhance consistency, synonymous terms and lexical variants were standardized using a controlled vocabulary developed collaboratively by the research team. Thematic maps were generated using centrality and density measures, allowing research clusters to be classified as motor, basic, emerging, or niche themes. Mathematical formulations for the equivalence index, centrality, and density were based on established bibliometric methodologies. The scientific mapping process was implemented using author keywords as the unit of analysis and co-word analysis as the relational technique. Prior to network construction, the keyword set was cleaned by normalizing spelling variants, singular and plural forms, and closely related expressions using a controlled vocabulary agreed upon by the research team. Only terms directly related to artificial intelligence, computer vision, and construction progress monitoring were retained for thematic interpretation. The thematic map was generated in Bibliometrix using Callon's centrality and density measures, which enabled classification of clusters as motor, basic, niche, or emerging themes. In parallel, the trend-topic analysis examined the temporal occurrence of keywords across the study period to identify shifts in conceptual emphasis and methodological development within the corpus. Finally, trend analysis examined temporal variations in keyword prominence, revealing shifts from early object recognition and as-built modeling toward deep learning–driven, three-dimensional, and operational monitoring workflows. This multi-layered analytical process supports a comprehensive interpretation of the maturation of AI and computer vision research for construction progress monitoring.

Evidence synthesis and analytical structure

The evidence synthesis was structured to directly reflect the three analytical dimensions defined by the research objectives. Performance analysis results describe growth patterns and the leading contributors shaping the field. Scientific mapping outcomes interpret the intellectual structure and thematic relationships among research fronts. Trend analysis findings highlight methodological transitions and emerging priorities in recent research. This organization ensures consistency between the analytical framework and the reported results, supporting transparent interpretation and replication. The methodological design emphasizes rigor, traceability, and reproducibility, providing a robust foundation for identifying future research opportunities in AI- and computer vision–based construction progress monitoring.

4 Results

4.1 Performance Analysis

The patterns of scientific production suggest both growth and concentration: from 2005 to 2026, the field has expanded rapidly as AI-driven monitoring capabilities have matured and diversified (**Error! Reference source not found.**).

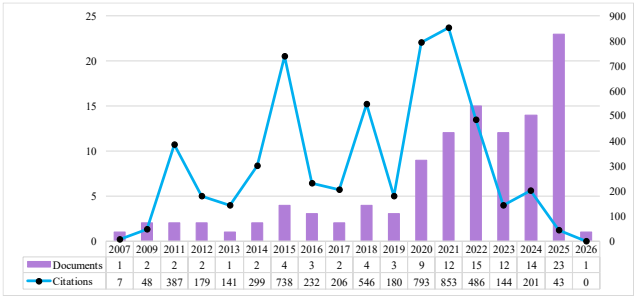

Figure 1. Scientific production by year.

The publication output indicates that the United States and China are the leading contributors in this area, with 61 and 43 publications, respectively, followed by the United Kingdom (19), Germany (14), Australia (13), and South Korea (13) (**Error! Reference source not found.**).

Figure 2. Scientific production by country.

Furthermore, the collaboration networks showed steady growth in international team interactions, indicating increased integration of global research in construction progress monitoring. The most frequently cited terms in the documents, such as 'machine learning' and 'deep learning,' were identified as the most influential in the field, highlighting the trend toward automating monitoring tasks with artificial intelligence. These results underscore the growing importance of AI and machine learning algorithms in

improving the accuracy and efficiency of progress tracking on construction projects.

4.2 Science Mapping

The thematic map suggests that the intellectual structure of research on artificial intelligence and computer vision for construction progress monitoring is not dispersed across isolated topics but rather concentrated around four interrelated fronts. Their relevance and developmental intensity can be interpreted in terms of their positions with respect to centrality and density (**Error! Reference source not found.**). This configuration indicates that the field has evolved through a combination of conceptual consolidation and methodological specialization, with certain themes gaining prominence by shaping the broader research agenda, while others advance along more focused, internally cohesive trajectories. Notably, the right side of the map, associated with greater centrality, highlights themes that exert a stronger influence on the domain's overall organization. Within this area, two clusters emerge as the main anchors of the literature, suggesting that the field is shaped by dual logic: one oriented toward methodological development and the other focused on assessing application-driven progress. Rather than representing disconnected lines of inquiry, these clusters reveal how the domain is increasingly structured around the interaction between enabling analytical techniques and the practical demands of construction monitoring. The first cluster is computer vision, marked by high centrality and dense associations with machine learning, activity recognition, image processing, and real-time monitoring, as well as newer links to digital twins and segmentation models. This highlights computer vision as a transversal methodological backbone supporting diverse monitoring tasks rather than an isolated application.

The second cluster corresponds to construction progress monitoring, a basic theme with high relevance but moderate density. It represents the main application driving the domain, though still consolidating. Emphasis lies on deep learning and 3D representations, oftenconnected with point cloud, object detection, semantic segmentation, and image recognition. These terms reflect a shift toward automated, data-driven interpretations of site conditions, moving beyond visual documentation to structured progress assessments.

In contrast, the upper-left quadrant groups photogrammetry as a niche theme, linked to UAV, laser scanning, 3D reconstruction, reality capture, and automated measurement. Its high density but low centrality shows methodological maturity in acquisition and reconstruction, yet isolation suggests it is treated more as an enabling technology than a driver of semantic interpretation.

Figure 3. Thematic map analysis.

The node interaction map (Figure 4) further supports these identified patterns, illustrating how construction progress monitoring acts as a central hub, intricately connected to point cloud data and deep learning techniques. Meanwhile, computer vision functions as a comprehensive aggregator, linking various recognition and inference tasks. This central role of progress monitoring within the network highlights its vital part in the ongoing development of AI-enabled monitoring systems. BIM (Building Information Modeling), in this context, serves as a key integration layer that connects technical innovations with management-focused objectives, helping to translate real-time data into actionable insights for decision-making. The structure shown in the map indicates an ongoing shift toward integrated monitoring pipelines, where 3D data capture, deep learning–based inference, and BIM-enabled environments work together. This shift suggests moving from isolated, independent technologies to a more operational, traceable, and decision-oriented approach to progress monitoring in construction projects. The implication is clear: the future of construction progress monitoring is evolving into a unified, adaptive system that tracks progress while continuously adjusting to the project's changing needs in real time.

Figure 4. Node interaction map.

Beyond identifying thematic clusters, analyzing node interactions reveals a layered structure in AI-enabled progress-monitoring systems. At the core, technologies like photogrammetry and three-dimensional reconstruction are essential for creating increasingly precise and reliable geometric models of

site conditions. These form the basis for higher-level analytical processes. Next, computer vision and deep learning conduct semantic inference, transforming raw visual data into recognizable construction components, activity states, and work progress assessments. This layer is crucial for converting large volumes of unstructured visual information into organized, usable data that supports progress evaluation. At the system-integration level, BIM functions as the backbone of a unified environment, connecting visual outputs with planning, scheduling, and control mechanisms. This link is vital to ensure that the insights produced by monitoring systems are not only accurate but also actionable within broader project management contexts. Connecting real-time data with decision-making tools in BIM creates a feedback loop that helps continuously assess and adjust project progress to meet overall goals. However, despite these advancements, the thematic structure also uncovers ongoing fragmentation in current research. Although the layers composing the monitoring pipeline are becoming more interconnected, they still tend to operate separately. While notable breakthroughs have been achieved in vision-based inference and geometric reconstruction, fewer studies have addressed interoperability and feedback mechanisms necessary to close the loop in progress monitoring systems. This fragmentation partly explains why many systems report high accuracy in controlled environments or pilot projects but face difficulties when scaled for real-world construction applications. The lack of a unified framework that integrates these components into operational systems may be a significant barrier to the widespread adoption of advanced monitoring solutions. Lastly, although individual parts of AI-driven construction progress monitoring have advanced markedly, further research into integrating these components into a seamless, closed-loop system remains vital. Moving beyond isolated technical innovations toward a fully operational, scalable system suitable for diverse construction environments presents the next challenge for research in this field.

4.3 Trend Analysis

The trend-topic analysis reveals a clear methodological and thematic transition in AI- and computer vision–based construction progress monitoring between 2009 and 2025 (**Error! Reference source not found.**). Early studies focused on as-built modeling and object recognition, emphasizing the alignment of site conditions with design intent through constrained recognition tasks. As the field evolved, topics such as laser scanning, daily construction images, image analysis, and imaging techniques became prominent, reflecting increased attention to reliable visual data acquisition and processing pipelines. From 2020 onward, the research focus shifted toward integrated progress assessment, with growing emphasis on BIM, 3D reconstruction, photogrammetry, and construction progress monitoring and evaluation. This evolution indicates a transition from isolated perception tasks to integrated monitoring workflows combining data capture, reconstruction, and interpretation. Recent trends further demonstrate the consolidation of contemporary AI paradigms.

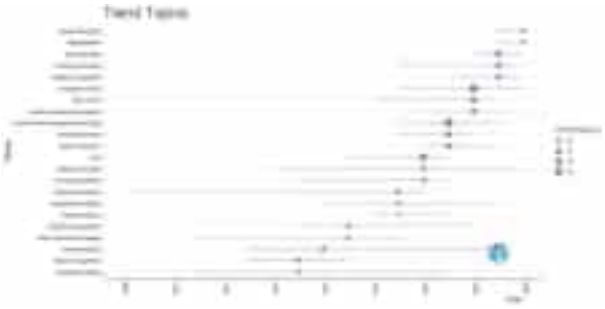

Figure 5. Trend analysis.

The increased frequency of computer vision and point cloud signals a maturation of 3D-driven monitoring. At the same time, the rise of deep learning, machine learning, and activity recognition reflects broader adoption of data-driven models capable of capturing complex spatial–temporal patterns in site environments. The emergence of digitalization and manual annotation near the end of the period suggests growing attention to dataset construction, labeling burden, and the governance of visual data at scale. Together, these trends depict a field moving beyond proof-of-concept to scalable, operational monitoring solutions that rely on robust 3D representations, learning-based inference, and tighter coupling with project information environments.

The trend analysis reveals not only technological advancements but also a progressive redefinition of construction progress monitoring. Early research approached progress assessment primarily as a visual correspondence problem, emphasizing object detection and the comparison between as-built conditions and design intent. As sensing and data acquisition technologies matured, the focus expanded toward automated spatial representation through photogrammetry and 3D reconstruction techniques, enabling more comprehensive and scalable monitoring workflows. More recently, the emergence of deep learning and activity recognition has shifted the field toward dynamic interpretations of construction progress, where monitoring is increasingly associated with evolving work states rather than static measures of completion. Despite these advances, the continued reliance on manual annotation and dataset preparation highlights a persistent challenge, as the rapid development of model architectures has not been matched by the availability of standardized and transferable training datasets, limiting model generalizability and large-scale implementation.

The corpus indicates that benchmark inconsistency is not merely a reporting issue, but a structural characteristic of the field. The analyzed studies address markedly different analytical targets, ranging from training image database development [6] and BIM-

linked indoor progress monitoring [8] to semantic information extraction [19], ontology-based image enrichment [20], and RTLS-integrated monitoring workflows [21]. This heterogeneity is also reflected in the thematic structure, where deep learning, point cloud, object detection, semantic segmentation, and BIM-related terms coexist within the same research domain. Trend analysis reinforces this interpretation, as the recent visibility of manual annotation and digitalization suggests continued dependence on project-specific data curation, while the relatively late prominence of BIM indicates that many studies still evaluate perception modules in isolation rather than within comparable end-to-end monitoring workflows. Consequently, reported performance is often tied to different tasks, datasets, validation settings, and deployment contexts, thereby weakening cross-study comparability and limiting the accumulation of transferable evidence.

5 Conclusions

This study contributes to the understanding of AI and computer vision applications in construction progress monitoring by consolidating research across methodologies, data acquisition strategies, applications, and evaluation approaches. The thematic analysis identifies four main research directions: construction progress monitoring, computer vision, photogrammetry and 3D reconstruction, and BIM integration with project information systems. The review also shows a methodological transition from conventional feature-based approaches to deep learning models capable of addressing the spatial and temporal complexity of construction environments. These findings reflect the evolution of monitoring systems from isolated analytical tools into integrated frameworks that support construction management and decision making.

The study also highlights practical implications for implementing automated monitoring systems in real construction projects. Effective monitoring frameworks require the integration of capture technologies such as fixed cameras, mobile devices, and UAVs with analytical models adapted to different monitoring levels, including activities, elements, operational states, and temporal changes. The integration of AI outputs with planning processes and BIM environments can improve performance tracking, reduce subjectivity, and support earlier detection of project deviations. However, some limitations remain. Bibliometric and thematic reviews depend on metadata quality, keyword consistency, and search strategies, which may restrict the inclusion of relevant studies. The absence of standardized datasets, evaluation metrics, and benchmarking practices also limits comparability across studies. Future research should focus on standardized evaluation protocols, open datasets, domain adaptation methods, and multimodal AI frameworks integrated with BIM-based management systems to improve robustness and applicability in real construction environments.

Multi-fidelity Surrogate-integrated Modelling Framework: Application to Tall Energy Structures

Abstract –

Tall renewable energy infrastructures are complex structural systems comprising numerous components. Under earthquakes, their designated energy-dissipating components may exhibit intricate material and geometric nonlinearities that require high-fidelity finite element (FE) modelling, whereas system-level seismic assessment typically demands extensive nonlinear time-history analyses, making uniformly refined modelling computationally prohibitive. This paper presents a multi-fidelity surrogate-integrated modelling framework that concentrates refined FE simulations on the critical component to construct a surrogate model, which is then integrated into an efficient system-level model with simplified representations for the remaining components. The surrogate was developed using a multilayer perceptron (MLP) trained to jointly predict a vector of hysteretic parameters, enabling shared representation learning to capture inter-parameter correlations and thereby improving predictive accuracy and output consistency. The framework was demonstrated on a representative 10-MW resilient jacket-type offshore wind turbine, in which an hourglass-like stiffened tower segment was characterised using a comprehensive hysteresis database – derived from 3,000 refined FE simulations – and integrated into an OpenSees-based system model. The results show that the joint-prediction MLP achieved higher predictive accuracy than independently trained single-output models, while enabling efficient large-scale nonlinear dynamic analyses.

Keywords –

Energy infrastructures; seismic assessment; surrogate; multi-fidelity modelling; hysteretic behaviour

1 Introduction

Over the past decade, renewable energy has expanded rapidly worldwide, driving the deployment of tall energy infrastructures such as wind turbine towers [1] and concentrated solar power towers [2]. The expansion of these installations into seismically active regions poses significant seismic risks to the infrastructures, owing to their highly slender and cantilever-dominated structural characteristics [3]. Such slender systems can be particularly sensitive to dynamic excitations, making it challenging to sustain functionality and structural integrity under seismic hazard demands [4].

To enhance the structural performance of tall energy infrastructures, several novel structural systems equipped with energy dissipation devices, such as tuned mass dampers [5, 6], tuned liquid dampers [7, 8], and ductile tower segments [9, 10], have been developed. Their seismic performance assessment is particularly challenging because it often requires extensive nonlinear time-history analyses (NLTHAs) to capture seismic response, damage evolution, and failure modes. However, modelling such systems inevitably involves a trade-off between computational accuracy and efficiency [11]. Applying uniformly high-fidelity modelling to the entire structural system becomes prohibitive when hundreds or thousands of NLTHAs are required for record-to-record variability or parametric studies [12]. For example, a prior study on the 10-MW jacket-type offshore wind turbine (JOWT) reported that a refined finite element (FE) model required 36 hours to compute a single case on a 24-core workstation, even without accounting for material nonlinearity [13]. In contrast, simplified beam-based models offer efficiency but may inadequately represent the critical components that exhibit strong geometric and material nonlinearities.

Recent advances in machine learning (ML) have provided a promising solution to address this trade-off by developing data-driven surrogate models that emulate high-fidelity nonlinear behaviour at a fraction of the

computational cost [14-18]. This paper proposes a multi-fidelity surrogate-integrated modelling framework to facilitate the seismic performance assessment of tall energy infrastructures. The key idea is to concentrate refined FE simulations on the critical component that dominates nonlinear deformation and energy dissipation, to construct a hysteresis database, and to train a surrogate model that maps structural design variables to a hysteretic representation. The trained surrogate model is then integrated into an efficient system-level model in which the remaining components are represented using computationally cheaper beam elements, without compromising the macroscopic fidelity of the nonlinear structural behaviour. This framework is demonstrated using a representative tall energy structure (a 10-MW resilient JOWT), where an hourglass-like stiffened tower segment (HSTS) is characterised using a hysteresis database derived from 3,000 refined FE simulations and integrated into an OpenSees system model.

A further emphasis of this study concerns the surrogate formulation. Instead of training multiple independent single-output regressors [15-18], this study adopts a single multilayer perceptron (MLP) trained to jointly predict a vector of hysteretic parameters. Multiple independently trained single-output models may yield outputs that are mutually incompatible and can violate the physical constraints implied by the actual structural behaviour. In contrast, the multi-output MLP leverages shared latent representations, allowing the model to learn cross-parameter dependencies, inherently constraining its outputs to a jointly feasible region, thereby promoting physical consistency among the outputs.

2 Methodology

This study develops a multi-fidelity surrogate-integrated modelling framework that combines refined FE simulations with data-driven surrogate modelling and an efficient system-level model. The framework targets the critical component (or component group) that dominates nonlinear deformation and energy dissipation, to which the accuracy of structural behaviour prediction is highly sensitive, while representing the remaining components using computationally cheaper modelling techniques suitable for system-level dynamics. Figure 1 shows the stepwise workflow of the proposed framework:

(1) Parameterised high-fidelity modelling of the critical component. A refined FE model is formulated and parameterised to support automated generation of component variants over a prescribed design space.

(2) Design-space sampling and database generation. A structural parameter matrix is constructed to span the practical design space, and cyclic/monotonic analyses are conducted on refined FE models to generate a hysteresis database representing the hysteretic behaviour.

(3) Hysteresis parameterisation. The simulated hysteretic curves are mapped to a phenomenological parameter set (e.g., stiffness, strength, ductility, hardening, and deterioration parameters) through calibration, yielding paired datasets of structural and hysteretic parameters.

(4) Surrogate model training with joint prediction. An MLP is trained to infer the hysteretic-parameter vector directly from the structural parameters by learning a shared latent representation and predicting all hysteretic parameters jointly.

(5) Reduced-order representation and system-level integration. The trained surrogate is assigned to a parameterised reduced-order representation of the critical component (e.g., concentrated plasticity formulation), which is then integrated into an efficient system-level model. All other components are modelled using simplified yet reliable elements that preserve global dynamics and essential interaction effects.

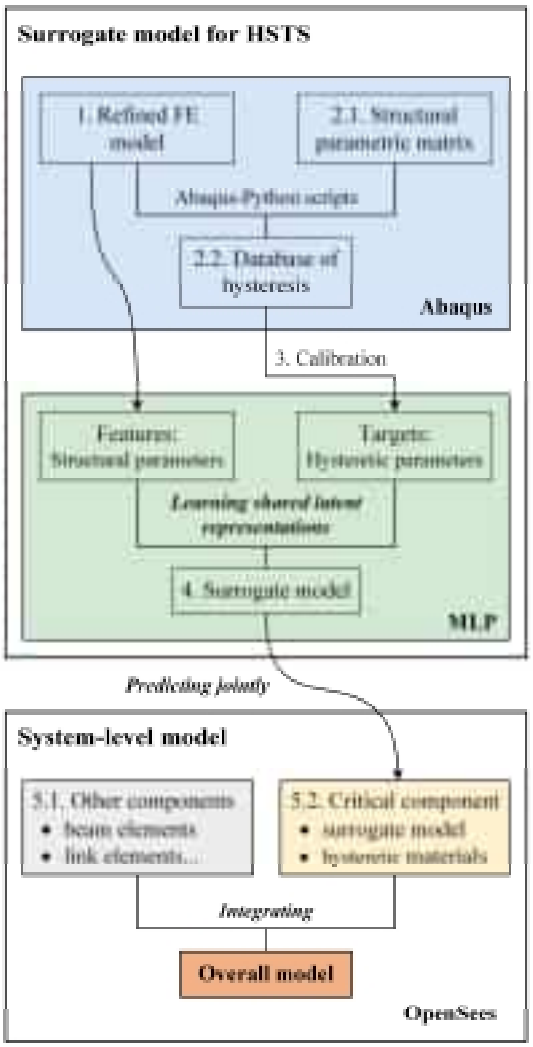

Figure 1. Multi-fidelity surrogate-integrated modelling framework

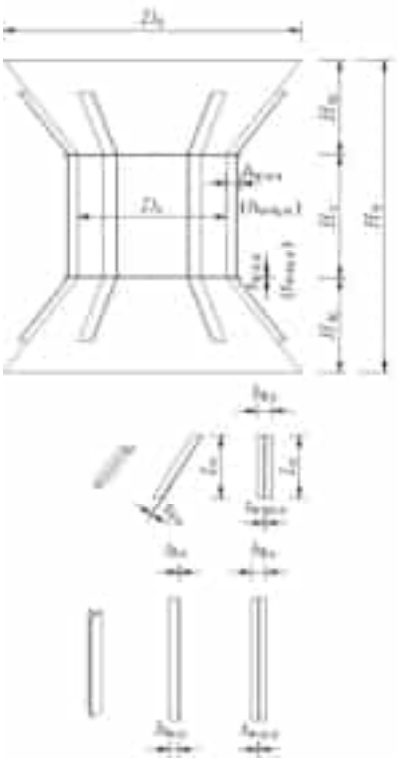
This multi-fidelity integration inevitably trades local micro-scale detail for system-level tractability. Nevertheless, by concentrating high-fidelity effort on the critical nonlinear component and ensuring that its macroscopic hysteretic behaviour is accurately reproduced via a joint-prediction surrogate, the framework provides an effective balance between fidelity and efficiency for seismic performance assessment of tall energy infrastructures.

3 Framework implementation on a 10-MW resilient JOWT



3.1 Reference structure

The multi-fidelity surrogate-integrated modelling framework is demonstrated using a representative 10-MW resilient JOWT proposed by Xie et al. [18]. This novel structural system introduces a HSTS – as the energy dissipation device – in lieu of the conventional cylindrical tower segment connecting the upper tower and transition piece of JOWTs. The HSTS is a novel component featuring complex thin-walled and stiffened configurations and necessitates a refined FE analysis to capture its initial imperfections, intricate material and geometric nonlinearities. In the following, a surrogate model is established for the HSTS and subsequently integrated into the system-level model, with the remaining components, such as the tower, rotor-nacelle assembly, and jacket foundation, modelled using computationally cheaper elements.

3.2 Automated FE modelling and hysteresis dataset generation

The refined FE models of the HSTS were established using Abaqus. Figure 2 provides further details regarding the basic geometry and structural parameters of the HSTS. This model adopted a simplified piecewise-linear material model, which is characterised by the following: (1) an elastic modulus of 210 GPa, (2) a yield stress of 355 MPa, and (3) a 1% kinematic linear strain hardening up to an ultimate stress of 470 MPa. Furthermore, the first-order 4-noded doubly curved rectangle (S4R) element was used.

Next, a comprehensive hysteresis database was generated. The database contains 3000 moment-rotation (M-θ) hysteretic curves obtained from refined FE simulations, covering a broad range of feasible HSTS design configurations. A structural parameter matrix was first constructed by Latin hypercube sampling within prescribed ranges selected to remain consistent with relevant design standards for stiffened-shell components. A set of Abaqus-Python scripts was then developed to enable automated processing, including:

	Symbol	Description	Value range for the design space
Shells	D_0	Diameter of the original tower segment	7465 (mm)
	H_0	Height of the original tower segment	8000 (mm)
	D_t	Reduced diameter	3000–5200 (mm)
	H_c	Height of the cylindrical shell	2400–4000 (mm)
	t_c	Thickness of the cylindrical shell	28–40 (mm)
	t_t	Thickness of the truncated conical shells	28–40 (mm)
	H_t	Height of the truncated conical shells	$(H_0 - H_c) / 2$ (mm)
Longitudinal stiffeners	N_s	Number of stiffeners	4, 5, 6, 7, 8
	$h_{w,s}$	Width of the web	150–300 (mm)
	$t_{w,s,1}$	Thickness of the web at the middle	20–40 (mm)
	$t_{w,s,2}$	Thickness of the web at the two ends	10–40 (mm)
	$b_{f,s}$	Width of the flange	100–200 (mm)
	$t_{f,s}$	Thickness of the flange	10–40 (mm)
	L_s	Height of the stiffener at the two ends	$(1/3 \sim 2/3) \times H_c$ (mm)
Ring stiffeners	$t_{w,r,1}$	Thickness of the web at the middle	20–40 (mm)
	$h_{w,r,2}$	Width of the web at the two ends	150–300 (mm)
	$t_{w,r,2}$	Thickness of the web at the two ends	20–40 (mm)
	$h_{w,r,1}$	Width of the web at the middle	$h_{w,r}$ + 100 (mm)

Figure 2. Basic geometry and structural parameters of the HSTS

(1) automatic generation of parameterised HSTS FE models for all sampled designs; (2) FE analyses under monotonic and cyclic loading histories consistent with FEMA 461 standard component-testing protocols; (3) post-processing of simulation results to extract the M-θ hysteretic curves; and (4) calibration of each hysteretic curve to a phenomenological representation using the modified Ibarra-Medina-Krawinkler (mIMK) model [19] parameters (Figure 3), including K_e, θ_p, θ_{pc}, M_y, M_c, and Λ.

Figure 4 summarises the calibrated mIMK parameters with their maximum, mean, minimum, and standard deviation (SD) values. Figure 5 presents representative hysteretic curves, comparing the simulations with their mIMK calibrations. The results demonstrate a high degree of accuracy.

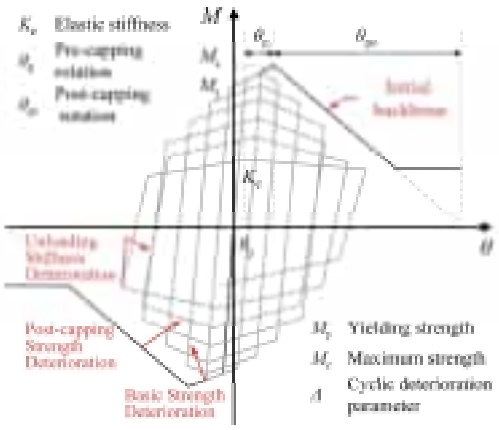


Figure 3. Illustration of the mIMK model

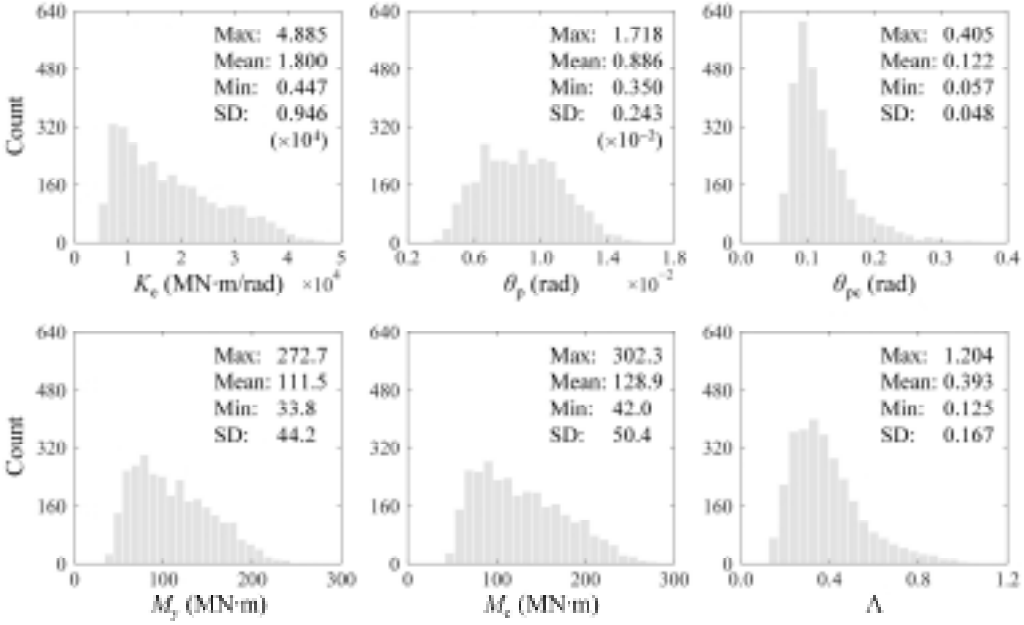

Figure 4. Calibrated mIMK parameters with the maximum, mean, minimum, and standard deviation (SD) values

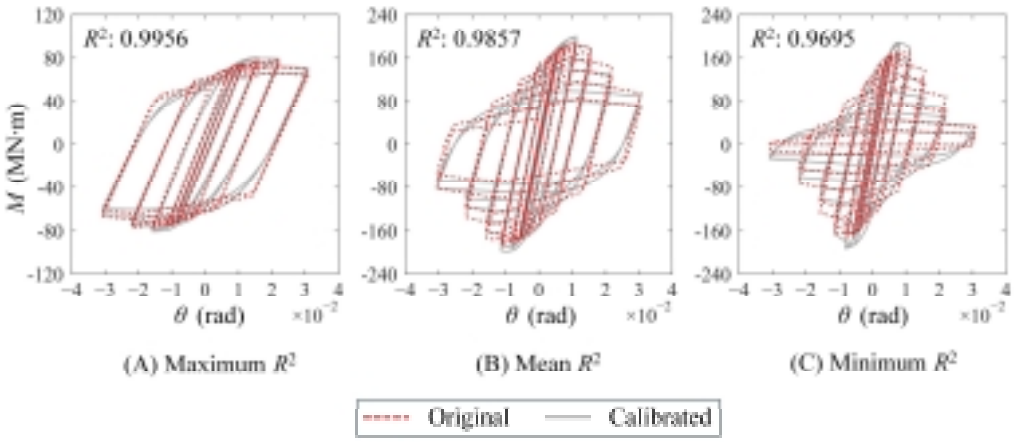

Figure 5. Representative results of hysteresis calibration

3.3 MLP surrogate model

An MLP is a feedforward neural network that learns a nonlinear mapping from input features to output targets through fully connected layers. In this study, the surrogate model is formulated as a single MLP with a vector-valued output, enabling the joint prediction of a vector of hysteretic parameters. The MLP model utilised the ReLU activation function and was trained using the Adam optimiser. The objective was to minimise the mean squared error (MSE) loss function. Training was terminated if the validation score did not improve by more than 10^{-4} for 50 consecutive iterations.

The dataset was first split into an 80/20 train/test partition (test set used only for the final evaluation). Within the training set, Optuna-based hyperparameter tuning used 5-fold cross-validation. For each fold, both inputs and outputs were standardised, and fitted on the fold training subset only to avoid data leakage. Table 1 summarises the hyperparameter search space for Optuna.

Table 1. MLP hyperparameter search space

Hyperparameter	Search space	Best
Number of hidden layers	[1, 3]	2
Units in layer *i*	[32, 320]	314/100
L2 regularisation	$[10^{-3}, 5\times10^{-2}]$	0.03634
Batch size	{32, 64, 128, 256}	32
Initial learning rate	$[10^{-3}, 5\times10^{-3}]$	0.00386

The Optuna objective maximised the mean cross-validated weighted coefficient of determination (R^2), computed as a weighted sum of per-output R^2 values. The weights for [K_e, θ_p, θ_{pc}, M_y, M_c, Λ] were set to [0.10, 0.25, 0.20, 0.10, 0.10, 0.25], following preliminary trials that indicated comparatively lower fit quality for θ_p, θ_{pc}, and Λ. The best hyperparameters were selected based on the cross-validated weighted R^2. Next, the final MLP model was trained on the full training set using the selected hyperparameters. Prediction performance was then reported on the held-out test set using per-output R^2.

Figure 6 demonstrates a good agreement between the predicted and calibrated data, confirming high performance. Table 2 further compares the R^2 and mean absolute percentage error (MAPE) achieved by the MLP model with those reported in a prior study [18] using six independently trained XGBoost models, demonstrating consistently higher accuracy for the MLP model – most notably for θ_p, θ_{pc}, and Λ.

Table 2. Prediction performance of the MLP model

Targets	MLP R^2	XGBoost R^2 [18]	MLP MAPE
K_e	0.9962	0.9966	2.90%
θ_p	0.9410	0.9264	5.34%
θ_{pc}	0.9666	0.9521	4.24%
M_y	0.9945	0.9929	2.38%
M_c	0.9954	0.9949	2.17%
Λ	0.9613	0.9439	5.83%

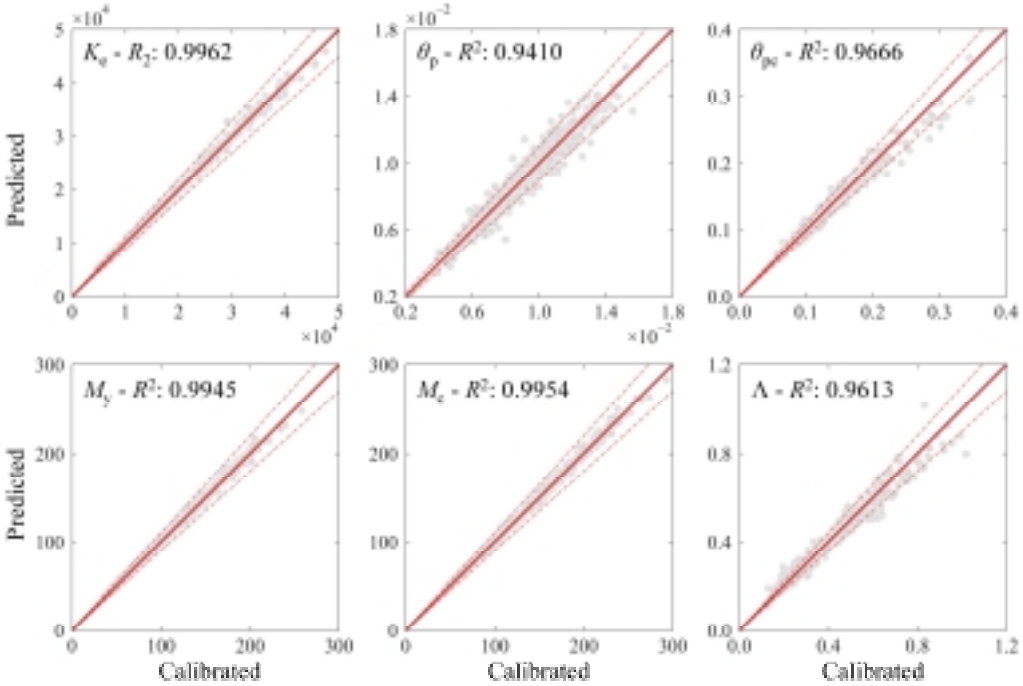

Figure 6. Comparison between the predicted and calibrated data

3.4 System-level integration

The system-level FE model was developed in OpenSees (Figure 7). The tower, blades, jacket members, and piles were represented using computationally cheaper beam elements. Following the well-established concentrated-plasticity approach, the HSTS was integrated into the system-level model using a coupled zero-length element assigned an mIMK uniaxial material whose parameters were provided by the MLP surrogate model, thereby forming an equivalent plastic-hinge representation.

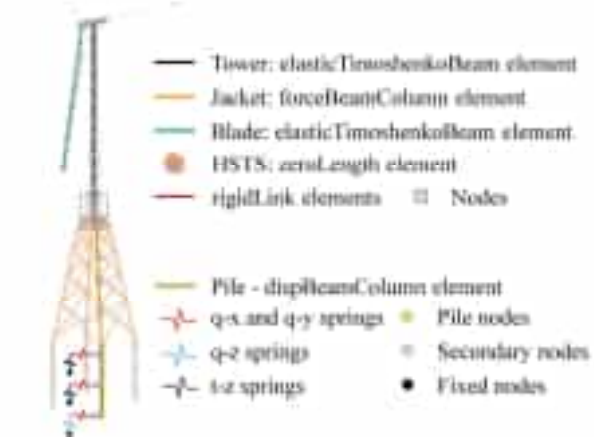

Figure 7. System-level FE model in OpenSees

4 Validation

4.1 Elastic structural dynamics

To validate the elastic structural dynamics of the developed surrogate-integrated FE model, a modal analysis was performed to obtain its periods of vibration in the fore-aft (FA) and side-side (SS) directions. Table 3 compares the periods of vibration of the FE model with the corresponding reference values for the prototype reported by von Borstel [20]. The differences are minor and the agreement is satisfactory, indicating that the proposed model captures the primary structural dynamics of the prototype with adequate fidelity.

Table 3. Periods of vibration of the surrogate-integrated FE model

Mode	Prototype (s)	FE model (s)
1st tower SS	3.49	3.52
1st tower FA	3.47	3.47
2nd tower SS	0.91	1.01
2nd tower FA	0.90	0.91

4.2 Hysteretic behaviour

The hysteretic response was finally reconstructed by feeding the predicted mIMK parameters and prescribed loading protocol into the HSTS FE model. Next, the reconstructed response was assessed against the corresponding FE-simulated response using the R^2 metric. Table 4 summarises the R^2 statistics over all 3000 samples, showing consistently accurate predictions with a mean R^2 value exceeding 0.96. In addition, approximately 3% of samples exhibit an R^2 below 0.90. Future research will prioritise the development of robust detection methods to ensure physical realism of hysteretic behaviour.

Table 4. Prediction performance of hysteretic behaviour

R^2	Train	Test	Overall
Mean	0.9649	0.9635	0.9646
Standard deviation	0.0284	0.0286	0.0284
Minimum	0.8538	0.8640	0.8539

4.3 Seismic behaviour

To validate the performance of the surrogate-integrated FE model regarding seismic assessment, a nonlinear time-history analysis (NLTHA) was conducted under the 1978 Tabas (Boshrooyeh) ground motion. Figure 8 compares tower-top displacements between the Abaqus model, comprising 19200 S4R and 1950 B31 elements, and the surrogate-integrated OpenSees model. The results demonstrate excellent agreement, with peak response discrepancies of around 8.6%.

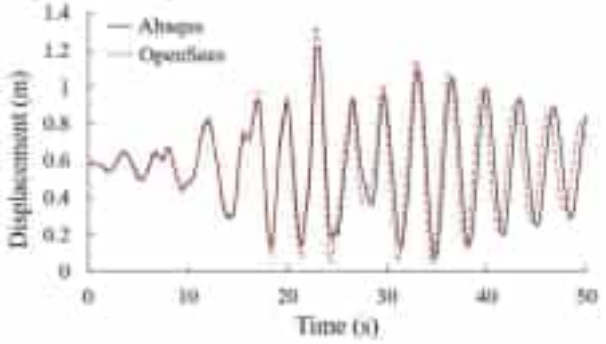

Figure 8. Seismic responses of the Abaqus model and the OpenSees model

Furthermore, to quantify efficiency gains, Table 5 summarises wall-clock times for representative analyses performed on an AMD Ryzen 9950X workstation. The surrogate model reduced hysteresis generation time from 16 minutes (Abaqus, 12-core configuration) to just 35 milliseconds. Moreover, the NLTHA was completed in 12.6 seconds via the OpenSees model, compared to 45 minutes for the Abaqus model, demonstrating its high computational efficiency for seismic assessment.

Table 5. Wall-clock times for representative analyses

Analysis	Abaqus	OpenSees
Hysteresis generation	16 min	35 ms
NLTHA	45 min	12.6 s

Overall, the proposed framework achieves a superior balance between predictive fidelity and computational efficiency. Beyond these performance gains, its modular architecture facilitates the integration of alternative ML algorithms, providing a versatile foundation for future comparative research into model performance.

5 Conclusions

This study presented a multi-fidelity surrogate-integrated modelling framework to enable efficient seismic assessment of tall energy infrastructures whose responses are governed by critical energy dissipation components.

The framework concentrates refined FE simulations on the critical component to generate a hysteresis database and trains a joint-prediction MLP surrogate to capture inter-parameter dependencies, thereby improving output consistency.

The approach was demonstrated on a representative 10-MW resilient JOWT, where an HSTS was characterised using a hysteresis database derived from 3,000 refined FE simulations and integrated into an OpenSees system-level model via a reduced-order plastic-hinge representation. The joint-prediction MLP model demonstrated consistently higher accuracy relative to independently trained XGBoost models – most notably for θ_p, θ_{pc}, and Λ. Validation results showed good agreement in modal properties and accurate hysteresis reconstruction (mean $R^2 > 0.96$), supporting the fidelity and efficiency of the proposed framework.

Abstract -

The digital transformation of existing building stock through Building Information Modelling (BIM) remains a significant goal and challenge in the Architecture, Engineering, and Construction (AEC) industry. This paper presents an automated Scan-to-BIM framework specifically designed for generating IFC-compliant roof model of buildings within a large urban environment from Unmanned Aerial Vehicle (UAV) photogrammetry data. The proposed method leverages geospatial building footprint data as semantic priors to intelligently filter the input large-scale 3D mesh and model the roofs of all individual buildings. A robust segmentation pipeline combining Taubin smoothing, region-growing algorithms, and adaptive height filtering successfully extracts planar roof surfaces. The extracted geometries are reconstructed into Industry Foundation Classes (IFC) compliant BIM objects using alpha-shape boundary regularisation, which preserves non-convex features such as conical spires and L-shaped roofs. Experimental validation is first conducted on a large building with a complex roof structure composed of 431 extracted roof patches, for which a patch-level correctness precision of 98.8% was achieved. The framework is subsequently demonstrated at the scale of a university campus to assess scalability and robustness.

1 Introduction

1.1 Background

A substantial proportion of the existing building stock lacks accurate and up-to-date digital representations. While new construction projects increasingly benefit from *born-digital* Building Information Models (BIM), many existing buildings—particularly those constructed prior to the widespread adoption of BIM—remain poorly documented in structured digital formats. This digital deficit limits the effectiveness of facility management, maintenance, retrofitting, and long-term asset monitoring.

Roofs constitute critical building elements that require regular inspection due to their continuous exposure to environmental stressors. Conventional inspection methods are labour-intensive, costly, and often pose safety risks. In recent years, Unmanned Aerial Vehicles (UAVs) equipped with high-resolution cameras have emerged as a practical alternative, enabling rapid and safe roof inspection at scale. Contemporary photogrammetry pipelines can transform UAV imagery into dense three-dimensional representations with centimetre-level geometric accuracy.

Despite these advances, a persistent *semantic gap* remains between raw geometric reconstructions—such as images, point clouds, and meshes—and structured, semantically-rich building models suitable for BIM-based workflows. Photogrammetric outputs are inherently unstructured and lack explicit semantic information, making it difficult to distinguish architectural elements such as roofs from surrounding terrain, vegetation, or urban clutter. As a result, manual interpretation and modelling remain common practice, leading to significant time and cost overheads.

Although extensive research has addressed large-scale processing and semantic labelling of aerial LiDAR and photogrammetric data, many Scan-to-BIM workflows still focus on individual processing stages, such as surface reconstruction or classification, rather than enabling end-to-end automated generation of IFC-compliant building components. In particular, approaches capable of robustly extracting roof geometry from dense photogrammetric meshes and directly translating it into interoperable BIM representations at scale remain limited. These challenges are further amplified by the size and geometric complexity of high-resolution UAV-derived datasets, underscoring the need for scalable and fully automated methods that bridge the gap between unstructured 3D data and structured digital building models. Importantly, the limitation is not the absence of individual algorithms, but the lack of an integrated and scalable framework that can bridge unstructured 3D data and structured smenatically-rich (BIM) representations in a fully automated manner.

2 Related Work

2.1 UAV Photogrammetry for Building Reconstruction

Unmanned Aerial Vehicle (UAV) technology is revolutionising building surveying and 3D reconstruction work-

flows. Besides, Structure-from-Motion (SfM) and Multi-View Stereo (MVS) algorithms first enabled fully automated 3D reconstruction pipelines from UAV imagery. Recently, depth-supervised neural radiation fields have also been growing rapidly to produce navigable 3D reconstructions from images [1]. Despite these advances, the resulting reconstructions—whether expressed as dense polygonal meshes, point-based representations, or implicit radiance fields—remain largely unstructured and lack explicit semantic information, limiting their direct integration into BIM-oriented workflows.

2.2 Roof Extraction from Aerial 3D Data

When processing aerial 3D data (3D LiDAR or photogrammetrically-reconstruction point clouds and/or meshes) of built environments, region growing is a commonly adopted strategy for roof plane extraction, where planar surfaces are incrementally expanded from initial seed regions according to geometric similarity criteria. To overcome the sensitivity of traditional region-growing approaches to seed selection and boundary leakage, Li et al. [2] introduced a hierarchical roof segmentation framework for airborne LiDAR data that combines clustering-based initialisation with boundary relabelling. Their method refines roof plane boundaries through multi-level segmentation, improving robustness in separating adjacent roof facets and handling complex roof structures.

Chen et al. [3] proposed a contour extraction method for UAV-derived point clouds that combines multi-level region-growing plane segmentation and plane fusion, followed by neighbourhood geometric feature analysis on the fused planes to robustly extract both roof and façade (wall) contours, including sparse structural boundaries.

Overall, existing plane segmentation strategies primarily rely on iterative grouping mechanisms—such as region growing, RANSAC-based fitting, or clustering—to aggregate coplanar points based on local geometric similarity. While these approaches are effective for extracting dominant planar structures, their performance is often sensitive to parameter selection, point density variations, and surface completeness, which can lead to boundary leakage or over-segmentation in complex roof and façade geometries.

2.3 Geospatial Data Fusion and Building Footprint Utilisation

The integration of geospatial building footprint data with 3D point clouds provides an effective means for spatial filtering and semantic guidance in large-scale urban reconstruction tasks. While numerous studies focus on extracting building footprints from remote sensing data, many practical applications——particularly in urban environments——benefit from the availability of pre-existing footprint datasets derived from cadastral maps or open geospatial repositories. Previous studies have demonstrated that integrating aerial imagery with LiDAR-derived elevation information can significantly improve building footprint delineation in dense urban environments [4, 5].

In contrast to these extraction-oriented approaches, the present work aims to leverage readily-available accurate geospatial footprint data directly as semantic priors to process new aerial 3D data (UAV photogrammetry). By using footprints to constrain spatial queries and filter large-scale UAV-derived meshes, the proposed framework efficiently isolates each individual building and corresponding roof regions, providing a reliable foundation for subsequent segmentation and IFC-compliant BIM reconstruction. The benefits are: (1) reduced computational demand (building-by-building processing reduces computational overload and removes the need for merging processes in tiling-based processing strategies); (2) enhanced quality where roofs are not searched in areas outside building footprints, reducing the risk of false positives.

2.4 Scan-to-BIM Methodologies

Automated Scan-to-BIM pipelines have been widely investigated, particularly for converting terrestrial laser scanning or indoor point cloud data into IFC-compliant BIM models. For example, Cloud2BIM [6] introduced a fully automated pipeline for reconstructing building elements from large-scale point clouds, while BridgeTwin [7] proposed a semi-automated workflow tailored to bridge infrastructure. They are predominantly designed for ground-based acquisition scenarios and structured geometries, relying on interior layouts, predefined templates, or significant user interaction. As such, they are not directly applicable to UAV-derived photogrammetric meshes.

2.5 Research Gap and Contribution

While significant progress has been made in individual elements of the Scan-to-BIM pipeline, several critical gaps remain:

1. **Geometric Complexity**: Many existing roof modelling and Scan-to-BIM approaches operate on sparse or abstracted representations, such as planar segments derived from aerial LiDAR or simplified point clouds. As a result, these methods typically favour simplified parametric roof models (e.g., gable or hip roofs), limiting their ability to represent complex roof morphologies, including conical spires, L-shaped roofs, and non-convex boundaries. Leveraging dense UAV-derived photogrammetric meshes offers the potential to capture roof geometry at a higher level of detail, but scalable methods capable of exploiting this richness while remaining fully automated remain limited.

2. **BIM-compliant Output**: Few automated pipelines generate IFC-compliant models preserving non-convex geometries suitable for downstream digital twin applications, with most focusing on simple primitives.
3. **End-to-End Automation**: Most workflows require manual intervention for quality control, parameter tuning, or geometric editing, preventing deployment at scale across large building portfolios.

This work explores a fully automated Scan-to-BIM framework for large-scale reconstruction of building roofs from UAV photogrammetry. Its main contribution is the use of geospatial building footprints as semantic priors to guide instance-level extraction of roof structures from dense photogrammetric meshes. This footprint-guided design improves the efficiency and robustness of roof reconstruction in complex urban environments and enables the automatic generation of IFC-compliant roof models, including non-convex geometries, without manual intervention.

3 Method

The proposed framework is designed as an end-to-end automated Scan-to-BIM pipeline that processes dense UAV-derived photogrammetric meshes together with 2D geospatial building footprints as semantic priors, in order to directly generate IFC-compliant roof models without manual intervention.

By leveraging geospatial footprint data to guide building-level segmentation, the method enables efficient and scalable processing of large-scale urban scenes, bridging the gap between unstructured 3D reconstructions and structured BIM representations.

The method works in three stages:

1. Building Photogrammetric Data Segmentation,
2. Planar Primitive Segmentation, and
3. Automated IFC Reconstruction.

3.1 Building Photogrammetric Data Segmentation

The proposed framework operates on two heterogeneous but spatially consistent data sources: a dense 3D photogrammetric mesh generated from UAV imagery and a set of 2D geospatial building footprints. Both datasets are georeferenced within a common projected coordinate system, as UAV photogrammetry workflows typically employ RTK-GNSS positioning and Ground Control Points (GCPs) to ensure accurate global geolocation.

Given this shared spatial reference, no additional geometric alignment between the photogrammetric mesh and the footprint data is required. Instead, the building footprints are directly exploited as semantic priors to spatially filter the mesh, enabling the isolation of roof-level geometry corresponding to known building extents while discarding unrelated scene elements such as terrain, vegetation, and surrounding infrastructure.

The input photogrammetric mesh is denoted as

$$M = (V, F),$$

where $V = \{v_1, v_2, \ldots, v_n\}$ represents the set of mesh vertices and $F = \{t_1, t_2, \ldots, t_m\}$ denotes the set of triangular faces. Each vertex $v_i \in V$ is defined in a Cartesian coordinate system consistent with the georeferenced UAV reconstruction. Each face $t_i \in F$ is associated with a surface normal vector $\vec{n}_i$ and a local adjacency neighbourhood $\mathcal{N}(i)$ defined by shared edges.

The building footprint dataset consists of a set of polygonal geometries

$$P = \{P_b\},$$

where each polygon P_b represents the known footprint of a building of interest b and is defined in a global geodetic reference frame, reprojected as necessary to ensure coordinate consistency with the mesh.

For each building b, its corresponding footprint polygon P_b is used to segment the overall UAV-derived mesh and extract the subset of geometry associated with that building. A mesh vertex $v_i \in M$ is retained if and only if its orthogonal projection onto the horizontal plane lies within the footprint polygon P_b:

$$M_b = \left\{ v_i \in M \;\middle|\; \mathrm{Contains}\big(P_b, v_i^{xy}\big) \right\}.$$

This footprint-guided cropping step removes non-building geometry at an early stage, substantially reducing data volume and computational complexity prior to subsequent geometric segmentation. By constraining processing to semantically relevant regions, the approach improves robustness and scalability when applied to large-scale UAV photogrammetry datasets.

3.2 Planar Primitive Segmentation

For each building of interest b, individual roof panels are extracted from the cropped mesh M_b using a multi-stage segmentation pipeline designed to be robust to noise, irregular sampling, and complex roof morphologies.

3.2.1 Geometric Smoothing and Decimation

UAV photogrammetric meshes typically contain high-frequency noise that can adversely affect surface normal estimation and segmentation stability. To suppress high-frequency noise in the photogrammetric mesh, Taubin smoothing [8], a non-shrinking signal-processing–based filtering method, is applied ($\lambda = 0.5$, $\mu = -0.53$, $N = 20$).

The selected parameters were chosen to suppress high-frequency noise while maintaining sharp roof edges and planar integrity. The smoothing strength (λ) controls noise attenuation, while the negative scaling factor (μ) compensates for contraction effects introduced by the Laplacian operator. Performing $N = 20$ iterations was empirically found to provide sufficient noise reduction for stable surface normal estimation without over-smoothing architectural features critical for subsequent planar segmentation.

Subsequently, mesh simplification is applied using Quadric Error Metric (QEM) decimation to reduce geometric complexity while preserving roof morphology. Rather than enforcing a fixed target triangle count, the level of decimation is adaptively determined based on the footprint area of each building. Specifically, the target triangle budget N_b for building b is defined proportionally to its footprint area A_b as

$$N_b = \lceil \alpha \cdot A_b \rceil ,$$

where α is a global density parameter controlling the number of retained triangles per unit area. This adaptive allocation ensures that larger buildings retain proportionally higher geometric resolution than smaller ones, while maintaining consistent surface fidelity across the dataset.

QEM decimation proceeds by iteratively collapsing edges while minimising the squared geometric error between the original and simplified surfaces, thereby preserving salient geometric features such as planar roof facets and sharp ridgelines [9]. By reducing mesh density in a controlled manner, this adaptive simplification significantly improves computational efficiency in subsequent processing stages, particularly during surface normal estimation and region-growing segmentation, without compromising the geometric fidelity required for accurate roof plane extraction.

3.2.2 Region Growing Segmentation

Planar roof segments are identified using a region-growing algorithm driven by surface normal consistency. Starting from an initial seed triangle t_i, a region is iteratively expanded to adjacent triangles $\{t_j \mid j \in \mathcal{N}(i)\}$ if the angular deviation between their surface normal vectors satisfies the following planarity criterion:

$$\arccos(\vec{n}_i \cdot \vec{n}_j) < \theta_{\text{th}},$$

where $\vec{n}_i$ and $\vec{n}_j$ denote the unit normal vectors of triangles t_i and t_j, respectively. The threshold θ_{th} is set to 10°, empirically selected to balance robustness to minor surface undulations against effective separation of adjacent roof facets with distinct orientations.

This process yields a set of planar roof regions

$$\mathcal{R}_b = \{\mathcal{R}_b^1, \mathcal{R}_b^2, \ldots, \mathcal{R}_b^K\},$$

where each region $\mathcal{R}_b^k$ consists of one or more connected triangles representing an individual roof panel of building b.

3.2.3 Adaptive Semantic Filtering via Height Analysis

To discriminate true roof surfaces from vertical façades, ground artifacts and secondary structures such as balconies, an adaptive height-based semantic filtering strategy is employed. Unlike fixed global height thresholds, which are unsuitable for scenes with varying terrain elevation, this approach dynamically adapts to the vertical extent of each individual building.

For each building b, a relative height threshold is defined as a fixed proportion of its vertical span:

$$z_b^{\text{th}} = z_b^{\max} - 0.3 \left(z_b^{\max} - z_b^{\min} \right),$$

where $z_b^{\max}$ and $z_b^{\min}$ denote the maximum and minimum elevations of all mesh vertices associated with building b, respectively.

Each segmented roof region $\mathcal{R}_b^k$ whose centroid elevation $z_c < z_b^{\text{th}}$ is classified as a non-roof element and discarded. This adaptive criterion ensures that only the primary roof structure is retained, even in the presence of multi-level buildings, terraces, or uneven terrain.

3.3 Automated IFC Reconstruction

The final stage converts the validated planar roof segments into georeferenced, IFC-compliant BIM entities without manual intervention.

3.3.1 Plane Estimation via Principal Component Analysis

For each retained roof patch P_b^k, an optimal planar representation is estimated using Principal Component Analysis (PCA). The covariance matrix of the patch vertices is computed, and the eigenvector corresponding to the smallest eigenvalue is selected as the surface normal $\vec{n}_k$. The patch vertices are subsequently projected onto the corresponding local 2D plane to facilitate robust boundary extraction.

3.3.2 Boundary Regularisation Using Alpha Shapes

To reconstruct complex and non-convex roof boundaries, such as L-shaped footprints or conical turrets, boundary regularisation is performed using the Alpha Shape algorithm. The algorithm operates on the Delaunay triangulation of the projected roof points, removing triangles whose circumradius exceeds a threshold α. This filtering yields polygonal boundaries that closely follow the true roof geometry while suppressing noise-induced artifacts [10].

In this work, the parameter α is set to 2.0 m, empirically selected to balance boundary smoothness and geometric fidelity. Smaller values preserve fine architectural details at the cost of boundary fragmentation, whereas larger values lead to over-smoothing and loss of concave features. The chosen value enables robust reconstruction of irregular roof boundaries while suppressing noise-induced artifacts, ensuring suitability for IFC-compliant BIM representation.

3.3.3 IFC Entity Instantiation and Georeferencing

The regularised 2D roof boundaries are reprojected into 3D space and instantiated as `IfcRoof` entities. Geometry is represented using `IfcShellBasedSurfaceModel`, which supports complex and non-manifold roof surfaces and ensures compatibility with downstream BIM applications.

Georeferencing information is inherited directly from the UAV-derived photogrammetric mesh, which is originally reconstructed in a projected coordinate system based on onboard GNSS and flight metadata. To preserve numerical precision, model geometry is maintained in a local Cartesian coordinate system, while global positioning is encoded explicitly using the `IfcMapConversion` entity. The associated `IfcProjectedCRS` defines the transformation to the global reference system, enabling consistent spatial alignment with GIS datasets and ensuring interoperability across BIM and geospatial platforms.

4 Experimental Results

The proposed framework is evaluated using UAV-derived photogrammetric data wit <2 cm GSD acquired over the University of Edinburgh Central Campus, a dense urban environment with diverse building typologies and complex roof geometries (fig. 1). To assess both accuracy and scalability, a two-stage evaluation strategy is adopted, consisting of detailed validation on a representative individual building followed by deployment across the full campus.

For single-building evaluation, the Edinburgh Futures Institute (EFI) is selected due to its complex roof topology (fig. 2a). The corresponding photogrammetric mesh comprises 11,772,857 vertices and 23,527,453 triangular faces, providing a high-resolution geometric representation suitable for detailed geometric assessment.

Then, to evaluate the performance of our method in large scale environments, the complete campus dataset (fig. 1) is processed. This dataset contains approximately 57 million vertices and 114 million triangular faces, covering an area of 0.476 km^2. The campus-scale evaluation includes multiple building types and roof configurations, enabling a robust assessment of scalability and consistency.

Table 1. Quantitative results summary.

Metric	Value
Roof Segmentation (section 4.1)	
Extracted patches	431
Precision	98.8%
Geometric Alignment (section 4.2.1)	
RMSE to BIM surfaces	0.84 m
Mean deviation	0.68 m
Min deviation	0.002 m
Max deviation	~2.0 m
Matched area (τ = 2.0 m)	99.0%
Object Consistency(section 4.2.2)	
Matched entities	270 / 292
Matching rate	92.5%
Mean consistency	0.66
Scalability(section 4.2.3)	
Mesh size	~57M V, ~114M F
Spatial extent	0.476 km^2

4.1 Roof Segmentation Results

The proposed pipeline successfully processed the raw photogrammetric mesh and extracted individual roof surfaces in a fully automated manner. For the EFI building, a total of 431 unique roof patches were identified across the study area. Patch-level precision is computed by manually checking whether each extracted patch corresponds to a valid roof surface.

Qualitative inspection further indicates that the segmentation achieves a clean separation of complex roof structures into distinct planar elements. Non-roof components, including ground terrain, facades, balconies and surrounding vegetation, were effectively removed during the semantic filtering stage, leaving only architecturally relevant roof surfaces.

As illustrated in fig. 2b, the resulting segmentation provides a noise-free and topologically coherent representation of the complex building roof. Individual roof panels are clearly delineated, which forms a suitable basis for subsequent geometric regularisation and IFC-based BIM reconstruction.

4.2 Geometric Accuracy Evaluation

The evaluation in this study is conducted at three complementary levels. First, patch-level precision assesses whether each extracted roof patch corresponds to a valid roof surface after segmentation and filtering. Second, surface-level geometric alignment evaluates the Euclidean distance between sampled points on the generated IFC roof surfaces and the nearest reference BIM roof surfaces. Third, object-level consistency evaluates centroid-based

(a) UAV-derived photogrammetric reconstruction.

(b) Automated roof detection and segmentation results.

Figure 2. UAV-derived photogrammetric reconstruction and automated roof detection and segmentation results for the EFI building.

association between extracted roof regions and BIM roof entities.

4.2.1 Evaluation of Global Geometric Alignment

To assess the geometric fidelity of the extracted roof surfaces, the spatial alignment between the generated IFC roof geometry and the corresponding roof surfaces in the reference BIM model was evaluated using a surface-based distance analysis. Specifically, geometric deviation was measured as the Euclidean distance between sampled points on the generated IFC roof surfaces and their nearest points on the reference BIM roof surfaces.

Minor geometric discrepancies between the reference BIM and the UAV-derived photogrammetric mesh are expected, as the two datasets were generated from different data sources and represent different abstraction levels (as-designed versus as-built geometry).

Within this context, the global alignment analysis between the generated IFC roof surfaces and the reference BIM roof geometry yielded a root mean square error (RMSE) of 0.84 m and a mean error of 0.68 m, with a minimum of 0.002 m and a maximum of approximately 2.0 m. It should be noted that a systematic vertical offset was observed between GPS-derived UAV elevations and the local coordinate reference system used in the BIM model, indicating a datum inconsistency of approximately 0.7 m.

To robustly identify valid extracted roof surface geometry under these conditions, a **detection threshold** of $\tau_{\text{match}} = 2.0$ m was adopted. A sampled point x_{gen} on a generated IFC roof surface is considered successfully matched if its distance to the nearest reference BIM roof surface S_{gt} satisfies

$$d(x_{\text{gen}}, S_{\text{gt}}) \leq 2.0 \text{ m}.$$

This threshold accommodates the observed systematic vertical offset, potential horizontal geolocation errors, and local geometric deviations at roof edges, while avoiding the exclusion of valid roof surfaces. Under this criterion, approximately 99.0% of the extracted roof surface area was successfully matched to roof elements in the reference BIM model, indicating that the derived roof geometry predominantly corresponds to genuine roof structures rather than noise.

4.2.2 Evaluation of Local Surface Fidelity and Higher-Level Object Consistency

Beyond patch-level precision and surface-based deviation analysis, we further assessed object-level consistency by associating extracted roof regions with reference BIM roof entities. Because the extracted roof regions are typically more fine-grained than the BIM representation, surface-level correspondence does not yield a one-to-one mapping. We therefore perform centroid-based association: each extracted roof region is matched to the nearest BIM roof panel entity within a search radius of $r_{\text{search}} = 5.0$ m. The larger tolerance (compared to the surface-distance threshold) accounts for the observed global offset and centroid displacement caused by region fragmentation.

For each matched pair, an object-level geometric consistency score is computed from area and slope agreement:

$$S_{\text{obj}} = 0.7 \cdot S_{\text{area}} + 0.3 \cdot S_{\text{slope}},$$

where the area similarity term is defined as

$$S_{\text{area}} = 1 - \frac{|A_{\text{gen}} - A_{\text{gt}}|}{\max(A_{\text{gen}}, A_{\text{gt}})},$$

penalising over-fragmentation, and the slope similarity term is defined as

$$S_{\text{slope}} = 1 - \frac{|\theta_{\text{gen}} - \theta_{\text{gt}}|}{45^\circ},$$

Using this evaluation, 270 out of 292 extracted roof panel entities were successfully associated with a BIM roof panel element (92.5%), with an average S_{obj} of 0.66. Slope agreement was consistently high, supporting the accuracy of PCA-based plane estimation, whereas lower area agreement mainly reflects differences in modelling granularity (a BIM roof panel versus multiple extracted planar regions).

4.2.3 Scalability and Campus-Scale Deployment

To evaluate scalability, the proposed framework was applied to the complete UAV-derived photogrammetric reconstruction of the University of Edinburgh Central Campus. Geospatial building footprints covering the entire campus were used as semantic priors to guide building-level mesh filtering and automated roof extraction.

Figure 3 shows (a) the spatial distribution of building footprints and (b) the corresponding campus-scale roof extraction results. The framework successfully processed all buildings in a fully automated manner, handling diverse architectural typologies without manual intervention or parameter adjustment.

These results demonstrate that the footprint-guided processing strategy enables robust and efficient scaling from individual buildings to large urban areas, confirming the feasibility of the proposed workflow for campus- and city-scale roof modelling applications.

To provide a concise overview of the quantitative findings reported across Sections 4.1–4.2.3, Table 1 summarises the key performance metrics of the proposed framework.

5 Discussion and Future Work

The proposed method demonstrates robust performance in automated geometric roof reconstruction. Building on this, several directions for future research can be identified to further enhance the method's performance as well as the semantic richness, generality, and applicability of the resulting BIM models.

5.1 Automated Defect Mapping via Texture Projection

The current framework produces geometrically accurate but textureless roof representations, effectively generating 'white-box' models. A natural extension is the retexturing of those dense meshes and then evaluate and record the condition of each roof panel. Using state-of-the-art computer vision methods (e.g., Mask R-CNN or YOLO-based detectors), the panels could be analysed to identify sub-components [11], individual slates [12], and their defects. As a result, defects could be spatially mapped back to their precise 3D locations and tracked over time (over multiple inspections), thereby transforming the static geometric BIM into a dynamic *digital twin* capable of supporting condition monitoring and predictive maintenance workflows.

5.2 Integration with Deep Learning–Based Segmentation

The current framework adopts a geometry-driven segmentation strategy based on footprint-guided filtering, surface-normal consistency, and adaptive height analysis. This design offers several practical advantages for large-scale Scan-to-BIM deployment. First, it avoids the need for large annotated training datasets, which remain scarce for UAV-derived roof meshes with IFC-oriented labels. Second, the method is computationally lightweight and interpretable, making it easier to deploy across new urban areas without retraining. Third, the reliance on explicit geometric constraints is well suited to planar and piecewise-planar roof typologies, which remain common in many existing building stocks.

Nevertheless, the present approach also has limitations. Because it relies on planarity assumptions and empirically selected thresholds, its performance may degrade for curved, free-form, or highly irregular roof structures, as well as in areas affected by noise, incomplete reconstruction, or weak geometric boundaries. Under these conditions, the method may produce over-segmentation of smoothly curved surfaces into multiple planar patches, incomplete recovery of roof boundaries, or simplified geometric approximations that do not fully preserve the original roof form. These limitations are inherent to the current geometry-driven design and should be interpreted within

the intended application domain of predominantly planar and piecewise-planar roof reconstruction. In such cases, deep learning-based approaches may provide complementary benefits by learning higher-level geometric and contextual features directly from data.

Future work will investigate hybrid strategies in which deep learning is used to support semantic pre-classification and boundary refinement, while the current geometry-based reconstruction and IFC generation stages are retained for interpretable and BIM-compliant model generation. In particular, multimodal learning on textured photogrammetric meshes could combine 3D geometric information with radiometric appearance cues, improving robustness for challenging roof typologies such as domes, vaults, spires, and curved shells.

6 Conclusion

This paper presented a fully automated Scan-to-BIM framework for large-scale roof modelling from UAV-based photogrammetric data. By exploiting readily available geospatial building footprints as semantic priors, the proposed approach enables efficient isolation of roof geometry from dense urban reconstructions and supports robust processing of complex roof structures.

The framework directly generates georeferenced, IFC4-compliant roof models attributed to a known set of buildings from unstructured photogrammetric meshes, preserving non-convex roof geometries through alpha-shape–based boundary regularisation and avoiding manual intervention. This establishes a practical link between reality capture outputs and interoperable BIM representations suitable for downstream digital twin and GIS applications.

Experimental results on a university campus dataset demonstrate both accuracy and scalability. For a representative complex building, 431 roof panels were correctly extracted with a precision of 98.8%, while campus-scale experiments confirmed the feasibility of applying the workflow to large urban environments.

Overall, the proposed method provides a scalable and fully automated Scan-to-BIM workflow for reconstructing planar and complex non-convex roof geometries from UAV photogrammetric meshes using geospatial building footprints as semantic priors. The contribution of this study lies not in replacing learning-based roof understanding methods, but in demonstrating that a geometry-driven and IFC-oriented pipeline can already provide robust and interpretable performance for large-scale deployment without training data or manual modelling. At the same time, the framework is not intended to address all roof typologies equally well. Curved and free-form structures remain a clear limitation and motivate future hybrid approaches that combine learned semantic understanding with the current geometric reconstruction and BIM generation stages.

Abstract –

Ballastless track slab systems are increasingly adopted in metro and high-speed rail projects due to their superior geometric stability, reduced maintenance requirements, and long-term performance. Construction of such infrastructure is more mechanised, driven by stringent requirements on construction speed, dimensional precision, and repeatability in processes such as material handling, batching, concrete distribution, and slab handling. Despite this high level of mechanisation, rebar cage assembly for track slabs remains largely manual, time-consuming, and ergonomically demanding, and continues to represent a critical bottleneck in ballastless railway track construction. This challenge is further exacerbated by constrained possession windows and limited spatial envelopes typical of metro environments.

This paper presents a feasibility assessment of a BIM-driven process planning and robotic assembly framework for rebar cages used in ballastless railway track slab construction. The study adopts a process-level automation perspective, recognising that track slab reinforcement exhibits manufacturing-like characteristics with repetitive yet bounded geometric variability across a project. Parametric BIM models are used to extract rebar geometry and connectivity, which are translated into robot-executable assembly sequences while accounting for geometric feasibility, interim cage stability, and robotic reachability. Feasibility is evaluated using a high-fidelity digital twin implemented in CoppeliaSim, where collision-free robotic pick–move–place operations are demonstrated under representative railway track slab geometries and spatial constraints. The results show that BIM-driven process planning and simulation provide a technically viable pathway for deploying robotic rebar cage assembly systems in metro and high-speed rail construction, subject to further physical validation.

Construction robotics, rebar cage assembly, ballastless track slabs, BIM-to-robot integration, digital twin, automation

1 Introduction

The growing need for fast and precise construction, as well as safety and scalability, in the expansion of metro and high-speed rail systems around the globe has led to the adoption of ballastless track slab systems like plinth track systems and precast slab track systems over ballasted track systems, especially in tunnels, viaducts, and urban areas. As a result, railway track construction has achieved a relatively high level of mechanization compared to conventional building projects, with activities such as rail welding, slab placement, and material handling being extensively mechanized.

Despite this progress, rebar cage assembly for track slabs remains largely manual and continues to form a critical bottleneck in otherwise mechanized workflows. In current practice, rebar cage preparation for cast-in-situ (CIS) track slabs requires large labor crews operating over extended durations. Similar challenges persist in precast slab manufacturing yards, where upstream processes such as batching and concrete distribution are automated, and Computer Numerical Control (CNC) machines are widely used for cutting and bending of rebars, yet cage assembly and tying remain predominantly manual. Figure 1 illustrates the typical manual preparation of rebar cages on site, highlighting the labor-intensive nature of reinforcement assembly that persists despite extensive mechanization in other track slab construction activities.

Unlike conventional building slabs, ballastless railway track slabs are designed with limited flexibility in geometry and detailing, as they must satisfy strict requirements related to track alignment, stiffness continuity, and long-term structural performance. Consequently, track slab reinforcement layouts are

highly standardized within a project. Even where horizontal curves, transitions, turnouts, or station zones are present, the resulting variations are typically confined to a finite and well-defined set of slab and reinforcement configurations. This characteristic renders track slab construction closer to a manufacturing process than a one-off site activity, with repetition and uniformity dominating over ad hoc geometric variation.

Figure 1 Manual preparation of rebar cage assembly on site and prefabrication yard respectively

From an automation perspective, this bounded variability is advantageous. The repetitive nature of track slab reinforcement enables reuse of motion planning strategies and robotic behaviors across multiple slab instances, reducing the need for continuous reconfiguration. While this study evaluates a representative track slab case, the emphasis is on assessing whether a BIM-driven robotic approach is technically feasible and operationally compatible at the project scale, where multiple slab variants typical of metro construction can be accommodated through automated adaptation rather than manual reprogramming, rather than on optimizing productivity for a single instance.

At the same time, large-scale railway projects operate under strict possession windows with multiple construction fronts active simultaneously. Manual assembly of rebar cage under such conditions introduces schedule uncertainty, quality variability, and safety risks, as labor-intensive tasks are difficult to scale across parallel work zones. Recent studies report that physically demanding and repetitive construction work, such as reinforcement work, is one of the least preferred jobs in the industry, which has resulted in the use of migrant workers in large-scale construction projects. Such conditions further emphasize the need to explore the possibility of applying automation techniques in railway construction.

Recent developments in construction robotics, digital twins, and BIM-based automation offer promising pathways to address these challenges. Nevertheless, current robotic technologies are mostly restricted to single-task automation, most prominently rebar tying, or are applicable only in stationary factory environments. Fully integrated, BIM-driven cage assembly frameworks that explicitly address the repetitive yet spatially constrained nature of railway track slab construction remain underexplored.

Against this background, this paper investigates the feasibility of a BIM-driven process planning and robotic assembly framework for rebar cages used in ballastless railway track slab construction. Productivity aspects are explored only at a conceptual level and are not intended as definitive performance predictions while economic evaluation is not part of this paper. Building upon existing studies on BIM-driven robotic reinforcement assembly and feasibility-oriented sequencing algorithms, the objective of this work is to evaluate whether such a framework can be technically realized and deployed within railway-specific geometric, spatial, and operational constraints. The study employs digital process planning and high-fidelity simulation to assess reachability, sequencing feasibility, and collision-free execution, thereby providing an informed basis for future physical implementation in prefabrication yards and, potentially, on-site metro construction using alignment-guided deployment platforms.

2 Literature review

Automation in the construction sector has continued to receive considerable attention from research and industry fields over the last two decades, owing to the challenges of low productivity growth, labour shortages, safety concerns, and variability in quality related to traditional construction methods [1]; [2]. In contrast to manufacturing, the construction sector remains largely site-based, labour-intensive, and fragmented, making it difficult to scale traditional productivity enhancement methods. In this scenario, reinforcement work has been identified as a domain of particular relevance for automation, involving repetitive, physically demanding, and time-consuming activities with well-defined geometric and structural constraints [3].

Availability of labour has emerged as a key bottleneck in the delivery of infrastructure projects across the globe. Recent global studies have pointed out that the construction sector is facing one of the most serious shortages of skilled labour compared to other key sectors, due to an ageing workforce, reduced entry of youth into the skilled trades, rising labour costs, and increased regulatory and safety demands [1]. Such issues are even more acute in large metro and railway projects, which are implemented with very tight possession windows, limited site space, and intense schedule pressures. Under such conditions, automation is increasingly being considered not only as a productivity solution, but also as a response to labour dependence, safety, and delivery

risks.

Rebar cage assembly is a key bottleneck in reinforced concrete construction. Manual handling, placement, and binding of rebars are prone to serious ergonomic hazards, introduce variability in quality, and often lie on the critical path of construction activities [4]. The physical workload associated with reinforcement installation has been shown to increase with spatial complexity and congestion, further reducing productivity and increasing execution time [5]. These limitations are amplified in slab-type infrastructure elements, such as metro and high-speed railway track slabs, where dense reinforcement layouts must be produced rapidly and within strict dimensional tolerances.

Automation of upstream processes of reinforcement preparation such as cutting, bending, and batching is relatively mature. CNC-controlled machines and digitally integrated fabrication systems are widely deployed in precast factories and rebar yards, and significant gains have been realized in terms of productivity, precision, and material efficiency [6]. However, the downstream processes, particularly sorting, sequencing, and rebar cage assembly, remain predominantly manual, offsetting gains achieved during earlier stages of mechanisation.

Significant advances have been made in task-oriented robotic systems, especially in the area of rebar tying.

Vision-based robotic tying systems using RGB-D sensing and learning-based perception have demonstrated high accuracy and industrial feasibility [7] [8], while commercial systems such as TyBOT confirm productivity and safety benefits for large planar reinforcement meshes [4]. More recent research has extended robotic tying to non-planar configurations using six-degree-of-freedom pose estimation [9]. However, these systems typically assume manual placement of rebars and do not address the assembly of rebar cages as an integrated process.

Robotic assembly of rebar cages has been investigated primarily under controlled laboratory or factory conditions. Early studies demonstrated feasibility for beams and columns [3], while more recent work proposed gantry-based robotic production cells validated through simulation and experimental trials [10]. A key challenge identified across these studies is the determination of a feasible installation sequence that avoids geometric blocking and ensures interim cage stability. Digital twin–based sequencing approaches, including depth-first search heuristics, have been proposed to address this challenge [11]. However, validation has largely been limited to generic or building-scale rebar cages and stationary production environments.

BIM-enabled robotic frameworks have further advanced automation by providing machine-readable representations of reinforcement geometry and enabling digital continuity from design to robotic execution. Several studies have demonstrated BIM-driven robotic workflows validated in simulation environments such as CoppeliaSim [10], [12]. Despite these advances, most BIM–robot pipelines still require manual refinement of sequencing logic and calibration, limiting their scalability for infrastructure-scale applications.

Importantly, existing studies do not explicitly address the specific characteristics of ballastless railway track slab construction, which is governed by elongated slab geometries, repetitive yet bounded reinforcement layouts, linear deployment conditions, and strict spatial constraints imposed by railway infrastructure. Unlike conventional building structures, track slab reinforcement exhibits limited design variability within a project, resulting in manufacturing-like repetition along the alignment. This characteristic suggests that automation feasibility in railway applications is governed less by geometric complexity and more by effective process planning, sequencing logic, and integration with construction workflows.

Against this backdrop, the present study builds on established principles of BIM-driven robotics and feasibility-oriented sequencing, but repositions rebar cage assembly within the context of railway track slab construction. The study focuses on integrating BIM-based data extraction, constraint-informed installation order assignment, and high-fidelity digital twin validation to evaluate whether robotic rebar cage assembly can be practically deployed under railway-specific spatial, operational, and constructability constraints.

3 Methodology

Figure 2 illustrates the overall methodology adopted in this study, showing the end-to-end workflow from BIM-based data extraction and installation sequence assignment to robotic simulation and digital validation. The workflow begins with parametric data extraction from BIM models, where reinforcement geometry and connectivity are automatically retrieved from Bar Bending Schedule (BBS) inputs. A feasible rebar installation sequence is then assigned using constraint-based & Depth-first-search (DFS) logic informed by prior robotic assembly research. The extracted data and sequencing information are subsequently integrated into a robotic simulation environment, where inverse kinematics, collision-aware motion planning, and gantry-based robot control are implemented. The complete process is validated using a digital twin to assess reachability, collision-free execution, and operational feasibility under railway track slab constraints.

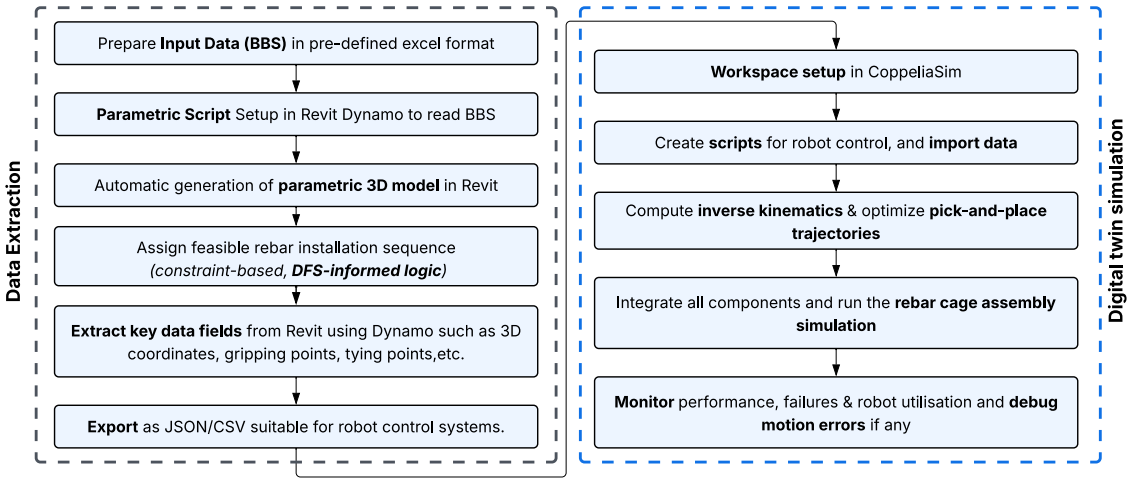

Figure 2 Methodology flow chart

4 BIM-Based Data Extraction for Railway Track Slab Reinforcement

The proposed framework relies on BIM as the authoritative source of reinforcement information for robotic process planning and simulation. A parametric rebar cage model corresponding to a ballastless railway track slab is developed as shown in figure 3 in accordance with typical BBS (figure 4) used in metro construction. The model captures the geometric definition of individual rebars, including bar diameter, length, bending shape, spatial coordinates, and layer information, as well as connectivity at intersections.

Assignment of the rebar installation order is formulated as a process planning problem rather than an optimisation task. In robotic rebar cage assembly, this sequencing problem can be represented as a constrained graph traversal problem, where individual rebars are treated as nodes and feasibility constraints such as geometric accessibility, collision avoidance, and interim structural stability-define precedence relationships. A Depth-First Search (DFS) based logic is employed to explore this solution space and generate a feasible installation sequence, consistent with established practices in robotic reinforcement assembly research. Similar DFS-based sequencing concepts have been previously reported for automated rebar cage fabrication in International Symposium on Automation and Robotics in Construction (ISARC) literature [11], where feasibility-oriented installation orders were shown to be sufficient for robotic execution.

In this study, rebars are grouped into layers based on their vertical position relative to the track slab base, with installation proceeding from lower to upper levels. Within each layer, the sequence is determined based on the distance from reference fixtures to ensure accessibility and avoid geometric blocking. The DFS algorithm incrementally builds the sequence while respecting constraints such as layer-wise progression, non-blocking placement, and support-first logic.

Compared to rule-based or layer-wise approaches, DFS offers greater flexibility in handling complex connectivity and non-uniform layouts, particularly where multiple valid sequences exist, while ensuring identification of at least one feasible, robot-executable sequence. The approach focuses on generating a consistent and repeatable sequence rather than outperforming human practices, enabling adaptability across varying slab geometries without manual reprogramming. Although DFS does not guarantee optimality in execution time or motion efficiency and may be sensitive to initial conditions, it is adopted here as the objective is feasibility validation. Given the bounded and repetitive nature of railway track slab reinforcement, identification of a single valid sequence is sufficient, making the approach computationally robust and well-suited for integration with BIM-derived data and digital twin environments.

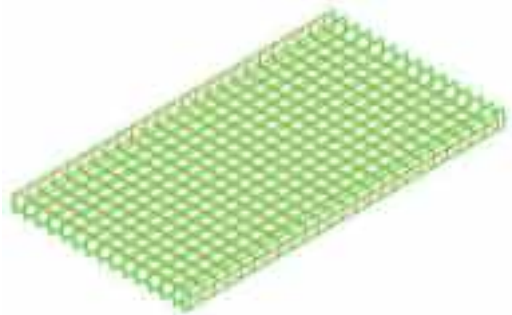

Figure 3 3D model of rebar cage

Slab Logitudinal/Transverse Reinforcement							
Description	Diameter (mm)	Spacing (mm)	a(mm)	b(mm)	c(mm)	Length (m) = a+b+c	No. of bars
Longitudinal Slab Top	12	200	150	4820	150	5.12	15
Longitudinal Slab Bottom	12	200	150	4820	150	5.12	15
Transverse Slab Top	10	200	150	2620	150	2.92	25
Transvere Slab Bottom	10	200	150	2620	150	2.92	25

Figure 4 BBS of the rebar cage

This combined BIM-based data extraction and sequencing approach ensures design-to-execution continuity while accommodating the repetitive yet constrained nature of railway track slab reinforcement. Following the assignment of a feasible installation order using DFS-based sequencing logic, the required reinforcement data are automatically extracted from the BIM environment using parametric scripting implemented through Dynamo within Autodesk Revit. This process eliminates manual interpretation of reinforcement drawings and manual data entry for robotic execution.

The extracted dataset includes unique rebar identifiers, bar diameter, assigned installation order, three-dimensional coordinates of grasp points defined at L/3 and 2L/3 locations along the rebar length for two-point gripping and the corresponding tie or placement points required for assembly so that deflection at ends of the rebar is minimum when picked up. These attributes are derived directly from the parametric BIM model, ensuring consistency between design intent and robotic process planning. The extracted information is structured and exported in a machine-readable format (JSON), enabling direct integration with robotic control and simulation environments without intermediate manual processing.

In addition to data extraction, Dynamo is used to parameterise the reinforcement model itself, allowing installation logic and attribute assignment to be embedded within the 3D model. This enables efficient handling of multiple slab variants with bounded geometric differences, such as those arising from curves, transitions, or station zones, by automating both parameter assignment and data extraction. As a result, clerical effort associated with repetitive data preparation is significantly reduced, and the framework supports scalable application across project-level variations in track slab geometry without the need for manual reprogramming of robotic tasks.

5 Simulation based evaluation for railway track slab

The proposed BIM-driven robotic rebar cage assembly framework is evaluated through simulation in CoppeliaSim using a high-fidelity digital twin configured for ballastless railway track slab construction. The digital twin models a gantry-based robotic system equipped with three six-degree-of-freedom (6-DOF) robotic manipulators mounted on a movable trolley, enabling movement in both longitudinal and lateral directions of the frame through linear actuators to ensure reachability within the assigned workspace. Of these, two robotic arms are dedicated to rebar pick–move–place operations, while the third arm is equipped with a specialised tying end-effector for executing reinforcement tying tasks. No vision sensors are required for tying as exact coordinates of tying points are being extracted from 3D model enabling accurate execution. This configuration supports coordinated operation while avoiding excessive workspace congestion.

The gantry–trolley system provides coarse positioning across the slab length and width, while the robotic arms perform localised manipulation tasks. This arrangement reflects the linear nature of railway track slab construction and enables efficient access to reinforcement locations distributed along elongated slab geometries without repositioning the entire system.

Motion planning is implemented using a hybrid strategy. First, the gantry and trolley perform coarse positioning to bring the robotic arm into the vicinity of the target rebar location in the longitudinal and/or lateral directions. Subsequently, fine positioning is achieved through inverse kinematics–based control of the 6-DOF robotic arm to execute precise grasping, placement, and tying operations. This layered approach reduces unnecessary arm motion, improves reachability, and reflects established practice in robotic reinforcement assembly research. The motion planning logic and kinematic modelling are inspired by previously reported robotic cage assembly frameworks, particularly the feasibility-oriented approaches presented by Momeni et al., while being adapted to the geometric scale and spatial constraints of railway track slabs. Conservative velocity and acceleration profiles are applied to ensure stable handling.

When importing BIM-derived reinforcement data into the simulation environment, a coordinate transformation formulation is applied to map BIM global coordinates into the local reference frame used in CoppeliaSim. This transformation accounts for differences in origin, orientation, and scale between the BIM model and the simulation environment, ensuring that rebar positions, grasp points, and placement targets extracted through scripting are accurately represented during robotic execution within the digital twin.

The simulation setup reflects typical railway site constraints, including limited lateral workspace, longitudinal deployment along the track direction, and interaction with rail-seat regions and embedded components. Spindles are planned to be temporarily placed at designated locations to fix the rail-seat base during casting and to ensure that reinforcement does not infringe upon the designed spacing. To accommodate railway-specific spatial restrictions, the complete robotic system including gantry structure, trolley, manipulators, and end-effectors is constrained within a predefined kinematic envelope representing the worst-case available construction space. This envelope is defined to prevent infringement with adjacent railway infrastructure such as overhead electrification (OHE) systems, cable trays, parapets, and other permanent or temporary civil works commonly present along metro alignments.

Collision-aware motion planning is enabled throughout the simulation to ensure safe interaction between robotic arms, partially assembled reinforcement cages, fixtures, and surrounding structural elements. The simulation experiments focus on evaluating robotic reachability, sequencing feasibility, and motion stability under conditions representative of metro construction, rather than on optimising cycle times or factory throughput. In addition to prefabrication yard scenarios, the simulation environment is intentionally constrained to reflect conditions applicable to cast-in-situ (CIS) track slab construction. By ensuring that the entire robotic system operates within the railway kinematic envelope, the framework demonstrates potential compatibility with deployment on alignment-guided platforms such as rail-mounted or road–rail vehicles (RRVs). This highlights the flexibility of the proposed approach to support both stationary prefabrication environments and mobile, track-based operations, which are essential for automation in linear railway infrastructure projects. To maintain focus on process-level feasibility and ensure comparability with existing robotic reinforcement studies, the following assumptions are adopted in the simulation:

1. The BIM-derived rebar geometry and connectivity accurately represent the as-designed reinforcement cage, and rebars are assumed to be geometrically rigid during handling and placement.
2. A feasible rebar installation sequence exists, and identification of a single valid sequence is sufficient for evaluating automation feasibility, recognising that multiple valid sequences may be possible.
3. Installation order assignments follow DFS-based, constraint-informed logic, which is not optimum but one feasible order
4. The robotic system operates in a controlled environment with known geometry; perception uncertainty, sensing noise, and real-time error correction are not considered at this stage.
5. Temporary fixtures and supports required to maintain interim cage stability are assumed to be available and correctly positioned throughout the assembly process.
6. Fixtures are provided on both directions of the table setup so that two different rebar can be placed on fixtures in their repsection directions. At any given fixture location, rebars are fed one by one to the system to eliminate the risk of pose uncertainty.

These assumptions are consistent with common practice in early-stage construction robotics research and allow the study to isolate the feasibility of BIM-driven process planning and robotic execution under railway-specific geometric and operational constraints.

When these assumptions are relaxed, several practical uncertainties arise. Rebar deflection during handling may influence placement accuracy; however, two-point gripping at one-third span locations reduces deflection, and the use of jigs helps maintain the rebars in a straight alignment during placement. Tolerance accumulation across sequential placements may affect overall cage geometry, although jigs used for spacing and cover control mitigate this effect under bounded variability. Pose uncertainty remains a limitation due to the absence of perception systems, while fixture misalignment and reinforcement congestion may further affect stability, accessibility, and placement precision. These factors indicate that incorporation of sensing, compliance control, and tolerance management strategies will be necessary for reliable real-world deployment. Key robot, gantry parameters used in the digital twin are summarised in Table 1 to ensure clarity and reproducibility.

Table 1 Robot and Gantry System Parameters Used in Simulation

Parameter	Specification	Remarks
Robotic arm-payload capacity	25 kg	Selected base on rebar + end effector weight including dynamic effect
Maximum reach of robotic arm	1.3 m	Sufficient for placement within slab region with the help of linear actuators
Gantry longitudinal travel (X-axis)	6 m	Covers slab length + margin
Gantry lateral travel (Y-axis)	3 m	Covers slab width + margin

6 Results and Discussion

Simulation results confirm that the proposed framework enables collision-free robotic rebar placement for railway track slab cages across all planned installation steps. All BIM-defined rebar target poses are reachable within the gantry workspace while maintaining compliance with railway spatial constraints. The process planning and sequencing logic successfully prevents geometric blocking and ensures interim cage stability, which is critical for elongated slab-type reinforcement assemblies typical of ballastless track systems.

Robotic motion remains stable throughout the simulation, with no kinematic singularities or unintended interference between manipulators or previously placed reinforcement. These results demonstrate that BIM-driven sequencing and digital validation are essential enablers for adapting robotics to railway reinforcement workflows, where precision, repeatability, and strict adherence to possession windows are more critical than maximising raw production speed. The framework is shown to be adaptable to both precast track slab manufacturing yards and on-site cast-in-situ (CIS) construction, subject to project-specific deployment strategies. A summary of key simulation-based performance indicators is presented in Table 2.

Table 2 Summary of Simulation-Based Performance Indicators

Parameter	Value
Number of rebars	80
Assembly completion	100 %
Average pick–move–place time (per bar)	~35 s
Total placement time	~2800 s (~47 min)
Number of ties	~750
Estimated tying time (per tie)	~ 2- 3 s (Based on literature/industrial systems)

The pick–move–place cycle times observed in the simulation are indicative and scenario-specific, as task duration is influenced by payload, travel distance, motion constraints, and placement accuracy requirements. Since the simulation assumes idealised conditions, observed cycle times are considered moderately reliable for comparative and feasibility assessment, but not as direct predictors of field performance.

In conventional practice, reinforcement cage assembly for ballastless track slabs is reported to achieve approximately 0.125 track m per man-hour, reflecting the labour-intensive and sequential nature of manual operations under constrained site conditions. Based on the simulation results for the representative slab configuration, the equivalent system-level production rate corresponds to approximately 2.5 track m per hour under idealised conditions. However, this value represents a theoretical upper bound, as the simulation does not account for real-world factors such as handling delays, coordination with other site activities, perception uncertainties, and operational interruptions. Therefore, the comparison should not be interpreted as a direct productivity gain, but rather as an indication of the potential for improved execution efficiency and reduced variability through automation. The primary contribution of this study remains the demonstration of technical feasibility, while quantitative productivity validation requires further experimental and field-based investigation.

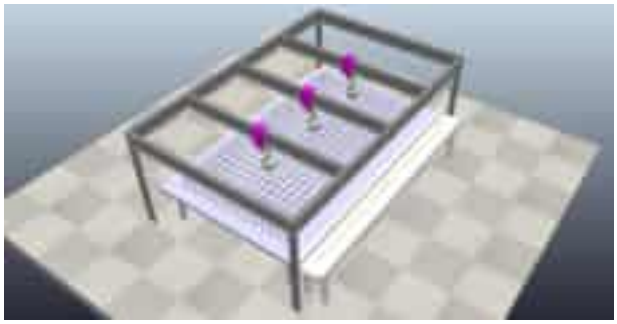

Figure 5 Simulation of rebar cage of metro track slab in CoppeliaSim

It is therefore emphasised that the objective of the simulation study is to evaluate the technical feasibility and deployability of the proposed robotic system under railway-specific spatial and operational constraints. Detailed cycle time optimisation and productivity assessment are outside the scope of this work, as reliable estimation would require physical prototyping, perception integration, and field validation. By constraining the system within the railway kinematic envelope, the framework demonstrates potential compatibility with deployment on alignment-guided platforms, such as rail-mounted or road–rail vehicles. When combined with coordinated logistics and alignment-guided mobility, the proposed approach offers a viable pathway for integrating robotic rebar cage assembly into metro construction workflows.

7 Conclusions and Future Work

This study presents a railway-specific feasibility assessment of a BIM-driven process planning and robotic assembly framework for rebar cages in ballastless track slab construction. It addresses a key gap in metro and high-speed rail projects, where rebar cage assembly remains largely manual despite mechanisation of other

activities. By adapting established BIM-driven robotic sequencing approaches to railway-specific geometric and spatial constraints, the study reframes rebar cage assembly as a process planning and digital integration problem.

Simulation using a high-fidelity digital twin confirms the feasibility of collision-free and stable robotic assembly under representative metro track slab conditions. The results demonstrate that BIM-derived data, feasibility-oriented sequencing, and hybrid motion planning can be effectively integrated to enable robotic execution without geometric blocking or kinematic conflicts. The findings highlight that feasibility in railway applications is governed primarily by sequencing logic, spatial compliance, and digital workflow continuity rather than optimisation of hardware or cycle times. The framework is applicable to linear railway infrastructure projects characterised by repetitive yet bounded reinforcement layouts and strict possession constraints. Compatibility with prefabrication yards and on-site cast-in-situ construction is demonstrated, with potential for deployment using alignment-guided platforms such as rail-mounted or road–rail vehicles and automated guided vehicles (AGVs), enabling scalable and mobile robotic operations.

Future work will focus on physical prototyping, integration of perception-based feedback for tolerance management, and validation under real or semi-controlled site conditions. Further investigation is required to evaluate coordinated operation with alignment-guided systems and to assess productivity, safety, and constructability impacts. A key limitation of this study is its reliance on simulation-based validation under controlled conditions. While the digital twin enables evaluation of reachability, sequencing feasibility, and collision-free execution, real construction environments introduce additional uncertainties, including geometric tolerances, bar deflection, fixture misalignment, and operational variability. These factors may influence positioning accuracy and system performance. Consequently, the applicability of the proposed framework to real-world deployment requires further validation through physical prototyping and field implementation.

Abstract –

Accurate indoor self-localization remains a fundamental challenge in environments where GPS signals are unavailable, such as construction sites, underground facilities, indoor spaces, and tunnels. This paper presents a smartphone-only indoor self-localization and navigation system that uses only sensors embedded in standard smartphones. The proposed system utilizes smartphone cameras and inertial sensors to achieve continuous indoor positioning without relying on external infrastructure or additional hardware. A key contribution is a patrol free floor plan-based map creation method using Map Creator, which generates navigable indoor maps directly from existing 2D floor plans without prior site surveys or environment scanning. Based on these maps, a smartphone-based indoor navigation application was developed to support real-time navigation and self-localized image acquisition with embedded position and orientation information. Experimental evaluations conducted in multiple indoor environments demonstrate an average relative localization error of 0.5–0.9%, confirming that high-accuracy indoor positioning can be achieved using only a standalone smartphone without external infrastructure. The proposed system offers a lightweight, scalable, and easily deployable solution for indoor localization and navigation in construction and facility management applications.

Keywords – Autonomous drone, Floor-plan mapping, Indoor localization, Indoor Navigation, Non-GPS, Smartphone-only

1. Introduction

Accurate indoor self-localization and navigation are essential for a wide range of construction-related activities, including inspection, progress monitoring, and safety management. While the Global Positioning System (GPS) is widely used for outdoor positioning, its performance degrades significantly in indoor and underground environments due to signal attenuation and blockage. As a result, reliable positioning in non-GPS environments such as construction sites, tunnels, and large buildings remains a critical research challenge [1,2].

To address this issue, various indoor localization technologies have been developed. These include wireless-based approaches such as Wi-Fi, Bluetooth, and ultra-wideband (UWB), as well as vision- and LiDAR-based methods such as simultaneous localization and mapping (SLAM) and feature-based localization [3–7]. In addition, visual–inertial sensor fusion using cameras and inertial measurement units (IMUs) has been increasingly adopted for mobile indoor positioning [8].

Recent studies have explored smartphone-based indoor localization as a practical and cost-effective alternative to infrastructure-dependent approaches, leveraging the widespread availability of consumer devices equipped with cameras and inertial sensors. These approaches have demonstrated sufficient accuracy for applications such as indoor navigation and spatially indexed image acquisition in non-GPS environments [9].

However, despite these advances, many existing systems still require additional preparation, including artificial marker-based initialization, deployment of wireless positioning infrastructure, or environment-dependent configuration processes such as prior feature database construction and repeated site patrol for mapping [10,11].

Such requirements limit scalability and practical

deployment, particularly in dynamic construction environments where indoor layouts frequently change and system reconfiguration is required. Therefore, achieving scalable and easily deployable indoor localization using only widely available consumer smartphones, without reliance on external infrastructure or site-specific preparation, remains an important research challenge.

To address this limitation, this paper proposes a smartphone-only indoor self-localization and navigation system that integrates floor-plan-based map creation with visual–inertial localization. The proposed approach enables navigation-ready indoor maps to be generated directly from existing 2D architectural floor plans without requiring site scanning or patrol-based mapping [12]. By constraining visual–inertial localization results using floor-plan-derived spatial information, the system improves localization accuracy while reducing setup effort and enhancing adaptability to layout changes.

Experimental evaluations conducted in representative indoor environments demonstrate that the proposed system achieves sub-1% relative localization error. These results confirm that high-accuracy indoor positioning can be achieved using standalone consumer smartphones without external infrastructure, making the proposed approach suitable for construction and facility management applications in non-GPS environments.

2. System Overview

This section presents the architecture and operational concept of the proposed smartphone-only indoor self-localization and navigation system. A standard consumer smartphone is defined as a device equipped with an RGB camera, inertial measurement unit (IMU), and onboard processor for visual–inertial computation. The proposed system performs indoor positioning and navigation in non-GPS environments using only these embedded sensors, without relying on external infrastructure or additional hardware.

To demonstrate device independence and applicability to widely available consumer hardware, experiments were conducted using both a recent smartphone model; iPhone 15, and a compact consumer-grade device: iPhone SE, confirming that the proposed approach does not depend on high-end sensing capabilities.

2.1 System Architecture and Components

The proposed system consists of three components: (1) a floor-plan-based map creation module, (2) a smartphone-based localization and navigation module, and (3) a smartphone-centered movement control interface. Their relationships are illustrated in Figure 1.

The first component, Map Creator, generates navigation-ready indoor maps directly from 2D architectural floor plans. Floor-plan-based mapping approaches have been shown to reduce deployment effort compared with scan-based or patrol-based methods, particularly in environments with evolving layouts [13,14]. In the proposed framework, Map Creator defines spatial reference parameters such as scale, orientation, and anchor points to derive walkable regions and connectivity relationships.

In practical construction environments, discrepancies often arise between design drawings and as-built layouts due to ongoing changes during construction. To address this issue, the proposed patrol-free map creation approach allows users to directly update walkable paths, connectivity relationships, and reference information on the floor plan without requiring additional site surveys or remapping. This enables efficient adaptation to layout changes while maintaining coordinate consistency.

The second component is a smartphone-based indoor localization and navigation module that performs continuous positioning using visual–inertial sensor fusion. Smartphones equipped with cameras and inertial measurement units (IMUs) have been shown to provide sufficient sensing capability for indoor motion estimation without external infrastructure [15,16]. In the proposed system, device pose is estimated by integrating visual features tracking from image sequences with inertial measurements, and the resulting trajectory is constrained using floor-plan-derived spatial topology to ensure consistency with indoor layouts.

The third component is a smartphone-centered movement control interface that converts localization and navigation output into motion commands for mobile platforms. Smartphone-centric control architectures have been shown to improve portability and system flexibility by decoupling localization from platform-specific control systems [17,18]. The proposed interface enables localization results generated on the smartphone to be reused across different navigation and autonomous movement applications without modification of the core algorithm.

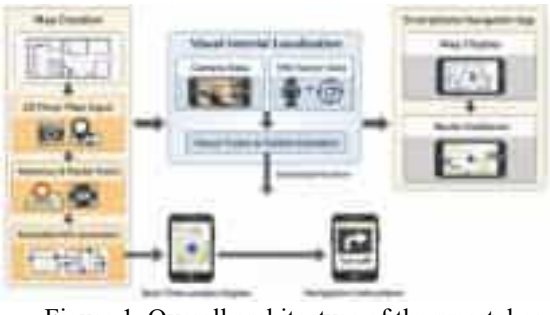

Figure 1. Overall architecture of the smartphone-only indoor localization and navigation system.

2.2 System Operational Flow

The operational flow ensures integration between

map creation, localization, and navigation. The sequence is illustrated in Figure 2.

The process begins with map creation using Map Creator, where a 2D floor plan is converted into a map by defining spatial reference information, walkable paths, and connectivity. The map is then transferred to the smartphone application.

During operation, the smartphone initializes its coordinate system and performs localization using camera and inertial data. The estimated pose is continuously updated and constrained using floor-plan-based spatial information. Based on the updated localization, navigation routes are computed and guidance is provided, as illustrated in Figure 2.

The operational flow of the proposed system is designed to ensure seamless integration between map creation, localization, and navigation execution. The overall operational sequence is illustrated in Figure 2.

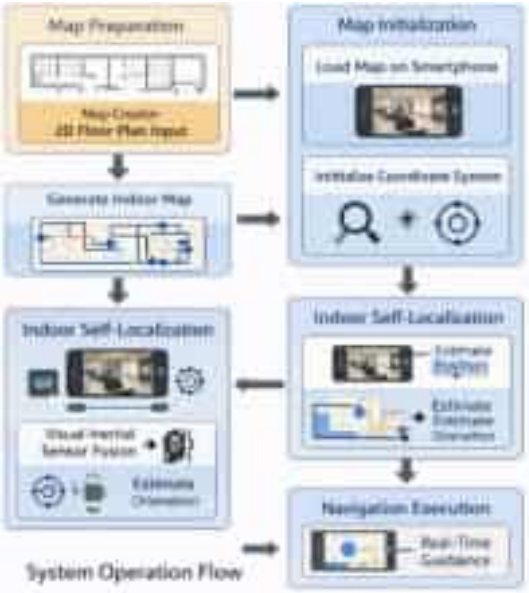

Figure 2. Operational sequence of the proposed smartphone-only indoor navigation system.

2.3 Data Flow and Information Exchange

The data flow separates static spatial information from dynamic sensor-driven data. The map creation module outputs static map data, while the smartphone modules handle real-time sensing, localization, and navigation.

The map creation module provides:

- Indoor coordinate reference information
- Walkable path networks and connectivity graphs
- Reference marker or anchor point data

These data are loaded into the smartphone application, where camera and inertial inputs are used to update localization results during operation. The interaction between static map data and dynamic localization is illustrated in Figures 1 and 2.

3. Patrol-Free Floor Plan based Map Creation System

This section presents a patrol-free indoor map creation method that generates indoor maps directly from 2D floor plans without site scanning or traversal. Spatial information is explicitly defined on architectural drawings, enabling efficient and repeatable map creation suitable for dynamic indoor environments. The workflow is shown in Figure 3.

To enable systematic indoor navigation representation, the walkable indoor environment derived from the 2D floor plan is formally modelled as a connectivity graph $G = (V, E)$, where V denotes discretized navigable nodes and E denotes feasible movement transitions between adjacent nodes. The graph is constructed from user-defined route segments on the floor plan, and connectivity is determined through reachability analysis. This graph-based representation supports route computation and serves as a constraint for localization by restricting estimated positions to valid navigable regions.

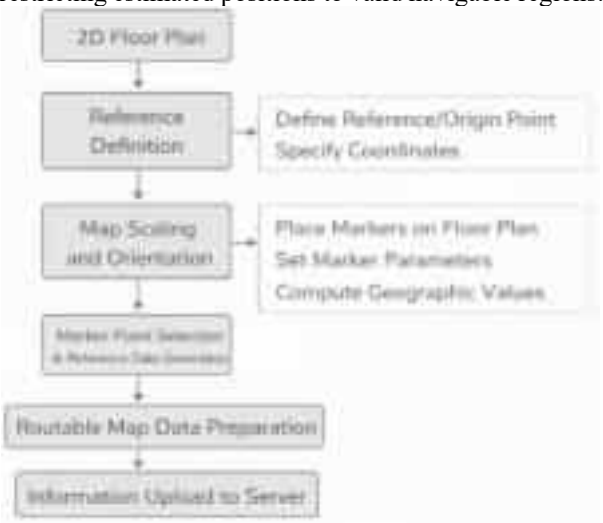

Figure 3. Patrol free indoor map creation workflow using Map Creator.

3.1 Floor-Plan-Based Spatial Definition and Coordinate Alignment

Figure 4. Map Creator screen with Floor Plan and associated geographic information.

Map Creator uses a 2D floor plan as the input for indoor map creation, where spatial relationships are derived directly from image geometry rather than sensor measurements [19].

A reference point is defined on the floor plan to establish the indoor coordinate system and enable alignment with real-world coordinates. The reference point is selected on the floor plan, and associated spatial parameters such as geographic position, orientation, and scale are defined in Figure 4.

By associating this reference point with known geographic coordinates, the indoor map is transformed into a globally consistent coordinate system without requiring on-site calibration [20].

Once the reference point is defined, all subsequent spatial elements, including marker points, walkable routes, and navigation coordinates are computed relative to this origin. This explicit reference-based approach enables repeatable and scalable map creation while maintaining consistency across devices and sessions

3.2 Marker Point Configuration and Reference Data Generation

Map Creator supports marker points that act as spatial anchors for indoor localization by linking the indoor coordinate system to real-world coordinates.

A single marker is sufficient for localization initialization; however, multiple markers can be used to improve robustness [21]. Marker configuration and reference data generation are illustrated in Figure 5. The system supports both artificial and natural visual features as markers, allowing flexible deployment without requiring dedicated marker installation [21].

Marker points are defined on the floor plan, and their spatial attributes are used to automatically compute geographic coordinates and orientation based on the reference point and map parameters. Marker data are stored for localization initialization. After initialization, continuous operation does not require persistent marker visibility, maintaining patrol-free operation.

3.3 Routable Map Generation

After defining the indoor coordinate system and marker reference information, Map Creator generates routable map data that represents valid movement paths within the indoor environment. Walkable routes are defined on the 2D floor plan as a red line segment to represent traversable paths as shown in Figure 6. These routes are connected to form a network of walkable paths, distinguishing traversable and non-traversable regions.

Once the walkable routes are defined, Map Creator applies a maze-based algorithm to analyze the connectivity of the red line network. The algorithm treats the connected red lines as traversable cells within a maze-like structure and automatically determines reachability between path segments. Through this process, valid routes, intersections, and alternative paths are identified based on the connectivity shown in Figure 6 [22].

The resulting routable map includes path nodes and connectivity relationships that are later used by the indoor localization and navigation application for route computation. This approach enables patrol-free and easily updatable route generation. When the indoor layout changes, the user can simply modify the red route lines on the 2D map, and the routable data can be regenerated without additional data collection or site traversal.

4. Smartphone-Based Indoor Localization and Navigation

This section describes the smartphone-based indoor self-localization and navigation system developed in this study. The system is designed according to a localization-first concept, in which indoor positioning is treated as the fundamental function, while navigation is implemented as an optional layer that operates on top of localization results. This design allows the system to function both as a standalone indoor positioning system and as a navigation system when route guidance is required. The flowchart illustrating the smartphone based indoor localization and navigation is shown in Figure 7.

Figure 8. Smartphone-based indoor self-localization results visualized on the floorplan.

4.1 Indoor Self-Localization

Indoor self-localization is formulated as a visual–inertial pose estimation problem in which the smartphone trajectory is incrementally estimated using sensor fusion. Relative motion between consecutive positions is computed by tracking sparse visual features extracted from sequential monocular RGB images, while inertial measurements from the accelerometer and gyroscope provide short-term motion propagation and orientation stabilization. Localization updates are performed at approximately 2 Hz, corresponding to the experimental image acquisition interval of 0.5 m.

At the start of operation, localization is initialized using a single reference marker whose known position establishes alignment between the smartphone coordinate frame and the floor-plan coordinate system. After initialization, continuous localization proceeds without requiring persistent marker visibility.

To suppress long-term drift, the estimated pose pt is projected onto the nearest feasible location defined by the floor-plan-derived walkable graph:

$$p_t' = \arg\min_{p \in \Omega} \|p_t - p\|$$

where Ω represents the set of valid walkable positions. This constraint ensures topological consistency between localization results and indoor layout structure while reducing accumulated positional deviation during extended indoor trajectories. The overall localization pipeline therefore consists of feature tracking, inertial motion propagation, pose fusion, coordinate initialization, and floor-plan feasibility projection.

Localization results are visualized directly on the indoor map, as shown in Figure 8, where the blue point represents the real-time estimated smartphone position and the green square box with arrow inside represents the position of the image captured in the direction of arrow.

4.2 Indoor Navigation using Smartphone

Based on the indoor localization results described in section 4.1, the proposed system performs smartphone-based indoor navigation using floor-plan-derived connectivity information. Navigation is executed directly on the smartphone, and all route planning, guidance generation, and position updates are computed using the estimated device position on the indoor map.

The navigation process follows a structured workflow, as illustrated in Figure 9. First, the user selects a target floor map and specifies a destination point on the map. After the destination is set, the system searches for reference markers and generates an optimal navigation route based on predefined walkable paths and connectivity information. Once the route is generated, indoor navigation starts, and the device position is continuously updated in real time as the user or mobile platform moves. During navigation, the system provides guidance until the destination point is reached.

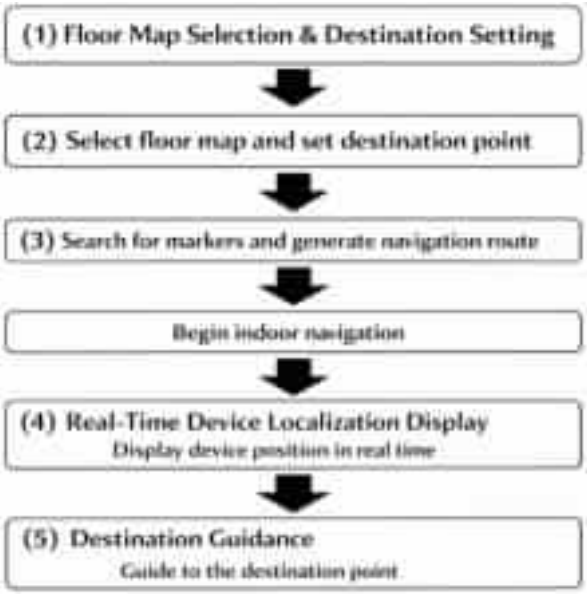

Figure 9. Workflow of smartphone-based indoor localization and navigation

The real-time navigation behaviour is visualized on the smartphone interface, as shown in Figure 10. The indoor floor plan is displayed together with navigation-related information, including the current estimated position, destination point, reference marker positions, and the planned route.

In Figure 10, the blue dot inside a blue circle represents the real-time estimated position of the smartphone, which is continuously updated based on the localization results. The destination point is shown in blue dot inside a red circle, the red dot inside a blue circle is the reference marker point. The route connecting the current position to the destination point is displayed on the map with blue line, providing intuitive visual guidance.

5. Experimentation and Evaluation

5.1 Experimental Setup and Localization Accuracy Results

Experimental evaluation was conducted to assess the accuracy and robustness of the proposed smartphone-only indoor self-localization and navigation system in non-GPS environments. Experiments were performed in two representative indoor environments at Waseda University. Environment A was a confined classroom space (Building 65, Room 504), while Environment B was a large open atrium area (Building 55, first floor). The experimental environments and predefined measurement paths are illustrated in Figure 11.

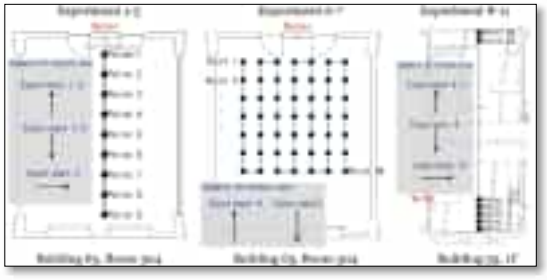

Figure 11. Experimental environments and predefined measurement paths used for accuracy evaluation

For localization initialization, a reference marker was placed at a known position in each environment. During experiments, images were captured at regular intervals of approximately 0.5 m along predefined walking paths. Most experiments were conducted using an iPhone 15, while one experiment was performed using an iPhone SE to examine the influence of device characteristics on localization performance.

A total of eleven experiments were designed to evaluate localization accuracy under different motion patterns and spatial scales. Experiments 1–5 focused on short straight-line motion with a total travel distance of 4 m. Experiments 6–7 evaluated grid-based motion following a 7 × 7 grid pattern to analyze accumulated positional drift. Experiments 8–11 involved long-range straight-line motion with a total travel distance of 32 m, representing extended indoor navigation scenarios.

Localization accuracy was evaluated using two quantitative metrics. First, relative localization error (%) was computed by comparing estimated step distance with the ground-truth step distance of 0.5 m. Second, accumulated positional drift was evaluated by measuring deviation from ideal grid reference positions in grid-based experiments. In addition, absolute positioning accuracy was quantified using the two-dimensional Euclidean error between estimated coordinates and tape-measured ground-truth positions.

The experimental results are summarized in Table 1, while detailed localization accuracy results for Environment A and Environment B are presented in Table 2 and Table 3, respectively. Figure 12 illustrates the distribution of relative localization errors across all experiments.

Table 1. Summary of Experiments for Indoor Localization

Exp. No.	Environment	Walking pattern	Travel distance	Purpose
1– 4	Bldg. 65, Room 504	Straight (forward/backward)	4 m	Short-range accuracy
5	Bldg. 65, Room 504	Straight (sideways)	4 m	Direction sensitivity
6	Bldg. 65, Room 504	7×7 grid	24 m	Drift evaluation
7	Bldg. 65, Room 504	7×7 grid	24 m	Camera orientation effect
8	Bldg. 55, Atrium	Straight (forward)	32 m	Long-range accuracy
9	Bldg. 55, Atrium	Straight (backward)	32 m	Motion robustness
10	Bldg. 55, Atrium	Straight (sideways)	32 m	Motion robustness
11	Bldg. 55, Atrium	Straight (forward)	32 m	Device dependency

Table 2: Localization Accuracy Results in Environment A (Room 504)

Experiment	Motion type	Evaluation metric	Result
1–4	Forward / backward	Total relative error	0.6–0.9 %
5	Sideways	Total relative error	1.53 %
6	Grid	Mean step-wise error	0.88 %
7	Grid	Mean step-wise error	0.87 %

Table 3: Localization Accuracy Results in Environment B (Atrium)

Exp. No.	Motion type	Device	Total relative error
8	Forward	iPhone 15	0.61 %
9	Backward	iPhone 15	0.18 %
10	Sideways	iPhone 15	0.27 %
11	Forward	iPhone SE	0.94 %

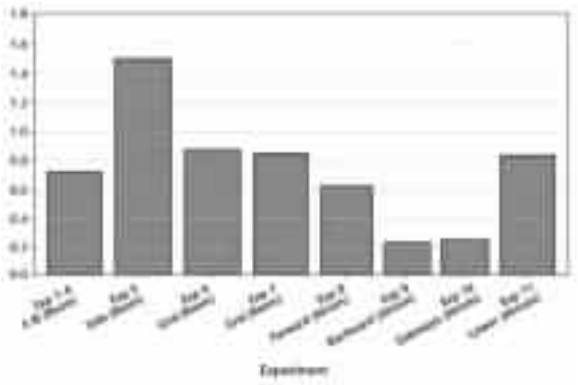

Figure12: Localization Accuracy from Experiment 1-11.

5.2 Baseline Comparison and Drift Growth Analysis

To further contextualize the localization performance observed in both experimental environments, a baseline comparison was conducted with unconstrained smartphone visual–inertial odometry (VIO). The localization accuracy results reported in Table 4 for Environment A and Table 5 for Environment B indicate that the proposed floor-plan-constrained approach maintains low relative error and controlled drift across different spatial configurations. These results are therefore compared with typical drift characteristics of infrastructure-free smartphone VIO to analyze the effectiveness of spatial constraint integration.

Because visual–inertial odometry provides relative pose estimation, accumulated positional drift generally increases with travelled distance. Engineering benchmarks suggest that consumer smartphones may exhibit approximately 0.3-0.8 m positioning error over short indoor trajectories (5-10 m), increasing to approximately 1-3 m after several tens of meters depending on motion conditions and visual feature availability.

To further validate drift growth behavior, an additional corridor experiment exceeding 50 m travel distance was conducted. Under stable motion conditions, the proposed method demonstrated approximately 0-1 m maximum drift relative to ground-truth references, whereas increased dynamic disturbances resulted in drift values approaching 3 m. The results indicate that floor-plan-derived spatial constraints significantly suppress drift accumulation during extended indoor navigation.

Table 4: Drift Growth Comparison between Baseline VIO and Proposed Method

Travel Distance	Baseline Smartphone VIO Drift (m)	Proposed Method Drift (m)
5-10 m	0.3-0.8	<0.2
20-30 m	0.8-2.0	0.2-0.4
>50 m	1-3	0-1

Table 5: Representative Indoor Localization Accuracy Comparison

Method	**Typical Absolute Horizontal Error**	**Remarks**
Smartphone GPS / generic mobile positioning	10-20 m	Indoor signal attenuation
Wi-Fi / BLE beacon systems	2-5 m	Requires infrastructure
Smartphone visual–inertial odometry	1-3 m (after ~30-50 m)	Drift accumulation
Proposed method	**~0-1 m**	Infrastructure-free

6. Discussion and Conclusion

This paper presented a smartphone-only indoor self-localization and navigation system for non-GPS environments that integrates a patrol-free, floor-plan-based map creation method with smartphone-based visual–inertial localization. Experimental results demonstrated that the proposed system consistently achieved sub-1% relative localization error across both confined and large indoor environments without relying on external positioning infrastructure, environment scanning, or specialized hardware. The results further showed that localization accuracy is influenced by motion direction and camera performance, while floor-plan-based spatial constraints effectively suppress accumulated drift during navigation.

In addition, the feasibility of extending the proposed smartphone-based localization and navigation framework to autonomous indoor mobile platforms was verified using a commercial off-the-shelf drone, demonstrating the platform-independent nature of the approach. Overall, the proposed system provides a lightweight, scalable, and easily deployable solution for

indoor localization, navigation, and spatial data acquisition, making it well suited for construction, facility management, and other indoor operational environments.

Abstract -

In construction and operational stages of buildings and in computer vision and construction robotics, accurate alignment of LiDAR point clouds to a building's 3D coordinate axes is an essential preprocessing step. However, existing point cloud processing tools handle a point cloud in a single batch, which can lead to high memory usage or even failures for very large clouds. This study presents a chunk-based, orthogonality-enabled method for aligning very large building LiDAR point clouds to the building's coordinate in parallel computing. Our method leverages the random-access characteristic of LiDAR's LASer (*.las*) format to divide a cloud into multiple chunks, then processes each chunk, with the number of concurrently running tasks being limited. Subsequently, the global orientation is estimated by extracting the dominant directions of the building's interior and exterior orthogonal structures to rotate and align the input cloud. Experiments on a 22 GB real-world LiDAR point cloud demonstrated the effectiveness of our proposed method: It reduced peak memory consumption from exceeding 60.5 GB to 4.1 GB and achieved a 3.85-fold speedup over the sequential method. 1 Introduction

Light Detection and Ranging (LiDAR) point clouds have become increasingly essential data sources in construction [1], surveying [2], computer vision [3], and robotics [4], thanks to LiDAR's high precision in measuring the 3D built environment. Yet, a LiDAR point cloud's local coordinate axes are usually inconsistent with the target building's or project's coordinate axes in 2D drawings, footprint on the map, or 3D building information modeling (BIM).

Axis alignment refers to aligning a point cloud to the project's local coordinate axes [5]. Axis alignment is an important step to enable many construction digitalization and automation applications, including existing condition modeling, 3D coordination, registration of 2D computer-aided design (CAD) drawings [6], scan-to-BIM [7], scan-vs-BIM for change detection [8], and construction progress monitoring [9]. In computer vision, many deep learning models for point cloud processing have been proposed and trained well on coordinate-aligned datasets [10], and some robots for building operation and maintenance also relied on axis alignment.

However, existing tools for aligning LiDAR cloud coordinates with buildings and construction often encounter challenges. Building floor areas and construction sites can span multiple thousand square meters, and modern LiDAR scanners produce 10,000–400,000 points per square meter; these factors result in LiDAR clouds that can reach up to billions of points and tens or even hundreds of gigabytes (GB). Existing 3D point cloud processing tools, such as `Open3D` [11] and `pypcd4`, always load the full cloud data into computer memory in a single batch. This one-batch processing of very large LiDAR clouds is memory-intensive and sometimes exceeds the capacity of computers, which are equipped with no more than 32 GB Random-access memory (RAM) in most cases. When memory demand exceeds system capacity, the operating system may terminate the process, causing the computation to fail and limiting the scalability of LiDAR data analysis.

To mitigate the problem of exceeding system memory capacity in axis alignment, this study presents a chunk-based, orthogonality-enabled parallel computing method. The method aims to achieve relatively efficient axis alignment for very large point clouds. The method leverages the random-access characteristic of LiDAR's LASer (*.las*) format to divide an input LiDAR point cloud into partitioned chunks, then processes them in parallel with controlled concurrency. To ensure balanced orthogonality detection, the point distances in each chunk are normalized (down-sampled) to 2 cm, and point normals are estimated from the normalized points. Finally, the method automatically estimates and optimizes the dominant orthogonal structural directions of LiDAR point clouds, in order to rotate the point cloud and align the coordinates. Overall, this parallel computing utilizing orthogonality in buildings can achieve better time and memory efficiency on daily per-

sonal computers.

The contribution of this paper is twofold:

1. A novel chunk-based, orthogonality-enabled parallel computing method for axis alignment of very large LiDAR point clouds, and

2. Preliminary evidence on the boosted time and memory efficiencies of the present method from experiments on real-world very large data.

2 Related Works

LiDAR has been widely applied in the construction industry [12, 13] for various applications, ranging from semantic enrichment of BIM models to derivative-free optimization-based (DFO) 3D reconstruction of architectural structures. For instance, Xue et al. [14] is the first to transform architectural symmetry detection from LiDAR point clouds as a nonlinear optimization problem and proposed a DFO approach to solve it. Furthermore, Xue et al. [15] extended the DFO method to register a small-scale indoor LiDAR point clouds with BIM components, enabling the reconstruction of detailed indoor scenes.

Although existing studies have demonstrated LiDAR point clouds' applications in 3D modeling and semantic enrichment, most have been limited to small-scale or exterior-level point clouds [14, 16], due to computational and memory limits. In practice, LiDAR point clouds collected from construction sites often contain millions of interior points, posing significant challenges for preprocessing using existing methods. Nevertheless, these interior point clouds are valuable for analyzing architectural symmetries and skeletons.

Orthogonality, a common characteristic of real-world architectural forms and designs, offers researchers an opportunity to understand and reconstruct urban point clouds [17]. For instance, Wu et al. [12] applied orthogonality and symmetry constraints to efficiently reconstruct 3D models from facade point clouds, and later extended this framework to support morphological analysis. This inherent architectural characteristic enables the development of chunk-based, orthogonality-enabled methods for the axis alignment of very large LiDAR point clouds.

In summary, it is of interest to design a chunk-based, orthogonality-enabled method for axis alignment of very large LiDAR point clouds, for LiDAR and construction digitalization practitioners who handle very large indoor or outdoor scenes in a time- and memory-efficient manner.

3 Our Method for Processing Very Large Point Clouds

3.1 LiDAR Scanning Principles and the LASer Format

LiDAR has been widely used in construction, robotics and mapping. It actively emits laser pulses and measures the time delay of their reflections from surfaces to estimate distances. Compared with passive sensors such as cameras, LiDAR is less affected by lighting conditions and can provide depth information even in poor lighting. After obtaining raw distance measurements, LiDAR point clouds can be combined with simultaneous localization and mapping algorithms to automatically estimate the scanner's position and orientation in unknown environments, reconstructing 3D environment with rich textures and high-precision geometric details [18]. This capability makes LiDAR a powerful tool for change detection, building modeling, and progress monitoring [13].

To efficiently manage various and massive LiDAR point clouds, The American Society for Photogrammetry and Remote Sensing defined an open format, LiDAR (with ".las" file extension), for the exchange and storage of LiDAR data. This format typically consists of four components: Public Header Block, Variable-Length Records, Point Data Records, and Extended Variable-Length Records. The header block contains the metadata indicating the byte offset to the beginning of point data and the byte size of each point, which can be used to access each point efficiently [19]. This benefits in parallel and distributed algorithms for very large point cloud processing.

3.2 Chunk-based Parallel Processing

Existing point cloud processing tools, such as `Open3D` and `pypcd4`, always load a LiDAR point cloud in a single batch. However, this approach is limited in handling very large LiDAR data, as loading the whole file in a single batch can easily cause out-of-memory failures. For instance, `Open3D`, a well-known point cloud processing library, stores point coordinates, colors, and normals using `std::vector<Eigen::Vector3d>` in memory, which is memory-intensive. Loading 789-million points into memory at once requires approximately 53 GB before any further processing. Such memory demand exceeds the capacity of computers and even some workstations. Therefore, it is essential to develop a memory-efficient method to deal with massive point clouds while maintaining time efficiency.

Leveraging the structure of the LASer format, a point cloud can be randomly accessed using the following formula:

$$\text{Offset} = \text{Offset}_{\text{header}} + i \times \text{TypeSize} \tag{1}$$

where i denotes the index of the specific point to be accessed directly, and TypeSize denotes the number of bytes used to store each point (coordinates and attributes) as defined in the LASer header. This random-access property enables data access without sequential reading, allowing the LiDAR point clouds to be divided into smaller chunks to trade off between memory efficiency and processing time.

However, processing these chunks in parallel straightforwardly introduces a new challenge: each thread requires dedicated memory allocation before execution. If all chunks are loaded and processed simultaneously, it will still raise an out-of-memory error. This is because earlier tasks may not finish in time to release their allocated memory before later tasks begin to require additional memory. To address this issue, our chunk-based parallel processing approach divides tasks into multiple batches (Fig. 1) and limits the number of concurrent processes. The next batch is launched after the slowest task in the previous batch finishes.

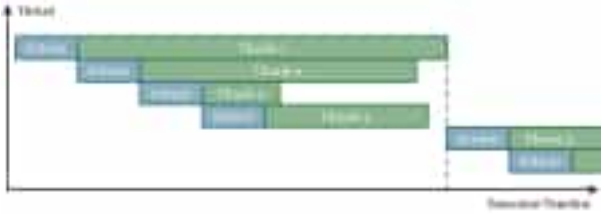

Figure 1. Illustration of chunk-based parallel processing

3.3 Axis Alignment of LiDAR point clouds

This section details the three steps of the axis alignment method that can avoid massive memory demands.

Normal estimation (Parallel computing). In the first step, we compute the normal vectors for each point. Given a point p_i, the set of neighboring points within a radius r are defined as $P = [p_1, p_2, ..., p_i, ...p_k]$. The covariance matrix of point p_i is estimated as

$$C(p_i) = \frac{1}{k} PP^T \tag{2}$$

The corresponding normal vector n_i is then obtained using Singular Value Decomposition (SVD):

$$n_i = \text{SVD}(C) \tag{3}$$

Rotation Estimation. Since the gravity direction is usually accurately provided by LiDAR scanners, the 3D rotation in axis alignment problem can be simplified to a 2D rotation estimation only around the z-axis. Specifically, by projecting each surface normal $\mathbf{n}i = (nxi, n_{yi}, n_{zi})$ onto the xy-plane, we can describe its horizontal orientation using a single rotation angle:

$$\theta_i = \arctan \frac{n_{yi}}{n_{xi}} \times \frac{180}{\pi}. \tag{4}$$

The whole angles range from $-180°$ to $180°$. We quantized the `float64` values to `uint16` integers by scaling with a factor of 100 to reduce memory usage. This is because $2^{16} = 65,536 > 360 \times 100$, all the possible angles can be represented with two-decimal precision. Therefore, three floating-point values representing normals can be compactly stored as integers without exceeding memory limits.

After chunk-based parallel processing, all rotation angles are collected in the range $[-180°, 180°)$. Since structural components such as walls, windows, and facades are often designed to fit orthogonal layouts (Fig. 3), their surface normals are distributed around 4 principal directions separated by $90°$ in the xy-plane. Leveraging this central-symmetric property, the angle distribution can be folded into the reduced range $[0°, 90°)$ to aggregate geometrically equivalent orientations, as illustrated in Fig. 2.

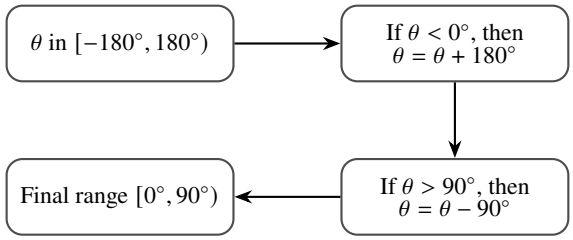

Figure 2. Range reduction from $[-180°, 180°)$ to $[0°, 90°)$

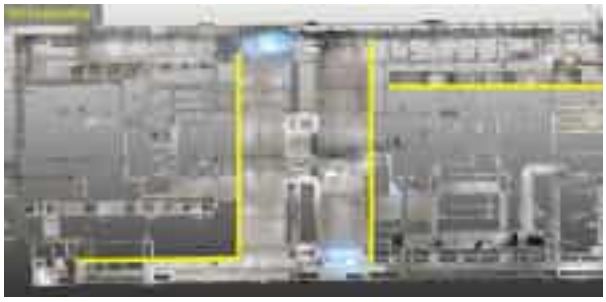

Figure 3. Illustration of the orthogonal structural components (e.g., walls) in LiDAR point clouds

Peak Direction Estimation In the final step, we extract the peak angle with the highest frequency in the range

$[0°, 90°)$. This angle denotes the dominant rotation angle between the current point cloud orientation and the global xy-axis. By rotating the point cloud around the z-axis by this estimated angle, the orthogonal building component can be parallel to the xy-axis. Note that a finer resolution in the bins of degrees can lead to more accurate peak direction estimation.

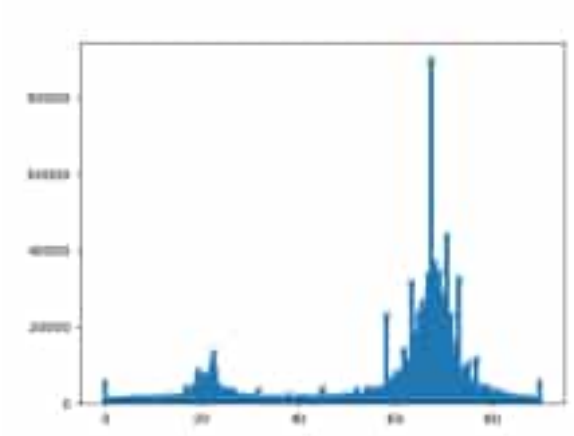

Figure 4. Degrees distribution of LiDAR point clouds normals in xy-plane

4 Experiments

4.1 Experimental Setup

To evaluate the proposed chunk-based parallel processing method for massive LiDAR point clouds, we conducted experiments on a real-world LiDAR scan dataset. The case study involves a real-world LiDAR point cloud dataset collected from the Hang Tai Road, Ma On Shan Area 86B Phase 2 construction project, a public housing development under the Hong Kong Housing Authority[1]. The scanned area covers approximately 3,392 m^2. The data were acquired using a NavVis VLX 3 system, which provides 5 mm accuracy and a capture rate of $2 \times 640,000$ points/s. The resulting LAS file is 22 GB in size and contains 789,448,875 points, with an average point density of approximately 232,738 points/m^2.

All experiments were evaluated on an HP Z2 workstation equipped with an Intel Core i7-13700K CPU, 64 GB RAM with 16 GB swap memory, running under the Windows Subsystem for Linux (WSL) environment.

Our evaluation focuses on the pipeline from reading the point cloud from disk to rotating it into alignment with the global coordinate axes. Specifically, there are three consecutive stages: (1) data loading, (2) normal estimation, and (3) axis alignment. We focus on these stages because they account for most of the memory demand throughout the point cloud preprocessing pipeline and often serve as the foundation for subsequent point cloud analyses. Therefore, evaluating these three stages can provide a comprehensive assessment of both memory efficiency and computational efficiency in very large point cloud processing.

[1]Approved Planning Brief from the Hong Kong Housing Authority

4.2 Results

We compared the proposed method with two baseline implementations, `Open3D`[2] and `pypcd4`[3], as well as a sequential chunks version of our method. As shown in Table 1, our proposed method significantly improves memory usage while maintaining computational efficiency.

Table 1. Comparison of methods for aligning the 789-million point cloud

Method	Runtime ↓	Peak RAM ↓
`Open3D` Baseline	N.A.†	>64 GB†
`pypcd4` Baseline	27.0 mins	60.5 GB
Sequential Chunks	98.6 mins	4.9 GB
Ours (this paper)	**25.6 mins**	**4.1 GB**

↓: Smaller is better; †: Failed at 23 mins.

Specifically, as illustrated in Fig. 5, `Open3D` takes around 30 minutes to load the point cloud into memory, occupying approximately 53.4 GB the system's available memory, and continues to allocate a large amount of memory, causing the process to be terminated by the system process manager. Compared with `Open3D`, which uses the `float64` format, `pypcd4` stores point coordinates in `float32` format in RAM for reducing both the memory demand (60.5 GB) and the time (27 mins) spent on memory allocation during evaluation.

The synchronization chunk processing method sequentially processes the chunk's point cloud, significantly reducing peak memory usage (Fig. 5). However, the total runtime is around 1 h 38 mins. In contrast, our proposed parallel chunk-based method achieves a trade-off between memory and time efficiency (Fig. 5). The whole process finishes within 26 minutes, which is 3.85-fold speedup compared with the synchronization chunk-based method. And the peak memory usage is also below 5 GB, considerably lower than the system's limits.

In addition to total runtime and peak RAM usage, Fig. 6 breaks the runtime into two stages, (1) data loading, (2) normal estimation and axis alignment. The results show

[2]https://github.com/isl-org/Open3D
[3]https://github.com/MapIV/pypcd4

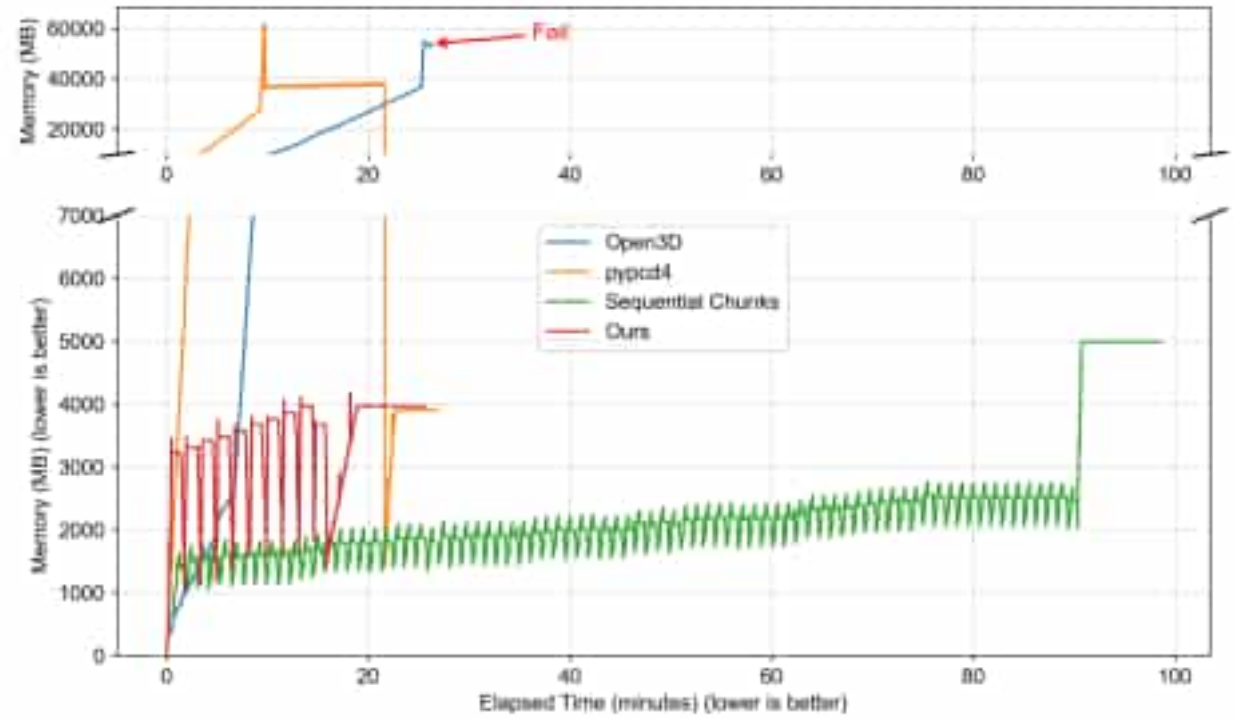

Figure 5. Memory usage comparison of `Open3D` (single batch), `pypcd4` (single batch), sequential chunk processing, and our proposed method

that most of the runtime is spent on data loading, indicating that I/O is the major bottleneck in this pipeline. Compared with the sequential chunk way, our proposed method significantly reduces the time spent on point cloud loading from disk, achieving a 4.98-fold speedup. This demonstrates that our proposed method efficiently avoids memory accumulation while maintaining time efficiency.

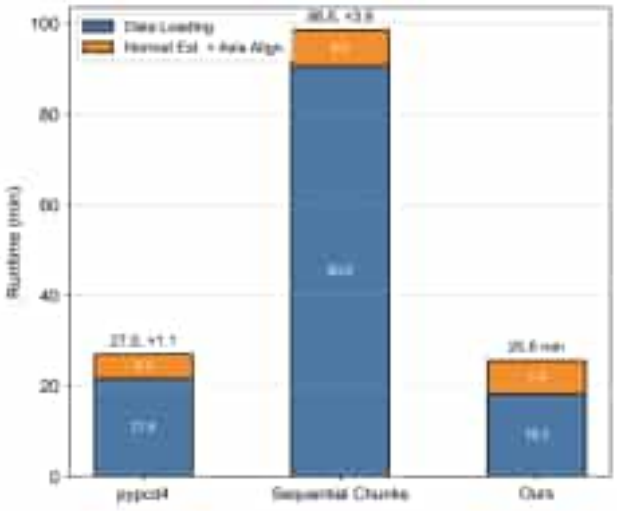

Figure 6. Runtime break down comparison of `pypcd4` (single batch), sequential chunk processing, and our proposed method

Axis Alignment Result After parallel processing, the point cloud was successfully aligned to the global 3D axis, as illustrated in Fig. 7. The red, green, and blue arrows represent the xyz-axis, respectively. The result demonstrates that our estimated dominant rotation angle enables efficient alignment of very large LiDAR point clouds to global coordinates.

Fig. 8 shows the registration result of LiDAR point clouds with the 2D drawings. As the point clouds have already been globally axis-aligned, the registration process only requires solving 2 degrees of freedom (translation along the xy-axes), significantly reducing human effort compared with full 3D registration.

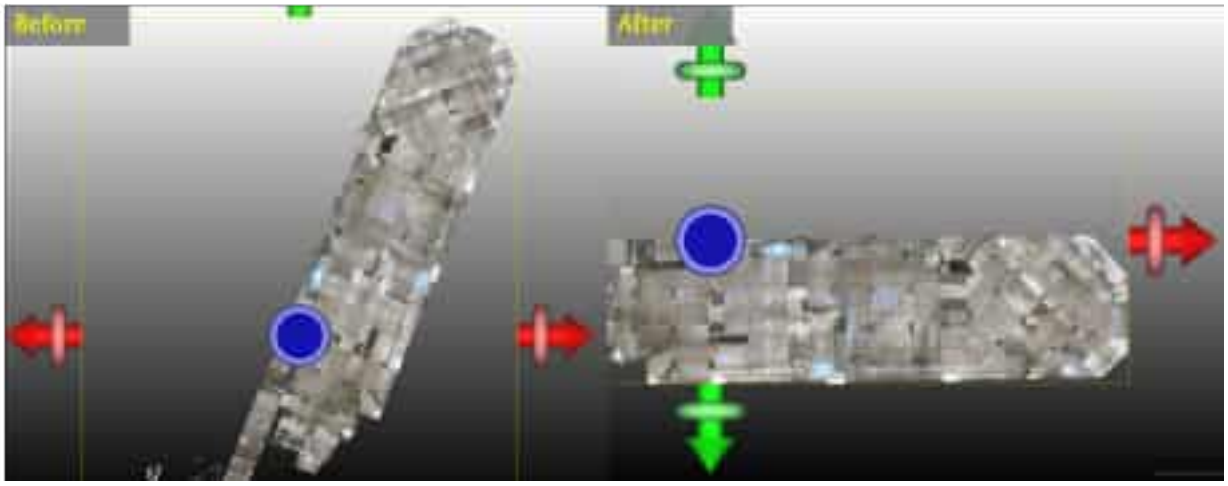

Figure 7. Axis alignment result of the LiDAR point clouds.

Figure 8. Registration result of 2D drawings with LiDAR point clouds. For better visualization, a sector along the z-axis is selected.

5 Discussion and Limitations

The experimental results demonstrated that the proposed chunk-based, orthogonality-enabled parallel computing method effectively estimates the global orientation of very large LiDAR point clouds and achieves both time and memory efficiencies. Compared with the single-batch loading approach in `pypcd4`, our method significantly reduces peak memory usage from over 60.5 GB to approximately 4.1 GB while maintaining comparable data loading time. These findings demonstrate that loading a very large point cloud into memory at once is inefficient when memory is limited. In contrast, aggregating local geometric cues from chunks without full memory access to the full point cloud can be a more efficient way to estimate global orientation and preprocess.

However, several limitations still exist. First, the proposed method currently supports only the LASer file format, although ".PLY" and ".PCD" also have random-access properties. Second, the hyperparameters, such as the chunk size and the number of concurrent processes, are set manually, leading to underutilization of RAM and CPU resources. Last but not least, the method was not tested across diverse building and construction scenes. More importantly, the assumption of dominant orthogonality may not fit for all buildings (e.g., curved facades and non-Manhattan layouts). In such cases, the degree distribution of surface normals may have multiple peaks, potentially degrading the global orientation estimation and failing the axis alignment. In addition, this study does not provide experiments on how chunk size affects runtime and memory usage, which should be further explored in future work.

6 Conclusion

This study presents a chunk-based, orthogonality-enabled method for automatically aligning the global axes of very large LiDAR point clouds. By leveraging the random-access property of the LASer file and controlling parallel concurrency, our proposed method efficiently achieves massive point cloud loading, normal estimation, and global axis alignment on very large LiDAR point clouds on computers. Experiments are conducted on a 22 GB real-world LASer file. The experimental results demonstrated that our method drastically reduces memory consumption and achieves a 3.85-fold speedup compared with the sequential chunk-based approach. The parallel computing mechanisms in this axis alignment method can also benefit other applications of LiDAR point clouds, including learning-based point cloud analysis, point cloud-to-CAD/BIM registration, change detection, and construction progress monitoring.

For future work, one can (1) extend the support for point cloud exchange formats, such as `pypcd4`'s ".PCD" and Stanford polygon ".PLY", (2) analyze the influence of chunk size and concurrency on the memory and CPU utilization, and (3) evaluate the method on a wider range of very large scanning datasets.

Acknowledgment

The data used in this study were collected and provided by Geosys Hong Kong Limited. The work described in this study was supported by the Hong Kong Research Grants Council (No. 17201325) and, in part, by the Hong Kong Innovation and Technology Commission (No. ITP/004/23LP).

Abstract

Reliable and rapid energy forecasting is essential for early-stage decision-making in office building design, yet data-driven modeling in Taiwan is hindered by the lack of region-specific datasets that reflect local building typologies and climates. This study addresses this gap by introducing TOBE (Taiwanese Office Building Energy), a BIM-derived dataset developed for Taiwanese office buildings and designed to reflect regional characteristics. 1,006 simulated office-building cases were created to provide three energy targets: annual electricity (AE), energy use intensity (EUI), and lifecycle electricity (LE). To enable high-accuracy prediction without manual hyperparameter tuning, four machine learning learners (RBFNN, LSSVR, AdaBoost, and XGBoost) were hybridized with the Forensic-Based Investigation (FBI) metaheuristic optimizer and evaluated using 10-fold cross-validation. Results show that boosting-based learners consistently outperform NN- and SVM-based baselines. The best models achieved strong generalization, including AE with FBI_AdaBoost (MAPE = 3.45%; R^2 = 0.944), EUI with FBI_XGB (MAPE = 1.86%; R^2 = 0.954), and LE with FBI_AdaBoost (MAPE = 3.51%; R^2 = 0.945). The proposed BIM-to-AI pipeline offers a practical route to scalable, data-driven energy assessment tailored to Taiwanese office buildings.

Keywords –

BIM-derived dataset; Taiwanese office buildings; building energy prediction; boosting algorithm; Forensic-Based Investigation (FBI).

1 Introduction

Building energy consumption accounts for approximately 17.5% of global greenhouse gas emissions and around 30% of annual carbon emissions from the construction sector [1]. Worldwide, building energy utilization is projected to increase by 1.3% annually between 2018 and 2050, indicating a long term upward trend that challenges global decarbonization efforts [2]. In Taiwan, service and residential buildings consumed roughly 15% of the nation's total energy demand in 2020, with office buildings contributing significantly due to intensive cooling and electrical loads [2]. These figures highlight the pressing need for accurate and scalable prediction tools that can support energy efficient office building design and long-term sustainability planning in Taiwan's dense urban environments.

Traditional simulation based tools such as EnergyPlus and TRNSYS provide detailed insights into building energy performance, yet they require extensive input specifications and long computation times that limit their practicality during early design stages [3-5]. A single detailed simulation may require hours to complete, making these tools unsuitable for evaluating large numbers of design alternatives. Machine learning (ML) methods address these limitations by rapidly modeling nonlinear interactions among building features, and studies have shown that ML informed design decisions can yield potential energy savings of up to 30% [6]. However, the development of robust ML models in Taiwan remains constrained by the lack of large scale, high resolution, and region-specific datasets that accurately represent local office building characteristics.

Understanding the physical and operational characteristics of Taiwanese office buildings is essential for developing reliable datasets. Typical buildings in Taiwan feature rectangular or square floor plans, range from 9 to 26 stories, and incorporate façade systems such as glass curtain walls, aluminium panels, and brick that reflect contemporary architectural practice and green building requirements [7, 8]. Climatic variations across northern, central, and southern Taiwan further influence cooling loads, underscoring the importance of incorporating geographic diversity into dataset

construction [9]. Building Information Modeling (BIM) offers an effective solution by enabling detailed 3D representations of building geometry, materials, and operational parameters. Leveraging BIM alongside cloud-based simulation tools makes it possible to generate thousands of consistent models, ensuring comprehensive coverage of design variables relevant to energy analysis [10-12].

Recent advances in building energy prediction have shown that ensemble learning models consistently outperform single model approaches. For example, XGBoost has achieved mean absolute percentage errors as low as 1.92% for electricity consumption prediction, while Random Forest models have reached classification accuracies near 78.7% for Energy Use Intensity (EUI) analysis [13, 14]. Achieving optimal performance nevertheless depends on effective hyperparameter tuning, which often involves searching for large and complex parameter spaces. Metaheuristic optimization algorithms have been employed to address this challenge, and the Forensic Based Investigation (FBI) algorithm has demonstrated strong stability and fast convergence without requiring algorithm specific tuning parameters [15, 16]. These characteristics make FBI a promising optimization strategy for developing hybrid ML models aimed at building energy prediction.

Despite these advancements, no existing study has proposed a Taiwanese office buildings dataset to support ML based energy prediction. To address this research gap, this study introduces a comprehensive TOBE (Taiwanese Office Building Energy) dataset, generated from detailed BIM models that capture geometric, material, and environmental attributes of real-world office buildings in Taiwan. Using this dataset, hybrid machine learning models optimized with the FBI algorithm are developed to predict the three key energy indicators for Taiwanese office buildings, including annual electric (AE), EUI, and lifecycle electric (LE). The proposed framework provides a scalable and data driven approach that strengthens early-stage decision making and supports long term energy planning for Taiwan's commercial building sector, contributing a region specific and comprehensive foundation for advancing sustainable office building design.

2 Research Methodology

This research was guided by two primary objectives. The first objective was to leverage BIM techniques to create a novel and robust dataset of energy consumption patterns for typical office structures in Taiwan - the TOBE dataset. The second objective was to develop and train AI models to predict related energy consumption patterns in order to provide accurate and early-stage insights into energy consumption to minimize future building energy demand. This approach contributes to a more comprehensive and sustainable framework for construction. The entire research process is presented in **Fig. 1**.

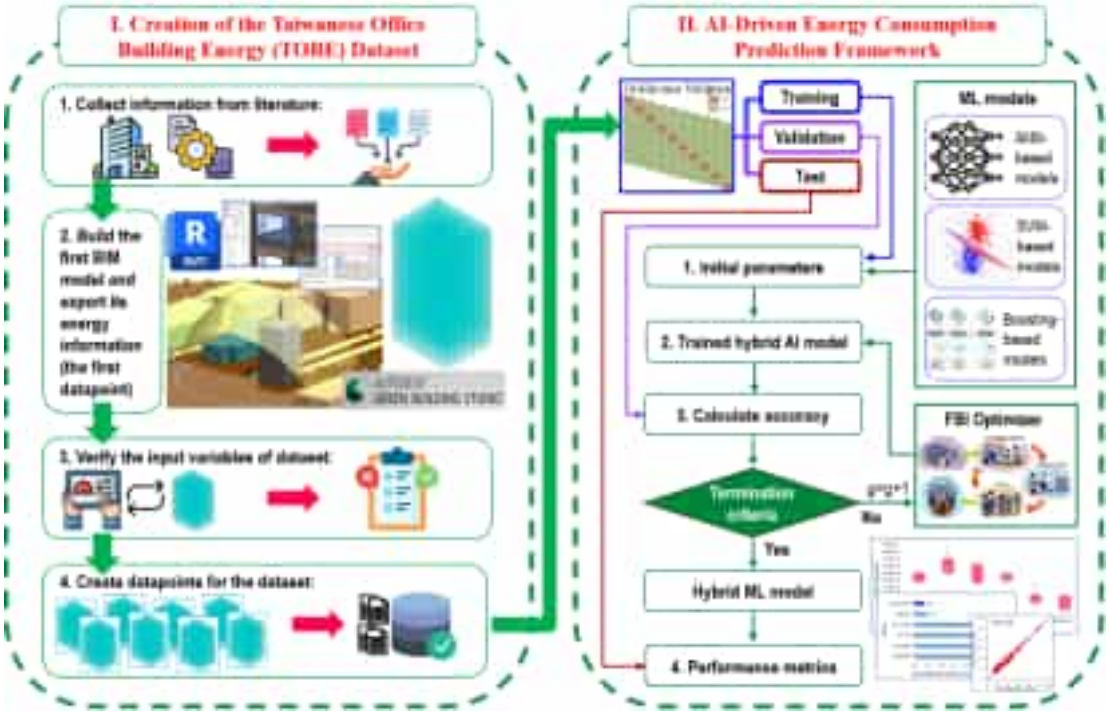

Fig. 1. Research process

2.1 TOBE Dataset Development

The TOBE dataset was established to represent the characteristics of contemporary office buildings in Taiwan systematically and to support machine learning based energy prediction. To identify the building attributes most relevant to energy consumption, a comprehensive review of previous studies and design guidelines, together with field surveys, was conducted for Taiwanese office buildings. Insights from literature, representative built examples, and field surveys highlighted consistent patterns in building geometry, façade systems, glazing configurations, and region specific climatic considerations. **Figure 2** illustrates some typical office buildings in Taiwan, and **Table 1** lists the initial set of variables derived from this investigation along with the typical ranges observed in Taiwanese office buildings. These variables capture the physical diversity required to construct realistic simulation scenarios for dataset creation.

A typical office building was modeled in Autodesk Revit using the characteristics identified earlier. All the input information required for this process was considered as input variables for the dataset. This initial model incorporated sixteen candidate variables, including: Floor area, number of stories, floor height, basement number, beam size, column size, floor thickness, stairs, roof thickness, walls, window materials, window-to-wall ratio, ceiling material, location, orientation, and HVAC system. After the BIM model was completed, the model's energy-related information was extracted using cloud-based Green Building Studio (GBS) software. Each variable was then independently modified and re-simulated to evaluate its impact on energy use, allowing non influential factors such as structural thicknesses, ceiling type, and stair configurations to be excluded.

Through this sensitivity based screening process, nine variables were identified as significant contributors to energy performance. These include floor area, floor height, number of stories, number of basements, exterior wall type, window type, window to wall ratio, geographic location, and orientation, as summarized in **Table 2**. By sampling across the ranges of these validated variables, a total of 1006 BIM models were generated and simulated to produce the final energy dataset. The value ranges of the three energy outputs derived from this dataset are also summarized in **Table 2**. Notably, these 1,006 TOBE cases were not produced through full-factorial enumeration; instead, constrained random sampling was used to achieve broad yet practical coverage of the feasible design space without generating an excessive number of combinations. As a result, the resulting TOBE dataset captures diverse combinations of geometry, envelope systems, and climatic conditions, ensuring a realistic and consistent foundation for training machine learning models aimed at early-stage energy assessment.

Output 1	AE	713651 ~ 10842300	Unit: kWh
Output 2	EUI	518 ~ 1443	Unit: MJ/m²/year
Output 3	LE	21409.5 ~ 235.27	Unit: MW

2.2 AI-Based Energy Prediction

To develop an effective energy forecasting tool for Taiwanese office buildings using the TOBE dataset, four machine learning techniques were employed: Radial basis function neural network (RBFNN) representing

neural network (NN)-based models, least squares support vector regression (LSSVR) representing support vector machine (SVM)-based models, and two boosting algorithms (AdaBoost, XGBoost). These models were selected based on prior literature indicating their high performance in energy prediction tasks. Boosting methods are especially suitable here because the TOBE dataset is structured tabular data with a moderate sample size (1,006 cases), where tree-based ensembles often generalize well with minimal preprocessing and can efficiently capture nonlinear interactions among BIM-derived geometric, material, and climatic variables. Meanwhile, the NN- and SVM-based models were retained as reference learners to ensure a balanced comparison.

To improve predictive accuracy, the hyperparameters of each model were optimized using the FBI algorithm, a parameter free metaheuristic designed to iteratively refine candidate configurations through an adaptive search strategy. The FBI optimizer evaluates each candidate model using validation data and updates the hyperparameters until convergence or until a stopping criterion is met. This automated tuning process eliminates the need for manual adjustments and enhances the robustness of model calibration.

Model training followed a 10 fold cross validation procedure to minimize sampling bias, prevent overfitting and improve generalizability. Throughout the optimization and training process, model performance was assessed using standard regression metrics, including mean square error (MSE), root mean square error (RMSE), mean absolute percentage error (MAPE), and the coefficient of determination (R^2). These metrics provide complementary insights into prediction accuracy, relative error magnitude, and model explanatory power, ensuring a comprehensive evaluation of each algorithm.

3 Results and Discussion

3.1 Annual Electric

AE is one of the important outputs in TOBE dataset. It defined as the total annual electricity consumption of a building. Offering insights into electricity consumption over a year, this metric helps determine building operational costs and environmental impact.

Table 3. Performance of the four hybrid models.

Method		Testing data			
		RMSE	MAPE	MAE	R^2
FBI_ RBFNN	Mean	1091754	28.80%	777582	0.700
	Std.	142479	3.49%	82746	0.063
FBI_ LSSVR	Mean	1082352	22.60%	632261	0.701
	Std.	108131	3.57%	62177	0.070
FBI_XGB	Mean	489026	5.01%	145527	0.933
	Std.	172772	1.51%	43359	0.048
FBI_ AdaBoost	**Mean**	**396941**	**3.45%**	**98827**	**0.944**
	Std.	**235577**	**1.78%**	**43953**	**0.067**

Table 3 presents the performances of the four hybrid models. The results reveal that boosting algorithm-based models (FBI_XGB and FBI_AdaBoost) outperformed both NN-based and SVM-based models in all metrics. FBI_AdaBoost achieved the highest accuracy, with the lowest testing RMSE (396,941 kWh), MAPE (3.45%), and the highest R^2 (0.944). FBI_XGB followed closely, maintaining high predictive reliability and narrow error distribution. In contrast, NN-based models, particularly FBI_RBFNN, recorded the highest MAPE and lowest R^2, indicating limited suitability for this dataset.

Performance comparisons are illustrated in **Figs. 3-5**. MAPE and R^2 plots (**Figs. 3-4**) highlight the superior consistency of the BA-based models. Boxplots of MAE (**Fig. 5**) show tighter distributions and lower medians for FBI_AdaBoost and FBI_XGB, confirming their robustness and reduced estimation bias.

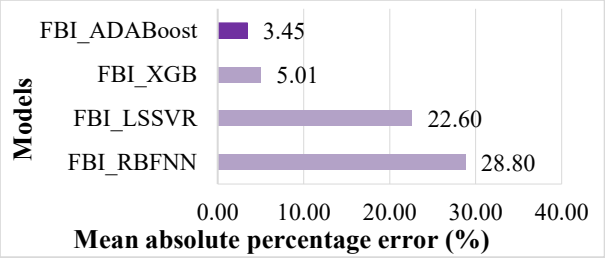

Fig. 3. Average MAPEs of hybrid models

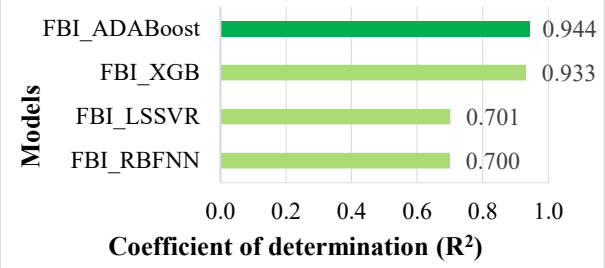

Fig. 4. Average R^2 of hybrid models

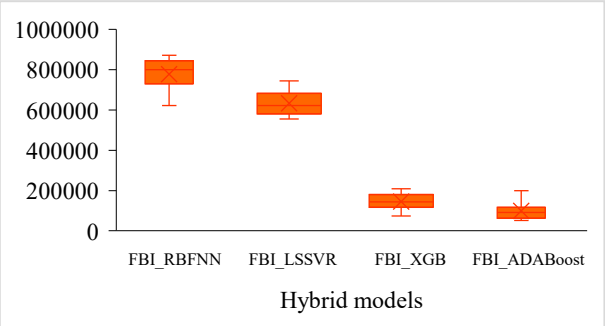

Fig. 5. MAE boxplot of hybrid models

These findings emphasize the critical role of model selection in energy prediction tasks. The BA-based models' strong generalization, high accuracy, and low variance make them well-suited for complex energy forecasting problems, particularly in data-rich environments like the TOBE dataset. Among them, FBI_AdaBoost emerges as the most effective model, offering practical utility for early-stage energy planning and decision-making in Taiwan's office building sector.

3.2 Energy Use Intensity

EUI is a straightforward but powerful measure of how efficiently a building uses energy. It is calculated by dividing the total energy consumed by a building in 1 year by its total floor area. Accurate EUI prediction models are essential for effective energy management, optimisation, and sustainability and can achieve potential energy savings of up to 30%. EUI is one of the energy performance indicators that can be extracted from GBS.

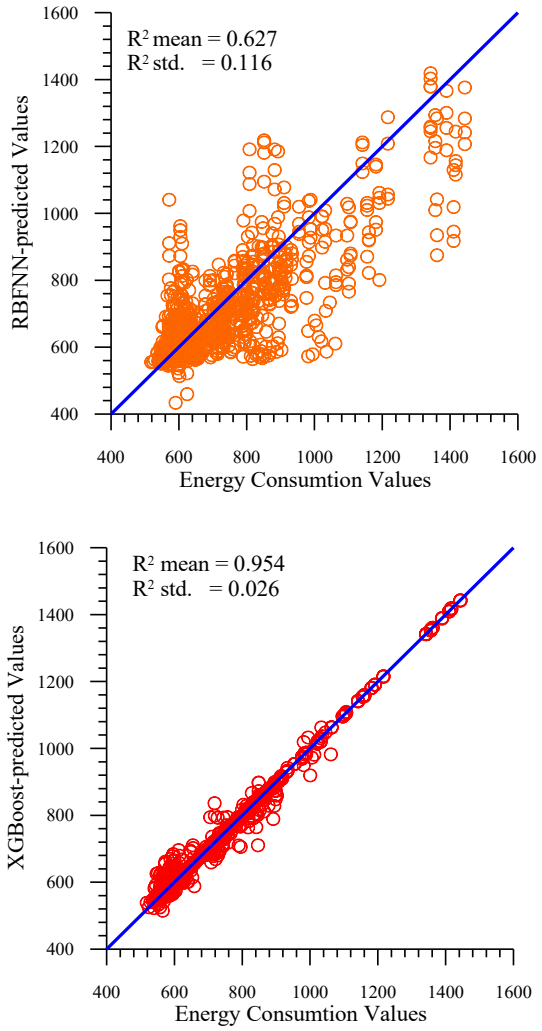

Fig. 6. Scatter plot of the EUI models

Table 4. Performance of the four hybrid models.

Method		Testing data			
		RMSE	MAPE	MAE	R^2
FBI_ RBFNN	Mean	113.22	9.66%	75.69	0.627
	Std.	14.85	1.23%	9.48	0.116
FBI_ LSSVR	Mean	92.65	8.67%	62.55	0.746
	Std.	17.14	1.14%	9.48	0.107
FBI_XGB	**Mean**	**37.98**	**1.86%**	**12.60**	**0.954**
	Std.	**11.81**	**0.50%**	**3.23**	**0.026**
FBI_ AdaBoost	Mean	46.09	2.85%	19.49	0.932
	Std.	12.91	0.79%	5.32	0.031

As seen in **Table 4**, the RBFNN and LSSVR models performed relatively poorly across all metrics. RBFNN gave the weakest results, with the highest RMSE (113.22 ± 14.85 MJ/m²/year) and MAPE (9.66% ± 1.23%) on the test set. In contrast, XGBoost achieved the best overall performance, with the lowest RMSE (37.98 ± 11.81 MJ/m²/year), lowest MAPE (1.86% ± 0.50%), and highest R2 (0.954 ± 0.026), demonstrating strong predictive accuracy and generalization. FBI_AdaBoost ranked second, showing that boosting-based methods outperformed the NN- and SVM-based models.

Figure 6 further illustrates the contrast between RBFNN, the weakest model, and XGBoost, the best-performing model, through predicted-versus-simulated energy consumption plots. RBFNN shows wide dispersion around the 45° reference line, indicating larger prediction errors and only moderate explanatory power, whereas XGBoost predictions cluster closely around the line with only minor deviations. This confirms that XGBoost provides substantially more accurate and robust energy consumption predictions than RBFNN.

3.3 Lifecycle Electric

In Autodesk GBS, the LE indicator quantifies the total electricity consumption of a building over a specified analysis period, typically aligned with its expected service life. It aggregates annual electric use from all major end uses, such as lighting, plug loads, HVAC systems, and auxiliary equipment, and projects this consumption forward using consistent operating assumptions. This indicator is often coupled with utility rate information to estimate long-term operating costs. As a result, LE provides a useful basis for evaluating the economic and environmental benefits of energy efficiency strategies across the whole building life cycle.

Based on the two preceding results, boosting-based models provide the strongest predictive performance on the TOBE dataset. Accordingly, this section employs FBI_AdaBoost and FBI_XGB to develop prediction models for lifecycle electricity in Taiwanese office buildings. **Table 5** summarizes the 10-fold cross-validation performance of both models. For visualization,

Figs. 7 and 8 compare the fold-wise test MAPE and R^2 values across the 10 folds, respectively.

Across the 10-fold cross-validation, both boosting models demonstrate strong predictive capability for LE in Taiwanese office buildings. FBI_AdaBoost achieves the best average performance, yielding lower mean errors (RMSE = 10,664; MAE = 2,891) than FBI_XGB (RMSE = 13,932; MAE = 4,146), together with a higher mean coefficient of determination (R^2 = 0.945 vs. 0.931). The low mean MAPE values (3.51% for FBI_AdaBoost and 5.02% for FBI_XGB) further indicate good relative accuracy, supporting the suitability of boosting-based learners for this dataset.

Table 5. 10-fold performances of boosting models.

FBI_XGB (testing performance)				
Fold	**RMSE (KW)**	**MAPE (%)**	**MAE (KW)**	**R2**
1	18,156.5	6.14	4,911.3	0.929

Mean	**10,664.4**	**3.51**	**2,891.0**	**0.945**
Std.	**8,590.8**	**1.33**	**1,802.1**	**0.099**

Nevertheless, robustness differs across folds. FBI_XGB exhibits more stable explanatory power (std. R^2 = 0.060) and does not show extreme deterioration, although weaker generalization is observed in a small number of splits. A brief diagnostic comparison of **Table 5** shows that Fold 10 is the most difficult test partition for both boosting models: FBI_XGB records its lowest R^2 (0.808) and highest RMSE (23,877.9) in this fold, while FBI_AdaBoost shows an even larger drop (R^2=0.671; RMSE = 31,229.0; MAE = 7,572.6). This concurrent degradation suggests that Fold 10 likely contains harder-to-predict or more extreme cases than the remaining folds. Therefore, the Fold 10 result is interpreted as evidence of a challenging partition, while the larger decline of FBI_AdaBoost indicates that it is more sensitive than FBI_XGB to such cases, despite achieving better average LE prediction performance overall.

4 Conclusions

This study aims to (i) establish a region-specific, simulation-consistent dataset for Taiwanese office buildings and (ii) develop a high-accuracy prediction framework suitable for early design without labor-intensive manual calibration. The proposed TOBE dataset was generated via a BIM-to-simulation workflow, in which representative office-building geometries were modelled in Autodesk Revit and evaluated using Green Building Studio. A sensitivity-based screening procedure reduced the input space to nine influential variables that are physically meaningful and readily extractable from standard BIM deliverables. The final dataset comprises 1,006 cases and includes three electricity-related targets: annual electricity, energy use intensity, and lifecycle electricity.

Four learning algorithms (RBFNN, LSSVR, AdaBoost, and XGBoost) were then optimized using the FBI metaheuristic and assessed through 10-fold cross-validation, with results indicating that boosting-based models are consistently the most effective for TOBE. From a feasibility and application standpoint, the proposed pipeline is designed for real-world deployment in early-stage decision-making. The nine retained inputs can be obtained directly from BIM or basic design

documentation, enabling rapid estimation of AE, EUI, and LE without repeatedly running computationally expensive simulations.

Overall, the combination of TOBE and the FBI-optimized boosting models provides a scalable foundation for data-driven electricity forecasting to support energy-efficient design and planning in Taiwanese office buildings. Because the inputs were pre-screened through BIM-based sensitivity analysis, the framework already focuses on energy-relevant variables. Nevertheless, enhancing model interpretability remains an important next step. Future research should quantify the relative influence of these variables using feature-importance techniques such as XGBoost gain and SHAP values, thereby enabling the predictive framework to provide more explicit and actionable support for design decision-making. In addition, the framework should be further validated using measured operational data, when available, to assess its real-world applicability and transferability.

Abstract –

Generating building digital twins from UAV imagery via 3D reconstruction is significant. However, reflective glass façades remain particularly challenging: their high-frequency, view-dependent appearance often causes photogrammetry to yield distorted geometry and corrupted textures. While Gaussian Splatting supports view-dependent rendering, its spherical harmonics color model mainly captures low-frequency components and fails to reconstruct high-frequency specular reflections. In addition, vanilla Gaussian Splatting tends to "explain" reflections by reconstructing ghost geometry behind the glass surface and producing a visually plausible view-dependent appearance, rather than recovering the true façade geometry. To address these issues, this paper proposes a novel Gaussian Splatting–based reconstruction and rendering framework for reflective glass façades, enabling both accurate geometry recovery and high-fidelity photorealistic rendering. First, UAV images are processed using photogrammetric reconstruction to obtain a coarse façade mesh with distorted geometry. Second, individual glass panels are segmented in 2D images using structural regularities and then projected onto the coarse mesh to correct geometric distortions in the façade. Third, using the corrected façade mesh as a geometric prior, a Gaussian Splatting model is trained with a rendering formulation that considers both diffuse color and specular reflection. For specular reflection, a novel reflection Multilayer Perceptron (MLP) is developed that takes the 3D surface position and the reflection direction as input to efficiently model near-field illumination with low computational and memory costs. Experiments on two buildings in Hong Kong show that our method reliably reconstructs reflective façade geometry and outperforms state-of-the-art approaches in rendering high-frequency, view-dependent appearances.

Gaussian Splatting; Reflective Glass Façades; 3D Reconstruction; Photorealistic Rendering; Reflection MLP; Digital Twin Modelling

1 Introduction

Using UAV-acquired imagery to reconstruct a building's 3D model can serve as a foundation for a digital twin [1-4]. Such a model can be further converted into a BIM representation [5-7], or used to inspect and annotate façade-level defects. This research direction is therefore highly valuable. However, for buildings with reflective glass façades, this pipeline faces challenges.

Optics-based passive 3D reconstruction, commonly referred to as photogrammetry, fundamentally relies on extracting and matching image keypoints across views and leveraging epipolar geometry to recover both the 3D coordinates of scene points and the camera poses [1]. A core assumption is multi-view consistency, i.e., that the same physical point exhibits similar appearance in overlapping images and can thus be reliably matched. For reflective surfaces, this assumption is violated: the observed color at the same surface point can differ significantly between adjacent viewpoints because the reflection directions change significantly. As a result, photogrammetry-based reconstructions often suffer from

severe geometric and textural distortions when applied to reflective façades.

For such view-dependent textures on reflective glass, conventional point cloud or mesh representations are inadequate, as they can only represent static textures. In recent years, learning-based 3D reconstruction and rendering methods such as Neural Radiance Fields (NeRF) [8] and Gaussian Splatting (GS) [9] have emerged. NeRF trains an implicit MLP that takes a 5D input (3D position and 2D viewing direction) and outputs color together with a density value representing geometry. In contrast, GS represents scenes as an explicit set of Gaussian geometries and renders novel views via rasterization. Compared with NeRF, GS enables real-time rendering and faster training, making it more suitable as a base representation for building digital twins.

GS typically models view-dependent color using spherical harmonics (SH). While SH can capture view dependence to some extent, it is primarily effective for low-frequency effects (i.e., appearance changes that vary smoothly with camera pose.) Specular reflections, however, are high-frequency view-dependent effect and can change dramatically with viewpoint. Consequently, SH provides an inadequate representation for reflections on glass façades.

Recent studies have attempted to enhance GS for reflection modeling. One line of work introduces a 2D environment map to represent global illumination and queries it using reflection directions to reproduce high-frequency, view-dependent appearance [10-11]. However, such queries inherently assume illumination originates from infinity. In real-world 3D environments, reflections on glass façades are induced by a near-field light field, where contributing sources lie at varying distances. Representing this with a 2D environment map leads to parallax errors. Another line of work attempts to reconstruct the 3D environmental light field [12], e.g., by fitting millions of "environment Gaussians" to approximate where in 3D space light of different colors is emitted and how it reaches and reflects off the façade. Although this explicitly approximates the reflection formation process, inferring a complete 3D environment solely from reflections is highly complex, and representing the entire surrounding scene with Gaussians leads to substantial computation and storage costs.

To address these limitations, this paper proposes a new approach: we train a reflection Multilayer Perceptron (MLP) that takes as input the 3D position on the reflective surface and the reflection direction computed from the viewing direction and the surface normal, and outputs the corresponding color. In effect, the MLP learns a surface light field, enabling efficient modeling of near-field illumination effects without reconstructing the entire environment, thereby providing an effective and computationally efficient solution.

Effective training of the reflection MLP requires accurate surface geometry and normal directions of the reflective façade. Photogrammetry often produces distorted and incomplete geometry for reflective surfaces. Notably, vanilla GS also tends to place Gaussians behind reflective surfaces to reproduce the illusion of reflection in rendering, rather than reconstructing the true reflective surface itself. Therefore, we further propose a new geometric correction method for reflective glass façades by combining (i) the distorted coarse façade mesh obtained from photogrammetry and (ii) individual 3D panel models derived from façade panel segmentation, resulting in an accurate reconstruction of the reflective glass façade surfaces.

In summary, our main contributions are as follows: (1) proposing a novel model that integrates GS with a reflection MLP to efficiently model near-field specular reflections. By decomposing diffuse color and reflection via a shading formulation, our method enables high-fidelity photorealistic rendering of reflective glass façades; (2) developing a mesh correction approach that combines photogrammetry with a façade panel segmentation model, enabling accurate reconstruction of reflective glass façade geometric surfaces; (3) validating the proposed method on two real-world buildings with reflective glass façades in Hong Kong, and the experimental results demonstrate that our method outperforms state-of-the-art methods in rendering high-frequency, view-dependent facades' appearance.

2 Preliminary of Gaussian Splatting

This paper adopts 2D Gaussian Splatting (2DGS) [13] as the basic primitive for reconstructing and rendering reflective glass façades. Unlike 3D Gaussian Splatting (3DGS), which represents scenes using volumetric Gaussian ellipsoids, 2DGS represents objects using Gaussian elliptical disks. This representation improves multi-view consistency in both surface normals and depth, facilitating accurate querying of façade surface geometry from different camera viewpoints.

Each 2D Gaussian is parameterized by a central point p_k, two principal tangential vectors t_u and t_v, two scaling vectors s_u and s_v, an opacity α, a color coefficient vector c represented using spherical harmonics. In the local tangent plane defined in world space, the 2D Gaussian can be formulated by Eq. (1) and Eq. (2). Given local coordinates $\mathrm{u} = (u, v)$ on the tangent plane, the corresponding Gaussian value is computed by Eq. (3).

$$P(u,v) = p_k + s_u t_u u + s_v t_v v = H(u,v,1,1)^{\top} \quad (1)$$

$$H = \begin{bmatrix} s_u t_u & s_v t_v & 0 & p_k \\ 0 & 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} RS & p_k \\ 0 & 1 \end{bmatrix} \quad (2)$$

$$\mathcal{G}(\mathrm{u}) = \exp\left(-\frac{u^2 + v^2}{2}\right) \quad (3)$$

Based on these definitions, rendering in 2DGS amounts to establishing the correspondence between a camera pixel $\mathrm{x} = (x, y)$ and the local tangent-plane coordinates $\mathrm{u} = (u, v)$ of each 2D Gaussian. This can be computed via a ray–splat intersection, where $W \in \mathbb{R}^{4\times4}$ denotes the transformation matrix from world space to screen space:

$$\mathrm{x} = (xz, yz, z, 1)^{\top} = WH(u, v, 1, 1)^{\top} \quad (4)$$

After obtaining the mapping from pixel $(x, y)$to the local coordinates (u, v), the Gaussian contribution to that pixel is evaluated using Eq. (3), and the intersection depth z is obtained from Eq. (4). The final pixel color is then computed by rasterization using volumetric alpha blending:

$$\mathrm{c(x)} = \sum_{i=1} c_i \alpha_i \hat{\mathcal{G}}_i(\mathrm{u(x)}) \prod_{j=1}^{i-1} (1 - \alpha_j \hat{\mathcal{G}}_j(\mathrm{u(x)})) \quad (5)$$

where $\hat{\mathcal{G}}$ denotes a low-pass filtered version of the Gaussian kernel, introduced to mitigate unstable optimization caused by strongly slanted viewpoints.

3 Methodology

The proposed Gaussian Splatting–based reconstruction and rendering framework is illustrated in Fig. 1. It consists of two main stages: (1) Geometric Reconstruction and Correction, and (2) Gaussian Splatting Reconstruction and Rendering.

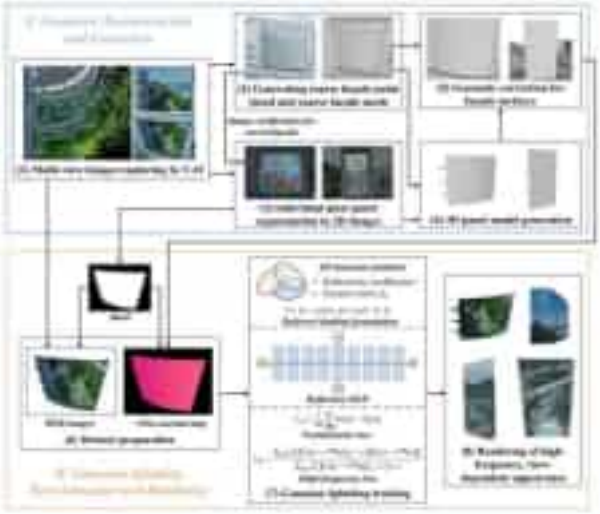

Fig. 1 Overall framework for the proposed method

3.1 Geometric Reconstruction and Correction for Reflective Glass Façade

The UAV-captured images were first used to generate a geometrically distorted coarse façade mesh and the corresponding coarse façade point cloud via photogrammetric 3D reconstruction. Notably, the coarse façade mesh exhibits uneven and broken glass panel surfaces, while the coarse façade point cloud contains missing points on the glass panels, as illustrated in Fig. 2.

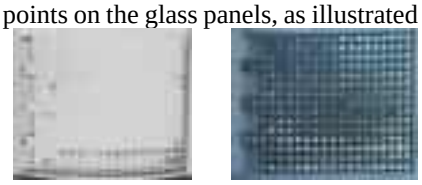

Fig. 2 Coarse façade mesh (left) and coarse façade point cloud (right) from photogrammetric 3D reconstruction

3.1.1 Image Rectification for Curved Façades

In the 2D images, the glass-panel segmentation method proposed in the authors' prior work is adopted. Leveraging the structural regularities of glass panels, specifically linear features and repetitive patterns, this method formulates a maximum a posteriori (MAP) estimation problem to extract panel corner points for the segmentation of the individual glass panels (see [14] for details). This method is effective in mitigating the adverse impact of reflections and background clutter on panel segmentation, and it performs well on frontal-view façade images. However, because it relies on line-based features, it is directly applicable to planar (flat) façade surfaces. For curved façades, an image rectification step is required to warp the curved surface into a planar surface in the image before segmentation.

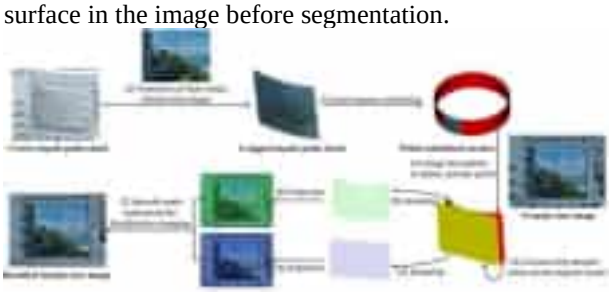

Fig. 3 Image rectification for curved façade surfaces

Fig. 3 illustrates the image rectification process for curved façades. First, a close-range frontal-view image is captured near the façade surface. This image contains only the façade, without any background clutter. Using the 3D-to-2D projection relationship between the coarse façade point cloud (3D points (X, Y, Z)) and the image pixels (u, v), as given in Eq. (6), the subset of 3D points that project into the image is extracted to form a cropped point cloud. A cylindrical surface is then fitted to the cropped point cloud via least-squares estimation, yielding the cylinder equation that represents the curved façade geometry.

$$\begin{bmatrix} u \\ v \\ 1 \end{bmatrix} = K \cdot \begin{bmatrix} R & T \\ 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} X \\ Y \\ Z \\ 1 \end{bmatrix} \quad (6)$$

where K is the camera intrinsic matrix; R and T are extrinsic rotation matrix and translation vector, respectively.

For image that requires panel segmentation, the image boundaries are used to determine the corresponding extent of the fitted cylindrical surface, thereby defining a patch on the cylinder (highlighted in red in the figure). This cylindrical patch is first sampled to obtain a set of surface points (green points). A tangent plane is then constructed at the angular center of the patch (yellow plane), and the sampled surface points are orthogonally projected onto this plane to form a planar point set (blue points).

Both the original cylindrical surface points (green) and their planar counterparts (blue) are projected onto the target image. In this projection, the green points indicate the pixel locations corresponding to the true 3D geometry of the curved façade, whereas the blue points indicate the pixel locations after unfolding the curved façade into a planar façade. Consequently, rectifying a curved-façade image into a planar-façade image amounts to estimating a mapping from the green-point locations to the blue-point locations in the image. A seventh-order polynomial is used to fit this mapping, enabling effective image rectification for curved façades.

3.1.2 Glass Panel Segmentation and Projection for 3D Panel Model Generation

For frontal-view image of planar façade and rectified frontal-view image of curved façade, glass-panel corner points are extracted using structural regularities-based MAP estimation. By pairing the four corner points belonging to the same panel, each glass panel can be segmented. For curved façades, the corner points extracted in the rectified image are further mapped back to the unrectified image using the fitted seventh-order polynomial. Fig. 4 shows the glass-panel segmentation results for both planar and curved façades.

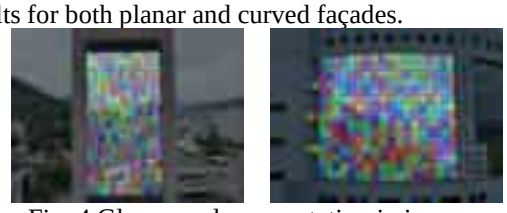

Fig. 4 Glass panel segmentation in images

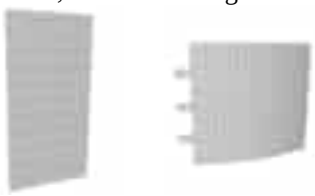
The extracted glass-panel corner points are further projected onto the corresponding coarse façade mesh via ray casting, producing the 3D locations of the panel corners. Because corner extraction in the image may incur subtle pixel-level errors, which can be amplified after ray casting over tens of meters, the resulting 3D panel corners are regularized: for each row of corners, the z-coordinates are averaged, and for each column, the x- and y -coordinates are averaged, thereby reducing segmentation-induced deviations. After pairing the regularized 3D corner points, the reconstructed 3D panel models are obtained, as shown in Fig. 5.



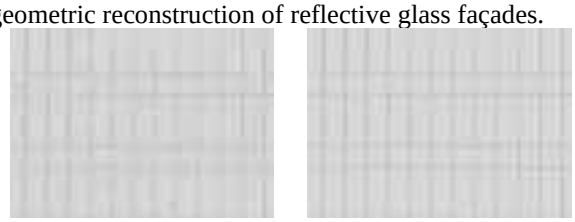


Fig. 5 3D panel models for planar façade (left) and curved façade (right)

3.1.3 Geometric Correction on Coarse Façade Mesh

Based on the obtained 3D panel models, geometric correction can be applied to the coarse façade mesh. Notably, simply overlapping the 3D panel models with the coarse mesh still results in an uneven façade surface (Fig. 6(a)), because the coarse mesh often contains local protrusions and irregularities on the panel regions. Conversely, directly replacing the corresponding mesh regions with the full 3D panel models would remove the surrounding frames.

To address this, each 3D panel is slightly shrunk in-plane about its center, and a small cuboidal region is defined along the panel normal. The portion of the coarse façade mesh within this cuboid is then replaced with the shrunk 3D panels. This procedure produces the corrected façade surface shown in Fig. 6(b), enabling accurate geometric reconstruction of reflective glass façades.

(a) (b)

Fig. 6 Geometric correction by (a) simply overlapping and (b) cuboidal region replacement

3.2 Gaussian Splatting Reconstruction and Rendering for Reflective Glass Façade

As the mesh models are unable to represent the high-frequency, view-dependent appearance of reflective glass façades, the final digital representation is constructed using the 3D model reconstructed by Gaussian Splatting. The accurate façade geometry obtained in Section 3.1 is incorporated as a geometry prior in the training of the Gaussian Splatting model.

3.2.1 Gaussian Augmentation and Deferred Shading Function

For each Gaussian, in addition to the parameters introduced in Section 2, two attributes are further included: a reflectivity coefficient r and a 3-dimensional

Fresnel vector f_0 for calculating the Fresnel term. The Fresnel term modulates specular reflectance as a function of the viewing angle, capturing the characteristic behaviour of glass surfaces, i.e., reflectance increases toward grazing angles and decreases near normal incidence. During rendering, different appearance components are first rendered into 2D images independently and then composited, following a deferred shading strategy.

For an image I, the deferred shading function is defined in Eq. (7). The diffuse color D is computed using Eq. (5) and represented with spherical harmonics. The specular reflection R is estimated by the reflection MLP described in Section 3.2.2. The reflectivity $refl$ is computed using the same volumetric alpha blending formulation as in Eq. (5). Since the surface roughness of reflective glass façades is negligible and can be approximated as ideal specular reflection, the Fresnel term F can be calculated using Schlick's approximation in Eq. (8), parameterized by F_0obtained via volumetric alpha blending of the per-Gaussian $f_0$values.

$$I = (1 - refl) \cdot D + refl \cdot F \cdot R \quad (7)$$

$$F = F_0 + (1 - F_0) \cdot (1 - \cos\theta)^5 \quad (8)$$

where θ denotes the angle between the surface normal n and the outgoing radiance direction ω_o (i.e., the direction opposite to the viewing direction).

3.2.2 Reflection MLP

To model near-field specular reflections, we design a reflection MLP that predicts the specular reflected color R from the surface position X_r and the reflection direction ω_r at that position (computed using Eq. (9)).

$$\omega_r = \omega_o - 2\omega_o^{\top} n \cdot n \quad (9)$$

The architecture of the reflection MLP is illustrated in Fig. 7. It comprises eight fully connected layers with ReLU activations and 512 hidden units per layer, followed by a final sigmoid-activated output layer. Since standard MLPs exhibit a spectral bias toward low-frequency signals whereas specular reflections contain high-frequency details, the inputs X_r and ω_r are first mapped to high-dimensional features using Fourier feature encoding, as defined in Eq. (10). Before encoding, X_r is normalized to the range $[-1,1]$, and ω_r is enforced to be a unit direction vector. We set $L = 12$ for both $\gamma(X_r)$ and $\gamma(\omega_r)$ to ensure sufficient capacity for modeling high-frequency content.

$$\gamma(p) = (\sin(2^0\pi p), \cos(2^0\pi p), \cdots, \sin(2^{L-1}\pi p), \cos(2^{L-1}\pi p)) \quad (10)$$

The encoded position $\gamma(X_r)$ is first processed by the first four layers alone, rather than being concatenated with the direction input from the beginning, so that the network can learn position-dependent material characteristics and extract relevant features. This staged fusion helps disentangle spatially varying properties from direction-dependent reflection. At the fifth layer, the learned position features are concatenated with the encoded reflection direction $\gamma(\omega_r)$, and $\gamma(X_r)$ is re-injected via a skip connection. The skip connection facilitates gradient flow and preserves positional information, mitigating over-smoothing in deep networks. Finally, a sigmoid activation is applied to produce the specular reflected RGB color R.

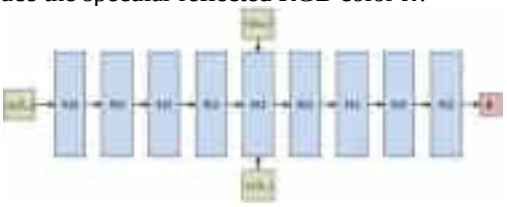

Fig. 7 Architecture of reflection MLP

3.2.3 Regularization

To effectively leverage the accurate façade geometry obtained in Section 3.1 and to ensure that high-frequency appearance details are properly learned, we introduce two additional regularization terms: a normal-prior loss and a high-frequency loss.

Normal-prior loss. As shown in Eq. (11), we compute an $\ell_1$loss between the rendered surface normals n and the reference normals $\hat{n}$ derived from the accurate façade geometry under the same viewpoint. This term enforces geometric fidelity of the reconstructed façade surface.

$$\mathcal{L}_{np} = \frac{1}{|\Omega|} \sum_{p \in \Omega} \|n(p) - \hat{n}(p)\|_1 \quad (11)$$

where Ω denotes the set of valid pixels, and p indexes image pixels.

High-frequency loss. As defined in Eq. (12), we focus the supervision on pixels whose color error exceeds a threshold τ. Specifically, we select the subset of pixels with large $\ell_1$residuals between the rendered color C and the ground truth C^{gt}, and average the residuals over this subset. Empirically, we observe that using only the standard RGB reconstruction loss $\mathcal{L}_c$ in Gaussian Splatting tends to distribute errors uniformly, yielding overly smooth reconstructions that fail to recover sharp, high-frequency reflections. The proposed high-frequency loss explicitly corrects these high-error regions.

$$\mathcal{L}_{hf} = \frac{\sum_{p \in \Omega} \mathbb{I}(\|C(p) - C^{\mathrm{gt}}(p)\|_1 > \tau) \, \|C(p) - C^{\mathrm{gt}}(p)\|_1}{\sum_{p \in \Omega} \mathbb{I}(\|C(p) - C^{\mathrm{gt}}(p)\|_1 > \tau) + \varepsilon} \quad (12)$$

where $\mathbb{I}(\cdot)$ denotes the indicator function, ε is a small constant to avoid division by zero, and τ is initialized to 0.2 and decreased in a stepwise manner over training iterations to a final value of 0.09.

Finally, the overall objective is given in Eq. (13).

Here, $\mathcal{L}_c$ combines an ℓ_1 term with the D-SSIM term, and $\mathcal{L}_n$ denotes the normal-consistency loss; both follow the original 2DGS definitions.

$$\mathcal{L} = \mathcal{L}_c + \lambda_n \mathcal{L}_n + \lambda_{np} \mathcal{L}_{np} + \lambda_{hf} \mathcal{L}_{hf} \quad (13)$$

where $\lambda_n = 0.05$, $\lambda_{\text{np}} = 1$, and λ_{hf} is initialized to 1 and increased in a stepwise manner over training iterations, reaching a final value of 10.

4 Experiment

The proposed Gaussian Splatting–based reconstruction and rendering framework for reflective glass façades is validated on two buildings in Hong Kong: the HKUST Library and the Sha Tin Office Building.

4.1 Experimental Setup

For the HKUST Library, 600 multi-view images were collected, while 560 multi-view images were captured for the Sha Tin Office Building. Since this study focuses on the reconstruction and rendering of reflective glass façades, the 3D panel models of both buildings were first projected onto the images to generate façade masks, which remove background regions outside the façades. The prior normal maps used for training were likewise restricted to the masked regions.

All images were captured using a DJI M3E UAV equipped with an RTK module, providing centimeter-level GPS positioning. Due to interference from view-dependent appearance, camera poses estimated by COLMAP can exhibit substantial errors. Therefore, the captured images were first processed in DJI Terra to perform photogrammetry by incorporating GPS positions and camera orientations. This procedure supports the geometric reconstruction and correction in Section 3.1 while providing more accurate camera poses. The resulting poses were converted to the COLMAP format for Gaussian Splatting training using 100,000 epochs.

The proposed method is compared with vanilla 3DGS [9], 2DGS [13], and state-of-the-art reflection-aware Gaussian models, including GaussianShader [10] and Ref-Gaussian [11]. The proposed model is trained for a total of 2×10^5 iterations, while all baseline methods are run with their default hyperparameter settings.

In addition, different designs of the reflection MLP are explored and compared to demonstrate the rationality of our proposed architecture. Performance is evaluated using PSNR, SSIM, and LPIPS. All experiments are conducted on an NVIDIA A40 GPU.

4.2 Baseline Comparison

Figs. 8 and Table 1 illustrate the baseline comparison results on the HKUST Library dataset, while Figs. 9 and Table 2 show the results on the Sha Tin Office Building dataset. Quantitatively, the proposed method achieves the best performance across all metrics, and improves PSNR by more than 5 dB over the SOTAs on both datasets.

As illustrated by the renderings in Figs. 8 and 9, the proposed method faithfully reconstructs the view-dependent textures of reflective glass façades while preserving high-fidelity high-frequency details, such as the circular fountain in the center of the top row in Fig. 8, the reflected building in the lower-right corner of the bottom row in Fig. 8, the blue sports court in the lower-left region of the top row in Fig. 9, and the fine details of the bridge and vehicles in the bottom row of Fig. 9.

For Ref-Gaussian, it can recover view-dependent appearance to some extent; however, it represents global illumination using a 2D environment map, which causes parallax errors for real-world 3D near-field reflections, leading to noticeably blurred high-frequency details. GaussianShader also relies on a 2D environment map, but uses 3D Gaussians as primitives and defines normals using the minor-axis direction of each 3D Gaussian. This representation results in inaccurate façade-surface geometry, which in turn yields incorrect reflection estimation. Consequently, Fig. 8 shows locally chaotic appearance in the middle of the façade, and Fig. 9 exhibits unstable appearance across large façade regions, both due to poor geometric reconstruction. In addition, vanilla 3DGS and 2DGS employ spherical harmonics to model color, which captures only low-frequency view-dependent variations and fails to reproduce high-frequency specular reflections.

Overall, these comparisons demonstrate that our method reconstructs façade surfaces with 2D Gaussian primitives, estimates near-field specular reflections with a reflection MLP, and incorporates a corrected façade mesh as a geometric prior, together providing an effective solution for high-quality reconstruction and rendering of reflective glass façades.

4.3 Reflection MLP Architecture Evaluation

One of the core contributions of this work is the proposed reflection MLP, whose architectural design has a substantial impact on performance. The architecture is primarily governed by four factors: (1) the Fourier feature encoding order L, (2) the network depth (number of layers), (3) the hidden-layer width (hidden dimension), and (4) whether to incorporate a skip connection that re-injects the encoded position features.

In the Sha Tin Office Building, different reflection MLP architectures are evaluated, as summarized in Table 3. Comparing Cases 1, 2, and 4 indicates that increasing the hidden-layer width and network depth benefits the reconstruction of high-frequency, view-dependent textures. This is because the reflection MLP effectively serves as a high-capacity function approximator that maps position and reflected direction to reflected color; wider layers improve feature expressiveness, while deeper networks enhance the modeling of nonlinear interactions between spatial location and direction.

Comparing Cases 2 and 3 shows that introducing a skip connection that re-injects the encoded position features improves near-field reflection estimation. Additionally, Cases 3, 5, 6, and 7 suggest that moderately increasing the Fourier feature encoding order helps the MLP represent high-frequency components, whereas excessively large encoding orders degrade performance, because high-order encodings introduce very high-frequency basis functions that amplify sensitivity to small pose/calibration errors and pixel-level noise.

5 Conclusion

This paper proposes a novel Gaussian Splatting–based framework for reconstructing and rendering reflective glass façades, enabling accurate geometric reconstruction and high-fidelity photorealistic rendering. The main contributions are twofold: (1) a geometry reconstruction and correction strategy that integrates segmented 3D glass panel models with photogrammetric coarse façade mesh to refine the façade surface geometry; and (2) an enhanced 2D Gaussian representation equipped with a reflection MLP, which supports

Table 3 Comparison of reflection MLP architecture

Case	Architecture	PSNR↑	SSIM↑	LPIPS↓
1	$L = 10$, 8 layers, 256 hidden dim, w/o skip connection	29.08	0.9267	0.0636

reconstruction and rendering of high-frequency, view-dependent façade appearance.

Future work will focus on leveraging multimodal large language models (MLLMs) to further optimize the overall pipeline and to enable more natural interaction with the generated façade digital models [15–17], as well as extending Gaussian-based models to downstream simulation and analysis tasks [18–20].

Abstract –

Railway sleepers form the structural interface between the rails and the ballast, governing track geometry stability through load transfer and positional restraint, making them a critical track component. Regular monitoring of sleeper condition and spacing contributes to maintaining track condition and supports safe railway operation for goods and passenger traffic. In current practice, sleeper spacing inspection on ballasted track relies on manual tape measurements and visual judgement, which are time consuming, labour-intensive, and difficult to apply consistently over long construction sections or during short night possessions.

This paper proposes an automated approach for sleeper spacing measurement using unmanned aerial vehicle imagery and a hybrid computer vision-based processing framework. The method applies a YOLOv11m object detection model to localise individual sleepers in near-nadir UAV images, followed by mask refinement using the Segment Anything Model to delineate sleeper regions. Sleeper centres and rail edges are extracted from the resulting masks, and pixel distances are converted to physical spacing through calibration based on the known effective track gauge.

The framework was evaluated on a dataset of straight ballasted track sections acquired under routine field conditions. Quantitative validation demonstrated a mean absolute error of 6.56 mm and a root mean square error of 7.67 mm, with 93.75% of predicted spacing values falling within ±10 mm of reference measurements. These results indicate that the proposed workflow enables reliable and physically interpretable sleeper spacing measurements from UAV imagery.

Keywords –
Ballasted Track, UAV-Based Inspection, YOLO-Based Object Detection, Image Segmentation, Sleeper Spacing.

1 Introduction

Railway networks rely on consistent track geometry to maintain safe operations, control dynamic wheel-rail interactions, and limit long-term degradation of sleepers, ballast, and fastening systems. Within this broader geometry envelope, the longitudinal spacing of sleepers plays a very practical role in how loads are distributed, how ballast consolidates, and how maintenance limits are defined in track standards and inspection manuals [1]. In day-to-day practice, however, sleeper spacing for ballasted track is still often checked through manual gauge and visual inspections or only at discrete locations using track recording cars, which can miss localised anomalies, construction non-conformities, or gradual shifts that emerge between scheduled runs [2]. For railways that are expanding or upgrading lines with limited track access, this combination of manual point-based measurements and visual checks is increasingly difficult to reconcile with the demand for more frequent, fine-grained quality control.

Image-based inspection offers a potential route toward denser geometric assessment. An ideal scenario would use nadir images of the track acquired from a UAV or similar platform under controlled conditions, with known camera parameters and stable flight geometry. In such a scenario, each sleeper could be detected, cleanly segmented from ballast and rails, and used together with calibrated reference dimensions to compute spacing in physical units in a transparent and interpretable manner. In practice, the conditions are far less controlled. UAV imagery is affected by variable altitude, camera tilt, motion blur, and changing lighting; tracks themselves may present occlusions due to vegetation, ballast pockets, or construction materials; and, in many projects, full camera calibration or ground control is either unavailable or only loosely specified. These factors make it difficult to move from visually plausible sleeper detection to reliable metric spacing measurements that can be trusted for acceptance and compliance checks [3], [4].

Recent vision-based railway work has advanced along several strands that do not always converge. Object

detection models, particularly YOLO variants, identify sleepers, fasteners, and surface defects at high frame rates in inspection vehicles or UAVs, prioritising throughput, and automation rather than geometric boundary precision [5], [6]. UAV imagery has supported track localisation, ballast assessment, and overhead line inspection, showing aerial data can integrate into workflows when operational constraints are managed. Visual metrology systems for gauge and other parameters achieve sub-millimetre to millimetre-scale engineering accuracy under careful calibration, but typically with fixed cameras, dedicated targets, and constrained environments rather than mobile UAV platforms.

Sleeper-level geometry highlights the trade-off between flexibility and rigour. UAV-based approaches using template matching or simple image processing report centimetre level spacing estimates, but over limited, visually clean segments and under stable scale/pose assumptions. Higher accuracy gauge or profile systems rely on controlled illumination, rigid setups, or track-mounted artefacts that are difficult to reproduce over long aerial surveys. This leaves a gap between fast, detection-centric pipelines treating sleepers as coarse pixel objects and metrology-centric systems handling geometry carefully but in constrained configurations. Despite these developments, a clear understanding of how detection-driven segmentation workflows perform as measurement-oriented tools under practical UAV inspection conditions remains limited.

The present study addresses this gap by focusing explicitly on the geometric reliability of sleeper spacing measurement from UAV imagery using a hybrid detection and segmentation framework. Rather than proposing a new detection architecture, the contribution lies in evaluating whether segmentation-refined detections combined with explicit geometric calibration can produce spacing outputs that are geometrically consistent and practically interpretable under typical UAV inspection conditions. The framework employs a YOLO-based model to localise sleepers in near-nadir UAV images, followed by the Segment Anything Model to refine detections into detailed masks. This refinement improves boundary definition and supports reliable centre estimation for spacing measurement. In addition, the workflow integrates an explicit calibration strategy using track gauge as a geometric reference, enabling conversion from pixel distances to physical units without requiring external ground control. The study focuses on defined straight track sections to establish a controlled baseline and assess whether such an integrated approach can support spacing measurement for construction verification and routine maintenance inspection. This study evaluates the reliability of a hybrid detection and segmentation workflow for sleeper spacing measurement.

2 Related Work

Vision-based inspection has become an important approach in railway infrastructure monitoring, enabling large networks to be inspected with reduced reliance on manual surveys and specialised geometry vehicles. Camera-based systems mounted on inspection vehicles, wayside installations, and mobile platforms are widely used to detect rails, sleepers, fasteners, and ballast conditions. Many of these systems rely on deep learning-based object detection models, particularly YOLO variants, which prioritise rapid localisation and automation rather than precise geometric boundary representation [5], [6].

UAV imagery has further expanded inspection coverage and deployment flexibility, particularly in construction zones and remote locations. Prior studies demonstrate the use of UAV data for track localisation, ballast assessment, and geometric parameter estimation such as track alignment or gauge using photogrammetric or model-based approaches [7]. While these methods confirm the feasibility of metric measurement from aerial imagery, they often rely on dense ground control, careful mission planning, or computationally intensive three-dimensional reconstruction, which limits their practicality for routine sleeper spacing measurement over short track sections.

A parallel body of work focuses on image-based rail geometry and metrology. Visual measurement systems for track gauge and wheel rail position show that millimetre level accuracy is achievable when camera calibration, reference geometry, and error modelling are treated explicitly [8]. However, such systems typically operate in controlled environments with fixed or stereo camera setups and do not readily transfer to UAV imagery acquired under variable pose and lighting conditions. Deep learning models such as YOLO and Mask R-CNN-based segmentation has been applied to estimate inter-sleeper distances from image data, demonstrating feasibility under controlled conditions [9].

Taken together, existing studies either prioritise detection performance without explicit treatment of geometric interpretation or achieve precise measurements under controlled configurations that are difficult to reproduce in routine UAV operations. As a result, the geometric reliability of sleeper spacing measurement derived from overhead imagery, particularly when calibration resources are limited and track gauge is the primary physical reference, remains insufficiently understood. This limitation motivates the present study, which evaluates whether segmentation-refined detection combined with practical geometric calibration can support reliable sleeper spacing measurement under realistic field conditions.

3 Data Acquisition and Study Area

UAV imagery used in this study was collected along straight ballasted railway sections in the Mau-Aunrihar corridor of the Varanasi Division, India, using a DJI Mavic 3 unmanned aerial vehicle equipped with an onboard RGB camera. Image acquisition was carried out in a near-nadir configuration to minimise perspective distortion and maintain a consistent geometric view of sleeper placement along the track. Straight sections were selected intentionally to isolate geometric reliability before extension to curved alignment.

All images were captured from a near-nadir viewpoint under natural daylight conditions without artificial markers, calibration targets, or ground control points. Natural variations in ballast distribution, sleeper surface condition, and surrounding track environment were retained to reflect routine field inspection conditions. Images were stored at full resolution and processed without geometric rectification beyond standard onboard stabilisation. Track gauge, clearly visible in the imagery, was used as the sole physical reference for pixel-to-millimetre scale conversion.

Table 1. Dataset Characteristics

Parameter	Description
UAV Platform	DJI Mavic 3
Imaging Orientation	Near-Nadir (Top-Down)
Flight Altitude	12-15 m
Image Resolution	4000 × 2250 pixels
Track Geometry	Straight, Ballasted Track
Track Coverage	Two parallel tracks
Sleeper Type	Concrete Sleepers
Scale Reference	Track Gauge

For this study, two hundred images were selected for experimental evaluation. The imagery was collected along an approximately 4 km operational railway stretch including both open track and yard regions. These environments introduced variation in ballast condition, sleeper surface wear, shadow intensity, and minor vegetation presence. Two different concrete sleeper types were present within the surveyed section, introducing additional geometric variability.

While the dataset was obtained from a single operational corridor, the extended spatial coverage, environmental diversity, and presence of multiple sleeper types provide a representative baseline for evaluating geometric measurement reliability under realistic field variability. Further validation across multiple corridors and track geometries will be required to establish full operational generalisation.

3.1 Data Pre-Processing and Annotation

Annotation was performed manually using rectangular bounding boxes for two object classes, sleeper and rail. Bounding box annotation was selected to ensure reliable localisation of sleeper regions rather than precise boundary delineation. Partially obscured sleepers affected by ballast, shadows, or surface wear were annotated using visible portions. Rail annotations were included only to support geometric reference and track gauge estimation in later processing stages.

The annotated dataset consisted of 200 images divided into training, validation, and test subsets using a 70 percent, 20 percent, and 10 percent split, respectively. This partitioning enabled model training, parameter tuning, and independent performance evaluation. Figure 1 presents representative annotated UAV images.

Figure 1. Sample of Annotated UAV Images.

To improve robustness under operational variability, the training data were augmented using controlled geometric, photometric, and noise-based transformations, as summarised in Table 2. After augmentation, the effective size of the training dataset [12] increased to 496 images.

Table 2. Augmentation applied to the training dataset.

Parameter	Range	Purpose
Rotation	−15° to +15°	To handle slight changes in camera orientation
Hue	−10° to +10°	To account for colour changes caused by lighting
Brightness	−15% to +15%	To capture differences in illumination
Gaussian blur	up to 0.5 px	To represent slight blur in some images
Random noise	≤ 0.1% pixels	To reflect minor noise during image capture

4 Methodology

This section describes the methodology for automated railway sleeper detection and spacing measurement using UAV imagery. The proposed hybrid

framework integrates detection, segmentation, and geometric processing to derive sleeper spacing from single-view nadir images using track gauge as the physical reference. The workflow is designed to ensure reliable localisation under variable visual conditions and consistent geometric handling prior to spacing estimation.

The framework is designed with two central considerations. First, reliable sleeper localisation must be achieved under variable visual conditions, including ballast overlap, shadows, surface wear, and changes in illumination. Second, spacing estimation requires explicit geometric handling of sleeper positions rather than direct use of object detection outputs. To address these requirements, detection and segmentation are integrated with a structured geometric processing pipeline that supports consistent centre estimation and longitudinal alignment prior to spacing measurement.

4.1 Overview

The proposed framework consists of four important sequential stages: sleeper detection, segmentation and mask refinement, sleeper centre estimation and alignment, and sleeper spacing measurement. The UAV image serves as the input, and spacing values are obtained independently for each track present in the scene. Track gauge is used as the sole physical reference for image (pixel)-to-ground scale conversion.

Deep learning models such as YOLO and the Segment Anything Model (SAM) are widely used for object detection and instance segmentation in complex visual environments. These models learn hierarchical [13] feature representations directly from image data, enabling robust localisation and boundary extraction under the variability present in UAV-based railway imagery.

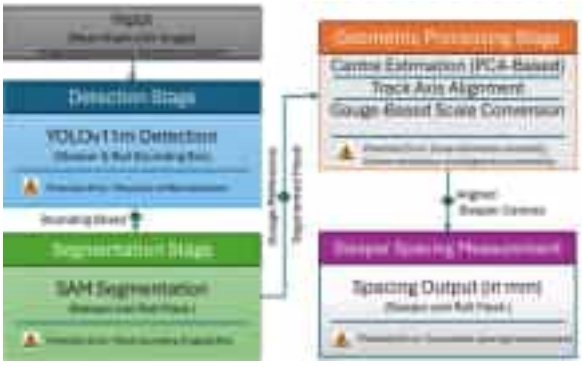

Figure 2. Proposed workflow illustrating detection, segmentation, geometric processing, and spacing measurement stages, with representative sources of uncertainty contributing to cumulative measurement error.

The framework adopts a hybrid deep learning approach that combines a single stage object detector with an instance segmentation model. YOLO operates on a convolutional neural network based single stage detection architecture to provide efficient coarse localisation of railway sleepers. SAM operates on a transformer-based segmentation architecture and uses detector outputs as prompts to generate refined instance level masks. An overview of the complete processing workflow is illustrated in Figure 2.

Each stage of the workflow introduces positional uncertainties that propagate into the final spacing measurement. Detection errors may slightly shift bounding box placement, while segmentation inaccuracies caused by ballast overlap or shadows influence boundary definition. These effects impact centre estimation and alignment, and any error in rail localisation affects the pixel-to-metric scaling process. The influence of these uncertainties is reflected in the spacing error statistics reported in Section 5.3.

4.2 Detection Model Training

Nvidia Tesla T4 GPUs with 16 GB of memory were utilised for model training within the Kaggle notebook environment. The YOLOv11m architecture was employed, initialised with pretrained weights from the COCO dataset. Using the annotated dataset described in Section 3.1, training was conducted on high resolution UAV imagery originally captured at 4000 × 2250 pixels. During training, images were resized to 1024 × 1024 pixels for computational consistency. Bounding box annotations were provided for two object classes: sleeper and rail.

The model was trained for 100 epochs with a batch size of 4 using the AdamW optimiser and an initial learning rate of 1×10^{-4}. Early stopping was enabled based on validation loss stabilisation to prevent overfitting. Data augmentation included controlled geometric and photometric transformations. The confidence threshold during inference was set to 0.25, and non-maximum suppression was applied with an intersection over union threshold of 0.50. Model performance was monitored using validation loss and mean average precision during training to ensure stable convergence.

Within the overall processing pipeline, the role of the detection model was intentionally limited. Detection outputs were not used directly for sleeper spacing measurement or geometric analysis. Instead, sleeper bounding boxes were used to initialise subsequent segmentation, while rail detections provided geometric references for track gauge estimation and track axis definition. All geometric accuracy related to sleeper centre estimation, alignment, and spacing measurement was handled in later processing stages.

4.2.1 SAM Vit-H Configuration

The Segment Anything Model (SAM Vit-H) was used in inference mode with pretrained weights and without additional fine-tuning. Bounding box detections generated by the YOLOv11m model were used as prompt inputs to initialise segmentation for each detected sleeper instance. Standard inference configuration was adopted to ensure reproducibility, with automatic mask generation applied to each prompted region. Predicted masks were filtered by retaining the largest connected component to remove small-isolated regions and noise. This post-processing step ensured consistent boundary representation for subsequent centre estimation and spacing measurement.

4.3 Sleeper Detection

In the first stage, individual sleepers are localised using a YOLOv11m-based object detection model trained on domain specific UAV imagery of railway tracks. Bounding box annotations for sleepers were prepared to support detector preparation. The detector processes the complete image and outputs bounding boxes corresponding to sleeper instances across both tracks. No assumptions are made regarding uniform spacing, sleeper orientation, or symmetry between tracks. The bounding boxes generated at this stage provide coarse spatial localisation, and the identified image regions are then analysed in the next stage. They are not used directly for geometric measurement; instead, segmentation is performed using the regions identified in the detection stage.

4.3.1 Rail Localisation for Geometric Reference

Rail instances were detected to establish track gauge and define the longitudinal track axis required for centre alignment and spacing computation. Rail outputs were used only for geometric reference.

4.4 Segmentation and Mask Generation

Segmentation was applied to refine the initial sleeper detections using the Segment Anything Model (SAM Vit-H). Detector outputs were used as prompts to generate binary masks representing sleeper regions. Segmentation improves boundary definition compared to bounding boxes and provides geometrically consistent regions for centre estimation. The resulting masks were used directly in subsequent geometric processing.

4.5 Sleeper centre estimation and alignment

For each segmented sleeper, a centre point is derived from the spatial distribution of its mask pixels, after which principal component analysis (PCA) is used to estimate the sleeper's longitudinal axis. The sleeper centre is defined as the midpoint along this axis.

To ensure consistent longitudinal measurement, the centres of individual sleepers are projected onto an estimated track axis derived from their overall arrangement along each rail. This alignment step reduces lateral variation caused by perspective effects, minor detection inaccuracies, and sleeper skew, and simplifies the spacing analysis by representing sleeper positions along a single one-dimensional track direction.

Following alignment, each sleeper centre is represented by a single scalar coordinate s_i corresponding to its projected position along the estimated track axis. Sleepers are then ordered sequentially along this axis, with indexing performed separately for the left and right tracks.

4.6 Sleeper spacing measurement

Following centre estimation and alignment, sleeper spacing is computed independently for each track using the one-dimensional representation established in Section 4.5. After alignment, each sleeper centre is characterised by a scalar coordinate s_i, representing its projected position along the estimated track axis in pixel units. Sleepers are ordered sequentially along this axis for the left and right tracks separately.

The sleeper spacing is defined as the longitudinal separation between the aligned centres of two consecutive sleepers. Accordingly, the pixel domain spacing between sleeper i and sleeper i+1 is computed as

$$d_i^{px} = s_{i+1} - s_i \quad (1)$$

To express the spacing in physical units, a pixel-to-metric scale factor is derived using the known nominal track gauge visible in the image. Let the physical track gauge be denoted by G_{mm} (in millimetres) and let G_{px} denote the corresponding gauge measured in pixel units from the detected rail positions. The pixel-to-metric conversion factor is then defined as

$$\alpha = \frac{G_{mm}}{G_{px}} \quad (2)$$

The sleeper spacing in real-world units is obtained by applying this scale factor to the pixel-domain spacing as

$$d_i^{mm} = \alpha d_i^{px} \quad (3)$$

Track gauge is used as the physical reference for scale conversion, enabling spacing values to be expressed in real world units without reliance on external ground control points, calibration targets, or multi-view reconstruction.

The complete sequence of processing stages, from (a) sleeper detection, (b) segmentation, (c) centre alignment, and (d) spacing measurement, is shown in Figure 3.

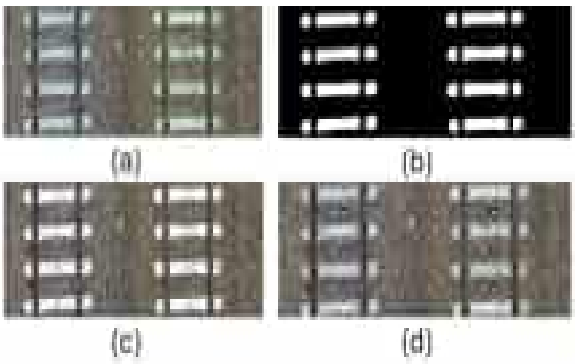

Figure 3. Stages of the proposed framework

5 Result and Discussion

5.1 Detection Performance Evaluation

The detection component of the framework was evaluated to verify that sleepers and rails could be identified reliably for use in later segmentation and spacing analysis. Performance was assessed on the test dataset using precision, recall, and mean average precision at an intersection over union threshold of 0.50.

Intersection over union is used to quantify the spatial agreement between a predicted bounding box B_p and its corresponding ground truth annotation B_g by comparing the area of overlap to the total area covered by both regions. It is defined as

$$IoU = \frac{area\ B_p \cap B_g}{area\ B_p\ \cup B_g} \tag{4}$$

Based on a predefined IoU threshold, detections are categorised as correct or incorrect, forming the basis for computing precision and recall following standard object detection evaluation practice [10]. Precision reflects the proportion of predicted objects that correspond to valid detections, while recall represents the proportion of ground truth objects that are successfully identified by the model [13] and are defined as

$$p = \frac{TP}{TP + FP} \tag{5}$$

$$r = \frac{TP}{TP + FN} \tag{6}$$

where TP, FP and FN denote true positive, false positive, and false negative detections, respectively. Mean average precision provides an overall measure of detection reliability across confidence thresholds and object classes [10], [11].

Performance on the test dataset shows a precision of 93.4% and a recall of 90% for the two object classes. The corresponding mean average precision at an intersection over union threshold of 0.50 is 95% [14]. With a recall of 0.90, the model captured nearly all sleeper and rail instances visible in the test imagery. These results confirm that the detection stage provides consistent and repeatable object localisation under near-nadir UAV imaging conditions.

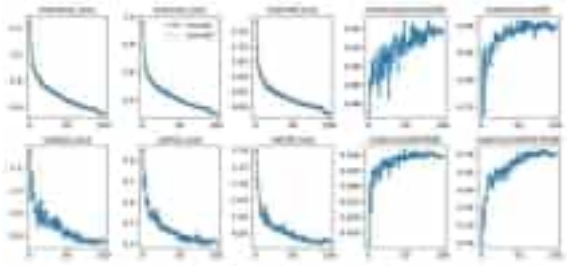

Figure 4. Training performance of the YOLOv11m detection model showing loss convergence and evolution of mean average precision across training epochs.

Figure 4 illustrates the training behaviour of the detection model, showing convergence of training and validation losses together with the progression of mean average precision across epochs.

Sleeper detection outputs are shown in Figure 3(a), where bounding boxes are overlaid on sleepers across both tracks in a near-nadir UAV image. The detections demonstrate consistent localisation across the image extent and provide reliable initialisation for subsequent segmentation and geometric processing stages.

5.2 Comparative Evaluation of Segmentation Models

To provide comparative context for segmentation performance, the proposed YOLOv11m-SAMvit-H workflow was evaluated alongside a Mask R-CNN instance segmentation model trained using the same dataset partitions. The Mask R-CNN model was trained for 50 epochs using the same GPU hardware and notebook environment as the YOLO-SAM implementation to ensure consistent training conditions.

The YOLO-SAM workflow achieved a mean average precision of 70% across IoU thresholds from 0.50 to 0.95, with a mean average precision of 92.78% at IoU = 0.50. The corresponding precision and recall values were 91% and 86%, respectively.

The Mask R-CNN model achieved a mean average precision of 64.2% across IoU thresholds from 0.50 to 0.95, with a mean average precision of 95% at IoU = 0.50 and a recall value of 70.9%. A summary of the segmentation performance comparison between the evaluated models is presented in Table 3.

Table 3. Segmentation performance comparison between the proposed YOLO-SAM workflow and Mask R-CNN evaluated on the same dataset partitions.

Model	Precision (%)	Recall (%)	mAP@0.50 (%)	mAP@ [0.50:0.95] (%)
YOLO + SAM	91.0	86.0	92.78	70.0
Mask R-CNN	88.4	70.9	95.0	64.2

The results indicate that the proposed YOLO-SAM workflow provides segmentation performance comparable to Mask R-CNN while supporting modular integration within the proposed measurement pipeline. Since sleeper spacing measurement in the proposed workflow depends directly on segmentation-derived centre locations, comparative segmentation performance provides an appropriate basis for evaluating the relative suitability of alternative models within the measurement pipeline.

5.3 Quantitative Measurement Validation Using Ground Truth Sleeper Spacing

Quantitative validation of the proposed measurement framework was performed using manually collected ground truth sleeper spacing data. A total of forty-eight consecutive sleeper spacings were measured manually under limited track access constraints to provide reference values for accuracy assessment. Ground measurements were obtained using a calibrated measuring tape with millimetre level resolution. Each value represented the centre-to-centre distance between adjacent sleepers along the track direction. Measurements were collected across both tracks to ensure representative coverage of the inspected section.

Corresponding spacing values were independently generated using the proposed UAV based pipeline. Predicted spacing values were derived from aligned sleeper centre coordinates and converted into millimetre units using the scale factor obtained from track gauge-based calibration. Predicted and reference spacing values were paired for direct comparison.

The comparison demonstrates consistent agreement between predicted and reference spacing values. Most predicted values remained within the allowable engineering tolerance range of ±10 mm, indicating reliable performance under practical inspection conditions. The observed spacing error distribution reflects the influence of uncertainties introduced across sequential processing stages illustrated in Figure 2. In particular, small positional deviations during detection influence segmentation boundary definition, which subsequently affects centre alignment accuracy, while uncertainty in rail localisation directly impacts the pixel-to-metric scaling factor. The cumulative effect of these sequential uncertainties is reflected in the final spacing error metrics summarised in Table 4.

Table 4. Summary of Quantitative Spacing Measurement Accuracy

Metric	Value
Number of samples	48
Mean Ground Truth Spacing (mm)	599.5
Mean Predicted Spacing (mm)	596.4
Mean Bias Error (mm)	−3.14
Mean Absolute Error (mm)	6.56
Root Mean Square Error (mm)	7.67
Standard Deviation of Error (mm)	6.99
Percentage Within ±10 mm (%)	93.75

5.4 Discussion

The results demonstrate that the proposed geometry aware pipeline enables reliable sleeper localisation and spacing measurement from UAV imagery. Consistent detection of sleepers and rails under realistic field conditions provided stable inputs for segmentation and geometric processing, supporting reliable centre estimation across consecutive sleepers.

A key contribution of the framework lies in treating detection outputs as intermediate geometric representations rather than final inspection results. Bounding box detections were refined into segmentation-based masks and aligned centre points, enabling spacing to be computed from structured positional data. Comparative segmentation results support the use of the YOLO-SAM workflow, which achieved comparable accuracy to Mask R-CNN while maintaining higher recall. This improved continuity across consecutive sleepers, which is necessary for reliable spacing computation.

Quantitative validation showed strong agreement between predicted and reference spacing values under near nadir imaging conditions. The mean absolute error of 6.56 mm and root mean square error of 7.67 mm indicate millimetre scale engineering accuracy suitable for spacing verification within practical tolerance limits. The high percentage of measurements within ±10 mm further confirms that cumulative uncertainties remained controlled across the processing stages.

From an operational perspective, the framework demonstrates potential to support preliminary inspection and construction verification tasks over short track sections. By reducing reliance on manual tape

measurements and enabling spacing evaluation from UAV imagery, the proposed workflow provides a scalable basis for extending automated geometric inspection to more complex track environments.

5.5 Future Work

Future work will focus on extending the dataset to multiple railway corridors with varying sleeper types, ballast conditions, and track geometries, including curved track sections. Additional validation will be carried out using independently measured field data collected under different environmental conditions to evaluate the robustness of the proposed framework. Further development will investigate integration of the workflow into routine inspection processes through automated data handling and reporting tools to support practical railway maintenance applications.

6 Conclusion

This paper presented a hybrid computer vision framework for railway sleeper detection and spacing measurement from UAV imagery, integrating a YOLOv11m-based object detector with the Segment Anything Model (SAM Vit-H) for segmentation driven geometric refinement. The study evaluated whether segmentation-refined localisation and geometric alignment could support reliable sleeper spacing measurement using track gauge as the sole physical reference.

Quantitative validation demonstrated consistent agreement between predicted and reference spacing values, with millimetre-scale engineering accuracy achieved across consecutive sleeper intervals. These results confirm that segmentation-refined localisation combined with explicit geometric alignment enables reliable spacing measurement under near-nadir UAV conditions.

The present study establishes a controlled baseline for spacing measurement using straight track sections and near-nadir UAV imagery. Extension to curved track geometries and more variable imaging conditions remains an important direction for future investigation. Overall, the findings demonstrate the feasibility of structured geometric measurement from aerial imagery for scalable railway inspection applications.

Reflective Twins for Deep Excavation using Physics-Informed Machine Learning

Nandeesh Babanagar[1] and Brian Sheil[1]

[1]Department of Engineering, University of Cambridge, United Kingdom
nb710@cam.ac.uk, bbs24@cam.ac.uk

Abstract

Basement construction projects often experience low productivity, schedule delays, cost escalation, safety risks, and high embodied carbon. These challenges largely arise from uncertainty in ground conditions and construction-stage soil-structure interaction, which cannot be fully resolved during design. The observational method offers a structured means of managing this uncertainty by updating design assumptions using monitored performance during construction. However, its adoption remains limited due to the lack of digital tools that robustly integrate monitoring data with predictive and reflective models within construction timescales.

This paper proposes a digital twin framework for deep excavations that embeds the observational method within a layered architecture to enable stage-wise model updating and adaptive decision-making. This structure supports progressive automation from descriptive to prescriptive operation while clarifying interactions between monitoring, data handling, modelling, and decision support. The central contribution of the paper is the development of a reflective twin enabling back-analysis engine, based on physics-informed neural networks. The engine enables continuous updating of the virtual model using field observations, allowing physically consistent inference of loads and deformation profiles from sparse and noisy monitoring data. Validation using canonical cantilever retaining wall problems demonstrates robust reconciliation between observed and predicted behaviour. This capability enables rapid model updating and adaptive construction control, thereby operationalising the observational method within a digital twin environment.

digital twins; observational method; Physics-informed machine learning;

1 Introduction

Urban densification is driving a rapid increase in deep basement and underground construction, including station boxes, high-rise foundations, and transport or energy infrastructure. These projects are typically delivered within highly constrained urban environments and close to existing assets, where construction-stage performance control is critical. A persistent challenge in such works is uncertainty arising from limited site investigation data, complex soil behaviour, and modelling idealisations. To manage this uncertainty, designs are often conservative, leading to inefficient construction sequences, increased material use, and elevated embodied carbon.

The observational method in geotechnical engineering provides a structured framework for managing uncertainty during construction through a learn-as-you-go process [1]. It enables continuous refinement of design assumptions using monitored performance, supported by back-analysis and predefined contingency measures. In deep excavation projects, the observational method is used to control construction-stage risk, optimise temporary works and excavation sequencing, validate soil-structure interaction models, and adjust support systems based on observed behaviour. Its application has demonstrated tangible benefits in construction control, safety, and efficiency, in several complex underground works and high-profile infrastructure projects [2], [3].

Despite its strengths, the practical implementation of observational method is constrained by analytical and computational limitations. The method relies on repeated back-analysis of non-linear ground-structure interaction, often using sparse and indirect measurements such as wall deflections. This process is typically manual and time-intensive, limiting its ability to operate within construction timescales and preventing monitoring data from being fully leveraged in predictive models.

Digital twins offer a pathway to overcome these limitations by integrating monitoring data with

computational models to create continuously evolving representations of underground systems. While sensing, data platforms, and visualisation tools have advanced significantly, a robust back-analysis engine capable of translating sparse field observations into an updated, physically consistent state remains a key bottleneck. The current study addresses this gap by developing a physics-informed back-analysis framework that forms the reflective core of a digital twin for deep excavation. Beyond a conceptual link between digital twins and the observational method, it provides a practical workflow for converting sparse monitoring data into an updated, mechanically consistent system state for stage-wise decision-making.

The main contributions of this work are:

- A digital twin framework tailored to observational method in deep excavations.
- A parsimonious inverse physics-informed neural networks (PINNs) for physically consistent back-analysis from sparse and noisy data.
- Validation on canonical examples, including a retaining-wall idealisation, to demonstrate feasibility in a reduced-order setting.

2 Related work

2.1 Digital twins and observational method

Digital twins are virtual representations of physical systems that are continuously updated using field data to reflect current behaviour and support prediction and decision-making [4]. For underground construction, Babanagar et al. (2025) [5] proposed a layered digital twin architecture (Figure 1) with increasing levels of intelligence, ranging from reflective twins that update models in real time to prescriptive twins that actively support decision-making. In this framework, the physical system, including ground, structures, and sensors, feeds into a data layer that manages monitoring and simulation outputs. These data are linked to modelling and visualisation tools such as BIM and numerical models, while an application layer delivers functions including model updating, stability assessment, risk evaluation, and decision support. While this architecture establishes a robust conceptual structure, it also highlights the opportunity to further develop practical guidance for digital twin frameworks tailored to specific requirements.

Recent developments in the observational method research have explored advanced sensing technologies and data-driven techniques to improve data processing and quantify uncertainty in monitoring data. However, in practice, the observational method still relies heavily on manual interpretation and expert judgement for model updating and construction-stage decisions, which limits responsiveness and consistency across projects.

Digital twins provide a natural platform to address these limitations by enabling automated data integration, real-time model updating, and continuous assessment of construction performance. Integrated analytics and visualisation allow alternative construction scenarios to be evaluated efficiently, supporting proactive risk management and cost control. The principles of observational method align closely with these capabilities. It requires continuous monitoring, comparison of observed and predicted behaviour, and timely adjustment of construction strategies when deviations arise. Digital twins directly support these steps through automated data pipelines, rapid model updating, and efficient evaluation of alternative responses [6]. Despite this strong conceptual alignment, the integration of observational method and digital twins have largely been unexplored in research [5]. Observational method studies typically treat monitoring, interpretation, and decision-making as loosely coupled processes, while digital twins research in underground construction has focused mainly on data integration, visualisation, and asset management, with limited attention to structured observational method workflows.

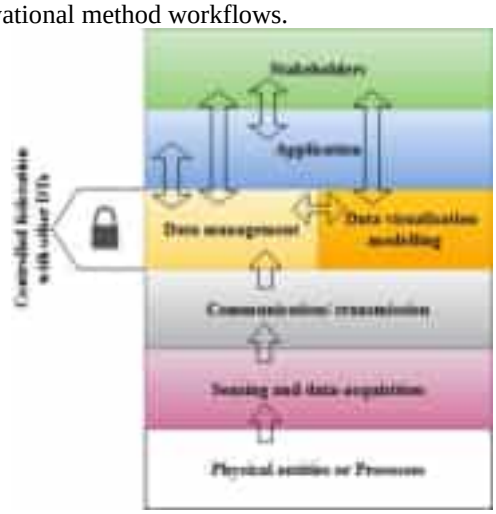

Figure 1: Layered architecture of digital twins for urban underground space.

A key barrier to effective integration is back-analysis, or system identification. Updating model parameters and load states from monitoring data is often iterative and computationally intensive, and typically requires specialist input, which limits its suitability for near real-time use. Without fast and reliable back-analysis, digital twins remain largely reflective and cannot fully support the adaptive decision-making that is central to the observational method. At the same time, the requirements of the observational method vary across underground construction types, including tunnels, deep basements, shafts, and caverns, due to differences in governing mechanisms, monitoring strategies, data characteristics, and decision timelines. This creates a

need for a tailored digital twin framework for the observational method that defines appropriate information flows, modelling and back-analysis techniques, and decision processes for each construction type, and that explicitly map these requirements across digital twin maturity levels, from reflective to predictive and prescriptive operation.

2.2 Back-analysis

Back-analysis of deep excavations has evolved from heuristic trial-and-error calibration and empirical case histories, through deterministic optimisation, towards probabilistic and hybrid data-driven approaches. Early practice relied on engineer judgement and empirical correlations between wall deflections and excavation geometry or ground conditions [2]. Formal optimisation-based back-analysis then coupled gradient-based or evolutionary algorithms with finite element models to minimise misfit between measured and simulated responses [7], improving objectivity but remaining computationally demanding and sensitive to local minima. Bayesian frameworks introduced probabilistic updating of soil parameters using staged monitoring data or related schemes, yet their cost can be prohibitive when combined with advanced constitutive models [8] . More recently, surrogate-assisted and deep learning-based methods have sought to reduce computational effort and exploit richer datasets, at the expense of reduced physical transparency [9]. In all these approaches, inferred parameters remain strongly dependent on the chosen constitutive soil model, so model-form error can be unwittingly hidden by best-fit parameters and propagated in future predictions. The evolution of back-analysis in the literature highlights a shift towards data-driven machine learning methods, while underlining that most existing techniques are either too costly for frequent updating or rely on black-box models that are difficult to trust in safety-critical decisions [10]. To address these issues, there is a need to adopt physics consistent methods such as physics-enhanced machine learning, which integrates domain knowledge and physical laws into data-driven models for greater transparency and reliability.

3 Digital twins for the observational method in deep excavations

Retaining walls supporting deep excavations are subjected to complex, stage-dependent earth pressures that evolve with excavation progression, support installation, and groundwater fluctuations. Temporary props or struts are designed conservatively based on stage-wise numerical models. These models often predict higher wall deflections and lateral loads than observed in the field, creating opportunities to optimise support systems, reduce prop requirements, and improve construction efficiency. Conversely, unforeseen variations in soil behaviour, groundwater conditions, excavation sequences, or environmental conditions can result in larger-than-anticipated wall movements, posing risks to wall stability and adjacent assets. Among these environmental factors, temperature fluctuations can have a significant influence on prop forces, as thermal expansion or contraction alters strut loads and can indirectly affect wall deflections. Accurate estimation of these effects is therefore essential to support adaptive construction decisions. Managing both opportunities and risks requires a system capable of continuously estimating the evolving structural state and forecasting future behaviour, which can be achieved by embedding the observational method within a digital twin framework tailored for deep excavation projects.

Practical application of the observational method in deep excavations is constrained by several factors. Monitoring networks are typically sparse and indirect, often comprising a few inclinometers, load cells, and piezometers, which cannot fully resolve the wall-soil-support system. Back-analysis is inherently ill-posed, as multiple combinations of lateral loads and support reactions may produce similar wall deflection patterns. Conventional approaches rely on iterative finite element calibration or empirical adjustments, which are often time-consuming, sensitive to model assumptions, and require dense instrumentation. In contrast, a physics-informed learning approach can directly incorporate governing mechanical laws, providing a data-efficient and physically consistent solution to the inverse problem. Moreover, repeatedly updating non-linear numerical models is computationally intensive, making stage-wise decision-making within construction timescales difficult. These limitations define the following specific requirements for a digital twin framework:

(i) data efficiency: ability to reconstruct structural states from sparse and noisy measurements.

(ii) computational speed: stage-wise updates and forecasts within construction timescales.

(iii) physical consistency: mechanically realistic and interpretable state estimates.

(iv) decision alignment: outputs directly mapped to pre-defined thresholds and construction controls.

3.1 Integrated layered architecture and maturity levels

The proposed digital twin framework for deep excavations is structured around four interdependent layers (Figure 2), enabling progressive levels of automation from descriptive to prescriptive operation. The physical layer captures the retaining wall, excavated soil, temporary supports, groundwater, and

instrumentation network, providing real-time measurements of structural response and environmental variables, including temperature, at each excavation stage. Measurements are acquired alongside construction metadata, such as excavation stage identifiers, prop configurations, and support layouts.

The data management layer consolidates measurements and metadata from multiple sources, performing data quality control, stage identification, time alignment, and contextual tagging. It acts as a central database where all project data are stored and enables federation of data with all stakeholders. The modelling and visualisation layer hosts numerical and surrogate models of the wall-soil-support system and maintains outputs from finite-element software (e.g., PLAXIS) and BIM-based structural representations. It integrates data from instrumentation dashboards, monitoring systems, and environmental sensors, ensuring that all observations, including temperature and water table variations are coherently visualised with the excavation sequence. Updated geometries, back-analysed lateral pressure distributions, and deflection profiles, are visualised through dashboards, providing interpretable insights for engineers. These outputs support assessment of wall performance against design criteria, trigger thresholds, and planned excavation stages. While these components are well established in conventional basement construction, they primarily provide descriptive or visual capabilities and do not inherently perform stage-wise back-analysis or forecasting.

The application layer forms the operational core and addresses the critical bottleneck of real-time system identification. It incorporates the inverse modelling or system identification engine, which performs reflective back-analysis to reconstruct a low-dimensional structural state vector describing wall deflections, lateral pressures, prop reactions, and environmental influences such as temperature-induced load variations. Forward simulation modules then use this state to predict system responses under planned excavation sequences, support adjustments, and environmental variations. Forecast envelopes, stage-wise load estimates, and trigger indicators guide adaptive construction decisions specific to deep excavation, including:

- Selective adjustment or removal of props when measured deflections and temperature-influenced loads remain within safe limits, optimising material use and schedule.
- Modification of excavation sequences, including stage height, duration, or order, based on current wall-soil system behaviour and anticipated temperature effects.
- Reconfiguration of temporary supports, such as strut repositioning or force redistribution by adjusting the hydraulic jacks in the props, to maintain stability under evolving loads and thermal variations.
- Groundwater control interventions, including controlling dewatering rate in response to changing hydrogeological conditions.
- Trigger-based contingency actions, such as temporary support installation, monitoring intensification, or staged excavation pauses, when forecasted deflections or temperature-influenced prop forces approach thresholds.

This layered organisation is aligned with digital twin maturity levels. At the descriptive level, monitoring data, dashboards, and PLAXIS/BIM visualisations allow engineers to track system behaviour and environmental variations. At the reflective level, the inverse engine reconciles observed behaviour with the virtual model to produce a physically consistent structural state. The predictive level propagates this state to forecast responses for subsequent excavation stages, supporting risk-aware planning under evolving conditions. At the prescriptive level, outputs guide adaptive decisions on excavation sequencing, prop management, support modifications, and groundwater interventions, enabling safe, efficient, and optimised construction.

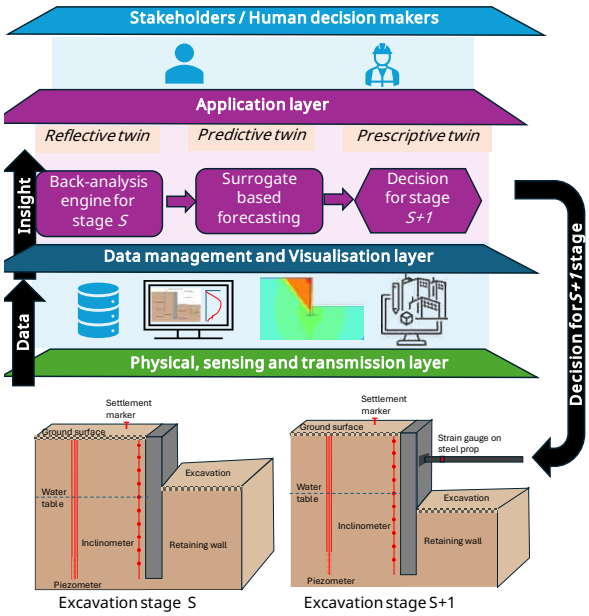

Figure 2: Layered architecture for digital twins of deep excavation to enable observational method.

As a first step in operationalising the framework, the back analysis or the inverse modelling engine serves as the critical component of the reflective twin, translating sparse monitoring data into a physically consistent representation of the wall-soil-support system. This structural state forms the foundation for both predictive forecasting and prescriptive decision-making within the

digital twin. To realise this capability efficiently and at scale, the framework employs PINNs, which provide a computationally effective and physically constrained approach for back-analysis in retaining-wall systems.

4 PINNs for back-analysis

The aim of the physics-informed neural networks is to perform inverse analysis i.e., to infer the lateral loads acting on retaining walls from sparse measurements of wall deflections. This provides the critical information required for reflective updating of the digital twin and supports stage-wise forecasting and adaptive decision-making in deep excavation projects.

4.1 Canonical cantilever beam

To develop and validate the core methodology, the PINNs-based inverse analysis is first applied to a canonical cantilever beam problem. This simplified model serves as a representative analogue of a retaining wall, capturing the essential mechanics of wall bending under lateral earth pressures. In this abstraction, the wall's flexural stiffness governs the deflection profile, allowing back-analysis to focus on inferring a small set of physically interpretable load parameters from sparse monitoring data. To simulate propped excavation conditions, temporary supports are modelled as discrete point loads applied at prop levels, representing measured prop reactions and further constraining the inverse problem. This approach maintains physical interpretability, computational efficiency, and practicality for stage-wise model updating in deep excavation projects.

In the canonical beam problem, the beam geometry, flexural stiffness EI, and boundary conditions were assumed to be known, while an unknown load distribution $q(x)$, is to be back-analysed from the sparse measured deflections, where x denoted the longitudinal coordinate along the beam axis. The transverse deflection $w(x)$ is governed by the Euler-Bernoulli beam equation which directly links the load distribution to the deflection profile and provides the core physical constraint in the PINN:

$$\mathrm{EI}\,.\,\frac{d^4 w(x)}{dx^4} - q(x) = 0 \qquad (1)$$

A synthetic benchmark was constructed by solving the beam analytically under a combination of a uniform load q and a mid-span point load P, and then sampling sparse deflection values corrupted with Gaussian noise to emulate inclinometer data (Figure 3). The inverse task is to recover both the continuous deflection field $w(x)$ and the underlying load distribution $q(x)$ from these noisy observations. Direct recovery of $q(x)$ by differentiating sparse, noisy deflections is ill-posed due to numerical instability of high-order derivatives, motivating a joint learning formulation where deflection and load are inferred simultaneously within a shared physics-informed network.

To regularise the problem and embed prior engineering knowledge, the distributed load is parameterised as a superposition of a uniform component and a localised (concentrated) component, representing lateral earth pressure and surcharge effects. In case of retaining walls, classical earth pressure formulations such as limit equilibrium method can be adopted as prior engineer knowledge.

The deflection *w(x)* is represented by a feedforward neural network with two hidden layers of 30 neurons and Swish activation. Automatic differentiation is employed to compute the high-order derivatives required by Equation (1), enabling stable enforcement of the governing equation during training.

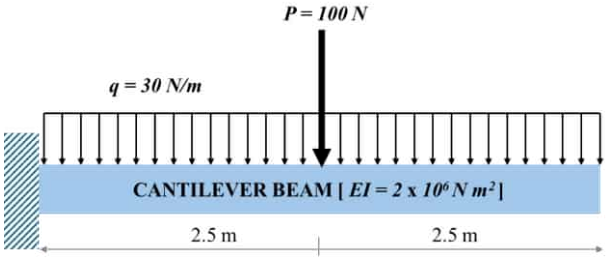

Figure 3: Canonical cantilever beam setup used for demonstrating PINNs framework.

The total training loss ($\mathcal{L}_{\text{total}}$) is defined as

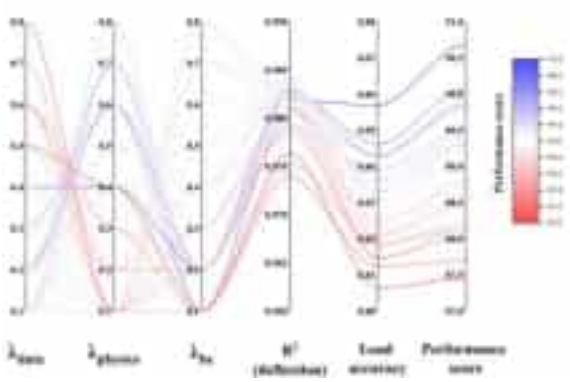
$$\mathcal{L}_{total} = \lambda_d \cdot \mathcal{L}_d + \lambda_{phy} \cdot \mathcal{L}_{phy} + \lambda_{bc} \cdot (\mathcal{L}_{bc}) \qquad (2)$$

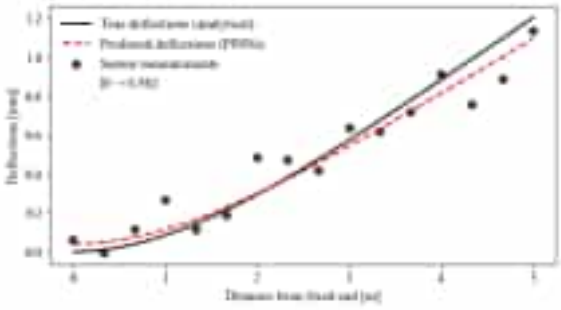
$$\mathcal{L}_{bc} = w(0)^2 + w'(0)^2 + w''(L)^2 + w'''(L)^2 \qquad (3)$$

Where $\mathcal{L}_d$ is the data loss enforcing agreement between predicted and observed deflections, $\mathcal{L}_{phy}$ is the physics loss penalising residuals of from Equation (1) at collocation points within the domain, $\mathcal{L}_{bc}$ is the boundary condition loss enforcing Dirichlet (deflection and slope at fixed end) and Neumann boundary conditions (Bending moment and Shear force at free end) of the beam (Equation (3). The weights λ_d, λ_{phy}, and λ_{bc} control the relative influence of data fidelity, physics consistency, and boundary enforcement. Two Adam optimisers are used: one updates the network weights, and the other updates the trainable load parameters (including the point load), constrained to be non-negative via a soft plus transformation.

The magnitude of the weights assigned to the data, physics, and boundary condition loss terms directly influences the accuracy of the inverse PINN solution. To identify the most suitable weighting scheme, a sensitivity analysis was performed in which 30 different weight

combinations were tested, and their results were compared. Solution accuracy was evaluated using two indicators: (i) the coefficient of determination R^2 (deflection) between the predicted deflection profile and the analytical reference, and (ii) the accuracy of the load distribution predictions. To enable balanced comparison, both deflection metric (R^2) and the load-accuracy metric were min-max normalised across all runs to place them on a common 0-1 scale. A single performance score was then defined as the arithmetic mean of the normalised values. Using only 16 sparse deflection measurements with 10% Gaussian noise, each model was trained for 8000 epochs. Figure 4 presents the sensitivity analysis results, from which the optimal weight combination ($\lambda_d, \lambda_{phy}, \lambda_{bc}$)=(0.4,0.4,0.2) were selected based on the highest overall score, indicating a balanced trade-off between data fit, physics enforcement, and boundary satisfaction. All computations were performed on a laptop with an Intel Core Ultra 7 165H CPU and 32 GB RAM; for the canonical inverse-analysis setup trained for 8000 epochs, the runtime was approximately 63 s per case





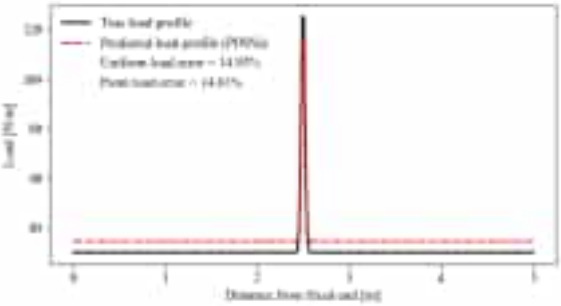


Figure 4: Sensitivity of PINN loss weights on predictive performance, evaluated by R2 for deflections, load prediction error, and overall performance score.

Figures 5a and 5b present the predicted deflection profile and the inferred load distribution obtained using the best-performing weight combination identified in the sensitivity study. The deflection predicted by the PINN closely matches the analytical solution, achieving a coefficient of determination of $R^2 = 0.982$. Despite the sparse and noisy measurement inputs, the incorporation of governing beam mechanics through the physics loss constrains the solution space, preventing overfitting and ensuring mechanically consistent behaviour along the beam. The recovered load distribution $q(x)$captures both the uniform and localised components of the applied loading with good agreement. The estimated uniform load exhibits an error of approximately 14.9%, while the recovered point load shows an error of 14.6%.

For comparison, Figure 6 shows the results obtained using a purely data-driven neural network of identical architecture and trained for the same number of epochs, using deflection data only. In this case, the predicted deflections exhibit a lower agreement with the analytical solution, with $R^2 = 0.913$. This comparison highlights the benefit of embedding physical constraints within the learning process, particularly when measurements are sparse and noisy, as is typical in field monitoring of retaining structures.

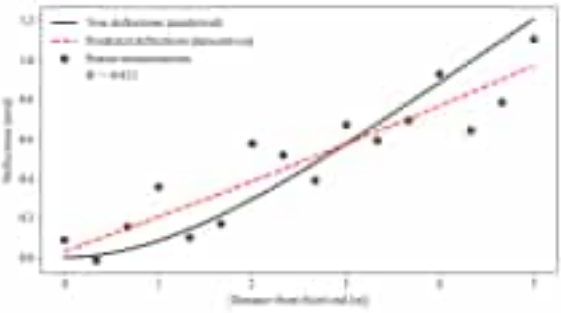
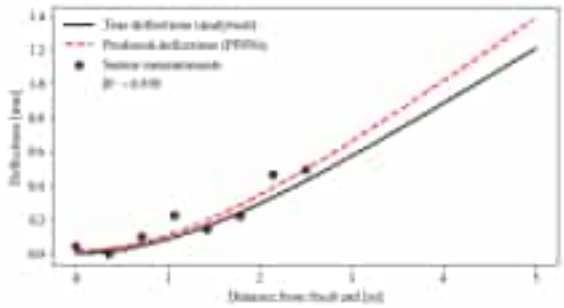
(b)

Figure 5: a) (a) Deflection and (b) Load profile - recovered from PINN framework compared with true values for cantilever beam canonical problem.





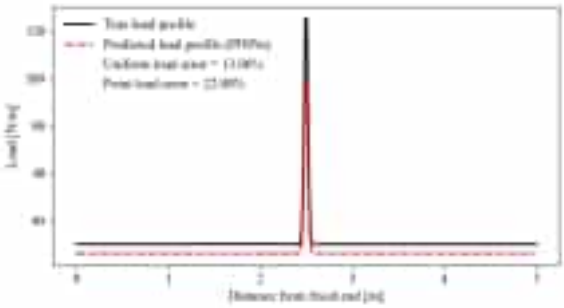


Figure 6: Deflections recovered from purely data-driven method compared with true deflections for cantilever beam canonical problem.

The extrapolation capability of the PINN was further assessed in an experiment where only eight sensors, each with 10% Gaussian noise, were assumed to be placed on the beam up to its mid-span. As shown in Figure 7a, the PINN still predicts the deflection profile with good accuracy ($R^2 = 0.939$), while Figure 7b shows that both the uniform load (13.1% error) and point load (22.8% error) are reasonably recovered. In contrast, the purely data-driven network (Figure 8) performs significantly worse, with a reduced accuracy ($R^2 = 0.850$) and clear signs of overfitting. This demonstrates that the PINN maintains stable and physically consistent inference even with sparse and spatially limited measurement.

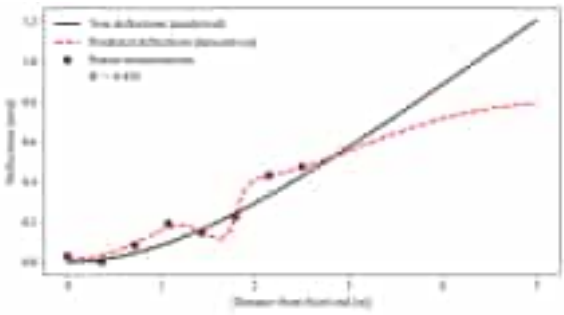

Figure 8: Deflections recovered from purely data-driven method for extrapolation task on cantilever beam canonical problem.

4.2 Back-analysis on a retaining wall

Building on the cantilever beam example, the inverse PINN framework is extended to a canonical propped retaining wall representative of deep-excavation behaviour. To keep the inverse problem tractable while preserving physical interpretability, the lateral earth pressures are represented by classical linear depth-dependent active and passive pressure distributions scaled by mobilisation coefficients m_a and m_p. These coefficients, bounded as $m_a, \mathrm{m_p} \in [0,1]$, act as lumped parameters capturing partial mobilisation and provide an inductive bias that stabilises inversion from sparse measurements.

Figure 9 illustrates the wall configuration, with total height H, retained height h, and a prop force P applied below ground level; wall deflections are observed at eight sensor locations along the depth. The inverse task is to recover m_a and m_p from these sparse deflection measurements, optionally incorporating measured prop force where available.

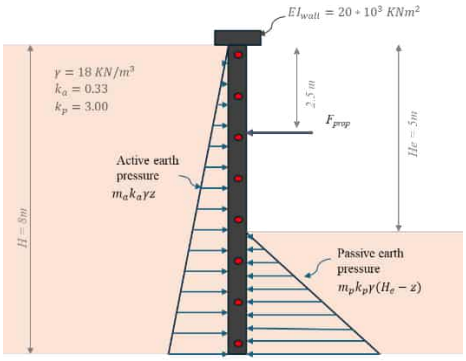

Figure 9: Illustration of the propped retaining wall canonical example.

Synthetic training data are generated by prescribing m_a, m_p, and P, solving the corresponding boundary-value problem, and perturbing the sampled deflections with 10% Gaussian noise. The network architecture and training strategy follow the cantilever-beam case, with depth as input, deflection as output, and automatic differentiation used to enforce the Euler-Bernoulli residual. Using the best-performing loss weights identified previously, the results in Figure 10 show that the PINN can recover excavation-relevant reduced-order state variables from sparse and noisy data. This retaining-wall example therefore provides a more application-relevant intermediate step between the beam analogue and future field deployment.

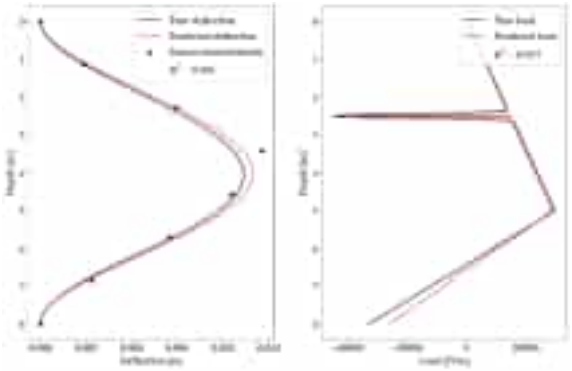

Figure 10: (a) Deflection and (b) load profiles recovered by PINN inverse analysis for the retaining wall.

5 Conclusions

This paper has presented a digital twin framework that embeds the observational method within a layered architecture for deep excavations, clarifying the roles of monitoring, data management, modelling, and application layers, and identifying key requirements including data efficiency, computational speed, physical consistency, scalability, and alignment with trigger-based decision-making.

Within this framework, a parsimonious inverse PINN was developed as the reflective engine of the twin. Validation on a canonical cantilever-beam analogue of a propped retaining wall showed that the method can recover deflection profiles and mobilised load distributions from sparse and noisy measurements, while outperforming a purely data-driven neural network and retaining mechanical interpretability and numerical stability.

Together, the framework and inverse PINN provide a basis for reflective digital twins that support stage-wise model updating and integration with construction monitoring and decision workflows. By enabling physically consistent interpretation of sparse monitoring data, the approach offers a pathway toward predictive and prescriptive digital-twin capabilities for deep excavation management.

Several important areas for future work include, validation using real excavation monitoring data, broader benchmarking against optimisation-based and probabilistic back-analysis approaches, and extension to more realistic retaining-wall idealisations and higher-fidelity 2D/3D soil-structure interaction models. Further work is also needed to assess robustness and computational performance for routine project deployment

Abstract

This paper presents a data-driven framework for inferring spatial interface dependencies in large-scale civil infrastructure design using empirically observed co-change as a proxy for coordination-related interactions. Using tender and as-built 3D models from an expressway project, object-level changes are identified and distance-based inter-category features are constructed to predict change occurrence. Among the evaluated classifiers, LightGBM achieved the best performance (average G-mean = 0.903). The results show that co-change is better explained by neighborhood-level spatial interactions than by single nearest-neighbor relationships. Distance cutoff analysis indicates that predictive performance saturates within limited spatial ranges, typically within about 30 m in this dataset. Furthermore, Individual Conditional Expectation (ICE) analysis reveals five distinct distance-dependent co-change patterns, while also identifying cases where distance reflects broader spatial heterogeneity rather than direct interface relationships. These findings suggest that spatial distance captures a substantial portion of co-change behavior and can support prioritization of interface checks and selection of search radii in infrastructure design coordination.

Co-change; Hard/soft clash; Building Information Modeling; Machine learning; Design change; Change Propagation

1 Introduction and Related Works

In large-scale Architecture, Engineering, and Construction (AEC) projects, resolving all inconsistencies during design is unrealistic because design and construction are separated, site conditions are uncertain, and production is largely project-specific [1, 2]. Consequently, design changes are unavoidable and are major drivers of cost overruns and schedule delays [3, 4]. The key challenge is therefore not to eliminate changes, but to clarify when they propagate across elements and to limit cascading coordination efforts.

Change propagation is governed by interface constraints between elements, particularly geometric relationships such as connectivity, proximity, and clearance [5]. Under these constraints, local modifications often require adjustments to related elements, which are observed as coordinated updates among multiple components. In this study, such coordinated updates are referred to as co-change.

In software engineering, several studies have analyzed version histories to identify software artifacts that tend to be modified together, often described as logical coupling, evolutionary coupling, or change patterns [6–8]. However, these studies primarily focus on temporal co-change relationships in software repositories and do not explicitly consider spatial relationships between physical components. In contrast, spatial dependencies are central in civil infrastructure systems and are explicitly addressed in this study through geometric distance-based analysis.

With the widespread adoption of Building Information Modeling (BIM), automated detection of interface-related inconsistencies has become widely used. Model-checking research has expanded from hard/soft clash detection to workspace conflicts in construction planning [9–11], and compliance checking against regulations and design rules [12–14]. However, these approaches depend on explicitly specified constraints and dependency rules, making large-scale deployment costly to develop and maintain. Even soft clash detection often requires clearance rules for each object pair, which is burdensome in practice [15].

In parallel, computer graphics and geometric learning have developed methods to extract implicit geometric relationships from large shape collections by learning regularities in component arrangements and encoding them as reusable knowledge or constraints [16–20]. However, these approaches typically assume stable component decompositions and limited interaction ranges, limiting their applicability to the AEC domain. While ML-based generative design has been actively

studied in AEC using drawings and photographs, existing work largely focuses on early-stage, single-building problems and does not adequately capture relationships among heterogeneous elements, due to the knowledge- and reasoning-intensive nature of AEC design [21].

These limitations motivate the use of co-change as an empirical signal for inferring interface dependencies. By treating change records as observable outcomes of coordination processes, spatial relationships between elements can be analyzed without explicitly defining all interface rules.

In this study, object-level changes **derived** from differences between tender and as-built models are used to analyze co-change among structural categories and its dependence on object-to-object distance. **Focusing** on geometric interface **conditions, distance**–co-change relationships are identified and organized into interpretable patterns using Individual Conditional Expectation (ICE) analysis.

2 Methodology

2.1 Workflow Overview

Figure 1 illustrates the workflow of this study. The inputs are the tender and as-built models of an expressway infrastructure project. As a preprocessing step, both models are segmented into category-specific analysis objects using predefined rules, and each object is assigned a binary change label indicating whether it has changed between the two models.

Based on these labeled objects, spatial interfaces between categories are represented using distance-based features. Specifically, multiple inter-category distance representations are constructed to characterize the spatial relationship between a target object and potentially related objects in other categories. These distance-based representations serve as explanatory variables for predicting object-level change occurrence.

The analysis proceeds in four stages. First, a suitable classification model is selected through comparative evaluation. Second, alternative distance-feature representations are assessed to examine how spatial information should be encoded. Third, effective distance cutoffs are determined to identify the spatial ranges within which distance information contributes meaningfully to change prediction. Fourth, important distance features are identified through feature selection to obtain a compact and informative representation.

For the selected distance features, Individual Conditional Expectation (ICE) is employed to examine how changes in distance are associated with changes in predicted change probability. By jointly interpreting the shapes of the mean ICE curves and the corresponding distance distributions, co-change behavior between categories is organized into interpretable interface patterns.

The outputs of the framework are (1) effective distance ranges for predicting change occurrence in each target category and (2) a typology of distance-dependent, interface-based co-change patterns.

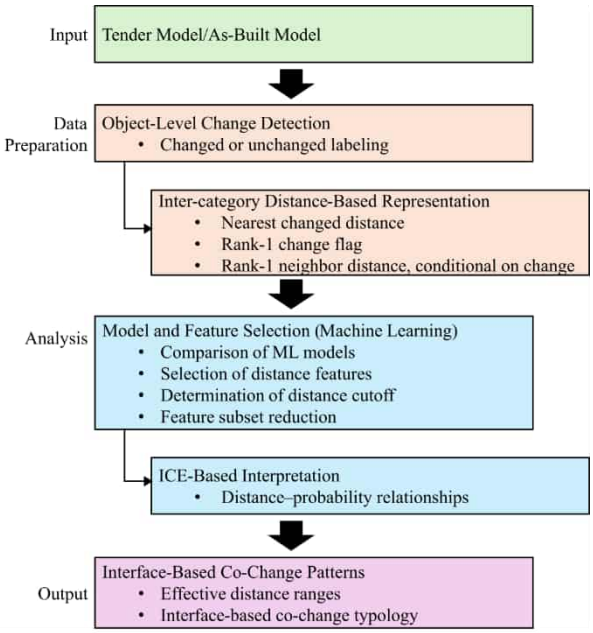

Figure 1. Overview of the proposed analysis framework.

2.2 Data and Preprocessing

2.2.1 Target Models, Categories, and Object Segmentation

The dataset comprises the tender and as-built models of an expressway infrastructure project. The study area covers approximately 350 m × 2100 m and includes bridge and embankment sections, excluding cut sections and tunnels. A total of 25 design categories are analyzed.

Because civil infrastructure models often include large continuous elements whose native BIM representations do not correspond to analysis units, category-specific segmentation rules were defined to obtain consistent object-level units reflecting structural boundaries and management units. Continuous elements were segmented based on structural or alignment-based rules. For bridge-related categories, segmentation followed structural boundaries, while for road and earthwork categories, objects were segmented along the road centerline at 20 m intervals, corresponding to the cross-section spacing in the tender drawings. In contrast, discrete components were treated as single elements without further subdivision. Table 1 summarizes the category definitions and sample sizes, and Figure 2

illustrates the bridge segmentation scheme.

Table 1. Summary of categories, sample sizes, and change rates.

Category	Sample Size	Change Rate
Expressway Pavement	**317**	**21%**
Service Road Pavement	93	95%
Earthwork Crest	38	26%
Earthwork Toe	41	49%
Deck Slab	**1,343**	**35%**
Main Girder	1,356	96%
Cross Girder	**1,332**	**30%**
Pier Shaft	107	3%
Pier Cap	66	5%
Foundation	70	4%
Bearing	199	2%
Bearing Pedestal	199	6%
Fall Protection	20	70%
Barrier Wall	**2,874**	**28%**
Bridge Inspection Walkway	93	99%
Bridge Drainage	100	89%
Detention Pond	11	100%
Drainage	**848**	**40%**
Temporary Support	207	99%
Construction Yard	75	28%
Girder Storage	401	100%
Crane Position	170	100%
Access Road	65	9%
River Diversion	7	100%

Note: Categories shown in **bold** indicate the target categories selected for analysis (Section 2.3).

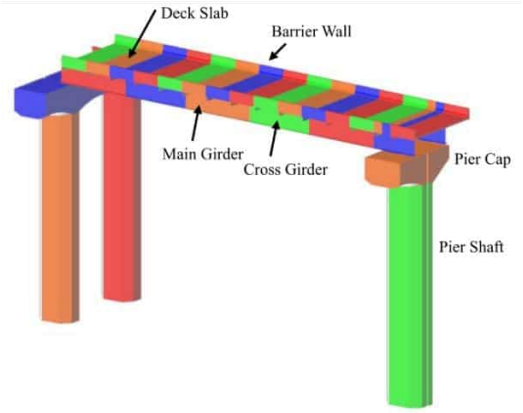

Figure 2. Example of object segmentation for bridge components.

2.2.2 Definition of Change Occurrence

Objects from the tender and as-built models are matched at the object level after projecting their coordinates onto a common 2D plane. An object is labeled as changed if (1) it appears in only one model, or (2) if present in both models, its centroid displacement is at least 10 cm. All remaining objects are labeled as unchanged.

The 10 cm threshold is used as a practical tolerance to mitigate minor positional noise introduced during model creation and integration while preserving substantively meaningful changes. Category-wise change rates are reported in Table 1.

2.3 Target Category Selection

Among the 25 categories, only categories that meet the following criteria are analyzed to ensure stable model training and interpretable results: at least 240 objects in the tender model and a change rate between 20% and 80%. For each target category, distance features are constructed using the other 24 categories as predictor sources. The minimum sample size of 240 was set as ten times the number of explanatory categories, and the change-rate range was used to avoid severe class imbalance that can destabilize the classifier and obscure distance–change relationships. Consequently, although only a subset of categories is used as prediction targets, all categories are retained as sources of explanatory distance features, meaning that their spatial influence on the analyzed targets remains represented in the model.

Based on Table 1, five categories satisfy these criteria: expressway pavement, deck slab, cross girder, barrier wall, and drainage.

2.4 Distance-Feature Construction

For each object in each of the five target categories, neighboring objects are extracted from all other categories. All objects are projected onto a common 2D plane prior to distance computation. In civil infrastructure models, most design categories occupy relatively consistent vertical bands (e.g., road-surface elements versus ground-level components). As a result, situations in which objects appear close in plan view but are vertically separated tend to occur systematically between specific category pairs rather than randomly at the object level. Because the model uses category-based distance features, such systematic vertical offsets are reflected consistently in the learned relationships rather than introducing random noise. To partially account for vertical structure, Earthwork and Pier categories were subdivided into two components each, representing distinct interaction zones even when distances are computed on a 2D projection.

For each target object and each non-target category, 50 candidate neighbors are first identified based on centroid distances. Exact boundary-based distances are then computed on the 2D plane, and the 20 closest neighbors are retained together with their distances and

change labels.

For each target category, four datasets are constructed using distance-based features derived from other categories. If no changed object is found within the 20 nearest neighbors, a sentinel value (maximum observed distance + 10 m) is assigned. This value is intentionally placed beyond the range of typical neighbor distances so that it functions as an indicator of "no nearby change" rather than a meaningful spatial distance, and therefore does not affect the learned splits of the classifier. The datasets differ in how distance information is represented:

- Dataset 1: the minimum distance to the nearest changed object in each category.
- Dataset 2: a binary indicator of whether the nearest neighbor (rank 1) is changed.
- Dataset 3: distance to the nearest neighbor, conditional on that neighbor being changed.
- Dataset 4: all features from Datasets 1–3 combined.

To assess whether nearest-neighbor relationships alone can capture design coordination effects, the rank-1 datasets (Datasets 2 and 3) are compared with Dataset 1, which can capture changed neighbors beyond the nearest object.

2.5 Machine Learning (ML) Setup for Change Prediction

For each target category, the prediction models use the change label of the target object as the response variable, while the distance-based features derived from the remaining categories (Datasets 1–4) are used as explanatory variables. Change prediction is formulated as a binary classification task, in which each object is labeled as either changed or unchanged. The following algorithms are compared:

- Logistic regression (L1/L2/elastic net)
- Random Forest
- Extra Trees
- HistGradientBoosting
- LightGBM

All models are implemented in Python using scikit-learn and LightGBM with default hyperparameters. For each target category, the data are split into 90% for training and 10% for testing. This procedure is repeated for 10 different random seeds, and evaluation metrics are averaged across seeds to improve robustness and reproducibility. To account for class imbalance, performance is evaluated primarily using the G-mean, defined as the geometric mean of sensitivity and specificity.

2.6 Distance Cutoff, Feature Selection, and ICE-Based Patterning

A distance cutoff sensitivity analysis is performed to identify the spatial range over which distance features contribute to explaining co-change. An upper distance limit is imposed on all features and progressively reduced, while classification performance is evaluated. Distances exceeding the limit are replaced with a large value, and the effective cutoff is defined as the smallest limit that retains at least 95% of the baseline performance.

Feature selection is then conducted using the selected ML model. Features are ranked by LightGBM gain and added sequentially while monitoring performance. The final feature set is defined as the smallest set that retains at least 95% of the baseline performance.

ICE is then computed for each target category and each retained distance feature using models retrained on the final feature set. For each feature, object-level ICE curves and their mean are derived to characterize the distance–change probability relationship. ICE is evaluated from 0 m to the effective distance cutoff or the maximum observed distance, whichever is smaller.

To stabilize estimation, distances are discretized into 30 equal-width bins. Bins with fewer than five samples are excluded, and features with fewer than three valid bins are removed as unreliable. In addition, ICE curves with less than 1% probability variation are excluded, as they indicate negligible sensitivity to distance. Such low-variation curves correspond to nearly flat relationships and primarily introduce noise rather than additional pattern types.

Co-change interface patterns are identified from the mean ICE curves and their associated distance distributions. Classification considers both the shape of the ICE curves (e.g., monotonic, plateau, or peak behavior) and the distribution of observed distances, and category pairs are grouped into patterns exhibiting similar distance-dependent behavior.

3 Results

3.1 Comparison of Classification Algorithms

Across all target categories and dataset settings, LightGBM achieved the highest mean G-mean (0.903) and showed stable performance across random seeds. Although performance varied by category, LightGBM generally maintained G-mean ≥ 0.80 and was selected for subsequent analyses.

3.2 Comparison of Feature Representations and Dataset Selection

Using LightGBM, Dataset 4 yielded the best overall performance, while Dataset 1 achieved a comparable G-

mean with substantially fewer features. As shown in Figure 3, Dataset 1 provided a stable and interpretable baseline across target categories, whereas Datasets 2 and 3 exhibited greater variability. Therefore, Dataset 1 was adopted for subsequent analyses. The baseline G-mean values with Dataset 1 were 0.817 (expressway pavement), 0.938 (deck slab), 0.942 (cross girder), 0.978 (barrier wall), and 0.889 (drainage).

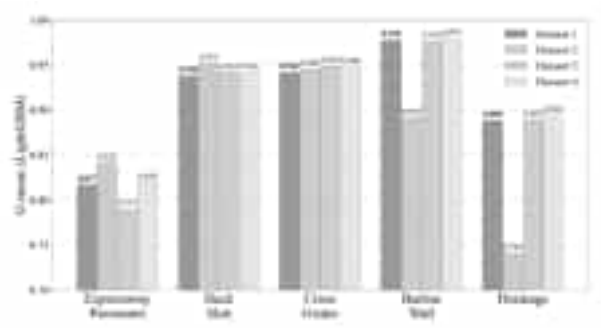

Figure 3. Comparison of distance-based feature representations using G-mean (LightGBM).

3.3 Effective Distance Ranges

Distance cutoff sensitivity analysis indicated that performance improvements saturated within a limited spatial range for most target categories. The resulting effective distance cutoffs (defined in Section 2.6) differed by category and are summarized in Figure 4: 15.5 m (expressway pavement), 0.5 m (deck slab), 0.5 m (cross girder), 2.0 m (barrier wall), and 28.5 m (drainage).

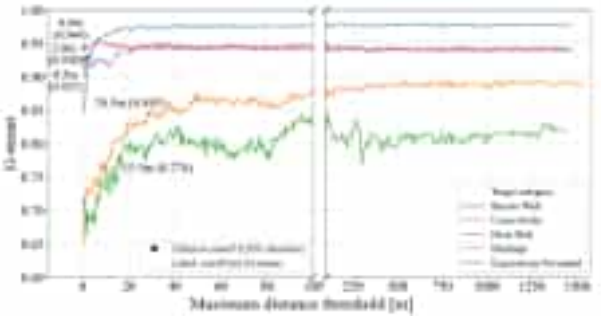

Figure 4. Distance Cutoff Sensitivity of G-mean Performance.

3.4 Important Features

Gain-based feature selection produced compact feature sets while retaining at least 95% of the baseline performance. The retained distance features are:

- Expressway Pavement (8): Barrier Wall, Girder Storage, Deck Slab, Crane Position, Earthwork Toe, Service Road Pavement, Fall Protection, Drainage
- Deck Slab (1): Cross Girder
- Cross Girder (1): Deck Slab
- Barrier Wall (4): Cross Girder, Deck Slab, Main Girder, Service Road Pavement
- Drainage (6): Detention Pond, Expressway Pavement, Service Road Pavement, Earthwork Toe, Earthwork Crest, Temporary Support

3.5 ICE Patterns of Distance-Dependent Co-Change Behavior

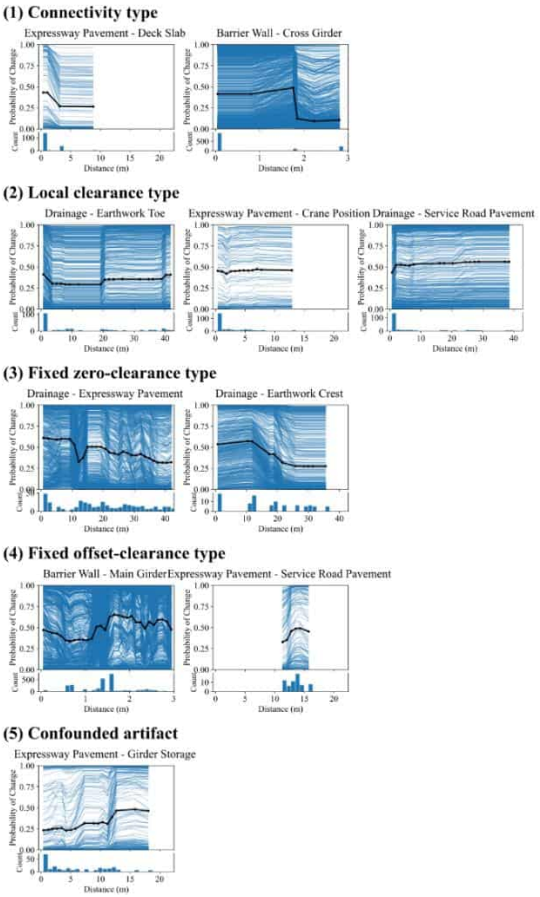

Figure 5. Classification of distance-based co-change interface patterns based on ICE analysis. *Note:* Blue lines show individual ICE curves, the black line indicates their mean ICE curve, and the histogram shows the distance distribution.

ICE analysis was applied to the features remaining after feature selection and reliability filtering, leaving only 10 category-pair distance features overall. Figure 5 presents the corresponding mean ICE curves and distance histograms. Following the criteria in Section 2.6, these profiles were grouped into five co-change interface patterns, reflecting differences in the mean ICE shapes

and associated distance distributions.

4 Discussion

4.1 Implications Beyond the Nearest Neighbor

Across the evaluated representations, Dataset 1, which uses the minimum distance to the nearest changed object in each category, provided higher performance and greater stability than Datasets 2 and 3, which rely on the change state of the single nearest neighbor (Figure 3). This indicates that co-change is not explained solely by the nearest object, but is more strongly associated with the presence of changed objects within a local neighborhood. These results suggest that spatial distance captures a substantial portion of the observed co-change behavior, highlighting spatial proximity as a key predictive signal for interface dependencies.

4.2 Implications of Effective Distance Upper Bounds

Distance cutoff sensitivity analysis showed that predictive performance was largely preserved as information from more distant objects was excluded, with performance generally saturating within approximately 30 m (Figure 4). This supports the view that coordination is primarily governed by local spatial interactions. However, the effective distance ranges varied across categories, indicating that a uniform threshold may be suboptimal and that category-specific search radii could provide a more rational basis for practical checks. In particular, categories with higher predictive accuracy were dominated by short-distance information, whereas lower-accuracy categories exhibited broader effective ranges, suggesting a greater influence of longer-range spatial constraints.

4.3 Differences in the Number of Important Features and Dependency Complexity

As shown in Section 3.4, some target categories preserved predictive performance using only a small set of distance features, suggesting that their change occurrence is strongly driven by a limited number of distinct interface relationships. In contrast, categories with lower predictive accuracy, particularly expressway pavement and drainage, required a larger set of important features, indicating more multifaceted dependencies on surrounding categories and/or the influence of factors not fully captured by distance features alone.

4.4 Interpretation of ICE-Based Patterns and Mechanism Hypotheses

As illustrated in Figure 5, ICE profiles of the important distance pairs can be grouped into five types, reflecting distinct ways in which distance is associated with co-change. Here, ICE refers to the mean ICE profile, and DD denotes the corresponding distance distribution.

1. Connectivity type (ICE: sharp drop after peak; DD: concentrated near zero)

High co-change probability at near-zero distances followed by a rapid decline suggests direct or near-contact interfaces, where coordination is driven by maintaining compatibility at connection points.

2. Local clearance type (ICE: plateau; DD: zero-peaked but widespread)

A flat ICE profile despite broad distance distributions indicates that effective clearance varies across objects, implying that uniform category-level rules may be insufficient.

3. Fixed zero-clearance type (ICE: gradual decay after peak; DD: zero-peaked and widespread)

A gradual decrease in co-change probability with distance suggests proximity-driven interactions without strict clearance requirements, primarily reflecting avoidance of hard clashes.

4. Fixed offset-clearance type (ICE: increase before peak, gradual decay after peak; DD: non-zero peak and widespread)

A peak at non-zero distances indicates characteristic clearance bands, consistent with standardized layouts or design rules.

5. Confounded artifact (non-mechanistic; reported for completeness)

Anomalous patterns driven by project-specific spatial heterogeneity rather than direct interface mechanisms are excluded from the primary typology.

4.5 Transferability and Prospective Use

The present results are derived from a single expressway project and should not be interpreted as universally transferable numerical rules. In particular, absolute distance cutoffs and detailed category-pair behaviors may remain partly project-dependent, reflecting the geometry, segmentation scheme, and revision history of the analyzed case.

However, the observed co-change relationships are unlikely to be entirely project-specific. Many spatial interfaces in civil infrastructure are governed by stable engineering conditions, such as structural connectivity, standard cross-sections, and clearance requirements, which are typically defined by design codes and common practices. As a result, while numerical thresholds may vary, the identified interface-pattern types and their

spatial tendencies are expected to generalize across comparable projects.

The framework can therefore be used to extract reusable coordination knowledge from completed projects. Patterns identified from historical revisions can inform subsequent projects by suggesting category pairs requiring closer coordination and by providing initial search ranges for spatial checks.

Transferability is expected to be highest among projects sharing similar asset types and regulatory environments, such as highway projects designed under comparable design codes and maintenance requirements. By contrast, application to substantially different infrastructure types (e.g., tunnels or coastal structures) or to projects developed under different national or organizational design regimes would require additional empirical data and revalidation.

5 Conclusion

This study proposed a data-driven framework to infer interface dependencies in a large-scale civil infrastructure project using empirically observed co-change events. Object-level changes between tender and as-built models were modeled using distance-based inter-category features, and distance–change relationships were interpreted using ICE.

Using the minimum distance to the nearest changed object within each explanatory category yielded higher accuracy than using only the change state of the single nearest neighbor, indicating that co-change is not adequately explained by one-to-one proximity, and is better characterized at the local neighborhood level. These results also indicate that spatial distance alone captures a substantial portion of the observed co-change behavior. Distance cutoff analysis further showed that most predictive power was retained within category-specific spatial ranges, generally saturating within about 30 m, supporting the use of category-dependent search radii rather than a uniform threshold. In addition, gain-based selection reduced the feature set while retaining at least 95% of baseline performance, and ICE analysis of the retained features revealed five distance-dependent co-change interface patterns, with confounded cases reported separately.

Taken together, these results suggest that the workflow can support the inference of plausible interface-related coordination mechanisms by identifying influential category pairs, the spatial ranges over which distance is informative, and characteristic distance–probability profiles. These outputs provide actionable guidance for prioritizing inter-category checks and designing distance-based search and coordination rules.

It is important to note that the numerical cutoffs and category-pair relationships identified in this study should be interpreted as case-grounded observations rather than universally applicable interface rules. Because the analysis is based on a single infrastructure project, the exact numerical values may vary depending on project geometry, design standards, and coordination practices. Nevertheless, many spatial interface conditions in civil infrastructure are shaped by recurring engineering requirements, such as structural connectivity, clearance provisions, and operation-and-maintenance needs defined in design standards. As a result, while the precise thresholds may differ across projects, the broader pattern classes and relative spatial tendencies identified in this study are expected to remain informative for similar infrastructure projects governed by comparable design regimes. In this sense, the framework provides a practical workflow through which reusable coordination knowledge can be extracted from completed projects and applied to guide interface analysis in future projects of the same type.

This study has several limitations. First, distances were computed based on 2D projections of object geometries, without considering vertical relationships. Although most infrastructure categories occupy relatively consistent vertical bands and vertically distributed elements were subdivided into separate categories, this projection may still simplify certain three-dimensional relationships. Second, object- or project-specific confounding factors, such as construction sections or work packages, were not incorporated. Third, the available dataset was limited in size, and consequently the typology of distance-based interface relationships remains incomplete. In particular, categories with extremely low or extremely high change rates could not be analyzed as prediction targets in the present dataset, although their interface behaviors may warrant investigation in larger datasets. Fourth, the analysis relied solely on spatial distance information derived from geometric changes in the models. Changes without spatial modifications (e.g., material substitutions or schedule adjustments) are therefore outside the scope of the present analysis and may not be represented in the inferred relationships. Addressing such non-geometric change dependencies would require additional data and modeling approaches beyond the scope of the current framework. Finally, the engineering interpretations assigned to the identified pattern types (e.g., connectivity or clearance relationships) should be regarded as plausible explanations of the observed statistical behaviors rather than formal validation against documented design coordination rules. Further validation through expert assessment and comparison with established design practices would help strengthen the practical interpretation of these patterns.

Future work will address these limitations by

expanding the dataset to further develop the typology and by incorporating additional parameters. In particular, beyond spatial distance, semantic information embedded in BIM will be integrated to extract interface relationships that cannot be explained by proximity alone.

Abstract

The shift toward Off-Site Construction (OSC) is constrained by the complexity of High-Mix, Low-Volume (HMLV) production, where geometric variability and reliance on manual labour create highly stochastic processing times. In these Dual-Resource Constrained (DRC) systems, workers act as flexible assets who move across stations to relieve bottlenecks—behaviour that static scheduling methods cannot capture. To address this, this study presents a Hybrid Simulation-Based Optimization (HSBO) framework that combines a Genetic Algorithm (GA) with a Hybrid Discrete Event/Agent-Based Simulation (DES/ABS) model. The simulation captures workforce-driven production dynamics, including cross-station assistance and bottleneck relief, enabling schedule evaluation under stochastic operating conditions. The framework was applied to a stair prefabrication line in Edmonton, Canada, to optimize the balance between Just-In-Time (JIT) delivery and internal flow efficiency. Results show that the optimized schedule reduced the external finished-goods buffer by 66% (from 3 days to 1 day), while increasing average internal lead time by approximately 20% (from 17 to 20.5 hours). These findings highlight the trade-off between delivery precision and internal flow efficiency in storage-constrained prefabrication systems and demonstrate the value of HSBO as a decision-support approach for dynamic scheduling in DRC environments.

Keywords – Off-Site Construction (OSC); Simulation-Based Optimization; Dual-Resource Constrained Scheduling; Hybrid Agent-Based Simulation; Just-In-Time (JIT) Production

1 Introduction

The construction industry is increasingly shifting toward off-site construction (OSC) and prefabrication to mitigate traditional inefficiencies [1]. Yet, unlike the high-volume, low-mix environments of automotive manufacturing [2], construction prefabrication operates under High-Mix, Low-Volume (HMLV) conditions where customized components—such as precast stairs or wall panels—produce substantial variability in processing times and resource allocation [3]. This variability intensifies logistical challenges, particularly on urban sites with limited storage, making precise Just-In-Time (JIT) delivery essential to avoid disrupting the critical path or causing site congestion [4,5]. Compounding this complexity is the Dual-Resource Constrained (DRC) nature of prefabrication, where productivity depends not only on machinery but also on a flexible, multi-skilled workforce capable of moving between stations to relieve bottlenecks [6–8]. While this flexibility can enhance efficiency, it also renders static scheduling tools (e.g., CPM, Gantt charts) ineffective, as they assume fixed resource allocations and cannot capture stochastic human performance or dynamic behaviours such as multi-station collaboration [9]. Consequently, static schedules quickly diverge from real shop-floor conditions, leading to "shop floor nervousness," widening plan–reality gaps, and reinforcing inefficiencies that deterministic models cannot resolve [6].

The optimization of production scheduling has been widely explored in manufacturing, with foundational work centered on the Job Shop Scheduling Problem (JSSP) and its Flexible variant (FJSP) [10]. Approaches in this domain range from exact methods such as Mixed-

Integer Linear Programming (MILP), which guarantee optimality but struggle to scale, to metaheuristics like Genetic Algorithms (GA), Particle Swarm Optimization (PSO), and Ant Colony Optimization (ACO), which efficiently navigate the combinatorial complexity of large production systems [11]. Although these algorithms excel at improving machine uptime and minimizing makespan in standardized, deterministic environments [12], they typically assume resources—both machines and workers—have fixed availability and constant performance [13,14]. Such static assumptions are incompatible with Dual-Resource Constrained (DRC) settings like construction prefabrication, where output depends equally on equipment and a flexible, multi-skilled workforce capable of shifting stations, assisting bottlenecks, and experiencing fatigue [15]. These dynamic behaviours—central in High-Mix, Low-Volume (HMLV) production—are largely absent from traditional JSSP/FJSP models [11,13], leaving a notable research gap in methods that merge the prescriptive strength of metaheuristic optimization with the behavioural realism needed to capture human-driven crew interactions in complex OSC environments.

To address this gap, following a Design-Science Research approach, this study introduces a Hybrid Simulation-Based Optimization (HSBO) scheduling artifact that couples an evolutionary search algorithm with a simulation-based behavioural model of workforce-driven production dynamics. At its core is a Hybrid Discrete Event/Agent-Based Simulation (DES/ABS), in which workers are represented as autonomous agents capable of collaboration and fatigue-driven performance changes [16,17]. This hybrid simulation serves as the fitness evaluator for a Genetic Algorithm (GA), enabling candidate schedules to be assessed based on emergent crew behaviours rather than nominal processing times. By iteratively exploring how alternative timetables influence system performance, the framework leverages worker flexibility to identify lookahead schedules that improve JIT adherence while controlling internal lead-time growth. The approach is validated using a stair prefabrication line at a modular construction facility in Edmonton, Canada, where a labour-intensive, HMLV process highlights the operational value of flexible crew coordination under real-world variability. Finally, the paper outlines a path toward integrating Reinforcement Learning to learn adaptive, policy-based scheduling—effectively a "digital scheduler" capable of generating plans across varying lookahead scenarios [18,19].

2 Methodology

This study adopts a Design-Science Research (DSR) methodology [20], which focuses on designing and rigorously evaluating prescriptive artifacts that address real operational problems. In this paper, the artifact is the proposed Hybrid Simulation-Based Optimization (HSBO) scheduling framework for Dual-Resource Constrained (DRC) prefabrication. This simulation-based optimization paradigm—where candidate decisions are iteratively evaluated through stochastic simulation and refined toward improved performance—has also been adopted in other uncertainty-driven engineering decision contexts [21,22]. Following the DSR cycle, the study proceeds through: (i) problem identification, formalizing the planning–execution gap in HMLV DRC environments; (ii) artifact design and development, coupling a Genetic Algorithm with a hybrid DES/ABS simulation evaluator to test candidate schedules under stochastic operating conditions; and (iii) demonstration and evaluation, assessing the artifact through the industrial case study and performance results reported in the subsequent section(s).

2.1 Artifact Design: HSBO Framework Overview

This research proposes an HSBO framework (Figure 1) designed to solve the dynamic scheduling problem in Dual-Resource Constrained (DRC) prefabrication. The framework utilizes a nested optimization architecture, where a Genetic Algorithm (GA) serves as the global optimizer for determining production timetables, and a Hybrid Discrete Event/Agent-Based Simulation (DES/ABS) serves as the fitness evaluation engine to test these timetables under stochastic operating conditions [23]. The simulation is implemented as a digital-twin-inspired virtual representation (digital shadow) of the physical production system that enables validation of schedules before execution, accounting for real-world variability and emergent workforce dynamics [24,25]. The artifact is demonstrated and evaluated in the subsequent case-study section by comparing its performance against baseline scheduling approaches under identical production scenarios. The artifact outputs a planned start-time timetable for projects in the lookahead window, which is then stress-tested in simulation before deployment.

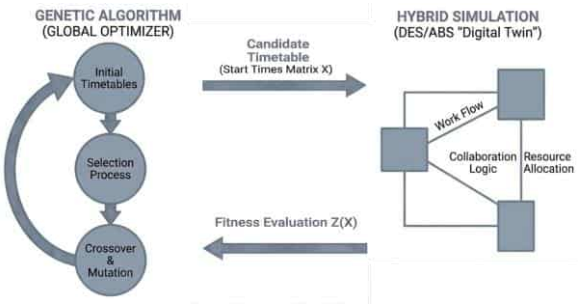

Figure 1: Schematic of the proposed HSBO framework, coupling a Genetic Algorithm with a

Hybrid DES/ABS model to generate and evaluate robust production timetables.

2.2 Problem Definition: Lookahead Scheduling

The scheduling problem is defined over a finite Lookahead Window—a bounded planning horizon representing the immediate, actionable production schedule for the factory. Specifically, let W denote the lookahead window duration (e.g., $W = 2$ weeks), and let P_{window} be the subset of projects (e.g., modular components, prefabricated stairs) released for production within this horizon. The production environment consists of a set of workstations K, where processing is constrained by both machinery availability and the flexible allocation of a multi-skilled workforce.

The objective is to assign a specific Planned Start Date ($ST_{p,k}$) for every project $p \in P_{window}$ at the initial workstation of its required assembly sequence. The scheduling problem is subject to three critical constraints. (1) Technological Precedence ensures that a downstream operation cannot commence until its upstream predecessor is complete, maintaining the assembly logic of complex prefabricated components. (2) Resource Availability dictates that a task cannot start if the required workstation or crew agents are occupied by other work. (3) Shift Constraints require that all processing must occur within valid factory shift hours and operational calendars.

Crucially, while the optimization algorithm generates Planned Start Times (ST_p), the Actual Start Times (S'_p) are stochastic, dependent on the emergent behavior and autonomous collaboration decisions of the workforce. The simulation bridges this planning-reality gap by predicting actual completion times under dynamic conditions.

2.3 Hybrid DES/ABS Simulation Model

To capture the gap between static planning and operational reality, the framework employs a Hybrid Discrete Event/Agent-Based Simulation approach. The simulation serves as a digital-twin-inspired virtual testbed, executing candidate schedules under realistic conditions to evaluate feasibility and performance.

2.3.1 Agent-Based Collaboration Logic

Unlike traditional scheduling models that assume fixed, immutable resource capacities, this framework models workers as autonomous agents capable of cross-training and dynamic collaboration [26]. Agents continuously monitor system state (e.g., queue lengths, throughput rates, bottleneck intensity) and autonomously traverse between compatible workstations to alleviate production constraints.

The simulation implements two primary behavioral rules governing crew agent decision-making:

Downstream Pull: An agent at a downstream station j may autonomously move upstream to station i to provide assistance if the feed rate drops below a critical threshold, preventing starvation (idle time) at downstream workstations.

$$\text{Count}_{\text{completed}}(j) > \text{Count}_{\text{completed}}(i) + \delta_{\text{pull}} \quad (1)$$

Upstream Push: An agent at an upstream station i may autonomously move downstream to station j to provide assistance if the intermediate buffer exceeds capacity, preventing congestion and excessive Work-In-Process (WIP) accumulation.

$$\text{QueueLength}(j) > \delta_{\text{push}} \quad (2)$$

These rules are continuously evaluated at each discrete event during simulation, enabling emergent, dynamic crew reallocation without explicit pre-planning.

2.3.2 Dynamic Processing Rates Under Collaboration

The simulation explicitly models the non-linear productivity impact of worker collaboration. When a workstation k operates with a primary crew and N_{helpers} assisting agents, the effective processing speed $v_{\text{eff}}(t)$ is formulated as:

$$v_{\text{eff}}(t) = v_{\text{base}} \times \left(1 + \eta \cdot N_{\text{helpers}}\right) \quad (3)$$

where v_{base} is the baseline processing rate of the primary crew working alone, η represents the Collaboration Efficiency Factor (e.g., $\eta = 0.5$), accounting for coordination overhead and diminishing returns, N_{helpers} is the number of agents simultaneously assisting at the station.

The parameter $\eta < 1$ reflects realistic crew dynamics: adding additional workers accelerates processing but with sublinear productivity gains due to coordination constraints and task indivisibility [27].

2.4 Optimization Model Formulation

2.4.1 Decision Variables

The decision variable X is a continuous vector of time values representing the Planned Start Time for each project in the current lookahead window:

$$\text{X} = \{ ST_p \mid p \in P_{window} \} \quad (4)$$

It is to be noted that the simulation logic determines the Actual Start Time (S'_p) as:

$$S'_p = \max\left(ST_p, \text{ResourceAvailability}_p\right) \quad (5)$$

The schedule is penalized if the planned time ST_p is infeasible (i.e., if $S'_p > ST_p$), reflecting poor schedule quality.

2.4.2 Objective Function: Multi-Criteria JIT-Aware Fitness

The fitness of a candidate schedule is evaluated by executing a complete simulation run, which returns the actual Completion Time and Start Time for each project under dynamic workforce conditions. The objective function minimizes a weighted sum of normalized Earliness, Lateness, and Maximum Lead Time, ensuring that objectives with different magnitudes do not dominate the optimization process:

$$Minimize Z(X) = \frac{\alpha}{T_d}\sum_{i=1}^{n} E_i + \frac{\beta}{T_d}\sum_{i=1}^{n} L_i + \gamma \frac{C_{max}}{N_{max}} \quad 6$$

where Earliness (E_i) penalizes early completion of project i to minimize site storage costs and outdoor exposure risks. Lateness (L_i) penalizes delays beyond the target due date to protect the critical path and maintain schedule adherence. Maximum Lead Time (C_{max}) minimizes the longest project cycle time, preventing excessive Work-In-Process (WIP) accumulation within the factory.

Normalization Factors scale raw time values into dimensionless, comparable ranges: T_d represents the maximum allowable JIT deviation (e.g., the lookahead window duration), while N_{max} represents the maximum theoretical project cycle time. This ensures that JIT and flow efficiency terms are commensurable and neither dominates due to scale differences.

Weighting Coefficients (α, β, γ) are user-defined values representing managerial priority. Typical values may include equal weight to earliness and lateness, with adjustments based on whether WIP or JIT precision is prioritized.

This multi-criteria formulation enables the GA to discover schedules that are both temporally precise (meeting JIT targets) and operationally efficient (minimizing internal WIP). The objective structure is flexible: additional metrics such as makespan, resource utilization, or crew overtime can be incorporated or substituted based on facility-specific constraints and priorities.

3 Framework Evaluation: A Case Study

3.1 Case Study Overview

This section demonstrates the framework's implementation in a prefabricated timber factory in Edmonton, Alberta. The Stair Assembly Station is used as the testbed, representing a High-Mix, Low-Volume (HMLV) system with high customization, variable processing times, and labor-intensive work Figure 2. The station operates as a Dual-Resource Constrained (DRC) flexible flow shop with four sequential phases: Stringer Construction (S), Landing Fabrication (L), Frame Building (F), and Final Cage Assembly (C). The workforce is organized into two semi-coupled teams—Upstream (S–L) and Downstream (F–C)—with the upstream team typically working one day ahead to sustain flow. When one team becomes ahead or idle, crews may move to assist the other ("partitioned flexibility"), requiring agent-based modeling to capture feasibility and throughput beyond rigid flow-shop assumptions.

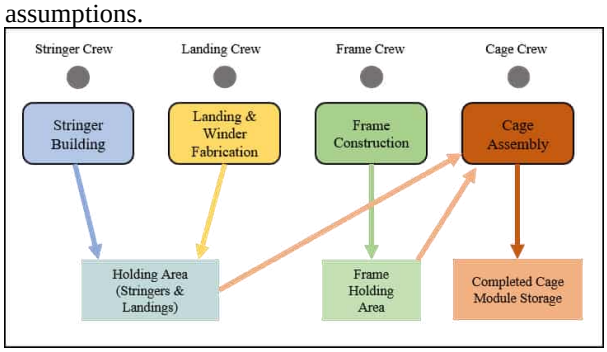

Figure 2: Schematic layout of the stair station.

3.2 Simulation Model Development

To capture the stochastic dynamics of the stair line, a Hybrid Discrete Event/Agent-Based Simulation (DES/ABS) model was developed in Python using the SimPy library. This hybrid approach enables the coupling of material flow logic (DES) with autonomous crew decision-making (ABS).

3.2.1 Data Collection and Parameterization

Historical production data were collected to characterize the variability of manual execution times. Probability distributions were fitted to the duration data for all four tasks (S, L, F, C). To ensure modeling accuracy and avoid double-counting of collaboration effects, only tasks completed independently by single crews were used for fitting; collaboration effects (which reduce duration) were excluded from the baseline distributions and instead generated dynamically by the simulation's agent logic.

3.2.2 System Constraints and Operational Logic

The simulation enforces system constraints observed during field studies. First, Resource Exclusivity ensures that each crew can process only one project at any given time. Second, Technological Precedence and Partial Dependencies are modeled to capture critical operational nuances where downstream phases may overlap with upstream work based on specific progress thresholds. Specifically, the Cage Assembly phase is permitted to commence once the upstream Framing phase reaches approximately 50% completion, and the installation of stringers and landings typically begins once the Cage assembly reaches approximately 70% completion. This partial overlap mechanism reflects the flexibility and adaptive nature of the modular construction workflow,

where work does not strictly follow finish-to-start dependencies but rather progresses dynamically based on material readiness and crew availability.

These partial-dependency rules were explicitly incorporated into the model to capture the realistic overlap between production phases. By allowing downstream tasks to begin before upstream completion, the model prevents the introduction of artificial blocking effects that would otherwise skew the simulation results and underestimate true system capacity.

3.2.3 Agent-Based Behavioural Logic

The simulation implements autonomous "collaboration" rules governing crew decisions. When the Downstream Team is idle or ahead of schedule, agents move upstream to assist the Upstream Team, and vice-versa. The model logic was validated through walkthroughs with production crews to ensure face validity, particularly regarding the fidelity of these autonomous collaboration behaviors.

3.3 Optimization Specification

The optimization problem focuses on generating an optimal production timetable for a representative Lookahead Window of two weeks. A dataset of 25 unique stair projects, sourced from the plant's operational backlog, served as the experimental sample.

3.3.1 Problem Formulation

The objective is to determine the optimal Planned Start Times (X) for both teams. The multi-objective function balances three conflicting goals:

- Lateness ($\alpha = 2$): Minimizing delays beyond target due dates to protect the critical path and maintain synchronization with site schedules.
- Earliness ($\beta = 1$): Minimizing early completions to prevent outdoor storage and weather-induced quality degradation.
- Maximum Lead Time ($\gamma = 0.5$): Minimizing internal production cycle time to enhance factory throughput efficiency.

The prioritization of JIT adherence (α, β) over lead time (γ) reflects the specific constraints of the Edmonton facility, as detailed below.

3.3.2 Managerial Rationale for Weight Assignment

This prioritization reflects specific facility constraints that distinguish this operation from standard manufacturing. The plant lacks indoor storage for finished goods; projects completed early must be stored outdoors, exposed to harsh Western Canadian weather conditions (snow, freeze-thaw cycles, temperature extremes, moisture). Such exposure poses significant quality risks to high-value prefabricated stairs, including material degradation, warping, and corrosion.

Conversely, Internal WIP (partially finished stairs in progress) remains sheltered indoors between workstations, where environmental conditions are controlled. Therefore, prioritizing a schedule that minimizes external exposure (balancing Earliness and Lateness) even at the cost of slightly longer internal lead times is logical. This reflects a realistic operational trade-off: in constrained facilities with outdoor storage vulnerabilities, *delivery precision* often outweighs *internal throughput* as the primary scheduling objective.

3.3.3 Algorithm Configuration and Search Enhancements

The Genetic Algorithm (GA) was configured with a population size of 50 individuals, an evolution horizon of 25 generations, and tournament selection with a tournament size of 3. To navigate the partitioned solution space effectively and accelerate convergence toward high-quality schedules, three domain-specific search enhancements were implemented.

Smart Initialization (Heuristic Seeding) seeded the initial population with heuristic schedules constructed using domain knowledge, where Buffer represents a conservative estimate of required lead time based on historical data. This approach accelerates convergence by providing high-quality starting points rather than relying on random initialization, allowing the optimizer to begin from a region of promising solutions.

Coupled Mutation (Topology-Aware Move) was implemented as a mutation operator that shifts linked Team 1 and Team 2 task start times simultaneously. This topology-aware move allows the optimizer to "slide" entire projects along the timeline while preserving the internal synchronization between the Stringer/Landing phase and the Framing/Cage phase. Formally, if a project's Team 1 start time is adjusted by Δ, the Team 2 start time is automatically adjusted by the same amount, maintaining the phase coupling relationships.

Deadline Snapping (Goal-Oriented Refinement) implemented a local search operator to force project start times toward their zero-penalty Just-In-Time dates. This operator refines temporal precision in the latter stages of evolution by exploiting the known good region of the solution space, thereby improving final schedule quality without excessive computational cost.

4 Results and Discussion

To evaluate the efficacy of the proposed HSBO framework, a comparative analysis was conducted

between the facility's baseline production schedule and the optimized timetable generated by the Genetic Algorithm. To ensure a rigorous comparison, the same set of stochastically sampled processing times across all four assembly stages was used for both the baseline simulation and the optimization routines. This ensures that any observed performance differences are attributable solely to scheduling decisions rather than random variation.

4.1 Baseline Schedule Performance

The baseline performance was established by simulating the 25-project sample schedule using the original planned start days and project sequence extracted from the factory's operational records. Figure 3 presents the resulting execution timeline for this baseline scenario, including the simulated project execution windows and their completion positions relative to the assigned crane dates.

Figure 3a illustrates the total project duration relative to the assigned "Crane Dates" (delivery deadlines). As shown, there is a consistent, significant buffer—averaging 2 to 3 days—between project completion and the deadline. While this buffer is strategically intended to absorb production variability, in the context of the Edmonton facility, it represents finished goods sitting outdoors in harsh weather for extended periods, incurring high quality risks.

Figure 3b provides a granular view of team-level execution. Visually, the gap between Team 1 (Stringer/Landing) and Team 2 (Framing/Cage) is minimal, indicating a tightly coupled flow with low Internal WIP. Quantitatively, the average project lead time in this baseline state is approximately 17 hours. However, comparing Figure 3a and 3b reveals a systemic imbalance: the facility maintains very low internal buffers (protected indoor WIP) but incurs massive external buffers (risky outdoor WIP).

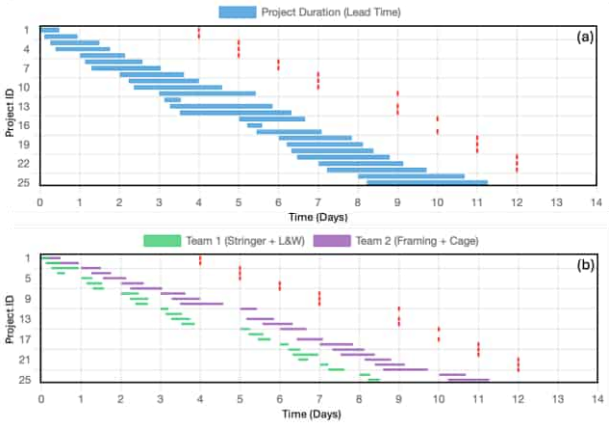

Figure 3: Baseline simulation results: (a) project execution windows relative to crane dates (red dashed lines); (b) Team 1 and Team 2 workload distribution.

4.2 Optimization Results

Following the baseline analysis, GA optimization was executed with objective weights prioritizing JIT adherence ($\alpha = 2, \beta = 1$) over internal lead-time minimization ($\gamma = 0.5$). The results are presented in Figure 4.

Compared with the baseline (Figure 3a), the optimized timetable (Figure 4a) shifts planned start times so completions align more closely with crane dates, reducing average outdoor finished-goods storage from 3 days to 1 day (66%). This does not eliminate the buffer entirely, but it substantially reduces exposure of finished stairs to harsh weather and related damage risk.

Figure 4b shows a clear structural change at the team level: increased spacing between Team 1 completion and Team 2 activity, indicating greater internal WIP (semi-finished components held indoors). Consistent with this, average project lead time increases by approximately 20% compared to the baseline (from ~17 hours to ~20.5 hours).

Overall, the optimizer trades a modest increase in safe indoor flow time for a large reduction in risky outdoor storage, with the Maximum Lead Time term ($\gamma = 0.5$) acting as a guardrail that penalizes excessive decoupling while still meeting delivery targets.

A side effect of JIT prioritization is schedule extension: the baseline executes from Day 0–11, whereas the optimized plan shifts to Day 1–13 and introduces a non-working gap at Day 12, increasing operational makespan. This occurs because delaying early projects reduces storage penalties, but the objective lacks an explicit makespan-compression term to discourage such gaps.

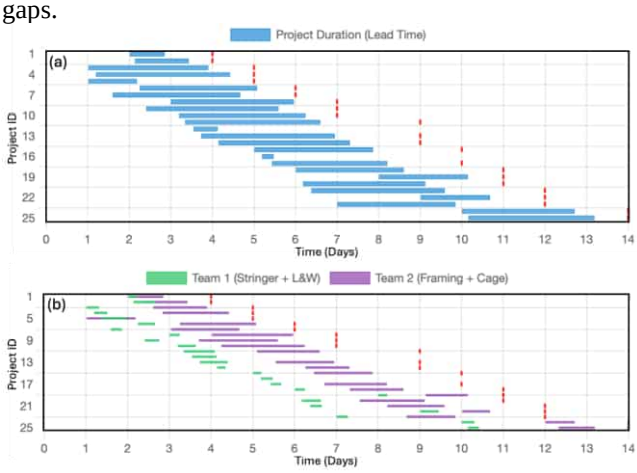

Figure 4: Optimized simulation results: (a) project execution windows relative to crane dates (red dashed lines); (b) Team 1 and Team 2 workload distribution.

From a managerial perspective, this trade-off should be interpreted as a deliberate buffer relocation rather than a simple loss in efficiency. In the case facility, reducing outdoor finished-goods storage from approximately 3 days to 1 day lowers the exposure of completed stairs to harsh weather, handling damage, and site coordination uncertainty, all of which carry quality, rework, and logistical risks. The corresponding increase in internal lead time indicates that more buffer is being held indoors as semi-finished Work-In-Process, where it is better protected and more controllable. For decision-makers, this means the proposed framework can support context-specific prioritization: in storage-constrained or weather-sensitive projects, accepting a moderate increase in internal lead time may be preferable if it substantially reduces external risk exposure. Conversely, in facilities where indoor space is more constrained or rapid flow is the dominant priority, the weighting structure of the objective function can be adjusted to place greater emphasis on lead-time compression or makespan reduction. Thus, the framework is not intended to prescribe a single best schedule universally, but to provide a decision-support tool that helps managers explicitly balance delivery precision, labor flow, and risk according to operational priorities.

4.3 Limitations and Future Directions

The results show the trade-off between delivery alignment and internal flow efficiency in HMLV systems. The 20% lead time increase indicates that reducing External WIP and improving Just-In-Time delivery required accepting some loss in factory flow performance. Two limitations remain. First, the objective function focuses on global maximum lead time, allowing local inefficiencies such as longer and more variable Team 2 flow times. Future models could include team-level penalties, though this would increase complexity. Second, the current Genetic Algorithm solves each schedule from scratch through repeated simulation, making it too slow for real-time use. Future work will explore DRL to learn reusable scheduling policies that can generate faster decisions while balancing delivery timing, lead time, and resource utilization.

5 Conclusion

This research addressed dynamic scheduling in High-Mix, Low-Volume (HMLV) off-site construction, where static planning tools struggle to represent the stochastic behavior of flexible, multi-skilled workforces. Following a Design-Science Research approach, the study developed and evaluated a prescriptive HSBO scheduling artifact that couples a Genetic Algorithm with a hybrid DES/ABS simulation model. The simulation served as a digital-twin-inspired evaluation testbed, enabling timetable optimization while capturing emergent collaboration behaviors in Dual-Resource Constrained (DRC) environments. Applied to a stair prefabrication line in Edmonton, Alberta, the optimized schedule reduced the average external finished-goods buffer from 3 days to 1 day (66%), lowering exposure risk, while increasing internal project lead times by about 20% (17 to 20.5 hours). The results also indicate that start-time decisions influence workforce dynamics by changing opportunities for upstream crews to assist downstream bottlenecks. Finally, the study highlights limitations of static evolutionary optimization: emphasizing JIT goals can increase schedule fragmentation and requires costly re-optimization as backlogs change. Future work will transition toward Deep Reinforcement Learning (DRL) to learn adaptive scheduling policies that provide real-time decision support under evolving system states.

Abstract -

Crane operations pose significant safety risks on construction sites, particularly when multiple mobile cranes operate concurrently in confined and dynamic environments. This paper presents a vision-based framework for real-time multi-crane safety monitoring using Scene Coordinate Regression (SCR). By directly regressing 3D scene coordinates from monocular images, the proposed approach enables accurate six-degree-of-freedom crane tip localization without requiring repeated camera calibration during deployment. Visual data acquired from crane-mounted cameras and aerial drone surveys are jointly leveraged to construct scene-specific spatial representations for SCR model training. The estimated crane-end poses are integrated into a BIM-aligned digital twin to support real-time visualization, operational envelope analysis, and automated near-collision detection. Experimental results demonstrate consistent centimeter-level localization accuracy, with median errors of approximately 1–1.3 cm, confirming the suitability of the proposed framework for interaction-aware multi-crane safety monitoring in construction environments.

Visual Localization; Crane Safety Monitoring; Computer Vision; Digital Twins

1 Introduction

Construction remains one of the most hazardous industries worldwide. In 2023, the construction sector recorded 1,075 fatal occupational injuries, the highest among all industries, according to the U.S. Bureau of Labor Statistics (BLS) [1]. Construction-related accidents also impose significant economic burdens, with workplace injuries costing nearly $1 billion per week as estimated by the Occupational Safety and Health Administration (OSHA) [2]. These statistics highlight the urgent need for proactive and technology-driven safety monitoring on construction sites.

On modern construction sites, multiple mobile cranes often operate simultaneously in confined and dynamic environments, where collision risks arise from interactions among cranes, surrounding structures, and workers. Traditional safety approaches, such as manual supervision and rule-based controls, are increasingly insufficient under these conditions, motivating the development of real-time monitoring and proactive collision avoidance systems [3].

Sensor-based approaches have been widely adopted to enhance crane operation management by integrating planning data, operational information, and monitoring technologies [4, 5]. These include laser scanning for visibility analysis [6] and multi-sensor systems for localization and collision prevention [7], often extended through IoT frameworks for coordinated safety management [8]. However, such approaches rely on dedicated hardware, calibration, and sensor fusion, resulting in high deployment complexity and cost.

In parallel, vision-based approaches have emerged as a lightweight alternative. Crane-mounted cameras enable continuous visual perception for tasks such as worker detection and hazard awareness [9], while image-based methods have been extended to 3D spatial understanding using multi-view reconstruction or depth estimation [10]. Hybrid systems combining cameras with additional sensors have also been proposed for crane localization and workspace analysis [11, 12]. Nevertheless, several limitations remain. First, many vision-based localization methods rely on explicit 2D–3D feature matching, making them sensitive to occlusions, illumination changes, and visual noise. Second, both vision- and sensor-based systems often require explicit geometric modeling and repeated calibration, limiting adaptability to dynamic construction environments. Finally, existing approaches provide limited support for unified spatial representation and interaction-aware safety reasoning in multi-crane scenarios.[12].

To address these challenges, this study proposes a vision-based crane localization framework based on Scene Coordinate Regression (SCR). By directly regressing 3D scene coordinates from monocular images, the proposed approach avoids explicit feature matching and enables efficient 6-DoF camera pose estimation from a single image.

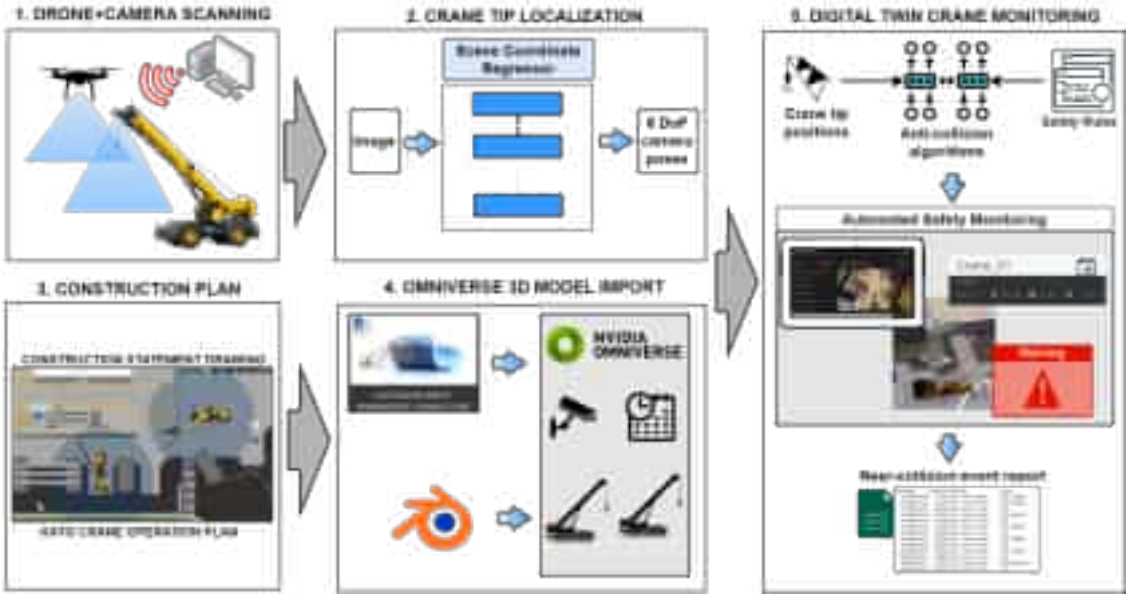

Figure 1. Overall framework of digital-twin crane collision monitoring.

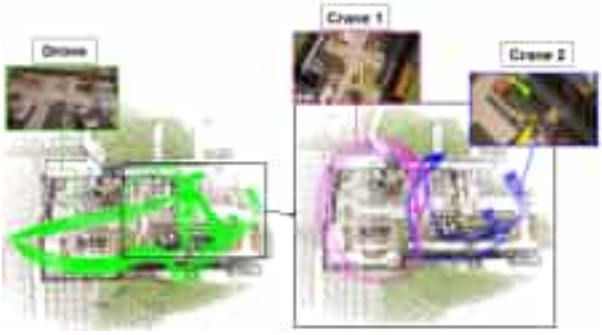

Figure 2. Drone and mobile crane operation path.

Visual data from crane-mounted cameras and drone surveys are jointly leveraged to construct scene-specific spatial representations without requiring additional sensing hardware. The estimated crane-end poses are integrated into a BIM-aligned digital twin to support real-time visualization and interaction-aware safety monitoring in multi-crane environments.

The main contributions of this study are summarized as follows:

- A real-time multi-crane safety monitoring framework that integrates vision-based localization with a BIM-aligned digital twin, enabling interaction-aware analysis of crane operations in shared workspaces.
- A unified spatial representation for multi-crane environments, where crane tip poses estimated from monocular images are directly mapped into a common BIM coordinate system for consistent safety reasoning.
- A lightweight deployment strategy using crane-mounted cameras and drone imagery, eliminating the need for additional sensing infrastructure while supporting continuous monitoring in dynamic construction sites.
- A digital twin–driven safety monitoring pipeline that enables real-time visualization, event logging, and near-collision detection for multiple cranes operating simultaneously.

2 Background

2.1 Advanced Crane Monitoring

The increasing complexity of construction sites has driven extensive research on advanced crane monitoring systems to improve operational safety and situational awareness [4, 5]. Early approaches relied on geometric and rule-based models to define crane working envelopes and collision constraints [3, 6], but their dependence on accurate modeling and frequent manual updates limits adaptability to dynamic site conditions. To improve localization accuracy, sensor-based systems incorporating GNSS, IMUs, UWB, and laser scanners have been widely adopted [7, 11], with multi-sensor fusion and IoT-based frameworks enabling real-time crane monitoring and fleet-level safety management [8]. However, these approaches rely on dedicated sensing infrastructure and precise calibration, resulting in high deployment cost and limited scalability. As a result, their applicability to rapidly changing construction environments and hetero-

geneous crane fleets remains limited. Vision-based crane monitoring has therefore emerged as a lightweight alternative, leveraging camera data and deep learning to support crane operation awareness [9]. While recent studies have extended vision-based methods toward three-dimensional spatial reasoning through image-based reconstruction or depth-assisted perception [10], many existing approaches remain constrained by explicit geometric assumptions or hybrid sensor dependencies [12, 11]. Moreover, most prior work focuses on single-crane scenarios, with limited consideration of interaction-induced safety risks in multi-crane environments [4].

2.2 Scene Coordinate Regression

Scene Coordinate Regression (SCR) is a deep-learning-based camera localization paradigm that directly regresses 3D scene coordinates from image pixels, enabling camera pose estimation without explicit 2D-3D feature matching [13]. SCR methods learn a mapping from image appearance to scene-specific spatial representations, from which six-degree-of-freedom (6-DOF) camera poses can be efficiently inferred [14]. By implicitly learning scene geometry, SCR demonstrates improved robustness to texture ambiguity, repetitive structures, and illumination variations compared with feature-based localization pipelines [15]. In addition, SCR-based localization can be operated using a single RGB image, enabling efficient fast inference for time-critical applications [16]. Although these characteristics make SCR well suited to dynamic and visually challenging environments such as construction sites, the application of SCR to construction equipment localization remains largely unexplored. In crane operation monitoring, SCR offers clear advantages. Crane-mounted and aerial cameras naturally observe consistent site geometry from diverse viewpoints, providing suitable visual input for learning scene coordinate representations. Unlike conventional vision-based crane localization methods, SCR does not require explicit camera-to-crane calibration or handcrafted geometric constraints, enabling flexible deployment across heterogeneous cranes and evolving site layouts. Furthermore, SCR-based localization can provide a unified spatial reference for interaction-aware safety analysis in multi-crane environments.

3 Proposed Approach

This section presents an end-to-end SCR-Digital Twins framework for real-time multi-crane safety monitoring, covering visual data acquisition, scene coordinate learning, crane-end localization, and digital twin–based collision analysis. Starting with multi-camera scanning, data from drone and crane-mounted cameras are then used to train the model for fully scene understanding. The trained model, which is adopted from [17] then is able to output the camera positions, which are also crane-end positions. Meanwhile, the 3D BIM model is built in Omniverse and the crane operation areas are defined based on construction plan. Finally, the anti-collision algorithms are used to analyze mobile crane-end positions with safety rules, then perform automated anti-collision monitoring and critical hazard event reports. The whole process is illustrated as in Figure. 1.

3.1 Data Processing

In order enable robust multi-crane monitoring with minimal site instrumentation, we construct a scene-specific sparse 3D representation by jointly leveraging crane-end mounted cameras that provide continuous close-range observations of the working area and a drone survey that ensures global coverage and mitigates blind spots as shown in Figure. 2. The drone flight can be conducted following site visit schedule to capture wide-baseline images of the entire operation zone and update on-site changes, while the crane-end cameras continuously record image streams during lifting operations. In the next step, a Structure-from-Motion (SfM) pipeline is then executed to recover a sparse point cloud and camera poses. Specifically, keypoints and descriptors are extracted for each image, feature correspondences are established across views, and a bundle-adjusted reconstruction yields a set of 3D points with associated multi-view feature tracks. This SfM model provides reliable 2D-3D associations that are later used as supervision for scene coordinate learning.

3.2 SCR-based Visual Localization

This subsection describes the D2S-based scene coordinate regression architecture adopted for real-time crane-end visual localization. The pipeline is divided into 2 parts: (1) Offline training where Scene Coordinate Regression model is trained with input images and their corresponding point cloud and (2) Online inference where the live-streaming data is feed directly into trained model to predict camera positions, as shown in Figure. 3.

3.2.1 Offline Training

Given the SfM reconstruction aligned with the BIM coordinate frame, each training image $\mathbf{p}_i \in \mathbf{P}$ provides a set of verified descriptor–scene coordinate pairs $\mathbf{V} = \{(d_i, \mathbf{X}_i)\}$ obtained from multi-view feature tracks. Following the D2S formulation [17], a scene coordinate regressor is trained to learn a direct mapping from local image descriptors to 3D scene coordinates. The architecture consists of a scene-agnostic local feature extractor and a scene-specific regression module equipped with self-attention to capture global descriptor context and suppress

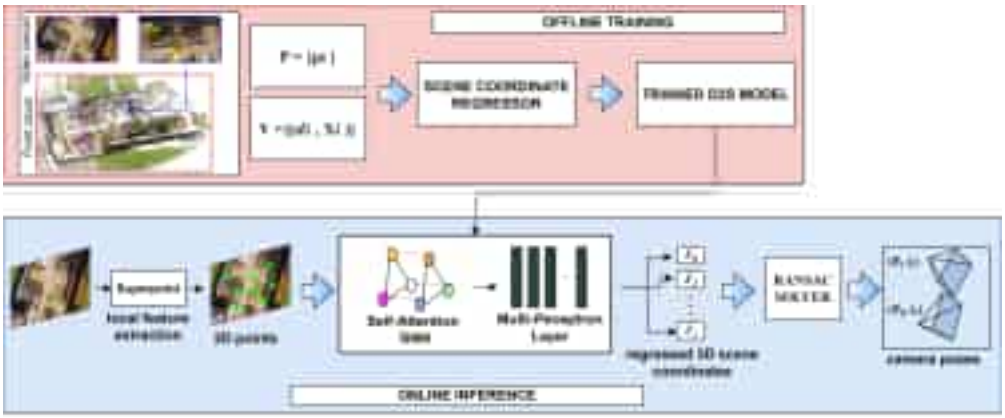

Figure 3. Overall SCR-based visual localization pipeline.

unstable regions such as moving objects or textureless areas. A shared MLP head outputs the regressed scene coordinates $\hat{\mathbf{X}}_i$ together with an optional reliability score $\hat{p}_i$. Once trained, the model is able to predict the new 3d feature coordinates from a single image without any SfM-guided descriptors.

3.2.2 Online Inference

During operation, each incoming crane-end camera frame is processed independently in a purely feed-forward manner. Sparse local features are first extracted from the image and passed through the trained D2S model, which directly regresses a set of 3D scene coordinates $\{\hat{\mathbf{X}}_i\}$ from the corresponding descriptors without explicit feature matching against a global 3D map. This regression-based formulation avoids costly nearest-neighbor search and scale-dependent matching, making the inference computationally efficient.

To ensure robustness, only the most reliable correspondences are retained based on the predicted confidence scores $\hat{p}_i$ (or by selecting the top-N correspondences). These sparse 2D–3D pairs are then fed into a RANSAC-based PnP solver to estimate the 6-DoF camera pose $(\mathbf{R}, \mathbf{t})$, followed by a lightweight nonlinear refinement. Since the camera is rigidly mounted at the crane tip, the estimated camera pose is directly transformed into the crane-end pose in the BIM coordinate frame using a pre-calibrated extrinsic transformation. This transformation is defined once and remains fixed during operation, eliminating the need for repeated calibration procedures in dynamic construction environments.

By avoiding dense reconstruction and global map matching, the proposed inference pipeline maintains low computational overhead and stable runtime behavior suitable for real-time deployment. The use of sparse descriptors, lightweight regression networks, and a single PnP optimization per frame enables real-time performance, allowing continuous crane-end pose tracking without reliance on dense reconstruction or iterative map matching. This real-time localization capability forms the basis for online multi-crane anti-collision monitoring and hazard analysis within the digital twin environment.

3.3 Digital Twin Visualization and Real-Time Monitoring

Based on the BIM-aligned scene coordinate system, a USD-based digital twin is constructed in NVIDIA Omniverse [18] to enable real-time visualization and monitoring of multi-crane operations. Each mobile crane is represented as a parametric articulated model with a fixed base and a dynamically updated arm. At each time step t, the estimated crane-end position $\mathbf{p}_i^t$ from the visual localization module is integrated by updating the corresponding USD transforms, rendering the crane arm as a line segment connecting the base $\mathbf{b}_i$ and the tip $\mathbf{p}_i^t$.

Following Algorithm 1, frame-wise crane operational metrics—including height, horizontal working radius, and azimuth angle—are computed directly in the BIM coordinate frame and compared against historical maxima to provide intuitive feedback on operating envelopes. All updates are performed in a frame-synchronous manner to ensure temporal consistency between geometry updates, metric computation, and visualization.

To assess collision risk between multiple cranes, the system evaluates the horizontal separation distance between crane tips at each frame,

$$d_t = \left\| (\mathbf{p}_1^t - \mathbf{p}_2^t)_{xz} \right\|,$$

where only the ground-plane components are considered to reflect practical collision risk during lifting operations. When the distance falls below a predefined safety threshold D_{th}, the system transitions from a *safe* to a *near-collision* state. These state transitions are logged with timestamps and frame indices, enabling post-event analysis and safety

auditing. In this study, the safety threshold D_{th} is set to 10 m as a conservative safety margin to account for crane motion uncertainties, load swing, and localization errors in dynamic construction environments, following general safety principles outlined in ISO 12480-1 [19].

Figure 4. NVIDIA Omniverse window for DT-based crane safety monitoring

In addition to geometric visualization, synchronized live camera streams from crane-end cameras are displayed alongside the digital twin, providing operators with complementary visual context. All visualization elements—including crane geometry, distance indicators, operational statistics, and safety status—are updated in real time within a unified dashboard interface, as illustrated in Figure. 4. The use of sparse crane-end pose updates, lightweight geometric primitives, and event-driven state evaluation allows the system to operate at interactive frame rates without requiring dense reconstruction or physics-based simulation. This tightly coupled integration of real-time visual localization, digital twin visualization, and rule-based safety assessment enables continuous multi-crane monitoring and forms the foundation for automated near-collision detection in complex construction environments.

Algorithm 1 Real-Time Multi-Crane Digital Twin Monitoring and Near-Collision Detection

Require: Frame-wise crane tip positions $\mathbf{p}_i^t$, crane base transforms $\mathbf{T}_i$, synchronized camera images, safety threshold D_{th}

4 Implementation and Results

This section illustrates the experimental setup to evaluate model performance and results of proposed method. First, a simulated construction site is built by Twin-motion platform replicating the real construction site at Central Florida Boulevard, USA, as shown in Figure. 5. In the next step, drone and mobile crane working activities are simulated to capture data for model training with image resolution of 1080x1920. The dataset consists of approximately 2000 images collected from drone and crane-mounted cameras. The data are split into training and testing sets at the sequence level to avoid frame overlap. Meanwhile, after real-time video stream is fed into train D2S model to predict mobile crane tips, the output are inputs in NVIDIA Omniverse to perform digital-twin visualization. The whole pipeline is implemented on a computer with NVIDIA RTX 4090 GPU, Intel i9-139000KF Chipset and 64GB RAM.

4.1 Visual localization results

In order to evaluate the accuracy of SCR-based D2S model in estimating spatial information of crane tips, we we establish a testbed from videos recording two KATO cranes operating and the camera poses extracted from COLMAP serving as ground-truth value to estimate the errors of model predictions. The SfM-derived camera poses are used only for evaluation and are not directly used to supervise camera pose learning.

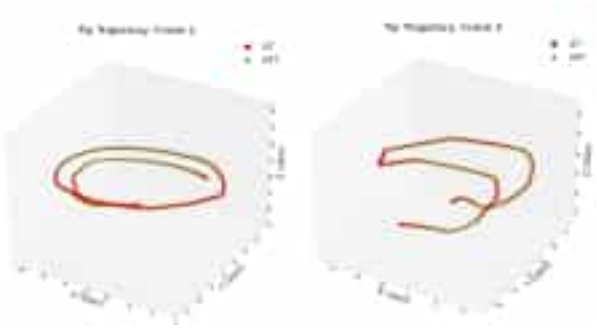

Figure 6. Qualitative results of SCR-based crane tip localization of Crane 1 (Left) and Crane 2 (Right). Axes are shown in units of 10 m for visualization clarity.

Table 1. Quantitative results of SCR-based crane tip localization.

Error threshold	Crane 1	Crane 2
$< 1\,cm$	48.89%	48.80%
$< 2\,cm$	81.89%	82.10%
$< 3\,cm$	93.11%	92.69%
$< 5\,cm$	96.89%	97.60%
Median error (cm)	**1.30**	**1.01**

The Figure. 6 compares the estimated crane tip trajectories with the reference trajectories for both cranes. The results show that the estimated positions closely follow the ground truth over the entire operation sequence, maintaining stable alignment during slewing motions, height changes, and direction transitions. In addition, the quantitative results are summarized in Table.1. For Crane 1, 81.89% of the estimated crane tip positions exhibit errors below 2 cm, increasing to 96.89% within a 5 cm threshold. Crane 2 achieves comparable performance, with 82.10% of estimates below 2 cm and 97.60% within 5 cm. The median localization errors are 1.30 cm and 1.01 cm for Crane 1 and Crane 2, respectively. These results demonstrate that the proposed SCR-based approach can provide reliable centimeter-level crane tip localization, which is sufficient to support downstream safety monitoring and near-collision detection tasks.

4.2 Digital Twin Crane Safety Monitoring

The Figure. 7 presents the digital twin–based real-time multi-crane safety monitoring results. By continuously integrating the estimated crane-end poses into a BIM-aligned digital twin, the system enables synchronized visualization of crane geometry, operational metrics, and live top-views for multiple cranes operating concurrently. During normal operation, a safe state is maintained when the inter-crane distance exceeds the predefined safety threshold, while real-time feedback on crane height, working radius, and azimuth angle is provided. After that, when the horizontal separation between crane tips falls below the safety threshold, the system automatically transitions to a near-collision state, which is immediately reflected in the digital twin visualization and monitoring dashboard. All state transitions are logged in a structured CSV format with timestamps and inter-crane distances, enabling post-operation analysis and safety auditing. The system achieves approximately 21.58 FPS on an RTX 4090 GPU, demonstrating near real-time performance for multi-crane monitoring .These results demonstrate that the proposed framework can effectively integrate vision-based localization with digital twin–based safety monitoring for real-time multi-crane operations.

Table 2. Runtime analysis of the proposed framework on i9-13900KF, RTX4090

Module	Time (ms)
Feature extraction + SCR inference	28.92
PnP + refinement	15.28
Digital Twin update	2.14
Total per frame	**46.34 ms**
Average FPS	**21.58 FPS**

5 Discussion

The proposed framework assumes a fixed rigid transformation between the camera and crane tip, as well as prior alignment between the SfM reconstruction and the BIM coordinate system. These assumptions may introduce deployment constraints in real construction sites. The results demonstrate that the SCR-based framework can support near real-time multi-crane safety monitoring using monocular visual inputs, achieving centimeter-level localization accuracy sufficient for inter-crane distance evaluation and safety threshold enforcement. Compared with feature-based localization methods, the proposed approach avoids explicit feature matching and shows improved robustness to illumination changes and occlusions. In contrast to sensor-based systems, it reduces hardware dependency and

Figure 7. Digital twin–based real-time visualization of multi-crane safety monitoring.

calibration complexity. From a methodological perspective, scene coordinate regression enables a unified scene-centric representation without explicit geometric modeling or repeated calibration, making it suitable for dynamic construction environments. The integration with a BIM-aligned digital twin further supports consistent spatial reasoning, real-time visualization, and rule-based safety assessment for interaction-aware monitoring. Nevertheless, the current implementation focuses on crane-tip separation and does not explicitly model dynamic effects such as load swing or interactions with workers. In addition, the evaluation is conducted in a simulated environment, and real-world conditions such as illumination variation, occlusions, and weather may affect performance. These limitations will be addressed in future work.

6 Conclusion

This paper presented a vision-based framework for real-time multi-crane safety monitoring using Scene Coordinate Regression (SCR) integrated with a digital twin. By directly regressing 3D scene coordinates from monocular images, the proposed approach enables accurate crane tip localization without relying on explicit feature matching or additional sensing hardware, thereby reducing system complexity, calibration requirements, and deployment overhead. Experimental results demonstrate consistent centimeter-level localization accuracy across different crane motions and configurations, indicating robust performance under dynamic operational conditions and varying viewpoints. When integrated into a BIM-aligned digital twin, the estimated crane-end poses support real-time visualization, operational envelope analysis, and automated near-collision detection among multiple cranes operating within shared workspaces, enabling interaction-aware safety assessment in complex site layouts. Furthermore, the unified spatial representation provided by the digital twin facilitates consistent safety rule enforcement and traceable event logging without manual reconfiguration. Overall, the proposed framework offers a lightweight and scalable alternative to conventional sensor-heavy crane monitoring systems and provides a practical foundation for proactive, data-driven, and interaction-aware multi-crane safety management in complex and evolving construction environments.

Abstract

Modular construction projects rely heavily on large trucks to transport prefabricated modules, making the design of on-site haul roads critical for ensuring safe and efficient logistics operations. However, the manual design process suffers from inefficiencies. To address this issue, this study proposes MiCRoadDiff, a diffusion model-based intelligent approach for modular construction on-site haul road layout generation. MiCRoadDiff, adopts a pre-trained Stable Diffusion model as an intelligent design backbone. LoRA is employed to achieve domain adaptation by injecting construction-specific knowledge, design experience, and implicit road design rules into the generative model. In addition, multiple ControlNet modules are introduced to enforce geometric and road layout constraints. A comprehensive evaluation framework that incorporates image fidelity and layout validity is proposed. Experimental results demonstrate that MiCRoadDiff exhibits strong domain adaptation capability and can rapidly generate diverse, high-quality haul road layout alternatives that satisfy practical engineering requirements. By integrating multi-source conditional information, it can robustly adapt to varying site conditions, generating coherent and feasible haul road layouts. The proposed framework significantly improves the efficiency and intelligence of construction site layout design workflows.

1 Introduction

Modular Integrated Construction (MiC) [1] is an innovative construction approach where modules are prefabricated in factories and then assembled on-site. In recent years, the Government of the Hong Kong Special Administrative Region (HKSAR) has actively promoted MiC [2] to tackle key challenges in the local construction industry, including labor shortages, site limitations, and the growing demand for environmental sustainability. The modules are transported to the construction site by trucks, entering through the main gate, being placed at designated unloading points, and then exiting the site. On-site haul roads play a critical role in ensuring the safety and efficiency of truck transportation [3]. Proper design of haul roads can significantly enhance logistic efficiency, safety, and ease of operation for truck drivers, thereby minimizing potential damage to the modules. However, traditional manual design processes face several limitations, such as low efficiency and the necessity for repetitive adjustments, which hinder overall productivity and effectiveness.

Researchers have explored classical optimization methods, including greedy algorithms [4], genetic algorithms [5], and Monte Carlo techniques [6], in various aspects of road planning. While genetic algorithms demonstrated potential in exploring design spaces, they were limited to producing near-optimal solutions and fell short of capturing the complex nature of the layout design process. Mixed-integer linear programming [3] was also employed to achieve exact solutions, but it suffered from prolonged computational times.

In recent years, advances in deep learning have significantly transformed automated engineering and construction design, enabling more efficient and

intelligent design workflows. Among these approaches, Convolutional Neural Networks (CNNs) have played a foundational role in processing spatial information and extracting meaningful features from visual data [7,8]. Their strong capability in analyzing complex spatial patterns has facilitated the automation of design tasks that traditionally relied on extensive manual effort. Subsequently, deep generative models based on convolutional architectures, particularly Generative Adversarial Networks (GANs) [9], have attracted considerable attention. Owing to their adversarial training mechanism, GANs are capable of producing designs that not only exhibit high visual realism but also satisfy certain engineering constraints. In the construction domain, GAN-based methods have been applied to layout generation [10], and defect detection [11]. Nevertheless, GAN models often suffer from training instability and limited output diversity [12], which restrict their scalability and robustness in practical engineering applications. Moreover, the rationality of a single generated design cannot be guaranteed, making model optimization and deployment challenging. In addition, existing studies on road design frequently depend on expert-based qualitative evaluation, which lacks standardized and objective metrics. Recent progress in state-of-the-art image generation techniques, particularly diffusion models [13,14] and their associated control mechanisms [15], which provide improved training stability, enhanced diversity of generated results, offers a promising pathway to overcome these limitations.

To address the aforementioned limitations, this paper presents MiCRoadDiff, a diffusion model-based intelligent approach for modular construction on-site haul road layout generation conditioned on construction plans and textual design conditions. Building upon the exceptional image synthesis capabilities of Stable Diffusion, this study aims to learn from designers' expertise to rapidly generate initial design proposals, serving as a valuable tool for assisting and streamlining the design process. This approach significantly contributes to the automation and efficiency of construction design workflows. This study integrates both textual and image design conditions to enable automated design. By utilizing the ControlNet architecture, the generated designs demonstrate strong alignment with the input conditions, facilitating the creation of customized and precise layout solutions. Domain adaptation technology, LoRA, is incorporated to improve model performance under limited data conditions. This effectively addresses the challenges of data scarcity frequently encountered in construction engineering applications. A comprehensive evaluation strategy is developed to assess the generated results, including the image quality aspect (FID, SSIM, and PSNR) and haul road layout aspect (transportation cost, accessibility, and number of corners). This approach aids in model optimization while ensuring both visual realism and compliance with engineering requirements.

2 Related Works

2.1 Deep Learning Methods for Site Layout Generation

Currently, there is limited research on using deep learning methods for site layout generation. Li et al. [10] utilized GAN-based methods to design tower crane locations for high-rise buildings, which overcomes complexity limitations and facilitates layout planning decision-making process. GAN models were adopted mostly for building layouts and floor layouts design [16]. However, GAN-based approaches encounter challenges such as training instability and limited output diversity. Additionally, existing research has yet to effectively address the critical issue of limited datasets, a challenge in the construction domain.

2.2 Diffusion Models in Image Generation

Diffusion models [13,14] are a powerful class of generative models that have recently gained significant attention for their ability to produce high-quality and diverse outputs. By employing an iterative denoising process, these models excel at capturing and modeling complex data distributions, making them particularly effective for tasks such as image synthesis and video generation.

To improve controllability and flexibility compared to GAN-based models, a multi-conditional model for residential floor plan design was developed using a diffusion model [17]. This approach demonstrated high-quality, diverse, and controllable results through experimental validation. An image-prompt diffusion model showed exceptional feature extraction capabilities and design effectiveness in shear wall design [18].

3 Methodology

3.1 Problem Formulation

MiCRoadDiff aims to automatically generate feasible and efficient haul road layouts for modular construction sites under complex spatial and operational constraints. Given a fixed construction site layout, and design conditions, the objective is to generate a temporary haul road configuration that ensures connectivity, safety, and constructability while minimizing conflicts with non-movable elements. Formally, the task is defined as a conditional image generation problem. Let A denote the site layout constraints (e.g., site boundary and building

footprints), *F* represent fixed facilities (e.g., tower crane bases and site gates), and *T* indicate textual design conditions (e.g., road width and minimum turning radius). The goal is to learn a generative model *G* that produces a haul road layout *R*: $R = G(A, F, T)$, where *R* satisfies geometric constraints imposed by *A* and *F*, and design logic encoded in *T*.

3.2 Overall Framework of MiCRoadDiff

The overall architecture of MiCRoadDiff is illustrated in Figure 1. The framework consists of three main components: (1) multi-layer conditional encoding, (2) conditional diffusion-based generation with ControlNet and LoRA, and (3) post-generation evaluation. First, for a construction site layout to be designed, multi-conditional maps (including boundary map and fixed facility map) are constructed, along with textual design requirements. These inputs are encoded and fed into a fine-tuned Stable Diffusion model. Then, the model leverages LoRA to perform experience-based haul road design, while ControlNet ensures compliance with the specified rigid constraints. Finally, the ideal generated layouts are evaluated using computer vision-related metrics and road design-specific models.

The core idea of MiCRoadDiff is to achieve flexible layout designs while satisfying rigid design constraints. Multiple condition maps are enforced through different ControlNet modules, while generalizable haul road design principles are learned via a lightweight LoRA adaptation of a pre-trained Stable Diffusion model.

Figure 1. The framework of the research

3.3 Stable Diffusion

Stable Diffusion is a latent diffusion-based generative model that synthesizes images by iteratively denoising a latent representation guided by conditional information. Instead of performing diffusion directly in pixel space, Stable Diffusion operates in a compressed latent space obtained via a variational autoencoder (VAE), which significantly reduces computational cost while preserving high-level semantic structure. During training, Gaussian noise is progressively added to latent variables, and a denoising U-Net is trained to predict and remove this noise step by step. At inference time, the model starts from random noise and gradually reconstructs an image that aligns with the provided conditions.

In the context of MiCRoadDiff, Stable Diffusion serves as the core generative engine responsible for synthesizing plausible haul road layout designs. Rather than explicitly encoding construction rules or geometric algorithms, the diffusion backbone provides strong priors for producing continuous, coherent, and visually structured layouts.

Among available Stable Diffusion variants [19], MiCRoadDiff adopts Stable Diffusion XL (SDXL) [20] as the backbone model. SDXL introduces a larger U-Net architecture, a higher-capacity text encoder, and a dual-stage conditioning mechanism compared to earlier versions such as SD v1.5. These improvements enable SDXL to better capture complex spatial relationships and long-range dependencies within an image, which are critical for construction site layout generation where global topology and local geometry must be jointly satisfied.

3.4 LoRA and ControlNet

Low-Rank Adaptation (LoRA) [21] is a parameter-efficient fine-tuning technique designed to adapt large pre-trained models to downstream tasks without updating the full set of model parameters. Instead of directly modifying the original weight matrices in the neural network, LoRA introduces a pair of low-rank matrices that approximate the weight updates. During training, only these low-rank matrices are optimized, while the original backbone parameters remain frozen. This significantly reduces memory consumption and training cost, while preserving the generalization capability of the pre-trained model. In MiCRoadDiff, LoRA plays a critical role in learning domain-specific haul road design logic that is not explicitly encoded in the condition informations. LoRA can capture higher-level design principles, including road continuity, transportation efficiency, and typical geometric patterns of temporary haul roads in modular construction sites. By integrating LoRA with the SDXL backbone, MiCRoadDiff leverages the strong generative prior of a large diffusion model while maintaining efficient and controllable domain adaptation.

ControlNet [15] is a conditional control architecture designed to extend large diffusion models with fine-grained and spatially aligned guidance, without disrupting their original generative capabilities. It introduces an auxiliary neural network that mirrors the structure of the diffusion model' s denoising U-Net and injects condition-specific features into the generation process through zero-initialized convolution layers. This design ensures that, at the beginning of training or inference, the ControlNet branch has no influence on the

output, thereby preserving the behavior of the pre-trained backbone, while gradually enabling strong conditional control as learning progresses.

In MiCRoadDiff, ControlNet is responsible for enforcing rigid spatial constraints that must be strictly preserved in construction site road layout generation. These constraints include site boundaries, building footprints, and fixed entities such as tower crane bases, ideal truck parking areas, and site entrances. Such elements are non-negotiable in practice and cannot be reliably handled by text prompts or learned implicitly through data-driven adaptation alone. MiCRoadDiff employs multiple ControlNet modules, each associated with a specific type of condition map.

3.5 Multi-conditional Image Generation

MiCRoadDiff performs haul road layout synthesis through a multi-conditional image generation process that jointly integrates multiple spatial condition maps and structured textual input within a unified diffusion framework, as shown in Figure 2. This design enables the model to handle heterogeneous constraints commonly encountered in construction site planning, where geometric feasibility, operational requirements, and design intent must be satisfied simultaneously.

Each condition map encodes a single type of constraint. Map-A encodes rigid and non-movable geometric boundaries, including site boundaries and building boundaries. Map-B encodes fixed entities including tower crane bases, ideal truck parking areas, and site entrances. This multi-conditional formulation allows MiCRoadDiff to explore diverse feasible solutions within a well-defined constraint space.

In addition to image-based conditions, MiCRoadDiff incorporates structured textual input to specify general design requirements that are difficult to encode spatially. The textual prompt follows a consistent and interpretable structure, following the format: "construction on-site haul road layout, modular construction site, top view site plan, road width approximately [Value] meters, minimum turning radius around [Value] meters, tower crane base location, truck parking area, site gate(s) location, road connects [Facilities], avoid [Obstacle]" This format ensures the generated images remain contextually and environmentally accurate by integrating both spatial and climatic factors. For example: *"construction on-site haul road layout, modular construction site, top view site plan, road width approximately 9 meters, minimum turning radius around 15 meters, tower crane base location, truck parking area, site gate(s) location, road connects site gate(s) and truck parking area, avoid buildings and crane base."* This structured prompting framework enables effective conditioning across haul road design intent. Through the joint use of multiple condition maps and structured textual input, MiCRoadDiff achieves controllable, robust, and flexible multi-conditional image generation tailored to the complex requirements of haul road layout design for MiC.

Figure 2. Multi-condition encoding for image generation

3.6 Post-generation Evaluation

To evaluate the quality and perceptual fidelity of the generated road layout images, three established metrics FID, SSIM, and PSNR are used. FID assesses realism and perceptual similarity, while SSIM and PSNR measure structural consistency and reconstruction quality. Besides, domain-specific metrics including transportation cost and accessibility, are used to evaluate layout performance in terms of efficiency and safety. Transportation cost is calculated as the product of the road centerline length and the unit construction cost. Accessibility evaluates how the designed road connects site components including gates and truck parking locations.

4 Experiment and Results

4.1 Experimental details

To train and evaluate LoRA, a dedicated dataset was constructed to reflect realistic modular construction site conditions. Ten real-world projects were sourced from renowned contractors in Hong Kong, resulting in the creation of a total of 10 data. Each data consists of image and corresponding textual description, enabling joint image–text conditioning during training. Textual descriptions are manually curated and aligned with each image sample. The constructed dataset highlights diversity in road types (one-way or two-way), road width (6m-10m) and turning radius (12m-18m), gate configurations (single or multiple), modular building shapes, and boundary shapes. This diversity allows the model to learn transferable haul road design logic rather than memorizing specific layouts. During training, the SDXL backbone parameters were kept frozen, and LoRA

modules were inserted into the attention layers of the U-Net architecture. Only the low-rank adaptation parameters were updated. No augmentation techniques were used during training. LoRA training and inference were performed on a workstation equipped with 13th Gen Intel(R) Core (TM) i7-13700KF@3.40 GHz CPU and NVIDIA GeForce RTX 4090 GPU. AdamW8bit [22] was used to optimize the low-rank decomposition of a subset of weights to minimize this loss. The batch size was set to 1. The learning rate for U-Net was set to $1e^{-4}$, while the learning rate for the text encoder network was $1e^{-5}$.

4.2 Training results of LoRA

The LoRA adaptation was trained for a total of 20 epochs, each consisting of 50 training steps. The evolution of the training loss over the entire training process is illustrated in Figure 3. The loss value shows a gradual decreasing trend with increasing training iterations, indicating stable convergence of the LoRA training process. The results generated by the SDXL model under the same text prompt under different training epochs were compared, as shown in Figure 4.

From the 5th to the 10th epoch, the generated results exhibit a clear shift toward a simplified semantic style suitable for site layout representation. By the 15th epoch, most critical layout components (haul road, tower crane base, truck parking area, site gate, and building boundaries) are correctly generated except site boundaries. While the 20-epoch model produces complete and well-organized layouts with road networks that satisfy engineering design requirements.

Overall, the LoRA-enhanced model shows a clear improvement in semantic alignment with modular construction on-site haul road planning intent. It also shows the effectiveness of the LoRA-based adaptation in capturing domain-specific haul road design logic for modular construction sites rather than memorizing specific site configurations.

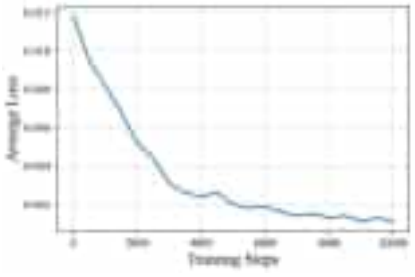

Figure 3. Training loss curves of LoRA

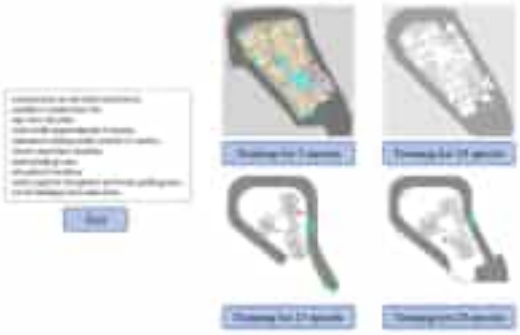

Figure 4. Comparison of model performance under different training epochs

4.3 Design results of MiCRoadDiff

The MiCRoadDiff model was built upon SDXL as the base diffusion model and incorporated a LoRA module trained for 20 epochs. In addition, two ControlNet modules were employed for image-based constraint control, with their parameters carefully tuned through multiple iterations to achieve optimal performance.

The MiCRoadDiff model was evaluated using new project cases that were not included in the training dataset. The generated haul road layouts were assessed through both qualitative and quantitative evaluations to comprehensively examine the model's generalization capability and design performance.

The project used in this study is a modular residential project located in Hong Kong. After simplification and semantic processing, the resulting design representations include condition image, design text, and corresponding haul road layouts, as shown in Figure 5. Black lines represent building boundaries and site boundaries, red squares denote tower crane locations, blue rectangles indicate truck parking areas with dimensions corresponding to real truck sizes, green symbols represent site gates, and grey regions denote haul roads, whose widths and turning radius reflect actual design dimensions. MiCRoadDiff was applied to design the haul road layout for this project, and the generated results are shown in Figure 6.

In this study, input construction drawings were pre-processed to standardize spatial resolution, enabling precise conversion of textual constraints into pixel units. Dimensional constraints are embedded into structured prompts, guiding the model toward geometrically plausible outputs during diffusion. Additionally, ControlNet ensures road layouts align with site geometry, preventing violations of spatial constraints. This ensures that the textual dimension can be accurately translated into spatial pixels.

From the design results, it can be observed that the model is capable of producing diverse haul road layout alternatives for designers' selection. The generated

layouts form relatively complete site plans with high image quality and clarity. Moreover, the generated haul roads satisfy the prescribed design conditions and are feasible from an engineering perspective.

Layout (a) was selected as the final design solution for quantitative analysis, with the results shown in Figure 7. The generated layout achieved favorable FID, SSIM, and PSNR scores, indicating high image clarity and strong structural similarity to the ground truth. In addition, the total road length of the designed haul road is 128 m, with an estimated construction cost of 385,101 HKD. The layout exhibits good connectivity by linking two site gates and effectively serving the designated truck parking areas. However, the presence of three turning corners may slightly increase driving difficulty in practice.

5 Discussion

5.1 Ablation test of MiCRoadDiff

To investigate the contribution of different modules to the generation performance of MiCRoadDiff, an ablation study was conducted. The experimental results are presented in Figure 8 and Table 1.

As shown in Figure 8, when the ControlNet modules are removed, the model no longer produces engineering drawings with fixed spatial constraints. Instead, it generates layouts with varying building and site shapes, randomly arranged tower crane locations, truck parking areas, and site gates. Although these results exhibit a certain degree of creativity, the model still maintains a consistent visual style and the design experience learned during training. When the LoRA module is removed, the model shifts toward a more photorealistic visual style. While the overall building and site boundaries are still preserved, the model fails to correctly interpret the design conditions specified in the text prompts, such as road width, turning radius, and connectivity requirements. When only the SDXL baseline model is used for text-to-image generation, the generated results appear visually realistic but lack a consistent design style and fail to satisfy engineering design constraints.

Reducing each module leads to variations in site configurations or drawings that cannot be evaluated using road-related metrics, as shown in Figure 8. Consequently, only image similarity metrics were employed for quantitative comparison. The results of the compared evaluation metrics are listed in Table 1. The symbol ↓ indicates that lower values are better while ↑ the opposite is. The results show that the MiCRoadDiff model achieves the greatest performance in all three metrics. As shown in Figure 9, all three metrics exhibit clear improving trends as the model evolves from the SDXL baseline to MiCRoadDiff. Compared with SDXL, MiCRoadDiff achieves improvements of 83%, 214%, and 214% in FID, SSIM, and PSNR, respectively. The introduction of the ControlNet and LoRA modules effectively enhances overall model performance. Removing the LoRA module results in a significant decline in performance, with FID, SSIM, and PSNR dropping by 272%, 50%, and 18%, respectively. Moreover, MiCRoadDiff significantly outperforms models with a single enhancement strategy, thereby verifying the effectiveness of the proposed framework for modular construction haul road design.

Figure 8. Comparison with baseline models

Table 1 Test results of ablation experiment

Model	FID↓	SSIM↑	PSNR↑
SDXL	530.41	0.27	3.95
SDXL+CN	326.85	0.42	10.19
SDXL+LoRA	243.40	0.83	11.51
MiCRoadDiff	87.66	0.85	12.44

(SDXL+LoRA+CN)

Figure 9. Comparison between different models regarding FID, SSIM, and PSNR

5.2 Layout design with different conditions

To investigate the adaptability of MiCRoadDiff under different design conditions, a series of experiments were conducted by modifying key site constraints, including truck parking area locations, site gate positions, and conditional maps. The qualitative results are illustrated in Figure 10.

When the truck parking area is relocated, MiCRoadDiff successfully generates distinct haul road layouts that build connectivity between the site gates and the designated parking area.

When the site gate position is changed, the generated haul roads could provide feasible access to the truck parking area, while respecting site boundaries and site gates. These results indicate that MiCRoadDiff is capable of handling changes in global access conditions.

When only Map-A (Building and site boundaries) is provided, the generated haul road generally follows the site boundary but lacks precise alignment with functional facilities, resulting in ambiguous or suboptimal connectivity. Conversely, when only Map-B (Site gates, tower crane, and truck) is used, the model correctly recognizes facility locations but may produce road geometries that are less compatible with the overall site shape. These observations highlight that a single conditional map is insufficient to fully constrain the haul road design task. The combination of multiple condition maps is necessary to simultaneously enforce geometric boundaries and functional requirements.

Overall, the experimental results demonstrate that MiCRoadDiff can robustly adapt to varying site conditions. The model effectively integrates multi-source conditional information to generate coherent and feasible haul road layouts.

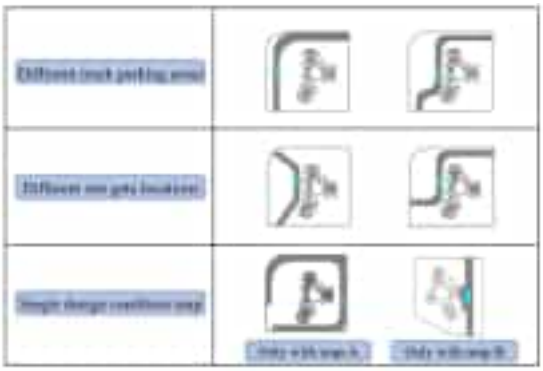

Figure 10. Comparison with different design conditions

6 Conclusion and Future Work

This paper proposed MiCRoadDiff, a novel generative design framework for automated on-site haul road layout generation in modular construction. Besides, the evaluation strategy takes into account both visual and layout-based metrics, ensuring a reliable assessment of design quality. By integrating a pre-trained Stable Diffusion backbone with LoRA-based domain adaptation and ControlNet-based geometric constraint control, the proposed method enables the efficient generation of feasible and high-quality haul road layouts under complex site conditions. The generated layouts of MiCRoadDiff form relatively complete site plans with high image quality and clarity, satisfying the prescribed design conditions and are engineering feasible. Experiments also highlight the significant contribution of LoRA to generation quality. Removing the LoRA module results in a significant decline in performance, with FID, SSIM, and PSNR dropping by 272%, 50%, and 18%, respectively. Meanwhile, ControlNet ensures the controllability of the design process, maintaining its reliability and precision. The experimental results demonstrate that MiCRoadDiff can robustly adapt to varying site conditions such as different site gate locations and truck parking areas. The proposed framework significantly reduces the manual effort required for haul road design while maintaining strong engineering feasibility. Future work will focus on extending the proposed framework to more complex construction scenarios, including larger-scale sites and irregular geometries, as well as incorporating road structural properties such as pavement strength classes. In addition, the influence of parametric variations in textual design conditions on generation outcomes will be systematically investigated. Integrating the generated haul road layouts with Building Information Modeling (BIM) platforms or professional traffic and road simulation tools provides a promising direction, which could further support engineers in preliminary design

evaluation and feasibility analysis.

Abstract –

Off-site construction offers significant potential to improve productivity and quality in the Architecture, Engineering, and Construction (AEC) industry; however, the practical adoption of Design for Manufacturing and Assembly (DfMA) remains limited due to the lack of explicit integration between product-focused Building Information Modeling (BIM) data and construction process knowledge. While BIM provides detailed geometric representations, assembly logic and process-related information are not explicitly expressed.

This paper proposes a BIM-based ontology framework for semantic knowledge representation in Light Gauge Steel (LGS) panel assembly. A BIM model is developed and exported to Industry Foundation Classes (IFC) format. Relevant component and geometric attributes are selectively extracted using IfcOpenShell and mapped to ontology individuals implemented in a semantic web-based ontology editor that supports formal knowledge modeling and reasoning. Product components and their connection relationships are explicitly modeled, and a connection-based reasoning approach is adopted to infer assembly operations, enabling a clearer linkage between BIM-derived product information and DfMA-oriented process knowledge.

BIM; Ontology; DfMA; Off-Site Construction; Light Gauge Steel

1 Introduction

1.1 Off-Site Construction

Off-Site Construction (OSC) refers to the manufacturing prefabricated building components in a factory or controlled facility, where elements are produced off-site under controlled conditions and then transported to the construction site for final assembly [1]. OSC has gained notable attention for its ability to address several limitations of traditional on-site construction. Major advantages include alleviating skilled labor shortages, shortening project timelines and reducing cost fluctuations, decreasing construction waste, employing environmentally friendly methods, and enhancing quality through controlled factory environments [2]. Although OSC offers several benefits, its adoption presents several challenges. Wuni and Shen [3] identified key obstacles in implementing OSC through literature reviews and categorized them into eight groups, including technical barriers related to design information management and constructability.

1.2 Role of Building Information Modeling (BIM)

Building Information Modeling (BIM) is defined in ISO 19650-1:2018 as the use of a shared digital representation of a built asset to facilitate design, construction and operation processes to form a reliable basis for decisions [4]. In practice, BIM acts as a digital model that supports planning, design, construction, and operation across the entire project lifecycle [5]. Consequently, BIM has proven to enhance decision-making in the architecture, engineering, and construction (AEC) industry by improving work efficiency, reducing modeling rework, and minimizing the repeated collection of building data for different analytical uses.

However, implementing BIM in construction practice still presents several limitations. In particular, extracting construction quantities and procedures from BIM design models requires specialized technical expertise and dedicated tools. This limitation arises because product and process information are typically structured using different schemas and classification systems: BIM product information is commonly represented using the Industry Foundation Classes (IFC) schema, whereas construction process information is usually organized according to material- and method-based classification systems employed in construction planning and management. BIM models represented using the IFC

schema describe buildings as assemblies of parametric objects with associated properties, while construction process models are structured as collections of activities organized by these classification systems [6]. This misalignment hampers the direct use of BIM data represented in IFC format for construction planning and execution, emphasizing the need to improve interoperability and integration between product and process information.

1.3 Ontologies for Knowledge Representation

Ontology is a formal approach to knowledge modeling that explicitly defines domain concepts and their relationships. An ontological model consists of classes, properties, and relationships [6][7]. In an ontology, classes represent domain concepts, properties describe their features, and relationships indicate connections among different concepts, enabling a clear and intuitive representation of complex information.

Ontologies enable custom, user-defined relationships among classes. They also allow for the explicit definition of semantic features such as symmetry, transitivity, and inversion of relationships. Based on formal logic, ontologies support automated reasoning and inference, which helps derive new knowledge and identify inconsistencies without requiring all information to be explicitly modeled [7]. Although BIM data represented in IFC can include custom property sets and attributes to describe information structures, the IFC schema itself does not provide ontology-level semantics, such as axioms and logical relationships that enable reasoning. Consequently, IFC can describe data and its structure but cannot infer new knowledge from existing relationships, whereas ontology-based representations can. This capability reduces the amount of data that must be extracted from BIM, as additional information can be inferred from existing data, and it enhances semantic interoperability by providing a shared conceptual framework through which BIM and construction-related information can be consistently integrated.

Ontology-based approaches have been successfully applied in construction to support construction-oriented quantity take-off [5], IFC-based cost modeling [8], automated verification of quality control specifications for off-site manufactured components [9], and formal representation of space and task-related constraints to enhance lean construction planning and execution control in steel fabrication projects [10]. These applications demonstrate the capacity of ontologies to structure domain knowledge and improve interoperability in BIM-driven workflows.

Beyond the construction domain, ontologies have been widely adopted to model complex cyber-physical and intelligent systems, including smart homes, smart farms, smart factories, and other Industry 4.0 environments. In these contexts, ontologies are often combined with machine learning and deep learning techniques to address interoperability challenges, support system monitoring and control, enable digital twin representations, and optimize design and operational parameters for improved performance and reduce cost [11]. This capability is particularly relevant for off-site construction, where design information, manufacturing constraints, and assembly knowledge must be systematically linked to support informed decision-making.

1.4 Design for Manufacturing and Assembly (DfMA)

Design for Manufacturing and Assembly (DfMA) is a structured design approach that incorporates manufacturing and assembly considerations early in the design process to enhance constructability, productivity, and overall project performance. In off-site construction, DfMA plays a vital role by facilitating the design of prefabricated components optimized for factory production and efficient on-site assembly [12]. Past research shows that DfMA helps reduce construction time, cut material waste, improve quality control, and boost coordination between design and construction teams [7][12]. These advantages are especially important for prefabricated systems like Light Gauge Steel (LGS) panel assemblies, where manufacturing efficiency and assembly sequencing directly influence project results.

However, the practical application of DfMA is limited by the absence of a structured and explicit way to represent manufacturability and constructability knowledge during the design process. DfMA-focused decision-making needs detailed information about component geometry, connection types, assembly logic, and construction procedures. Although BIM provides a detailed, product-centered view of building components, it does not explicitly include construction processes or assembly information needed to support DfMA-based analysis fully [6]. Several researchers have highlighted the importance of supplementing BIM with knowledge-based approaches to facilitate the integration of product and process information for prefabricated construction [6][7]. Ontology-based modeling has been recognized as an effective way to formally represent construction knowledge, establish relationships between components and processes, and enable semantic reasoning to support advanced analysis and automation [7].

In this context, this paper proposes a BIM-based ontology framework for the semantic representation of product and process knowledge in Light Gauge Steel (LGS) panel assembly. The proposed framework acts as a crucial step toward enabling DfMA-oriented analysis by connecting BIM-derived product information with construction process knowledge.

2 Related Work

Ontology-based approaches are increasingly used in the AEC industry to improve the semantic representation and use of BIM data for construction-related applications. Current studies show that ontologies can support decision-making, automate validation tasks, and enhance information sharing across different stages of the construction process, as well as exploring the use of ontologies to support Design for Manufacturing and Assembly (DfMA) in prefabricated construction. Qi and Costin introduced a BIM and ontology-based DfMA framework to help verify manufacturability and constructability requirements for prefabricated components [7]. Their work focused on representing stakeholders' needs and constraints with an ontology to enable automated checking and feedback during the design phase. This highlights the role of ontology in formalizing DfMA knowledge and improving design validation for prefabrication. Ontology-based methods have also been applied to construction-focused quantity take-off (QTO). Liu et al. created a semantic approach that combines BIM and ontology to support QTO in the light-frame building industry [5]. Their work shows how ontology can connect BIM product models with construction process information, allowing for accurate quantity extraction through semantic queries. Additionally, ontologies have been used to extend IFC-based representations for cost-related applications. Isatto proposed an IFC ontology to support process-based cost modeling, emphasizing the semantic representation of construction processes and their costs [8]. This work demonstrates the potential of IFC-based ontologies to improve interoperability and enable analysis linking product, process, and cost information.

More recently, ontology-based decision support systems have been developed to assess manufacturability in prefabricated framing systems. An et al. [13] presented a BIM-based decision support system for automated manufacturability checking of wood frame assemblies. Their system integrates BIM data input, geometric feature detection, ontology formulation, and machine eligibility determination to evaluate whether a given frame assembly can be manufactured using specific machinery. This study represents an important step toward linking BIM-derived product information with manufacturing constraints and operational feasibility.

Despite these advances, existing ontology-based approaches in the AEC industry generally focus on specific applications or isolated aspects of the construction process. While Qi and Costin [7] emphasize DfMA requirement validation, Liu et al. [5] concentrate on construction QTO, Isatto [8] addresses cost modeling, and An et al. [13] focus on manufacturability assessment for wood frame systems, these studies tend to treat product, process, and operational knowledge separately. Furthermore, limited attention has been given to explicitly linking BIM-based product geometry, component-level connection types, and the corresponding fabrication or assembly operations required for prefabricated systems. There remains a need for an integrated ontology framework that connects BIM-based product information with DfMA-oriented process knowledge, particularly for Light Gauge Steel (LGS) panel assemblies. This paper addresses this gap by proposing a BIM-based ontology framework that represents LGS components and their connections and associates them with fabrication and assembly operations, establishing a semantic foundation for knowledge representation and reasoning in prefabricated LGS construction.

3 Methodology

3.1 Overall Approach

The proposed framework creates a structured process for integrating BIM with ontology-based knowledge representation to support the semantic modeling of LGS panel assembly. It is an essential step toward DfMA-oriented analysis by systematically linking product information from BIM models with process-related construction knowledge.

The workflow starts with developing a BIM model of an LGS wall panel using Autodesk Revit. This BIM model serves as the main source of digital product information, including structural components like studs, tracks, and fasteners, along with their parametric and geometric properties. Simultaneously, a domain-specific ontology is defined using Protégé to represent relevant product and process knowledge, such as component classifications, geometric attributes, connection types, and assembly operations.

Next, the BIM model is exported from Revit to the IFC format to enable open and standardized data exchange. The IFC file is validated with BIMVision to check schema compliance and ensure accurate representation of building elements. IFC acts as an intermediary schema to facilitate interoperability and automated access to BIM data across various software platforms [2].

Relevant BIM attributes are then extracted from the IFC file using a Python-based workflow with IfcOpenShell. This tool allows computational access to IFC entities and their properties, enabling the extraction of attributes necessary for manufacturability and constructability, such as component identifiers, classifications, and geometric data [13]. The extracted information is organized to support subsequent semantic mapping and reasoning.

After data extraction, the BIM information is mapped

to ontology individuals and properties. Each LGS element becomes an individual in the ontology within Protégé, linked to relevant classes and data properties, resulting in an ontology-enhanced BIM that explicitly captures product semantics.

Connections between components are modeled explicitly in the ontology and used as a basis for linking product elements with construction processes [13]. In this approach, connections rather than component types are used to associate assembly operations. By formally representing these connection relationships within the ontology, the proposed framework builds upon the geometric and relational information available in the IFC schema and extends it with semantic constructs that enable process inference. While IFC can represent component geometry and basic relationships, it does not natively support the logical rules required to derive construction operations from connection types. The ontology, therefore, introduces a semantic layer that enhances the expressive capability of IFC to support the DfMA-oriented assembly use case presented in this study.

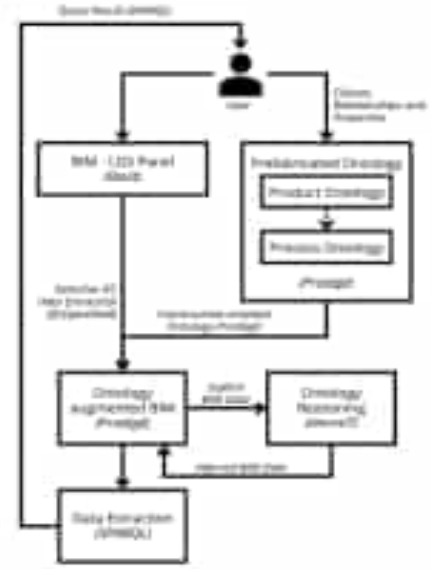

Figure 1. Overview of proposed methodology

Ontology-based reasoning is performed using the HermiT reasoner to ensure logical consistency and to infer implicit knowledge from formally defined class restrictions and object property relationships. Assembly operations are inferred through predefined axioms that associate specific connection types with corresponding construction activities; when the required semantic conditions are satisfied, individuals are automatically classified into the appropriate operation classes. This reasoning process enriches the ontology by generating product–process relationships that are not explicitly represented in the original BIM model. HermiT was selected due to its reliable support for OWL-based classification and instance reasoning, as well as its stable integration with the ontology development environment used in this study.

Finally, the populated and reasoned ontology facilitates semantic querying using the SPARQL Protocol and RDF Query Language to retrieve both explicit and inferred information related to LGS panel assembly. The query results support validation and analysis of product-process relationships and provide a structured semantic representation that can enable future developments in automated assembly planning and BIM-ontology interoperability.

3.2 Ontology Development

The ontology development process adopted in this paper follows established methodologies reported in the literature [12]. The major steps are summarized as follows:

1. Determine the purpose and scope of the ontology.

The purpose of the proposed ontology is to support BIM-based information modeling for DfMA-oriented fabrication. The scope of the ontology includes all information related to light-gauge steel panel components and their associated fabrication and assembly processes.

2. Review existing ontology.

The ontology for manufacturability and constructability of prefabricated components proposed by Qi et al. [12] is used as a reference to extract and structure product-related information from the BIM model. The shared ontology is adapted and simplified to focus on the relevant concepts needed for light gauge steel panel components. Additionally, the ontology-based knowledge modeling approach for frame assemblies proposed by An et al. [13] is reviewed to help guide the representation of relationships between product and process knowledge.

3. Enumerate main classes and build the corresponding class hierarchy.

Product-related knowledge is broken down from the product level to geometry and connection types, while process-related knowledge is shown through operation classes.

4. Construct a machine-readable ontology.

The ontology is implemented using the Protégé platform, where classes, properties, and relationships are formally defined.

Figure 2. Core ontology classes

3.2.1 Product Ontology

The product ontology describes the physical components and attributes of an LGS panel assembly. Structural elements such as studs, tracks, joists, noggings, and fasteners are modeled as subclasses of a general Structural_element class. Each component is represented as an ontology individual derived from BIM data and linked to relevant geometric and identification attributes. Geometric details, including length, height, width, thickness, and cross-sectional area, are represented through data properties and populated with values extracted from the BIM model.

In addition, component relationships are explicitly modeled through connection types (e.g., perpendicular, lateral, angled), allowing the representation of assembly logic between elements. This structured representation enables product information to be interpreted beyond purely geometric descriptions and establishes a semantic foundation for linking product and process knowledge.

It is important to note that the product ontology presented in this study represents the first iteration of the proposed framework. Further refinement and extension of the ontology structure are planned through expert feedback, validation exercises, and additional case studies to improve coverage, consistency, and applicability to broader prefabricated construction scenarios.

Figure 3. Product class hierarchy.

3.2.2 Process Ontology

The process ontology describes construction and assembly operations related to LGS panel fabrication and installation. Assembly procedures are modeled as subclasses of a general Operation class, representing actions such as positioning, aligning, and screwing.

The proposed framework adopts a connection-based modeling strategy in which assembly operations are inferred from the type of connection established between components, rather than being directly assigned to component categories. Connection types are explicitly represented in the ontology and semantically linked to corresponding fabrication or assembly operations through predefined relationships and logical restrictions.

By structuring process assignment around connection semantics, the framework enables a more precise representation of product–process relationships derived from BIM data. This approach supports DfMA-oriented reasoning by translating geometric and relational information into construction-relevant operations through formal semantic rules.

Figure 4. Process class hierarchy.

Figure 5. Object Property requiresOperation.

3.3 BIM to Ontology Mapping

The BIM-to-ontology mapping establishes a semantic link between the BIM design model and the ontology-based knowledge representation, following the ontology-driven mapping approach proposed by An et al. [13]. The LGS panel developed in Autodesk Revit is exported to Industry Foundation Classes (IFC) format as an intermediate schema for interoperable exchange. Rather than mapping the full IFC schema, only BIM attributes relevant to prefabrication and assembly are selectively extracted, consistent with the strategy in [13].

IfcOpenShell is employed to parse the IFC file and retrieve component-level data, including identifiers and geometric properties of LGS elements. The product data extraction process is based on IFC entities and property sets that represent structural components and their geometric information. Structural members are primarily retrieved from entities such as *IfcMember*, while geometric representations are accessed through shape information associated with the IFC product representation and processed using ifcopenshell.geom. Element placement and orientation are derived from local

placement information, and element attributes are accessed through property sets using IfcOpenShell utilities such as ifcopenshell.util.element.get_psets, including BaseQuantities and Identity Data, which provide dimensional and identification information. The overall implementation is carried out through the following steps:

1. Product data extraction:

A Python-based script automatically extracts element identifiers (GlobalId), semantic roles, and dimensional attributes from IFC entities and property sets using IfcOpenShell.

2. Connection detection and classification:

Geometric information derived from the IFC model is used to automatically detect potential connections between structural members using a tolerance-based proximity (AABB) method. Each detected interaction is classified into a predefined connection type (e.g., Perpendicular, Lateral, Angled) based on geometric overlap and angular relationships.

3. Ontology instantiation:

The extracted elements and classified connections are automatically transformed into RDF triples. Each component is instantiated as an ontology individual and linked to predefined classes and data properties, while connection instances are created to explicitly relate connected elements and assign their corresponding connection types. Connections between components are explicitly represented in the ontology and used to link product elements with construction operations defined in the process ontology. This connection-based mapping separates process definitions from specific component types, allowing flexible reasoning over assembly operations. Through this mapping process, BIM data are converted into structured semantic knowledge, forming the basis for ontology-based reasoning and querying in subsequent stages.

4 Validation and Results: A Case Study

A Light Gauge Steel (LGS) wall panel is selected as the case study to demonstrate the applicability of the proposed BIM-based ontology framework. The panel represents a typical prefabricated wall assembly composed of studs, tracks, and fasteners commonly used in off-site construction.

The LGS panel is modeled in Autodesk Revit using parametric definitions for its structural components. The BIM model captures geometric dimensions, spatial configuration, and connection arrangements relevant to panel fabrication and assembly. The model is exported to IFC format and processed through the proposed BIM-to-ontology mapping pipeline. Figure 6 presents the three-dimensional representation of the LGS panel used in this study.

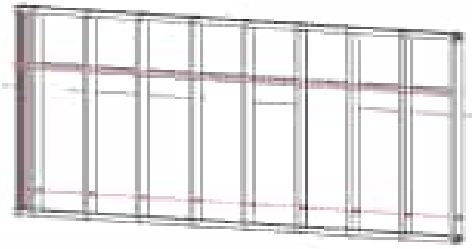

Figure 6. LGS panel case study

Through the mapping process, BIM-derived product information is transformed into a semantically structured ontology populated with both product and process knowledge. A total of 144 structural elements were extracted from the IFC model and mapped directly into ontology individuals. Each element corresponds to one ontology individual and is enriched with geometric and identification attributes derived from IFC property sets. Among these, a subset of primary structural members was considered for connection detection, including 10 studs, 2 tracks, and 2 straps. For the purpose of connection detection and process inference, only load-bearing members (i.e., studs and tracks) were used, while secondary elements such as straps were excluded from the connection detection stage.

By formalizing these relationships, the framework establishes an explicit and machine-interpretable link between product geometry and construction processes. This connection-based semantic modeling enables BIM-derived product information to be systematically translated into DfMA-oriented assembly knowledge, thereby supporting more integrated and construction-aware decision-making.

The ontology is evaluated using four validation metrics adapted from prior ontology-based studies [14]: competency, consistency, completeness, and clarity. The adopted evaluation structure is summarized in Table 1.

Table 1. Validation metrics and approaches implemented

Metrics	Approach	Tool
Competency	Competency questions	Case study + SPARQL queries
Consistency	Automated consistency checking	HermiT and Pellet reasoners
Completeness	SPARQL query	SPARQL query engine
Clarity	Structural modeling review	OOPS! (Ontology Pitfall Scanner)

4.1 Competency

Three competency questions were defined based on the purpose and scope of supporting BIM-based modeling for DfMA-oriented LGS fabrication:

1. Can the ontology retrieve geometric and identification attributes of LGS components extracted from BIM?
2. Can the ontology explicitly represent and classify connection relationships between structural elements?
3. Can the ontology infer appropriate assembly operations based on identified connection types?

The proposed ontology successfully answered all three questions. The developed ontology includes 30 classes, 6 object properties, and 22 data properties. Through the BIM-to-ontology mapping process, 144 structural component instances were automatically generated from the IFC model. Geometric attributes (e.g., length, thickness, positional data) were successfully assigned to each individual. The AABB-based geometric detection identified 20 connection instances, which were classified into predefined connection types (e.g., Crossing, Perpendicular, Lateral, Angled, Double_Angled).

To validate inference capability (Competency Question 3), the SPARQL query in Figure 7 was executed.

Figure 7. SPARQL query for validation

The query successfully retrieved connection instances, associated elements, classified connection types, and inferred assembly operations. A total of 20 operation instances were inferred automatically through ontology reasoning without manually assigning operations to specific component categories. These results confirm that assembly operations are derived semantically from connection relationships rather than explicitly encoded within the BIM model.

4.2 Consistency

Logical consistency and classification were verified using both the HermiT and Pellet reasoners. Automated reasoning confirmed the validity of class hierarchies, object property restrictions, and inference rules linking connection types to operations. The ontology was processed in 0.388 seconds using HermiT (v1.4.3.456) and 0.411 seconds using Pellet, demonstrating computational feasibility for the case study scale. No logical inconsistencies were detected.

4.3 Completeness

Completeness was evaluated through SPARQL-based query testing against the defined competency questions. Queries successfully retrieved:

- All structural component individuals and their geometric attributes.
- All detected connection instances and their classified types.
- All inferred assembly operations associated with each connection type.

The successful retrieval of expected results demonstrates that the ontology sufficiently covers the defined product and process scope.

4.4 Clarity

Clarity was evaluated through structural inspection of class hierarchies, object property definitions, and naming conventions. The ontology maintains a clear separation between product, connection, and process concepts while preserving semantic coherence. Additionally, the ontology was analyzed using the OOPS! (Ontology Pitfall Scanner) tool. The evaluation reported no critical errors and only minor warnings, indicating acceptable modeling quality for this first implementation.

4.5 Interpretation

The case study confirms that the proposed framework establishes an explicit, machine-interpretable link between product geometry and construction processes. By associating assembly operations with connection types rather than component categories, the framework addresses the research problem of integrating product-oriented BIM data with process-oriented DfMA knowledge. Although this implementation represents the first iteration of the framework, the validation results demonstrate its feasibility, logical soundness, and reasoning capability. Future work will focus on incorporating expert feedback, expanding case studies, and enhancing automation of connection recognition to further strengthen the ontology model.

5 Conclusion and Future Work

This paper introduced a BIM-based ontology framework for semantic knowledge representation in LGS panel assembly. The proposed approach combines

BIM-derived product data with ontology-based process knowledge to support DfMA-oriented analysis in off-site construction. Using IFC-based data extraction, ontology modeling, and reasoning, the framework allows for structured representation and inference of assembly-related information. The case study demonstrated the feasibility of mapping BIM elements to ontology individuals, enriching them with geometric attributes, and associating construction operations through a connection-based reasoning approach. The results confirm that the proposed framework can bridge the gap between product-centric BIM models and process-oriented construction knowledge.

Future work will focus on extending the proposed ontology framework to incorporate formal constraint modeling beyond product–process relationships. Ontology-based approaches have demonstrated strong potential for representing quality control requirements, manufacturing constraints, regulatory specifications, and task-level planning rules within BIM-driven workflows. Building on this direction, future developments of the framework will investigate the integration of design standards, regulatory requirements, and task-level constraints into the ontology, enabling automated compliance checking and enhanced decision support during LGS panel design and assembly planning. This extension will further strengthen the ontology as a knowledge base for DfMA-oriented optimization and constraint-aware design in prefabricated construction.

Acknowledgments

This study has been supported by the Construction Sector Digitalization and Productivity (CSDP) program under the project "NRCC CSTIP CSDP-018-1 – BIM-Integrated Multi-Robot Platform for Customized and Sustainable Offsite Construction Manufacturing". The authors would like to extend their sincere gratitude to all the stakeholders who participated in this research and contributed to the findings presented in this paper.

Abstract

Deep learning-based computer vision in construction has often assumed that more training data leads to better performance. This quantity-driven approach overlooks the detrimental effects of redundant, noisy, or mislabeled samples that can degrade model accuracy while inflating computational costs. To overcome this limitation, we propose and test an alternative hypothesis: selectively removing low-quality training samples can outperform indiscriminate use of all data. Specifically, we present a reinforcement learning (RL)-powered data quality evaluation framework that scores individual training images and prioritizes the most beneficial samples for model learning. Within a unified environment, the RL agent (referred to as the RL-evaluator) interacts with an object detector by probabilistically selecting subsets of high-quality samples for model training and using validation performance as a reward signal to optimize its selection policy. Experiments on a construction benchmark dataset of varying sizes show that removing low-quality samples identified by the RL-evaluator consistently improves detection performance compared to training on the full dataset, while also reducing computational overhead. These findings demonstrate the proposed method as a scalable and robust way for enhancing computer vision in construction.

Construction; Computer Vision; Reinforcement Learning; Data Quantity; Data Quality

1 Introduction

Deep learning-based computer vision has emerged as a key driver in the construction industry's shift toward digital project delivery and robotic automation. Instead of relying on manual site monitoring, which is often inconsistent and labor-intensive, automated computer vision systems can systematically interpret large volumes of visual data with greater speed and reliability. Such capabilities make it possible to detect and track resources [1], analyze ongoing activities [2], and identify operational irregularities [3], thereby supporting practical needs such as safety management [4], progress monitoring [5], and efficiency optimization [6]. Computer vision also provides the perceptual input required for robotics, equipping autonomous machines with spatial awareness and adaptability in unstructured environments. This connection between visual perception and autonomous operation further contributes to the development of digital twins, which integrate physical processes with virtual models. Taken collectively, these advances signify not only incremental improvements in construction monitoring and control but also a redefinition of construction practice toward intelligent, automated, and fully digitalized production systems.

Although computer vision in construction has advanced rapidly, much of the progress is based on the widely accepted hypothesis that larger datasets lead to better model performance [7]. This reliance on sheer data quantity has led to massive image collections covering a wide range of objects, activities, and site conditions, thereby enabling state-of-the-art benchmarks. However, model performance depends not only on dataset size but also on the quality of individual training samples. Redundant, noisy, and mislabeled data can introduce bias, slow or even prevent convergence, and even reduce accuracy. Meanwhile, data redundancy imposes heavy computational and storage demands. We therefore advance an alternative hypothesis: excluding some low-quality or harmful data may lead to superior results compared with using the full dataset. Despite its intuitive appeal, this hypothesis has rarely been systematically tested for computer vision in construction. Existing methods—such as leave-one-out and Shapley-based evaluation—are computationally prohibitive for high-

dimensional visual tasks, while active learning techniques typically rely on uncertainty measures, which do not directly reflect how each sample influences the learning dynamics or final model accuracy. As a result, the lack of scalable and reliable data quality evaluation strategies continues to constrain further improvements in the field.

To investigate our hypothesis, we present an RL-powered framework that evaluates the quality of individual training images and prioritizes those most valuable for model learning, while discarding samples deemed harmful or redundant. In this setup, the RL agent—referred to as the RL-evaluator and a computer vision model are embedded in an RL training environment. The RL-evaluator assigns quality scores (potential contributions for shaping model performance) to individual images and stochastically selects subsets of high-quality samples, which are then used to update the computer vision model. The model performance on a validation dataset is then used to provide the reward signal for refining the evaluator's policy. Through these repeated interactions, the RL-evaluator progressively learns a policy that guides sample selection toward improved model accuracy and data efficiency. We validate this framework on the Moving Objects in Construction Sites (MOCS) [7] dataset of different scales. We design and compare model performance using the following data curation strategies: (i) full data, (ii) low-quality removal, (iii) high-quality removal, and (iv) random removal. As an initial attempt, our experiments focus on worker detection, a fundamental and well-represented task in construction, allowing detailed investigation of the proposed framework.

This work contributes to advancing computer vision in construction in three aspects. First, we present an RL-powered framework for object detection tasks, where the training of a detection model is jointly integrated with the RL evaluator to enable fine-grained assessment of individual training samples. Second, we challenge the prevailing belief that larger datasets yield better model performance and instead demonstrate that removing low-quality samples identified by the RL evaluator can improve detection accuracy while reducing computational cost. Third, we show that the framework achieves consistent and reliable data quality evaluation under different construction benchmark dataset sizes, highlighting its robustness and adaptability. Collectively, these contributions lay the groundwork for more data-efficient and effective computer vision model deployment in dynamic and complex construction environments.

2 Data Quality Evaluation in the AI and Construction Domains

While extensive efforts have focused on enlarging datasets to enhance computer vision model performance, such quantity-oriented strategies often overlook the quality of individual samples, leading to redundant or noisy data that undermines model efficacy and efficiency. Consequently, there is a pressing need to shift focus from mere volume to data quality. However, unlike evaluating an entire dataset—which is straightforward via aggregate metrics—assessing the actual contribution of a single training sample remains a complex challenge.

One foundational strategy for isolating the specific contribution of a training sample is the Leave-One-Out (LOO) method. Conceptually, LOO operates on a perturbation principle: it quantifies the value of a datum by excluding it from the training set, retraining the model from scratch, and measuring the resultant shift in test performance. A notable degradation in accuracy signals that the omitted sample contained unique and valuable information. However, since the computational cost of literal retraining for every sample is prohibitive, Koh and Liang [8] addressed this bottleneck by proposing the use of influence functions. By differentiating through the model's training parameters, they derived a closed-form approximation that estimates how upweighting or perturbing a specific point would affect model parameters and loss, all without the need for actual retraining. This technique has proven instrumental for diagnostic applications, such as debugging domain mismatches, explaining model behavior, and detecting mislabeled examples. Yet, despite its rigorous theoretical basis, the computational complexity of calculating Hessian-vector products remains a barrier for large-scale datasets and deep architectures [9]. Furthermore, LOO suffers from a structural deficiency known as the "masking effect": in the presence of redundant or correlated data, it tends to assign near-zero value to individual samples because removing a single instance rarely impacts global performance, thus failing to recognize their collective importance [10].

To capture these complex interactions between data points, a parallel line of research leverages the Shapley value, a solution concept originally derived from cooperative game theory [11]. While originally utilized for interpreting supervised models and performing feature attribution, this framework has been systematically extended to the realm of data valuation. Spearheading this adaptation, Ghorbani and Zou [12] modeled the training process as a cooperative game where data points act as players working together to maximize model performance. To overcome the combinatorial explosion inherent in exact Shapley value calculations, they introduced a truncated Monte Carlo sampling strategy (TMC-Shapley). This stochastic

approximation method renders the evaluation computationally feasible by estimating marginal contributions over a subset of permutations rather than the full space. However, even with such algorithmic optimizations, the computational burden remains substantial, particularly when scaling to massive computer vision datasets [13]. Moreover, a critical limitation of both Shapley-based and influence function approaches is their static nature; they typically evaluate sample importance as an offline process completely decoupled from the active training loop. This separation prevents the joint optimization of data valuation and model learning, which may lead to value estimates that are suboptimal for maximizing downstream task performance [9].

Beyond traditional greedy search methods, recent research has explored more adaptive strategies, most notably Active Learning. This paradigm prioritizes selecting the most informative unlabeled samples for annotation, typically guided by uncertainty or entropy metrics. In the construction domain, such techniques have proven effective for minimizing labeling effort; for instance, Kim et al. [14] developed a deep active learning framework that significantly reduced the data requirements for object detection by automatically querying meaningful images. However, active learning relies heavily on heuristics that often lack robustness in complex visual conditions [15]. More critically, its primary objective is to acquire labels for newly collected data rather than to retrospectively identify and remove harmful samples from existing datasets. Consequently, it falls short in unlocking the full potential of models trained on noisy or redundant data [16].

To bridge these gaps, Reinforcement Learning (RL) has emerged as a promising avenue, offering the ability to model fine-grained data valuation through dynamic trial-and-error interactions. Yoon et al. [17] pioneered this direction with Data Valuation using Reinforcement Learning (DVRL), a framework that employs the REINFORCE algorithm to learn probabilistic weights for training samples. Unlike LOO and Shapley value, DVRL's computational complexity does not scale directly with dataset size, making it highly scalable for large-scale applications. Building on this, Batanero et al. [9] introduced RLBoost, a trajectory-free approach leveraging Proximal Policy Optimization (PPO). By integrating the valuation process directly into the supervised training loop, RLBoost achieves superior evaluation performance compared to both traditional methods and DVRL, demonstrating the potential of RL for joint data-model optimization.

Despite these advancements, a critical methodological gap remains: existing RL-based data quality evaluation methods [9,17] are predominantly limited to simpler tasks such as classification or regression. Extending these frameworks to object detection is not a trivial adaptation; unlike prior methods that rely on simple classification accuracy, it requires redefining the RL reward formulation and state representations to handle significantly higher-dimensional outputs, intricate architectures, and heightened sensitivity to visual noise. This challenge is particularly acute in the construction domain, where data is inherently diverse and prone to redundancy. Moreover, the robustness of these methods under varying dataset scales and diverse visual contexts has not been rigorously examined, leaving their scalability and generalization capabilities unverified. To bridge these gaps, we propose an RL-powered data quality evaluation and sampling framework explicitly designed for object detection within construction environments. We systematically investigate its effectiveness on a representative benchmark dataset of differing sizes and characteristics. Uniquely, our approach involves the joint optimization of an RL-evaluator and a visual detector within a unified RL environment. We then conduct controlled data curation experiments to benchmark the detection performance of models trained on these selectively curated data subsets.

3 RL-powered Data Quality Evaluation Framework

3.1 Problem Definition

The overall workflow of the proposed framework is illustrated in Figure 1. It integrates two learnable components: (i) an object detector $f(;,\omega)$ and (ii) the RL-evaluator $h(;,\theta)$, trained within a unified environment. The RL-evaluator interacts with the detector by a closed feedback loop, generating quality scores for training samples, selecting subsets for model updates, and refining its policy based on the reward signal derived from the model's validation performance. Through this iterative feedback, the RL-evaluator gradually refines its scoring policy to emphasize informative samples and down-weight noisy or harmful ones, thereby enhancing the detector's performance.

Formally, we denote the training dataset as $D = \{(x_i, y_i)\}_{i=1}^{N}$, where x_i is an input image and y_i is its corresponding annotation set. Each annotation consists of n_i object instances, i.e., $y_i = \{b_i^{(1)}, b_i^{(2)}, \dots, b_i^{(n_i)}\}$. Each object instance $b_i^{(j)}$ is represented as a 5-dimensional vector (c, c_x, c_y, w, h), where $c \in \{1, \dots, C\}$ is the class ID and $(c_x, c_y, w, h) \in [0,1]^4$ are the normalized bounding-box coordinates. Model performance is finally evaluated on a test dataset $D^t = \{(x_i^t, y_i^t)\}_{i=1}^{M}$, while a validation dataset $D^v = \{(x_i^v, y_i^v)\}_{i=1}^{L}$, assumed to share the same distribution as the test set, is used both to monitor performance during training and to provide

feedback to the RL-evaluator.

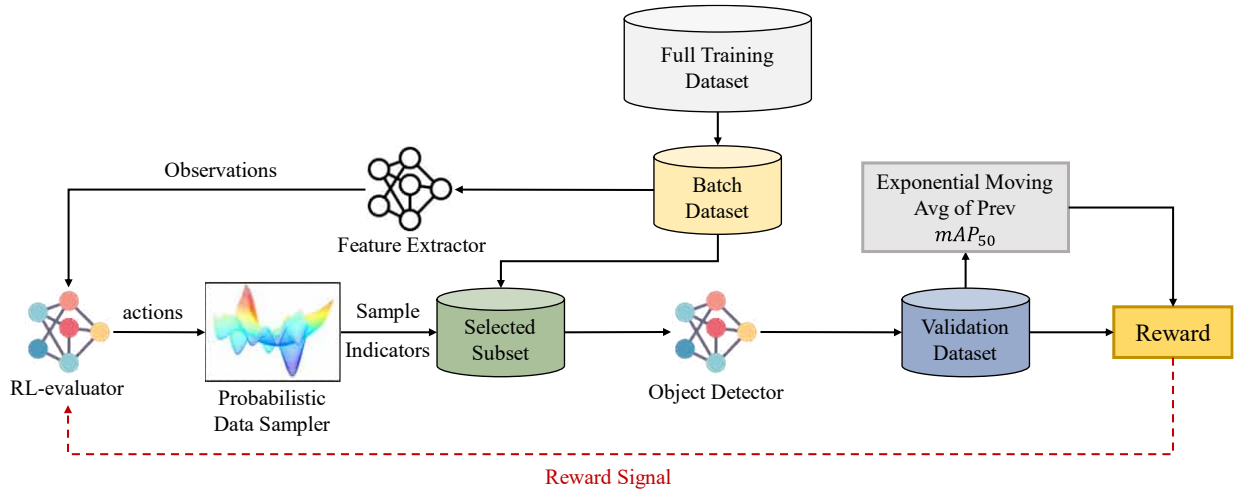

Figure 1. The overall workflow of the RL-powered data quality evaluation framework

In each training epoch, a mini batch $D^b = \{(x_i^b, y_i^b)\}_{i=1}^{B_s} \subset D$ is randomly sampled and passed to the RL-evaluator. The RL-evaluator generates quality score (i.e., selection probability) for each image, estimating its contribution to improving detection performance. A subset $S = \{(x_i^s, y_i^s)\}_{i=1}^{n} \subset D^b$ is then drawn according to these probabilities and used to update the object detector $f(;,\omega)$. The updated model is evaluated on the validation dataset D^v, and the performance is converted into a reward signal that guides the update of the evaluator's policy $h(;,\theta)$.

3.2 RL Formulation

The data quality evaluation can be formulated as Markov Decision Process (MDP), where the RL-evaluator interacts with an environment comprising the detector $f(;,\omega)$, the training data, and the reward derivation process. A standard MDP $(\mathcal{S}, \mathcal{A}, \mathcal{P}, \mathcal{R}, \gamma, T)$ involves observing a state $s \in \mathcal{S}$, taking an action $a \in \mathcal{A}$ according to the policy $\pi_\theta(a|s)$, and receiving a reward signal $\mathcal{R}$. In this study, we adopt a contextual bandit setting [18], where the evaluator assigns selection probabilities to samples within each mini-batch and receives immediate rewards from validation performance. As a result, the state transition $\mathcal{P}$, time horizon T, and discount factor γ are not relevant and are excluded from the formulation. In the following, we detail the definitions of state, action, and reward under this bandit MDP setting.

3.2.1 State

Each sample state s is its image-level feature embedding extracted via a ResNet50 [19] pretrained on ImageNet. Using features instead of raw pixels reduces input dimensionality, improves efficiency, and provides semantically rich, task-agnostic representations that enhance generalizability.

3.2.2 Action

For a sample (x_i, y_i) with state s_i, the evaluator outputs a probability $p_i = h_\theta(s_i) \in [0,1]$, which is then passed to a probabilistic data sampler characterized by a Bernoulli distribution to decide selection z_i : $z_i \sim Bernoulli(p_i)$, where $z_i \in \{0,1\}$. Here, $z_i = 1$ means the sample is chosen for training the detector, while $z_i = 0$ excludes it. Since this action directly determines the sampling behavior, the probability p_i serves as a proxy for data quality.

3.2.3 Reward

The reward signal measures the benefit of selected samples by evaluating detection accuracy on the validation set. We use mAP_{50} as the performance metric, and define the reward at iteration t as the difference between current mAP_{50} and the exponential moving average (EMA) of past values:

$$\mathcal{R}_t = mAP_{50_t} - EMA_{t-1} \quad (1)$$

$$EMA_t = \alpha \cdot mAP_{50_t} + (1-\alpha) \cdot EMA_{t-1} \quad (2)$$

where $\alpha \in (0,1)$ is the smoothing parameter for EMA.

3.3 Network Structures: Object Detector and RL-evaluator

The detector $f(;,\omega)$ can be any learnable object detection architecture. Specifically, $f(;,\omega): x_i^s \rightarrow y_i^s$ is

trained by minimizing the detection loss $\mathcal{L}_{det}$ on the selected subset S:

$$\omega \leftarrow \underset{\omega}{argmin} \frac{1}{n} \sum_{i=1}^{n} \mathcal{L}_{det}(f(x_i^s; \omega), y_i^s) \quad (3)$$

The RL-evaluator $h(;,\theta)$ is optimized using the PPO algorithm [20], which generally outperforms standard Policy Gradient methods such as REINFORCE. PPO offers two key advantages: (i) a clipping mechanism to prevent excessively large policy updates and (ii) advantage estimation to evaluate the relative benefit of actions. The evaluator follows an actor–critic paradigm: the actor $\pi_\theta(a|s)$ models the sampling policy, while the critic $V_\emptyset(s)$ estimates the expected return, yielding the advantage $A = \mathcal{R} - V_\emptyset(s)$. The actor is trained using the clipped surrogate loss:

$$\mathcal{L}^{clip}(\theta) = \mathbb{E}_{(s,a)}[min(r_\theta(a|s)A, clip(r_\theta(a|s), 1 - \epsilon, 1 + \epsilon)A)] \quad (4)$$

where $r_\theta = \frac{\pi_\theta(a|s)}{\pi_{\theta old}(a|s)}$ is the probability ratio between new and old policies, and ϵ is a clipping hyperparameter that bounds the update within $[1-\epsilon, 1+\epsilon]$.

The critic network is optimized by minimizing the squared value loss:

$$\mathcal{L}^v(\emptyset) = \|\mathcal{R} - V_\emptyset(s)\|^2 \quad (5)$$

Additionally, an entropy regularization term is introduced to encourage exploration:

$$S(\theta) = -\pi_\theta(a|s) log \pi_\theta(a|s) \quad (6)$$

The final PPO objective integrates all three components into a joint loss:

$$\mathcal{L}_{PPO}(\emptyset, \theta) = \mathcal{L}^{clip}(\theta) - c_1 \mathcal{L}^v(\emptyset) + c_2 S(\theta) \quad (7)$$

where c_1 and c_2 are hyperparameters that balance the critic and entropy terms.

This formulation enables joint optimization of the detector and RL-evaluator within the proposed framework, ensuring tight coupling between data selection and task performance.

4 Experiment, Results and Discussion

We conducted an experiment to address three knowledge gaps: (i) whether removing low-quality images can improve model performance compared to using the full dataset; (ii) whether RL-powered evaluation can extend to complex tasks like object detection in construction; and (iii) how robust such methods are under varying dataset sizes.

We focused on detecting human workers, given their prevalence and importance in construction safety and productivity monitoring. Experiments were performed on the MOCS dataset [7], a publicly available benchmark which contains worker annotations collected from diverse construction sites and is well suited for evaluating robustness under varying conditions. We first filtered images containing worker instances and constructed three subsets of different sizes (500, 5,000, and 10,000 instances) to represent small, medium, and large dataset sizes. Each subset was split into training and validation sets at a ratio of 8:2. In addition, an independent test set of 5,000 worker instances was built for consistent evaluation.

YOLO11 [21] was used as the detector, chosen for its balance of accuracy and efficiency. Batch sizes were scaled with dataset size—4, 8, and 16 images for the small (500 instances), medium (5,000 instances), and large (10,000 instances) sizes. Each epoch involved 30 inner updates to provide sufficient learning while ensuring timely feedback to the RL-evaluator. Default hyperparameters were used with a learning rate of 0.01.

The RL-evaluator was trained with PPO using a two-layer actor–critic network (64 units, ReLU activations). The actor's output was initialized at mean 0.5 with standard deviation $log(0.2)$. PPO used Adam with a learning rate of 1×10^{-4}, clipping ratio $\epsilon = 0.1$, and an EMA smoothing factor $\alpha = 0.05$. Regarding hyperparameter sensitivity, empirical tests indicated that a tight clipping ratio and a low EMA factor were crucial for maintaining stable convergence. Mini batch sizes B_s were 100, 200, and 400 for the small, medium, and large datasets, respectively. PPO training was run for 1,000 epochs, while all other hyperparameters followed standard defaults. The joint training of the RL-evaluator required approximately 48 hours on a single NVIDIA RTX 4090 GPU. To account for the stochastic nature of RL training, experiments were conducted across three independent runs for each dataset size.

The RL-evaluator's output probabilities $p_i = h_\theta(s_i) \in [0,1]$ were used as image quality scores. After sorting image qualities based on these scores, four data utilization strategies were compared:

1. Full data: training on the entire dataset as a baseline.
2. Low-quality removal: progressively removing the lowest-scoring 5%, 10%, … of samples.
3. High-quality removal: removing the top-scoring samples at the same rates.
4. Random removal: removing the same proportions randomly.

Model performance was measured by average precision (AP) at IoU 0.5 (AP_{50}) and IoU 0.5–0.95 (AP_{50-95}), reflecting both detection accuracy and localization quality.

We first report the validation results on the MOCS dataset to verify whether the RL-evaluator can reliably distinguish data quality during training. As shown in

Figure 2, removing a small proportion of the lowest-quality samples consistently improved performance compared to training with the full dataset, whereas removing random samples led to gradual performance degradation. Moreover, progressively removing high-quality samples resulted in the greatest performance reduction. These trends confirm that the RL-evaluator learns an effective policy for differentiating useful from harmful samples.

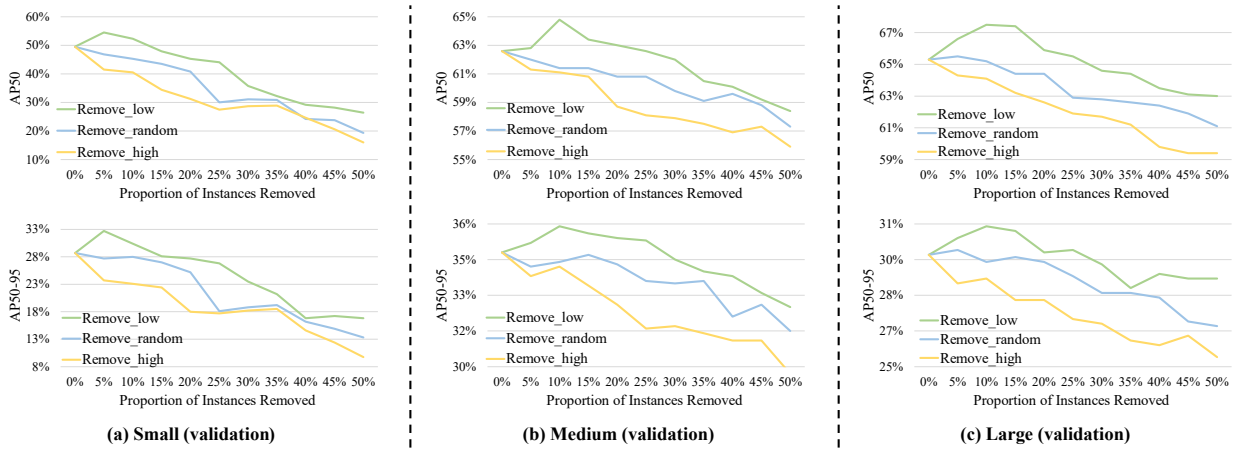

Figure 2. Validation results on MOCS dataset across different dataset sizes

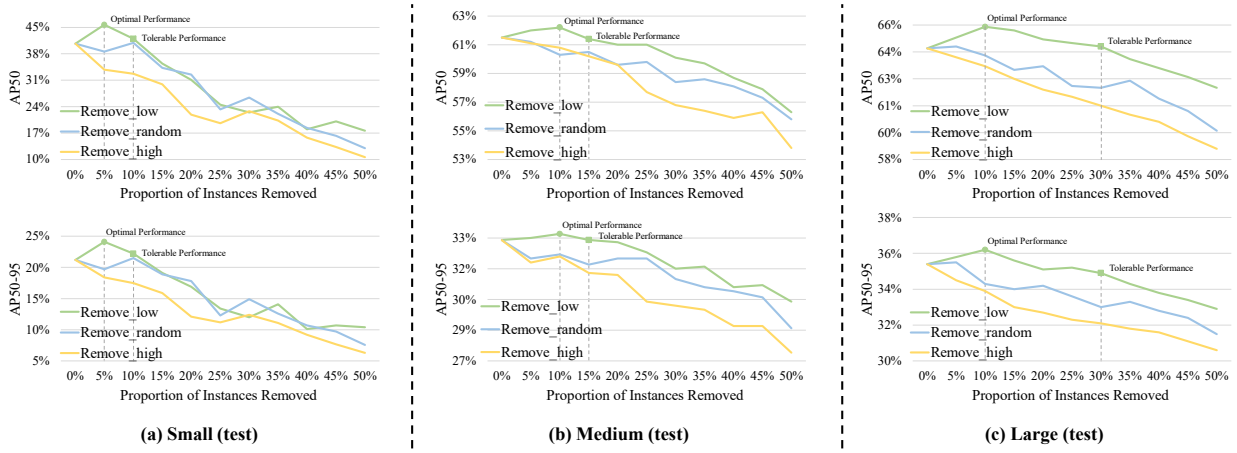

Figure 3. Test results on MOCS dataset across different dataset sizes

We then evaluate our framework on the test dataset. As summarized in Figure 3, the test outcomes are consistent with the validation results. For example, in the small dataset setting, training on the full dataset achieved an AP_{50} of 40.7%. After removing 5% of the lowest-quality samples identified by the RL-evaluator, detector performance improved to 45.7%. In contrast, random removal of the same proportion reduced accuracy to 38.6%, while discarding the top 5% of high-quality samples led to the most severe drop (–6.9%). Similar patterns were also evident in the medium and large dataset settings. Moreover, the benefits were not limited to AP_{50} along: consistent gains were also observed in AP_{50-95}, indicating that the learned data quality scores capture both overall accuracy and localization precision, showing the framework's reliability even with a coarse reward metric. These findings first confirm the conventional belief that "more data leads to better performance," as randomly discarding samples consistently degraded model accuracy. However, this principle does not hold universally. The results validate our alternative hypothesis: selectively removing low-quality samples can in fact yield higher performance than using the full dataset. This counterintuitive outcome underscores the heterogeneous nature of real-world training data—where mislabeled, redundant, or noisy samples can obscure gradient signals and impede learning. By removing such harmful data, the training process becomes clearer and more focused, enabling the detection model to leverage high-quality data more

effectively. Conversely, discarding high-quality samples deprives the model of essential visual and contextual information, resulting in sharp performance degradation.

We further observe that the proportion of removable low-quality samples varies with dataset size. In general, both the optimal removal rate—at which performance peaks—and the tolerable removal rate—at which performance remains comparable to the full dataset—increase as dataset scale grows. For example, on the large MOCS dataset, training with the full data yielded 64.2% AP_{50} , while discarding 10% of the lowest-quality samples achieved optimal performance to 65.4%. Moreover, performance remained close to full data baseline even after removing up to 30% of such samples. By contrast, the optimal removal rates for the small and medium sets were 5% and 10%, with tolerable rates of 10% and 15%, respectively. These results highlight a consistent trend: larger datasets allow more aggressive pruning without degrading performance, demonstrating that our framework improves data utilization efficiency by enabling superior accuracy with fewer, higher-quality samples.

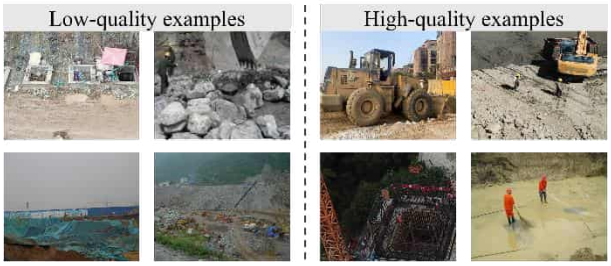

Figure 4. Visual examples of low- and high-quality images in MOCS

Figure 4 shows examples of low- and high-quality images identified by the RL-evaluator on MOCS. It can be observed that low-quality samples often suffered from blur, low resolution, or small and occluded worker instances that provided limited learning signals. In contrast, high-quality samples generally contained clearly visible workers, meaningful context, and diverse construction scenes representative of real conditions. Nevertheless, some exceptions were also observed—certain visually acceptable images contributed little to model performance due to high information redundancy, while some visually challenging ones (e.g., with blur or occlusion) were still valuable as informative hard examples that improve model generalization. These results suggest that the RL-evaluator captures not only superficial visual clarity but also deeper aspects driving the learning dynamics—such as semantic relevance, contextual informativeness (e.g., rare poses or diverse backgrounds), and annotation reliability, offering a more reliable alternative to heuristic or manual filtering.

In summary, the proposed RL-powered framework demonstrates strong potential for improving computer vision in construction by enhancing both detection accuracy and data efficiency. Across different dataset scales, it consistently boosted performance by identifying and removing low-quality samples, validating our alternative hypothesis that low-quality data removing can outperform training on the full dataset. Moreover, the framework enables more efficient training data utilization. By discarding a substantial amount of low-quality data, the model still achieved equal or even superior accuracy compared to using the entire dataset.

5 Conclusion and Future Work

This study presents an RL-powered data quality evaluation framework for computer vision in construction. Experiments on the MOCS dataset across different scales demonstrated that removing a small proportion of the lowest-quality samples—identified by the RL-evaluator—consistently outperformed training on the entire dataset. Furthermore, even after discarding a substantial amount of low-quality data, the detector still achieved competent or even better performance relative to training on the full dataset, thereby significantly reducing computational and data storage overhead. These findings challenge the common belief that more training data leads to better performance and instead highlight the crucial role of data quality and optimizing data utilization to enhancing computer vision model training.

Looking ahead, several research directions remain open. Firstly, our work focused on single-class worker detection; extending the framework to multi-class detection and more complex tasks such as segmentation or pose estimation would help assess its generalizability. Moreover, efforts could also validate the robustness of RL-powered data quality evaluation and broaden its applicability beyond construction vision to other data-intensive AI domains.

Abstract -

Robotic total stations have transformed surveying and construction mapping through precise, efficient, and automated measurements. These instruments integrate a theodolite, which measures horizontal and vertical angles, with an electronic distance measurement (EDM) unit, allowing accurate 3D measurement of observable points. Traditionally, users manually aimed the total station at a target. Recent advancements in robotic motor control and integration of cameras now enable automatic rotation and aiming, typically requiring only a single operator to position the target. Automated aiming is commonly performed using retroreflector prisms, which reflect light back to the source with minimal scattering, enabling high-precision measurements over long distances. However, retroreflectors, especially those designed for 360° visibility, can be expensive and impractical for certain applications. This paper presents an algorithm for automating the center detection of low-cost disposable tape targets using the total station's onboard camera and a template matching algorithm. The algorithm identifies the target's center pixel in the image, and the instrument is commanded to aim at that location. We evaluated the performance of this template-matching-based centering method under various distances, angles, lighting conditions, and field environments, comparing its results to both manual aiming and conventional automated aiming of tape targets. Manual aiming was used as the baseline operational reference in the absence of an independent ground-truth measurement. The proposed approach achieves target centering results comparable to the manual baseline. This method provides a cost-effective alternative for high-precision applications where retroreflector targets are constrained by budget or logistics.

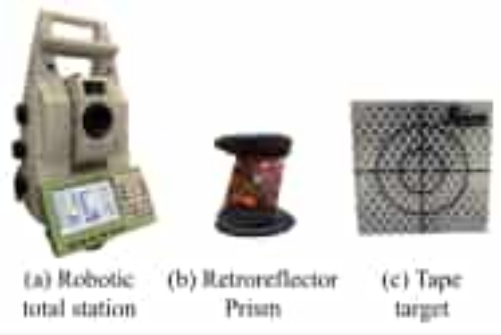

Figure 1. Surveying hardware and targets

1 Introduction

The integration of robotic image-assisted total stations into land surveying and construction mapping represents a significant advancement in geospatial measurement. These instruments have transformed traditional surveying practices by enabling precise, efficient, and largely automated data collection, thereby reducing labor requirements and improving measurement accuracy [1, 2].

Robotic total stations (Fig. 1A) combine three essential components: (1) a theodolite for measuring horizontal and vertical angles, (2) an electronic distance measurement (EDM) unit for determining distances to a target, and (3) an onboard computer that synthesizes angular and distance data to compute three-dimensional coordinates [1]. Traditionally, total stations required manual operation, with surveyors physically aiming the instrument at a target to acquire measurements, a labor-intensive process that often necessitated a two-person crew.

Recent advancements in robotic motor control and automation have enabled these instruments to autonomously rotate, track, and precisely aim at targets, significantly streamlining field operations [2]. This automation allows a single operator to conduct surveys by simply positioning a target, typically a retroreflective prism, while the instrument tracks the target and performs the measurements. Additionally, the integration of cameras onto robotic total stations has added another level of sensing for improved automation; however, the onboard cameras are historically

underutilized especially with the advent of advanced computer vision algorithms and image segmentation.

Retroreflective prisms (Fig. 1B) are essential to this system, as they reflect incident light directly back to the source with minimal angular deviation, enabling high-precision distance and angle measurements over long ranges. Among these, 360-degree prisms are particularly valued for their ability to reflect signals from any direction, enhancing flexibility and efficiency in dynamic field environments. However, despite their advantages, such prisms can be prohibitively expensive and may not be suitable for all applications, especially in cost-sensitive or temporary deployments.

As a lower-cost alternative, disposable tape targets (Fig. 1C) are often used. These targets are inexpensive, easy to deploy, and can be left in place without concern for recovery. However, current methods for automating the centering of the total station's telescope on these targets often result in reduced accuracy. Consequently, users must manually aim the telescope at the center of each target to ensure reliable measurements, reintroducing inefficiencies in labor and time.

Surveying with total stations to evaluate the placement accuracy (tolerances) of building components is common practice. For example, surveys crews often manually aim at installed wall panels to confirm they fall within the required tolerances. In some cases, particularly for challenging installations, a crew may even take measurements in-process and guide crane operations in real time to ensure components are positioned correctly. Recent research has investigated automated measurement systems that use a total station to guide crane placement of building components [3, 4]. In these systems, retroreflector targets are attached to building components enabling automated measurements of installation error in real time and providing guidance during placement. However, these retroreflector targets must be manually retrieved after installation. A more effective alternative is to enable automated, precise measurement of disposable targets. Such targets could be left in place, either falling off naturally over time or being removed later, eliminating the need for retrieval during installation.

This paper presents a novel workflow for automating the detection of and centering on low-cost disposable tape targets using the total station's onboard camera and a template matching algorithm. The proposed method identifies the center pixel of the target in the captured image and commands the instrument to aim accordingly. We evaluate the performance of this template-matching-based centering approach under a range of distances, angles, lighting conditions, and field scenarios, comparing its accuracy to both manual aiming and conventional automated methods for tape targets. This approach offers a cost-effective alternative for high-precision applications where the use of retroreflectors is limited by budget or logistical constraints.

1.1 Literature Review

Research focused on automating the precise measurement of tape targets remains limited. Schwieger, Kerekes, and Lerke explored methods for detecting object features using the onboard camera of a total station [1]. However, their approach still relied on active measurement using a retroreflective prism to determine precise object positions.

Zschiesche and Schlüter [5] investigated potential applications of machine learning and image segmentation in image-assisted total stations. Their work focused on identifying various types of targets, including reflectorless ones, within images captured by the various cameras of the total station. However, they did not explore methods to automate the precise centering of the telescope on these targets.

Lian et al. [6] developed a machine vision-based approach for automating the aiming process at tape targets using template matching. While promising, their method achieved peak accuracy of approximately 5 millimeters at distances of 70 meters and 131 meters.

The method proposed in this paper builds upon Lian et al.'s work, aiming to demonstrate improved accuracy at medium ranges up to 100 meters. Sub-3-millimeter accuracy is needed to meet tolerance requirements for typical building component installation such as precast concrete or steel structure [7, 8]. For these construction tasks, tolerances can be as low as 3 millimeters. The proposed method improves the template matching algorithm to achieve sub-3.3-mm accuracy up to 100 meters.

2 Methodology

2.1 Multi-Scale Template Matching

Automated aiming is performed using a multi-scale template matching pipeline consisting of (1) image capture, (2) green-channel extraction, (3) Gaussian blurring, (4) multi-scale template matching, and (5) telescope pointing.

The template was approximated in code rather than photographed under a single condition. Feature shapes, colors, and relative sizes were iteratively tuned using a diverse set of sample images to ensure robust matching across the range of conditions evaluated. Exact proportional replication was unnecessary for accurate matching since the apparent template shape varies with viewing angle.

Two template versions were developed. The first included only the center black cross on a white rectangular background. The second included concentric gray circles (intensity = 100) on a similar background. Feature sizes were visually tuned to match their appearance at distances between 10–130 m. Since the template shape distorts at

oblique angles, exact proportional replication was not required for reliable matching.

These templates, shown in Fig. 2 prior to preprocessing, were lightly blurred (Gaussian kernel size = 3, σ = 1.0). Testing with approximately fifteen representative images showed that matching consistently failed at long distances ($\geq$ 70 m) without template blurring.

High-resolution (2560x1920) telescopic color images were captured and transferred via USB to a remote laptop. The green channel was extracted to improve feature contrast, as most camera sensors are optimized for green light. This step improved template matching under low-light conditions and allowed a successful match at 100 m. The images were then lightly blurred with the same Gaussian parameters used for the templates, allowing the pipeline to correctly match more templates from the dataset at larger distances (> 70 m).

To enable matching across a range of distances, the templates were scaled over representative size ranges. For each scaled template, the OpenCV template matching algorithm [9] computed the best score and corresponding pixel location. This process was performed with the first template (cross-only) for 4 scales (1.0-1.3). If the maximum correlation score across the evaluated scales exceeded 0.7, the second template was skipped.

The correlation threshold (0.7) was empirically selected by evaluating a varied test set and choosing the lowest value that consistently produced correct matches across all test cases.

If the maximum correlation score from the first template did not exceed the threshold, the second template was applied across 18 scales (0.3-1.3). These scale ranges were determined by comparing template size to the apparent size of the target in the closest and furthest images (10–130 m for the circular template; 10–40 m for the cross template, which becomes too small to match reliably at longer distances).

Fig. 3 shows an example of the detected template and center pixel. The total station was then aligned with this pixel location using its built-in turn-to-pixel function.

Matching accuracy degraded quickly when using the circular template under oblique viewing angles, as the circles appear elliptical. In contrast, the smaller cross exhibited less geometric distortion at high angles, enabling successful matching at angles up to 50° with a maximum error of 0.3 mm.

2.2 Experiments

A series of experiments were conducted to evaluate the accuracy of the proposed centering algorithm compared to manual aiming and the existing automated centering method. All tests were performed using a consistent set of hardware and a standardized experiment methodology.

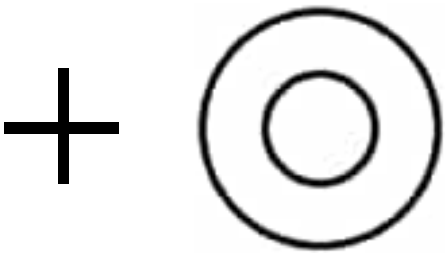

Figure 2. Illustration of templates

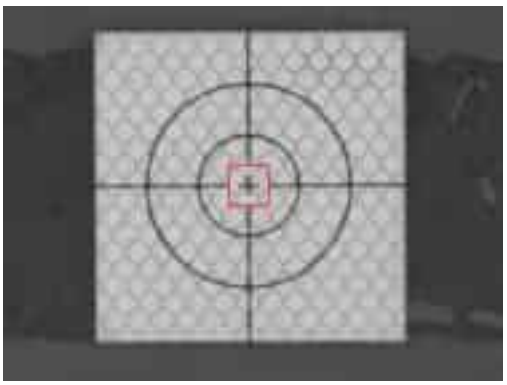

Figure 3. Template matching in telescope camera

2.2.1 Hardware

The experiments utilized a Leica MS60 robotic total station, operated via the GeoCOM protocol through a custom Python interface [10]. This unit features a 5-megapixel telescope camera.

Tape targets manufactured by Leica, measuring 60 mm by 60 mm, were used throughout the tests. A tape target was mounted on a mock brick wall assembly measuring 80 cm by 80 cm. Since several smaller tape targets were also mounted on the wall, covering these targets with pieces of paper was required to prevent either algorithm from finding different targets. This assembly was affixed to an adjustable arm configuration, allowing placement at various angles.

For indoor tests, a synthetic light source was used to control illumination, and a lux meter was employed to measure lighting conditions for each test case. The indoor tests were performed at a light level of 85 lux, and the outdoor tests were done on a partly sunny day with an average illuminance of 5000 lux.

2.2.2 Experiment Workflow

Experiment for Proof-of-Concept. The experimental workflow was designed to generate baseline comparisons and assess the accuracy of both the existing and proposed centering methods. Each test followed the steps below:

1. **Manual Aiming:** The total station was manually aligned with the center of the tape target. Five rapid distance measurements were collected and averaged to reduce EDM readout jitter.

2. **Existing Method:** The instrument was rotated to a random vertical and horizontal offset (within limits to ensure it remained visible). The existing method was executed and five distance measurements were averaged. Because of noticeable run-to-run variability, this procedure was repeated three times per setup (Sec. 4.1).

3. **Proposed Method:** A telescope image was captured, downloaded to the remote computer, and processed using the multi-scale template matching algorithm. The computed center pixel was used to re-aim the instrument using a builtin turn-to-pixel function. The algorithm was run only once per setup because little variability had been observed previously (Sec. 4.1). Finally, five distance measurements were averaged.

The existing automated centering method is proprietary, and its internal operation is undisclosed. Based on observable behavior, the method appears to use a flashing guide light, detecting and centering on the reflected shape of the tape target, similar to the procedure used for retroreflective prisms.

The experimental workflow was repeated across a predefined combination of viewing angles, distances, and lighting conditions. Table 1 summarizes the experimental setups. Set A varied horizontal viewing angle at a fixed 10 m distance (0°–60°), and Set B varied distance from 10–130 m under near-normal incidence. For each setup, telescope images were also recorded for qualitative comparison.

Template matching performance depends on both image resolution and the target distance. Lighting conditions also affect the matching accuracy. Some tests were performed indoors at shorter distances and under low light conditions, while longer range tests were done outdoors. The distance range of 10 - 130 m targeted medium-range applications (precise measurement of component locations with attached tape targets [3, 4]), while also identifying the upper slope distance limit given the available hardware.

Another factor influencing algorithm performance is the skew of the target within the image relative to the template. At extreme viewing angles, the algorithm may struggle to match the tape target accurately. To assess angular robustness, the tape target was rotated horizontally relative to its surface normal (0°), as illustrated in Fig. 4. The horizontal viewing angle, H, was varied from 0° to 60°. Because the tape target is symmetric, only one rotation direction was assessed.

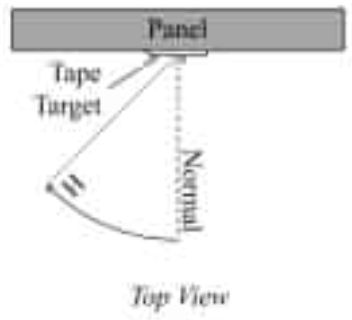

Figure 4. Illustration of horizontal viewing angle

Illumination was controlled to represent low light indoors (85 lux) and bright outdoor daylight (5000 lux). Higher illuminance levels are expected to enhance algorithm performance by improving image clarity and contrast.

Experiment for Statistical Analysis. A separate experiment evaluated run-to-run variability in the error across each algorithm. Manual centering was performed initially as before using Setup A1 (Table 1). The instrument was given a programmed random angular nudge within predefined limits before each run. The existing method was repeated 20 times and the average of 5 distance measurements was recorded for each run. The procedure was repeated for the proposed method to allow a direct comparison.

3 Results

The experimental results compare tape target centering performance across the three methods evaluated: manual aiming, the existing onboard centering method, and the proposed template matching centering method.

For each test, telescope camera images were captured at three stages: (1) after manual aiming, (2) after centering using the existing method, and (3) after centering using the proposed template matching method.

A representative subset of images from five tests is shown in Fig. 5. For each condition, the figure shows the following:

- **Manual Method**: crosshair placement after manual alignment.
- **Existing Method**: the median-error result from the three onboard centering attempts.
- **Proposed Method**: crosshair placement after executing the proposed method.

These visual comparisons illustrate how the proposed method tends to produce centering results that are closer to

Table 1. Experiment conditions and setups

Test No.	Conditions			
	Location	Target Distance (m)	Viewing Angle, H (°)	Illumination
Set A				
A1	Indoor	10	0	Low
A2	Indoor	10	10	Low
A3	Indoor	10	20	Low
A4	Indoor	10	30	Low
A5	Indoor	10	40	Low
A6	Indoor	10	50	Low
A7	Indoor	10	60	Low
Set B				
B1	Outdoor	10	0	High
B2	Outdoor	20	0	High
B3	Outdoor	30	0	High
B4	Outdoor	40	0	High
B5	Outdoor	70	0	High
B6	Outdoor	100	0	High
B7	Outdoor	130	0	High

the apparent target center under the conditions shown. A brief quantitative analysis of error variability is provided in Sec.4.1.

To verify that averaging five sequential readings sufficiently suppresses readout jitter, we examined within-run dispersion under representative conditions. For example, for Setup A4 (existing method, run 3), the five readings yielded a mean error of 0.03 mm with a standard deviation of 0.03 mm, indicating negligible short-term variability. Comparable levels were observed across other runs; therefore, we report per-run averages for all experiments.

Fig. 6 records the mean, minimum, and maximum error for the existing method and the corresponding error in the proposed method. As described in Sec. 4.1, the existing method exhibited substantial run-to-run variability, whereas the proposed method did not. Consequently, the proposed method was executed once per setup, with its design choice validated by the variability analysis.

Entries marked "Algorithm Failed" indicate conditions in which the method did not identify the target in any run (0% detection success). In all successful cases, the method identified the target in every run (100% success).

Manual aiming provided the baseline for computing errors. Since no ground-truth reference was available, these values represent only a relative reference. The errors reported for the existing and proposed methods are Euclidean distances between the method-measured positions and the corresponding manual measurement. These representative errors are reported in Fig. 6.

4 Discussion

The user manually aligned the crosshairs with the tape target center using the telescope view. As shown in Fig. 5, the manual method exhibited visually consistent target alignment. However, manual centering is inherently subjective and sensitive, particularly at long slope distances, where wind-induced vibrations, reduced image quality, and temperature gradients further decrease accuracy. A single user performed all manual aiming tasks to minimize variability in the baseline measurements. Although this introduces potential operator-specific bias, maintaining consistency in the manual reference measurements was prioritized.

Visual inspection of the existing method in Fig. 5 combined with the calculated errors in Fig. 6 indicates significant variability. Particularly at longer distances or angles, the onboard proprietary algorithm struggled to center on the target, frequently leading to variable and inaccurate results.

The largest mean error observed for the existing method was 8.5 mm, and the mean errors across all experimental setups had an overall average of 4.9 mm (see individual means in Fig. 6). These values exceed many common construction installation tolerances, some of which are as small as 3 mm [7, 8].

At target slope distances above approximately 30 m, the existing method fails to identify the target in all trials (0% detection or measurement success).

The proposed method demonstrated lower centering error than the existing method under all successful trials, achieving a maximum deviation of 3.3 mm from the baseline. Within 70 m, the deviation decreased to less than 1 mm. Although performance declines at extreme distances and angles, the algorithm consistently outperformed the existing method across all tested scenarios.

Although the primary goal of this investigation was to develop a method for accurate automated measurement of tape targets at intermediate distances (20 to 40 m), testing extended until failure occurred at a slope distance of 130

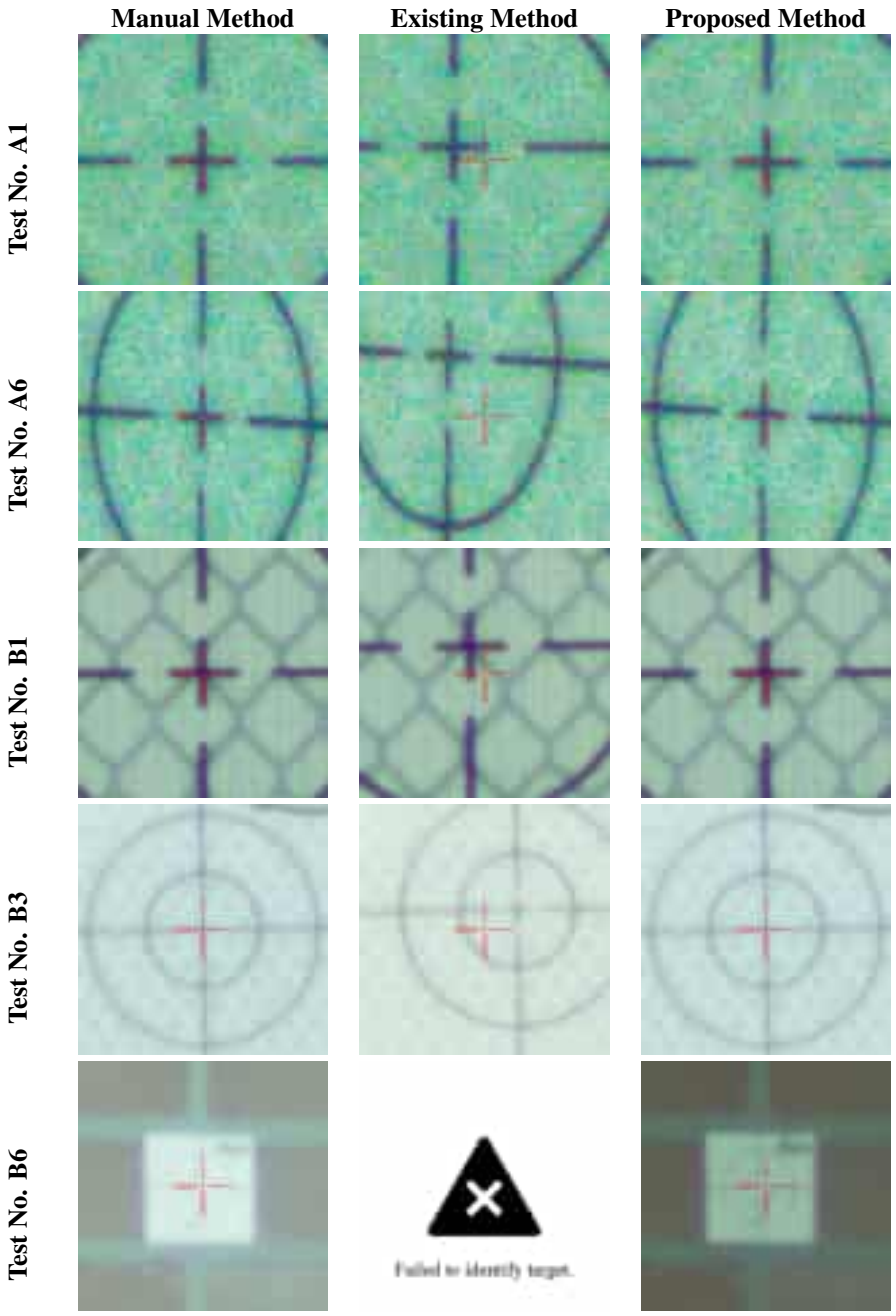

Figure 5. Representative telescope images of aiming methods for multiple test conditions

m, substantially beyond the onboard method's limit of 40 m. The cause of failure at this distance is not yet clear, as image statistics and background conditions were comparable to those in successful trials. Additional investigation will be needed to determine the specific factors governing long-range performance.

4.1 Statistical Analysis of Measurement Error

In addition to the proof-of-concept experiments, a statistical analysis was performed to quantify measurement variability and validate the experimental design. Two primary variability sources were considered for the proposed method: (1) small differences in the captured images and (2) the onboard turn-to-pixel function. Despite these factors, the proposed method exhibited low variability compared to the existing method (Fig. 7). In Setup A1, the

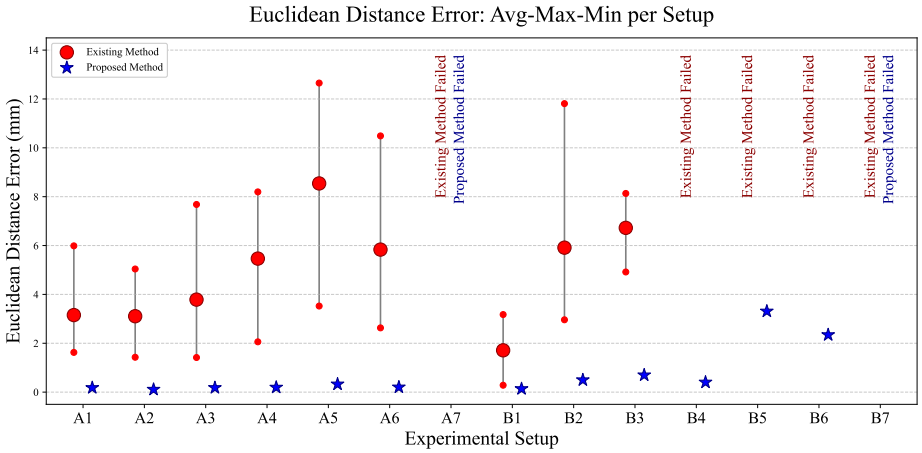

Figure 6. Avg-max-min Euclidean distance error per experimental setup.

existing method produced a mean error of 5.2 mm with a standard deviation of 3.1 mm (95% CI: ±1.5 mm), whereas the proposed method produced a mean error of 0.16 mm with a standard deviation of 0.04 mm (95% CI: ±0.02 mm).

4.2 Limitations

The proposed template-matching algorithm requires the full tape target to be visible within the telescope camera's field of view. During testing, the existing method provided this initial coarse alignment; therefore, the current implementation of the proposed algorithm is not yet fully autonomous. A fully autonomous workflow could incorporate image-segmentation techniques to coarsely align the target before precisely centering with template matching.

A second limitation is the 10–20 s required to download a telescope image from the instrument to the remote computer. This delay is specific to the instrument used in testing and dominates the cycle time, preventing real-time tracking of moving targets. The image-processing stage itself requires only about 0.5 s and could be further optimized for tracking. Eliminating the download time by real-time video streaming or running the proposed method directly onboard the instrument would allow the method to be competitive with manual operation times and track targets in real-time.

5 Conclusions

A template-matching algorithm was developed to automate the centering of a robotic total station on disposable tape targets. The method was evaluated across a range of distances, angles, and lighting conditions. Within the tested envelope, the algorithm achieved centering performance comparable to manual centering for viewing angles up to 50° and distances from 10-100 m. Since no independent ground-truth reference was available, all reported errors represent deviations from the manual baseline.

The current implementation is not fully autonomous, since the template must be positioned within the camera's field of view. Additionally, overall cycle time is dominated by instrument-specific image-transfer delays rather than by algorithmic processing. Eliminating this bottleneck with a live video stream or through onboard execution would allow real-time performance.

Quantitatively, the proposed algorithm increased the usable range from less than 40 m (existing method) to 10–100 m, and reduced the overall average centering error (relative to the manual baseline) from 4.9 mm to 0.7 mm. These results demonstrate that the proposed method provides a cost-effective and substantially more accurate alternative for high-precision applications where retroreflectors are impractical.

5.1 Future Research

Future research will extend the tape centering algorithm to dynamic scenarios, including real-time target tracking. This will require optimizing the algorithm's processing time, improving its robustness in challenging lighting and viewing conditions, and eliminating the image-transfer latency. Additional work will explore integration with higher-resolution imaging systems and the development of a fully autonomous pipeline that does not require coarse alignment with the onboard method.

Abstract

The increasing volume and heterogeneity of data generated during building inspections pose significant challenges to maintenance management (MM). Although digital technologies are frequently discussed in the literature, their integrated application to support maintenance decision-making remains scarce. This study proposes an integrated data visualization workflow to support building MM by integrating information from inspections, UAS, BIM model data, and GIS geospatial information, and by leveraging analytical visualization in a BI (Business Intelligence) environment. A case study was conducted in a building of a Higher Education Institution (HEI) using real inspection data on facades and roofing systems. The results, presented through an interactive dashboard, demonstrate the potential of BI to integrate heterogeneous data sources and support the identification, location, and analysis of construction anomalies. Furthermore, the study highlights practical challenges in interoperability and data organization, and presents lessons learned that can support future applications of integrated digital environments for building maintenance management.

Keywords: Maintenance Management; BIM; GIS; UAS; Power BI; Dashboard; Business Intelligence.

Introduction

The increasing complexity of buildings has amplified the demand for more precise information management in maintenance processes [1,2]. In the work of Dompey et al. [3], it is noted that increases in operational costs and the growing volume of information to be managed highlight the limitations of traditional maintenance methods. This scenario becomes even more critical in exposed building envelope subsystems, such as roofs and facades, which are more susceptible to degradation and decline in building performance due to constant exposure to weather. Studies indicate that anomalies such as cracks, detachments, and surface wear serve as early indicators of failure and can compromise the building's performance, underscoring the importance of preventive strategies and periodic inspections [4, 5, 6, 7].

Sena et al. [2] identified that the main problems in building maintenance are related to the management and organization of processes, highlighting the absence of standardized procedures and a structured preventive maintenance plan. According to this study, there are also limitations in human, financial, and technological resources, as well as operational and informational deficiencies, which hinder efficient maintenance, access to up-to-date building data, and communication among the actors involved. In response to these demands, practices based on digital technologies have emerged to improve operational efficiency in building maintenance. The integration of BIM models, digital twins, and reality-capture systems has expanded monitoring and analysis capabilities, enabling greater precision and supporting informed decision-making [3,8]. Among these technologies, Unmanned Aerial Systems (UAS) have been employed for systematic inspections, providing a massive collection of visual data and supporting the construction of digital models [19]. However, expanding this volume of information reveals challenges in processing and organizing the collected data [7].

Therefore, recent studies highlight the role of Business Intelligence (BI) environments in structuring, integrating, and making large volumes of data accessible, thereby facilitating continuous, up-to-date analyses [9].

When combined with Geographic Information Systems (GIS), such platforms expand analytical capacity by associating spatial and non-spatial data. This feature has proven particularly relevant for projects involving multiple buildings distributed across different areas [10, 9].

Given these challenges, this study proposes an integrated workflow for visualizing building maintenance information that combines building envelope data from UAS-automated inspections, BIM models, and GIS in a Business Intelligence environment. Furthermore, this study aims to report the lessons learned during this integration process.

The novelty of this study lies in the structured integration of heterogeneous data sources into a unified, decision-oriented workflow. Unlike previous studies that focus on isolated integrations, such as BI–GIS [9] or BIM–GIS [10,7], this research proposes a reproducible data integration pipeline that connects data acquisition, organization, spatial contextualization, and analytical visualization within a single environment. This approach addresses the fragmentation of maintenance information by enabling the consolidation of inspection records, spatial data, and building components into an integrated and interactive system. As a result, it enhances the ability to interpret data and supports more informed decision-making in building maintenance management. This differentiates the proposed approach from prior studies that primarily focus on tool-level integration, rather than on structured workflows and decision-oriented data transformation.

This work contributes to the literature by: (i) proposing a structured workflow for integrating BIM, GIS, UAS, and BI data in building maintenance management; (ii) demonstrating the application of this workflow using real inspection data; and (iii) identifying practical challenges and lessons learned to support future implementations of integrated digital environments.

Application of digital technologies for Maintenance Management

Recent studies suggest that the adoption of digital technologies has enhanced the quality and reliability of information used in building maintenance management [2,6]. Thus, Building Information Modelling (BIM) serves as a central repository of information throughout the building lifecycle [11], while Business Intelligence (BI) tools, such as Power BI, are being explored for their potential for analysis, data integration, and decision-making support [1]. Recent studies investigate integrating Power BI with Python scripts, cloud services, and immersive technologies to support Facilities Management and the development of Digital Twin prototypes [12,13].

However, using BI tools alone has limitations for representing and analyzing spatial information, leading to their integration with Geographic Information Systems (GIS) to visualize dynamic, spatially referenced data [9]. Meanwhile, studies have examined the integration of BIM-GIS to support utilities management and the automated recording of inspections performed with UAS, emphasizing the technical feasibility of interoperability between these platforms [10,7]. During the operation and maintenance phases, BIM has served as a repository for inspection and maintenance data, with progress in data standardization through IFC and integration with UAS imagery and automated update systems [2,14,15].

Despite these advancements, the literature suggests that building maintenance management continues to face challenges related to information fragmentation and the lack of integrated data visualization and analysis workflows. In particular, there is a gap in interoperability between BIM models, GIS spatial data, and information from UAS inspections in Business Intelligence environments, especially during the operation and maintenance phases. Furthermore, many applications still rely on manual processes or ad hoc integrations, which limit the potential of these technologies to effectively support the location, documentation, and monitoring of anomalies. In this regard, the need for research focused on creating integrated, reproducible workflows that connect BIM, GIS, and BI to better manage building maintenance information is clear.

Research methodology

This study employed an exploratory case study strategy, which is suitable for investigations of complex and contemporary phenomena, where understanding data integration processes in their real-world application context is necessary [16]. The objective of the methodology was to establish a standardized workflow for collecting, preparing, integrating, and visualizing building maintenance data in a BI environment.

The research was conducted in two phases: a theoretical-practical investigation and a case study, including tool testing and the development of an integrated visualization environment (Figure 1).

Investigation of the theoretical and practical problem

The investigation of the problem was conducted through a literature review focused on identifying studies that address the integration of BI tools, GIS, BIM models, and UAS imagery. This stage aimed to understand how these technologies have been combined in previous research and to analyze the limits and challenges associated with the interoperability and visualization of building maintenance data. Meanwhile, secondary data were identified and analyzed, involving the collection and interpretation of records previously compiled by [6,2]. The goal was to confirm the nature, structure, and possible uses of this information. It is important to note that this initial analysis was not only about the problem's foundation but also served as the database for the later stages of the case study.

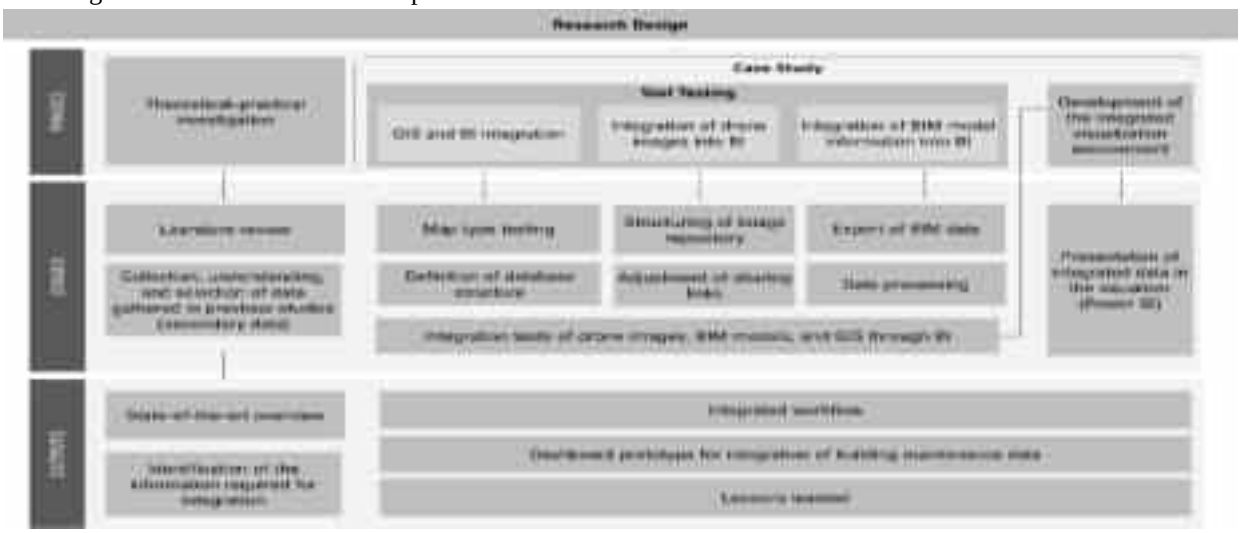

Figure 1: Protocol for developing information flow

Subject-of-Study Characterization

The selected building is in an unfinished state, with construction activities currently on hold, leading to deterioration, particularly of external components such as facades and roofing. The facades include areas with paint finishes, ceramic cladding, and incomplete sections. The roofing system has sections with fiber-cement sheets and exposed concrete slabs.

The building was selected as the only one with a consolidated BIM model and prior research data [6,2]. It is worth noting that the data related to roof inspections are organized separately, without a direct connection to the BIM model, which enabled the analysis of two complementary scenarios: the management of information integrated into the model and the processing of data outside it.

Assessment of digital tools

The tests covered the integration between GIS and BI tools, the incorporation of UAS imagery into the BI environment, and the integration of the BIM model into the analytical dashboard. Subsequently, tests were conducted on the integration process and the relationships among the datasets.

GIS-BI Integration

The tests were conducted using Power BI software, evaluating four native map viewers: Map, Azure Maps, Filled Map, and ArcGIS Maps for Power BI. This stage aimed to analyze the spatial representation capabilities of the building under study, focusing on how clearly its geographic location and placement in the urban environment can be identified. To this end, more detailed tests were performed with the Map viewer, which allowed publication of results online and met the requirements for displaying elements such as streets and neighborhood organization. Also, this viewer enabled integration of spatial information with data from other databases, such as spreadsheets containing building attributes, including name, built area, and year of construction.

Integration of UAS imagery and BI data

Tests focused on applying images collected by UAS in the Power BI environment were conducted using three distinct visualization strategies. The first involved making images available via external links; the second, presenting the images in a table arranged in a matrix; and the third, using the Simple Image visualization method. These approaches aimed to enable dynamic image access for users by integrating their queries into the analytical environment. During testing, the image file formats with the best platform compatibility were evaluated, along with the suitability of the links used to access images stored in cloud repositories.

Integration of BIM model and BI data

The tests for integrating the BIM model with Power BI were conducted in two complementary stages. Initially, the inspection data incorporated into the BIM model was exported from tests performed in Revit, where this information was associated with the building elements. In the next stage, the BIM model was integrated into the analytical dashboard, enabling both the visualization of data in tabular structures and the direct exploration of the three-dimensional model on the dashboard. To enable this integration, the Speckle plugin for Revit was utilized, along with the corresponding viewer in Power BI. This approach enabled interaction with the 3D model and the integrated analysis of inspection data, along with other information presented on the dashboard.

Development of the Integrated Visualization Environment

The development of the visualization environment involved preparing and organizing data for integration into Power BI. Inspection images were consolidated into a unified repository, using standardized nomenclature, file formats, and associated metadata. Accessible addresses were generated for each image via OneDrive shared links, allowing direct connection to dashboard visuals. Simultaneously, the buildings' geographic database was structured using their identifiers and coordinates, enabling their spatial representation in the analytical environment.

To support data integration, heterogeneous datasets were structured using a unified schema for both BIM-based and non-BIM-based information. When available, the BIM model generates two datasets: a tabular export (CSV BIM Data) and a geometry-based dataset via Speckle (BIM Data), which share attributes that enable integration. The CSV BIM Data structure was also adopted in scenarios without a BIM model, ensuring consistency and future compatibility. Inspection data are recorded following the same schema, including links to associated images.Data linkage is established through two identifiers: Building_ID, used for general building information, and Anomaly_ID, used to connect inspection records and images, and to associate them with BIM elements when available.

Based on this structure, a relational model (Figure 2) integrates building information, inspection data, images, and spatial data, supporting dashboard configuration and visualization.

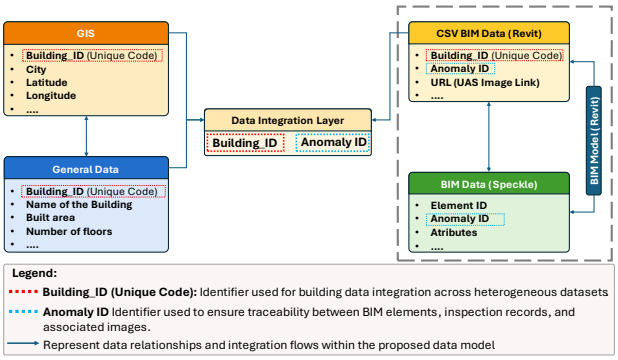

Figure 2: Data structure

Results

Integrated workflow

Figure 3 presents the interoperability flow among the various tools used in the study, demonstrating how data from facade and roof inspections, spreadsheets, geographic information systems (GIS), and the BIM project were integrated.

This process facilitated the organization and management of data within a single environment, enabling its visualization in Power BI dashboards and supporting the integration of information for the case study analysis.

The prototype developed in Power BI (Figure 4) shows the integration of the proposed data sources, featuring an interface with six main viewers and four dynamic filters (Buildings, Anomaly, Gravity, and Envelope). This structure enables the integrated analysis of maintenance data, thereby promoting a coordinated link between the databases. The integration of GIS and BI is evident in the location field, where map layers enable the visualization of buildings in their urban context.

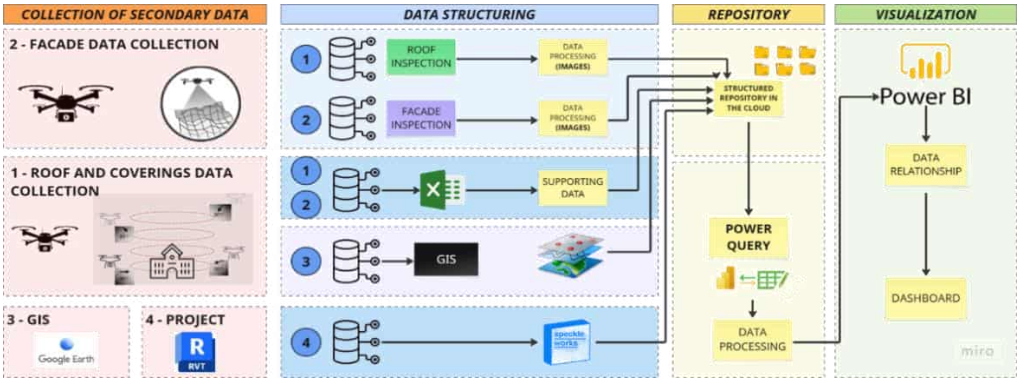

Figure 3: Integrated workflow

This feature links geographic coordinates to building attributes, allowing users to view information such as name, roof area (2,122 m²), and number of floors (3) by hovering over the building on the map. The chosen building is incomplete, with construction on hold, leading to deterioration, especially of its external parts, such as facades and roofing.

The building's geometric representation was incorporated into the panel via the BIM model using the Speckle plugin, enabling three-dimensional navigation directly on the dashboard. This integration linked inspection data to the model geometry, enabling the three-dimensional elements to respond to filters applied in the other sections of the panel. However, the automatic association between photographic records and model components is limited to the facade inspections documented by [2], whose images were already previously linked to the BIM elements.

Figure 4: Proposed Power BI dashboard

For roof inspections, data visualization occurred independently, without the corresponding automatic indication in the three-dimensional model. Even so, the panel maintains its functionality, as its architecture enables the presentation and analysis of inspection information autonomously, without reliance on linking to the BIM model. Thus, the dashboard provides an overview of the building's state of conservation at different levels of technical detail, preserving interface consistency and supporting analysis.

Functional Verification

Functional verifications were conducted during dashboard development to assess the consistency and reliability of the integrated workflow. Four aspects were evaluated. First, the building's geographic position matched its known location, confirming accurate spatial representation. Second, the number of anomalies in charts was consistent with the inspection records. Third, anomaly images and descriptions were validated against the source data, showing full consistency, with minor delays in image loading due to cloud-based storage.

Finally, BIM integration was tested: selecting an item in the table correctly highlighted the corresponding 3D element, while roof inspection anomalies did not affect the model, as expected, since they are not linked to BIM elements (Section 3). Overall, the dashboard performed consistently across all evaluated functions.

Lessons Learned

Despite the satisfactory results of the exploratory case study, integrating digital data into maintenance management poses challenges that require careful consideration, as summarized in Table 1.

Table 1: Challenges and lessons learned

Challenges	Lessons learned
Decentralized repositories	Organization of data from different sources into a centralized structure, with specific repositories defined for each type of information
BIM–BI data interoperability	Export of BIM model information to a CSV file, followed by data processing
GIS–BI data interoperability	The Map viewer was used due to its support for free web publishing and its adequate representation of georeferenced points. In contrast, ArcGIS Maps for Power BI presented restrictions on free publishing, and other map visuals showed limitations in spatial visualization
Integration of UAS imagery into BI	Development of workflows to adjust image sharing links for visualization
Visualization of UAS imagery using BI	Application of the Simple Image visual in Power BI for enhanced image visualization
Unrelated datasets	Use of Building_ID and Anomaly_ID as unique identifiers to ensure relational integration.

Discussions

Building on previous studies, this study advances by presenting the results of a Power BI dashboard that integrates real data on facade and roof maintenance, highlighting practical difficulties and lessons learned from an exploratory case study. While previous research explores, in isolation, the integration between BIM and Business Intelligence [17], the automation of maintenance data recording in BIM models [18], or the standardization and sharing of information through IFC schemas [15,14], this study focuses on the joint integration of data from BIM, GIS, and images obtained by UAS in a single visualization environment in Power BI.

In contrast to the work of Harode et al. [12], which integrates Power BI dashboards with HoloLens 2 for facility management using lifecycle data embedded in BIM models, this study does not rely on augmented reality technologies; instead, it emphasizes the interoperability between multiple spatial and visual data sources applied to building maintenance. Even so, the focus group validation adopted by these authors is identified as a potential strategy for future validation of the results presented here.

Regarding data analysis to support decision-making, Viveros et al. [13] demonstrate the potential of integrating Power BI and Python scripts for evaluating preventive maintenance policies. In contrast, this study prioritizes the organization, visualization, and interpretation of real inspection data, highlighting the technical and operational limitations of the integrated workflow. Compared to the work of Wang et al. [10] and Chen et al. [7], which explores BIM-GIS integration and UAS image registration, focusing on spatial modeling and urban networks, the role of GIS in this study was intentionally defined as a spatial context layer. This layer enables the geographic identification of buildings on campus and helps understand how location affects maintenance conditions. This complementary role aligns with the scope of the proposed workflow, which emphasizes data integration and visualization over complex spatial analysis. Nonetheless, the authors acknowledge that GIS could support more analytical functions in future iterations of this work, such as spatial prioritization of maintenance based on anomaly density, analysis of environmental exposure by facade orientation, or overlay with climatic and microclimate data [9,10].

Finally, this work builds on the findings of Sena et al. [2] and Silva et al. [6] by providing an integrated dashboard that displays the previously collected inspection data, making it easier to visualize, group, and analyze the information all in one place to support better decision-making. Therefore, the study contributes to advancing discussions on integrated data flows for building maintenance, highlighting, in an applied manner, the challenges of interoperability and opportunities for future research. Based on these findings, several

implications and future directions can be highlighted. In this context, beyond identifying practical challenges, this study highlights the need to move from isolated integration efforts toward structured and scalable workflows. The lessons learned indicate that interoperability issues are both technical and organizational, requiring data standardization and consistent identifiers. In this context, future implementations should prioritize semi-automated pipelines and the incorporation of automated methods, such as the use of UAS and machine learning models for anomaly detection, thereby reducing manual effort and improving data reliability. Furthermore, expanding GIS functionalities to include spatial analysis can strengthen decision-making support. These findings are consistent with previous studies [7,2,6], reinforcing the importance of integrating digital technologies in maintenance management. Finally, the value of integrating BIM, GIS, UAS, and BI extends beyond data visualization, enabling a continuous data-to-decision workflow in which field-collected data are transformed into actionable insights for maintenance management. This positions the proposed approach as a step toward more integrated and intelligent maintenance management systems within the context of digital construction.

Conclusion

This study proposed an integrated digital data visualization workflow to support building maintenance management, combining data from UAS inspections, BIM models, GIS geospatial information, and BI tools. The application of the workflow was evaluated through an exploratory case study, using real data from facade and roof system inspections of an institutional building.

The results indicate that combining these data sources into a unified environment is practical and aids in identifying, locating, and analyzing anomalies, while enhancing data organization and accessibility. The use of an interactive dashboard in Power BI enabled integration among spatial analyses, analytical exploration, visualization of the 3D BIM model, and direct access to inspection images, thereby enhancing decision-making support during the operation and maintenance phase.

Limitations include the research's exploratory nature and the application of the workflow to a single object of study, both of which limit the generalizability of the results. Furthermore, the evaluation focused on the feasibility of data integration and visualization, and did not include quantitative metrics on performance, costs, or operational impacts.

Notably, although the proposed workflow was evaluated for technical feasibility and integration, no formal end-user usability testing was conducted. Aspects such as user experience, perceived ease of use, cognitive workload, and effectiveness, as experienced by facility managers and maintenance professionals, were not systematically measured. Therefore, the practical usability and user-centered performance of the developed environment still need empirical validation. Future research should address this gap by using structured usability assessment methods, such as standardized questionnaires and participatory evaluation approaches, to better understand how the system supports real operational decision-making in building maintenance contexts.

Future work recommends applying the proposed workflow to a broader range of buildings and incorporating performance indicators and criteria for prioritizing interventions. The adoption of participatory validation methods, such as focus groups with managers and specialists, can also help improve the developed environment and advance discussions on the integrated use of digital technologies in building maintenance. Furthermore, advancing the automation of UAS-related inputs represents a key opportunity for improving the workflow. Future implementations could incorporate automated flight planning with pre-defined waypoints for systematic envelope coverage, automatic image naming based on GPS coordinates and building component identifiers, and direct upload to cloud repositories upon flight completion. Integration with anomaly detection models, such as those based on deep learning architectures applied to roof damage detection, could further enable the automatic registration of defects in the dashboard without manual intervention, closing the data collection loop from UAS acquisition to maintenance decision-making. In parallel, expanding the analytical role of GIS by spatially prioritizing interventions and overlaying them with environmental exposure data would strengthen the methodological contribution of the integrated workflow. This reinforces the potential of integrated digital workflows as a foundation for more data-driven and proactive maintenance management practices.

Abstract –

Automatic concrete spalling detection on bridge surfaces using unmanned aerial vehicles (UAV) is essential for improving inspection efficiency and operational safety. However, instance segmentation models employed in UAV-based inspections are sensitive to environment-related variations in image appearance. In practice, inspection data are usually collected under limited conditions, which reduces model reliability when applied beyond standard operating scenarios. To address this limitation, weather condition modelling strategies were examined from a data construction perspective. Three datasets derived from the same UAV inspection imagery were used: a baseline, a traditionally augmented dataset based on global statistical transformations, and a generative-AI-based dataset representing diverse inspection environments. All datasets shared identical pixel-level annotations. A unified instance segmentation model, YOLOv11 seg, was trained under identical configurations and evaluated using cross-dataset testing to assess generalization under simulated weather variability. Results demonstrate that the model trained with generative-AI-enhanced data achieves stable segmentation performance in challenging inspection environments. Meanwhile, the segmentation accuracy on the original test set remained high, indicating that improved environmental adaptability was achieved without sacrificing performance under regular inspection conditions. These findings demonstrate that generative-AI-based environment synthesis effectively reduces training data bias and enhances model reliability without additional annotation, thereby providing a practical data construction strategy for UAV-based bridge inspection in real-world applications.

1 Introduction

Bridges are critical components of transportation infrastructure, and their service conditions directly affect public safety and the stable operation of transportation systems [1]. Surface concrete spalling is a typical bridge deterioration and damage form [2,3]. Such damage compromises the concrete cover and accelerates reinforcement corrosion, thereby reducing structural load-bearing capacity and durability [3]. According to the 2025 National Bridge Inventory of the United States, approximately 620,000 highway bridges are currently in service, more than 260,000 of which exhibit structural deficiencies, with an estimated investment of approximately $467 billion USD required for comprehensive rehabilitation [4]. If surface damage such as concrete spalling is not identified and repaired at an early stage, it often progresses to structural deterioration, substantially increasing maintenance costs and operational risks [1–3].

In current bridge operation and maintenance systems, surface concrete spalling identification relies primarily on manual inspection methods [3,5]. Such inspections typically require close-range visual examinations using aerial work equipment and exhibit limitations in inspection efficiency, operational safety, and result consistency, with outcomes largely dependent on inspector experience and judgment [1,2,5–7]. With the development of unmanned aerial vehicle (UAV) platforms and computer vision technologies, automated bridge surface damage detection based on UAV imagery has become a feasible technical approach [1,6,7]. Combined with deep-learning-based instance segmentation models, fine-grained localization of concrete spalling regions can be achieved under non-contact conditions, thereby improving inspection efficiency and reducing inspection risk [6,8]. However, the effectiveness of these methods is highly sensitive to training data quality and diversity [9]. In actual engineering environments, variations in weather and lighting conditions significantly affect the appearance of bridge imagery, limiting the model applicability under complex conditions [10,11].

To alleviate the shortage of data under complex environmental conditions, prior studies have expanded original imagery using conventional image augmentation techniques, including global statistical transformations such as brightness and contrast adjustment and noise perturbation [10,11]. Although these methods can increase the appearance diversity of training samples to a certain extent, their image level operations make it difficult to represent the local texture variations induced by weather conditions and the spatial interactions between such variations and structural surfaces [11,12]. In recent years, generative methods have gradually been introduced for the synthesis of complex scene samples. Style transfer networks such as CycleGAN have been applied to simulate road or structural scenes under different weather conditions [13,14]. However, the domain transformation process may introduce geometric distortions, making it difficult to preserve the spatial consistency of damage boundaries. Diffusion models have demonstrated advantages in image quality, yet their training cost remains high and the controllability of the generation process is still limited. As a result, targeted environmental modification while maintaining pixel level annotation consistency continues to present a challenge [15,16]. In contrast, multimodal large language models represented by ChatGPT and Gemini have shown strong semantic understanding and instruction following capabilities in image editing tasks [17–20]. Through structured prompting mechanisms, these models can perform targeted modification of environmental appearance while preserving the original geometric structure [19,20], thereby offering a new paradigm for expanding environmental diversity at zero annotation cost. However, the application of model driven environmental synthesis methods of this kind to bridge damage detection remains at an exploratory stage, and systematic experimental evaluation and method comparison are still lacking.

Based on this background, this study proposes a multi weather data generation and evaluation framework for bridge surface concrete spalling detection. To enable a systematic comparison of data construction strategies, three datasets were established, namely, the Base Dataset, the Traditional Augmentation Dataset, and the Generative Artificial Intelligence Dataset. Under a unified instance segmentation model and consistent experimental settings, comparative training and cross dataset testing were performed to evaluate how different data construction strategies affect segmentation performance and generalization ability under complex weather conditions. The results verify the effectiveness of the proposed framework in expanding environmental diversity without additional annotation cost and in improving the stability of automated bridge surface damage detection.

2 Material and Methods

2.1 Overview

To analyze the impact of weather conditions on UAV-based bridge defect detection performance, three datasets were constructed using the same set of bridge surface concrete spalling images acquired from UAV inspections. The Base Dataset was constructed without introducing artificial weather variations. The TA and GAI datasets incorporate weather conditions using different modeling strategies. The three datasets differed only in the adopted weather modeling approach, whereas all other image content and pixel-level annotations remained identical. Each dataset was consistently divided into training, validation, and test sets at a ratio of 6:2:2.

The instance segmentation model YOLOv11 seg was employed as a unified analytical model and trained separately on the Base, TA, and GAI datasets. The inference and evaluation were conducted on the Base and GAI test sets. This cross-testing configuration enables a direct detection performance comparison under conditions without weather interference and complex weather scenarios, thereby facilitating the analysis of the effects of weather variations and different weather modeling strategies on defect detection outcomes. The overall experimental workflow is illustrated in Fig. 1.

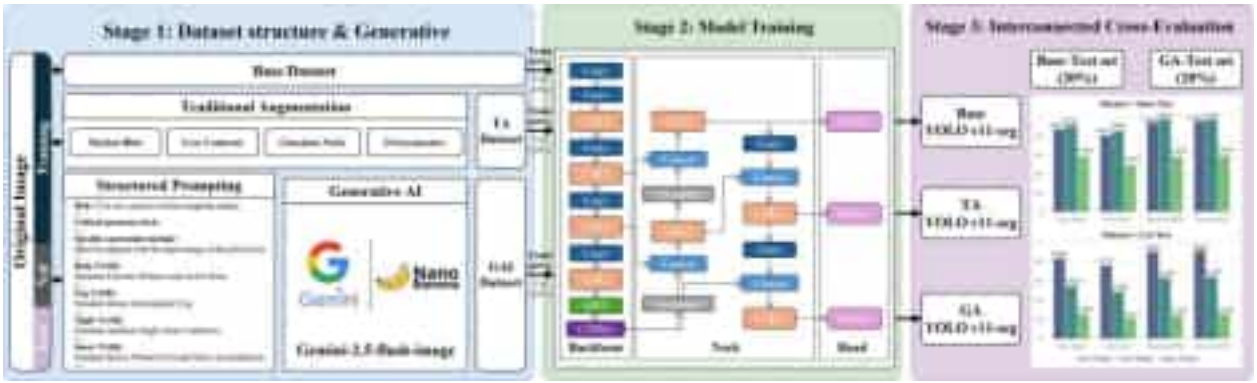

Figure 1. Overview of the experimental framework.

2.2 Data collection

This study used a publicly available bridge façade orthophoto dataset released by the National Information Society Agency of Korea through the AIHUB platform [21]. The dataset covers 27 bridges with different structural types, including PSC I Girder, Steel Box Girder, and Preflex Bridge, and was collected using a DJI Mavic 3 UAV in a close-range inspection mode with a ground sampling distance of 0.3 mm/px and an imaging distance of approximately 1.33 m.

All images were uniformly cropped to 512 × 512 pixels, corresponding to a physical coverage of 15.4 cm × 15.4 cm. Based on these images, a Base Dataset containing only concrete spalling defects was constructed, comprising 551 images and 930 instances annotated with LabelMe polygon masks. Instance areas showed a long-tailed distribution, with small, medium, and large scales accounting for 41.7%, 39.6%, and 18.7%, respectively, where the corresponding pixel ranges were <32 px, 32 to 96 px, and >96 px. The physical size of defects ranged from 0.34 to 79.1 mm. On average, defect regions occupied only 2.85% of the image area, corresponding to a foreground to background ratio of approximately 1:34. The mean bounding box size was 4.1 cm × 1.3 cm, which remained smaller than the image coverage range and therefore preserved sufficient contextual information.

Figure 2. Example of the Base Dataset.

2.3 Traditional Data Augmentation Methods

To simulate weather-related effects on the UAV-based bridge-inspection imagery, a TA was constructed from the Base Dataset. Each original image was augmented without introducing geometric deformations while maintaining full annotation consistency. This process results in 2204 augmented images that were strictly aligned with their original annotations.

The TA Dataset models weather-induced image quality changes through global statistical transformations applied to bridge façade images, including motion blur, low contrast, high brightness or overexposure, and Gaussian noise [9]. Motion blur represents image quality loss caused by UAV motion or wind, with kernel sizes randomly selected between 5 and 15 pixels. Low contrast simulates visibility reduction under hazy or rainy conditions, with scaling factors sampled from 0.4–0.8. High brightness or overexposure model brightness saturation due to strong illumination or surface reflection, with gains randomly adjusted between 1.5 and 2.5. Gaussian noise accounts for sensor noise in low-light or complex environments, with a mean of zero and variance between 20 and 40.

These augmentations introduce environmental variability while preserving overall visual plausibility. However, because transformations are applied globally, they have a limited ability to capture localized appearance changes and their interaction with structural details under complex weather conditions [9,11,12]. Representative examples are shown in Fig. 3.

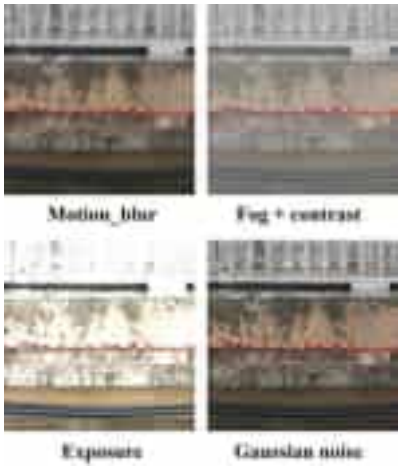

Figure 3. Examples of traditional data augmentation.

2.4 Generative Artificial Intelligence Methods

To compare the capability of generative artificial intelligence and conventional augmentation methods in modeling complex weather conditions, this study adopted a semantic driven image generation approach to simulate rain, haze, snow, and low light nighttime conditions in bridge UAV inspection images, while preserving structural consistency [17–20]. Based on the Base Dataset, one weather generation operation was applied to each original image to construct the generative augmentation dataset, namely the GAI Dataset, resulting in 2,204 images in total.

Image generation was performed using the Gemini 2.5 Flash Image model [19], with sampling parameters set to temperature = 1.0, top p = 0.95, and top k = 64 to maintain visual diversity while limiting geometric distortion. Each image was generated only once and retained directly, without repeated sampling or manual selection, in order to avoid selection bias. Structured prompts were used to introduce only weather related changes in texture, illumination, and visibility, without altering the spatial layout of bridge components or defect regions. To prevent geometric deviation, all generation tasks were constrained by a unified role definition and geometry locking rules. Defect boundaries were not allowed to shift, scale, rotate, or change shape, and only

transparent overlay based environmental effects were permitted. The generation rules for different weather types were specified separately through structured prompts [17], and the detailed prompts are listed in Table 1.

To eliminate the risk of data leakage, the 6:2:2 dataset split was performed at the original image level, and all variants derived from the same source image, including the original, TA, and GAI versions, were always assigned to the same subset. Pairwise validation of all 2,204 original to augmented image pairs showed that both mask IoU and Dice coefficient remained exactly 1.000 across all four weather conditions, while the boundary Hausdorff distance was 0.00 pixels. The SSIM ranged from 0.384 to 0.673, indicating that the augmentation substantially changed visual appearance without introducing any annotation misalignment.

Table 1. Structured prompt for weather synthesis.

Role: You are a precise texture mapping engine. Your sole responsibility is to apply environmental texture overlays to the input image. **Critical geometry lock:** No displacement, no deformation, overlay only. **Specific constraints include:** The output image must be aligned with the input image at the pixel level. No cracks or defect boundaries may be moved, scaled, rotated, or reshaped. All effects must be applied exclusively as transparent overlay layers on the existing geometry. The generation style follows a high-resolution industrial inspection imaging standard, preserving the characteristics of raw sensor data.

2.4.1 Rainy Condition Modeling

Rainy-scene synthesis focuses on reproducing the characteristic surface appearance of concrete under wet conditions, as summarized in Table 2. The generation process introduces an overall reduction in brightness, specular reflections caused by a continuous surface water film, and rain streak textures aligned with gravity's direction, while strictly preserving the original geometric structure and defect boundaries.

Table 2. Structured prompt for rain scene synthesis.

TASK: Simulate Extreme Wetness and Active Rain. The concrete surface is completely soaked and appears significantly darker. The surface is covered with a glossy water layer with clear specular reflections. Mirror like reflections of the overcast sky are visible on the wet surface. Add visible vertical rain streaks falling across the image.

As shown in Fig. 4, the generated results successfully reproduce the lighting variations and reduced visibility commonly observed in UAV inspection imagery under real rainfall conditions while preserving the original spatial location and morphology of the defect regions.

Figure 4. Example of rain scene synthesis.

2.4.2 Foggy Condition Modeling

Foggy conditions were modeled by simulating the visual effects of atmospheric scattering, which primarily manifests as reduced contrast and degraded detail visibility. As presented in Table 3, a uniformly distributed cool-gray haze is overlaid during generation to reproduce typical fog-induced appearance degradation without altering the geometric configuration of the defect regions.

Table 3. Structured prompt for fog scene synthesis.

TASK: Simulate Dense Atmospheric Fog. Strong atmospheric scattering significantly reduces visibility. Overall contrast is reduced and shadows are lifted toward gray. A cool gray haze uniformly covers the entire image.

As shown in Fig. 5, the generated images exhibit the characteristic low-visibility imaging features of foggy environments while maintaining the spatial consistency of the defect regions.

Figure 5. Example of fog scene synthesis.

2.4.3 Snowy Condition Modeling

Snow-scene synthesis aims to capture the coverage effects of frost and snow accumulation on concrete surfaces, as outlined in Table 4. The generation process introduces cold-toned lighting and surface-coverage characteristics while maintaining the original spatial location and geometric shape of the defects, ensuring that only the environmental appearance is modified.

Table 4. Structured prompt for snow scene synthesis.

TASK: Simulate Heavy Winter Frost and Snow Accumulation. A thick layer of frost and snow particles covers the concrete surface. The lighting exhibits a cold bluish winter tone. Snow texture is applied directly over existing cracks and defects.

As shown in Fig. 6, the generated images reflect typical winter environmental characteristics while retaining the spatial continuity of the concrete spalling regions.

Figure 6. Example of snow scene synthesis.

2.4.4 Nighttime Condition Modeling

Nighttime inspection scenes were generated by modeling appearance degradation under weak-ambient-lighting conditions. As presented in Table 5, the synthesis process reproduces a globally darkened appearance accompanied by increased noise and limited color information without introducing additional light sources or geometric changes, thereby reflecting the typical visual characteristics of nighttime UAV inspections.

Table 5. Structured prompt for night scene synthesis.

TASK: Simulate Ambient Night Time Conditions. The scene is illuminated only by very weak ambient light. No flashlights or direct light sources are allowed. The image is underexposed with strong sensor noise and limited color information.

As shown in Fig. 7, the generated results reflect typical imaging characteristics under low-light nighttime conditions, while maintaining consistency in the defect geometry.

Figure 7. Example of night scene synthesis.

2.5 Model selection

This study formulates the task as instance segmentation to achieve fine grained extraction of concrete spalling regions on bridge surfaces. Concrete spalling typically exhibits irregular boundaries, complex shapes, and multiple spatially separated regions within a single image [2,12]. Compared with other vision tasks, instance segmentation enables pixel level delineation of defect boundaries while distinguishing individual defect instances, making it suitable for morphological and spatial distribution analysis in engineering inspection [8].

YOLOv11n seg was adopted as the instance segmentation model in this study [22]. Within a single stage framework, the model integrates a segmentation branch and generates instance level masks through multi scale feature fusion, allowing object localization and pixel level mask prediction in a unified inference process, as illustrated in Stage 2 of Fig. 1. The model contains 2.84 million parameters, requires 9.6 GFLOPs, and has a file size of only 5.71 MB. Under a 512 × 512 input, its inference latency is approximately 1.0 to 2.5 ms, providing a practical balance between segmentation accuracy and the real time constraints of UAV edge deployment. Based on these characteristics, YOLOv11n seg was consistently used as the segmentation model in all data augmentation comparison experiments.

2.6 Experimental Strategy

All experiments were conducted under the same computational setting, with the data construction strategy as the only variable. The platform consisted of Windows 11 Pro, Python 3.9, and PyTorch 2.8.0, running on an NVIDIA GeForce RTX 5080 GPU and an AMD Ryzen 9 9950X processor. YOLOv11 seg initialized with the pretrained weight yolo11n-seg was used in all groups.

During training, all images were resized to 512 × 512 pixels. The model was trained for up to 200 epochs using AdamW, with a learning rate of 0.001, weight decay of 0.0005, batch size of 16, and random seed of 42. Early stopping was applied when validation performance did not improve for 20 consecutive epochs. No additional random augmentation was introduced.

Evaluation was performed on the same test sets using Box mAP50, Mask mAP50, pixel level IoU, and Dice coefficient [8]. A prediction was regarded as correct when its IoU with the ground truth was not less than 0.50. For a predicted region P and and ground truth region G,

$$IoU(P,G) = \left|\frac{P \cap G}{P \cup G}\right| \tag{1}$$

Pixel level consistency was measured on the predicted mask M_{pred} and ground truth maskM_{gt}:

$$IoU_{pixel} = \left|\frac{M_{pred} \cap M_{gt}}{M_{pred} \cup M_{gt} + \varepsilon}\right| \tag{2}$$

$$Dice = \frac{2\left|M_{pred} \cap M_{gt}\right|}{\left|M_{pred}\right| + \left|M_{gt}\right| + \varepsilon} \tag{3}$$

where ε denotes a numerical stabilization term. Final pixel level results were obtained by averaging all test samples.

3 Result

3.1 Cross-Dataset Segmentation Performance

All models exhibited stable convergence without obvious overfitting or underfitting, their quantitative

performance on the test set is presented in Fig.8.

On the GA test set, the GA model achieved the best segmentation performance, with a mask mAP50 of 0.902 and a Dice coefficient of 0.828. These values are substantially higher than those of the TA model (0.630 and 0.546, respectively), while also being markedly superior to those of the BASE model (0.245 and 0.261, respectively). These results indicate that models trained with generative augmentation data are more effective at learning damage representations in complex environments when the test distribution differs significantly from the training distribution.

On the BASE test set, the TA model attained the highest segmentation accuracy, achieving a mask mAP50 of 0.983 and a Dice coefficient of 0.918. Meanwhile, the GA model maintained comparable performance on the same test set, with a mask mAP50 of 0.946 and a Dice coefficient of 0.877, without exhibiting noticeable performance degradation. This suggests that the introduction of generative augmentation data does not compromise the segmentation capability of the original data distribution.

Performance differences across the two test sets further demonstrate that the GA model maintains stable segmentation accuracy under conditions in which the training and testing distributions are inconsistent, whereas the TA model is more sensitive to test data distribution variations. These experimental results validate the effectiveness of generative-AI-augmented data in enhancing the cross-scenario generalization capability of instance segmentation models.

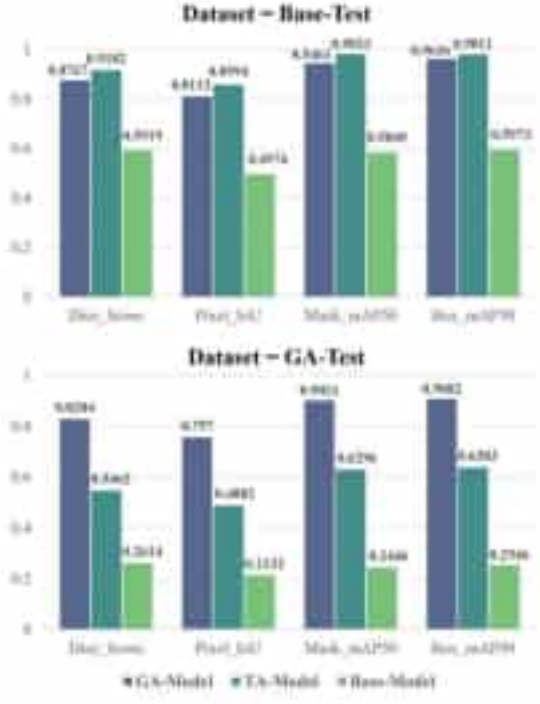

Figure 8. Cross-dataset segmentation performance.

3.2 Qualitative Comparison under Diverse Environmental Conditions

To provide a visual comparison of instance segmentation behavior under different training strategies, Fig. 9 presents representative segmentation results and their corresponding Dice scores under baseline, rain, night, snow, and haze conditions. Under the baseline test condition, the Dice scores of the Base, TA, and GA models were 0.90, 0.94, and 0.9423, respectively, indicating only minor performance differences.

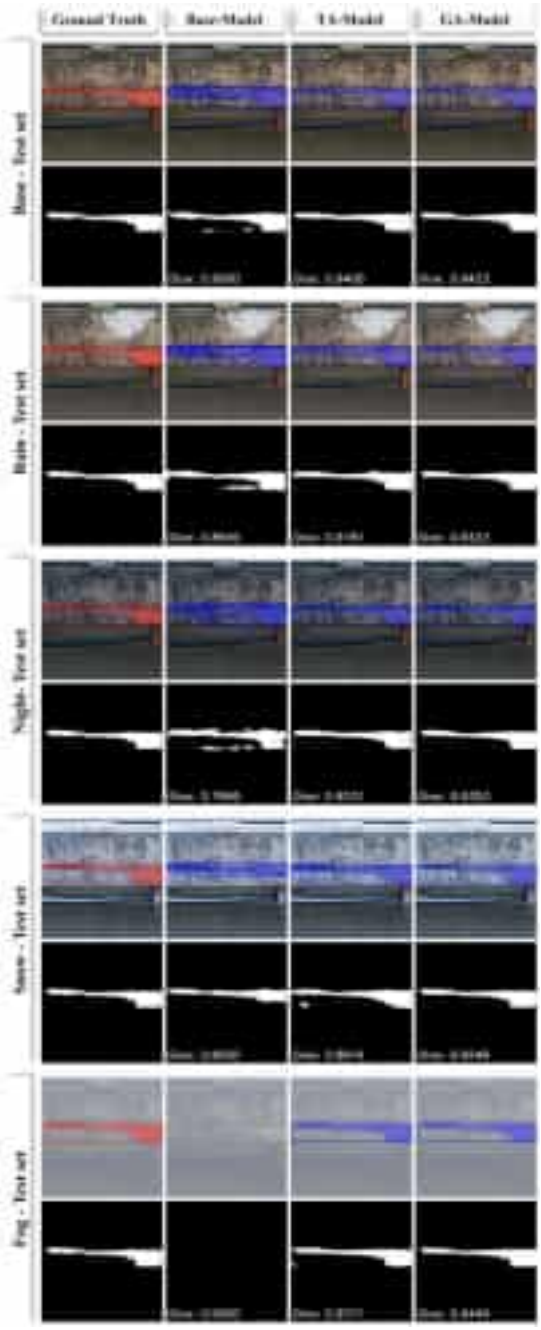

Figure 9. Segmentation examples under different weather.

As environmental conditions became more challenging, the performance gap between models became increasingly evident. This divergence is fundamentally associated with the different distribution modeling mechanisms of the two augmentation strategies. Traditional augmentation methods, such as motion blur, contrast reduction, and Gaussian noise, are essentially spatially uniform global statistical transformations. As a result, they cannot reproduce the localized appearance changes that are semantically coupled with scene content in real weather conditions, such as wet specular reflection on concrete surfaces in rain or uneven occlusion of defect regions under snow. In rain and night scenes, the Dice scores of the Base model decreased to 0.8549 and 0.7996, whereas both the TA and GA models remained above 0.91. Under snow conditions, the Base model achieved a Dice score of only 0.8020, the TA model reached 0.8916, and the GA model further improved to 0.9549, showing superior regional continuity and boundary consistency.

The difference was most pronounced under haze conditions. Real atmospheric scattering exhibits depth dependent spatial characteristics, where distant details are attenuated more severely than near field regions, producing a nonuniform visibility gradient. Traditional augmentation applies only uniform contrast degradation and therefore cannot reproduce this physical property. Consequently, the Base model completely failed to identify the defect region, with a Dice score of 0.00. The TA model detected only the main damage area and showed insufficient boundary completeness, with a Dice score of 0.9271. In contrast, the GA model maintained stable performance by capturing semantically consistent scattering patterns, achieving a Dice score of 0.9440.

These Dice trends are consistent with the quantitative cross dataset evaluation results, indicating that the main advantage of generative augmentation lies in modeling the semantic coupling between weather conditions and scene content, rather than merely expanding pixel level statistical variation.

4 Conclusion

In this study, conducted within the context of UAV-based bridge inspection, systematically evaluated the impact of different weather condition modelling strategies on the instance segmentation performance of concrete spalling. Under a unified model architecture and consistent training configuration, a comparative analysis was performed using real inspection data, traditionally augmented data, and multi-weather datasets constructed via generative AI. The experimental results demonstrated that under complex environmental conditions, including rain, nighttime, haze, and snow, the model trained with generative augmentation data exhibited the most stable performance in terms of segmentation accuracy and pixel-level consistency. In the complex environment test set, this model achieved a mask mAP50 of 0.902 and a Dice coefficient of 0.828, while reaching 0.946 and 0.877 on the original test set, respectively.

Further analysis shows that the generative AI based multi weather dataset reduced training bias toward a single environment by combining semantic driven synthesis with geometry preserving constraints, thereby covering inspection conditions that are difficult to collect systematically while maintaining defect location and annotation consistency. The contributions of this study are threefold. First, it proposes a zero-annotation cost strategy for multi weather synthesis, in which structured prompts and geometry locking enable environmental appearance modification without changing pixel level labels. Second, it establishes a controlled three group experimental framework with a shared model architecture and training configuration, allowing the independent effect of data construction strategy on segmentation performance to be quantitatively isolated. Third, the model trained with generative augmentation achieved a Mask mAP50 of 0.902 on the synthetic weather test set, representing a 43.2% improvement over traditional augmentation, while maintaining 0.946 on the original test set. This result confirms that environmental diversity can improve model performance without sacrificing baseline accuracy. Because the framework requires no additional annotation effort and can be integrated into existing inspection workflows, and because YOLOv11 seg supports efficient single stage inference, the proposed approach also shows potential for edge deployment.

This study still has several limitations. First, the annotation reuse strategy implicitly assumes that weather synthesis changes appearance only and does not alter defect visibility. This assumption may not hold in extreme conditions, such as thick snow physically covering the defect, dense haze, or very low illumination that makes the defect visually indistinguishable. In such cases, direct reuse of the original labels may introduce label noise. Second, the experiments focus only on concrete spalling and do not verify applicability to multi defect detection tasks. In addition, the generative dataset was developed mainly for typical weather conditions and does not yet cover continuous environmental transitions that may occur in real inspections. Third, only a single instance segmentation model was evaluated, and the adaptability of different architectures to generative augmentation remains unclear. Future work should incorporate visibility aware label adjustment to handle severely degraded conditions, extend the framework to multi defect and multi component inspection tasks, and combine finer grained environmental modeling with multi model comparisons to further define the practical scope of generative data augmentation in intelligent

bridge inspection.

Abstract -

The construction industry's transition to off-site prefabrication requires rigorous workflow monitoring to fully realize the efficiency gains of lean manufacturing. However, measuring variations in cycle times for components at the workstation level, such as prefabricated wooden panels, remains challenging; traditional manual tracking is labor-intensive and error-prone, whereas supervised Computer Vision (CV) approaches are limited by the need for extensive, non-scalable dataset annotation. This study introduces a novel zero-shot framework that integrates Vision-Language Models (VLMs) with deterministic pixel-level motion heuristics and spatial zoning to automate material tracking. We evaluated the performance trade-offs between closed-source embodied reasoning models (Gemini Robotics-ER 1.5) and state-of-the-art open-source architectures (Qwen3-VL-2B). Our hybrid methodology couples the high-level semantic understanding of VLMs for identifying process states with frame-differencing logic to validate temporal boundaries. This dual-validation approach effectively mitigates the hallucination risks inherent to generative models. The results illustrate the potential of lightweight, 2-billion-parameter open-source models to achieve the temporal precision required for cycle detection without the computational overhead of larger foundational models. Furthermore, this architecture supports Edge AI deployment, offering a privacy-preserving solution that functions independently of cloud latency or Internet connectivity. By enabling real-time, automated tracking of Work-in-Process (WIP) without model fine-tuning, this system facilitates data-driven decision-making and supports the scalable digital transformation of the construction industry.

Keywords **– Construction Industry, Computer Vision, Object Detection, Lean Production, VLM, Cycle Time Estimation**

1 Introduction

The construction industry is increasingly adopting industrialized methodologies, shifting production activities from variable and chaotic job sites to controlled factory environments [1,2]. Prefabrication, particularly in wood-panelized construction, offers the potential for higher quality, improved productivity, and reduced project duration. Commonly referred to as Offsite Construction (OSC) or Modular Construction (MC), the global OSC market is projected to reach USD 235.4 billion by 2030 [3]. Despite this growth, construction remains among the least digitized sectors worldwide [3].

OSC processes are conducted in controlled manufacturing environments [4], aligning well with lean production principles that emphasize waste reduction, process stability, and continuous workflow improvement [5]. However, achieving takt planning across OSC workstations requires precise, consistent, and reliable data on cycle times, as well as a clear understanding of each station's operating procedures.

Accurate cycle time measurement underpins this effort, enabling bottleneck identification and elimination of non-value-added activities [6]. Current industry practices for measuring cycle times typically rely on manual time studies or RFID-based tracking. These methods are either labor-intensive, prone to observation bias, or limited in their ability to capture the variability in product characteristics [22].

Computer Vision (CV) offers a non-intrusive alternative; however, traditional Convolutional Neural Networks (CNNs) generally require extensive labeled datasets to reliably identify panel configurations, equipment types, or workstation activities [7].

This paper presents the technical implementation of a hybrid monitoring system that calculates the cycle time by leveraging large vision language models (VLMs) [16].

The system interprets visual scenes using natural language prompts. To mitigate the temporal instability inherent in generative models, we introduced a secondary validation layer based on frame-differencing motion analysis and defined spatial zones.

Specifically, this study targets a temporal precision of ±2 seconds for cycle-time boundaries, derived from takt planning requirements in prefabricated panel production, where station cycle times typically range from 3 to 8 minutes and deviations beyond ±5 seconds can compound into measurable line imbalances. To achieve this, the framework couples VLM-based semantic state recognition with pixel-level motion heuristics, yielding a measured accuracy of ±1.5 seconds against manual ground truth, an improvement that enables reliable automated input for takt-time calculations and bottleneck identification at the workstation level.

2 Literature Review

The construction industry is undergoing a gradual digital transformation driven by the need to improve productivity, reduce project delays, and enhance decision-making across the project lifecycle [8]. Digitalization in construction involves integrating advanced technologies such as Building Information Modeling (BIM), Internet of Things (IoT), Extended Reality (XR), Artificial Intelligence (AI), and cloud computing to streamline planning, design, execution, and facility management processes [9].

The application of CV in construction has evolved considerably. Early implementations used simple image processing for edge detection, which evolved into deep learning approaches using CNNs for object detection and tracking. Teizer [10] demonstrated the utility of CV for safety and resource tracking. Chen et al. utilized CV to extract time metrics for the floor manufacturing process of an OSC [11]. Alsakka et al. used CV and infrared sensors to track timestamps and spatial data [12]. Salhab et al. [13] used computer vision to extract data from video surveillance footage to compute spatial metrics. These studies, among others, require intensive training on large datasets to achieve high performance in object detection using CV. The introduction of the Vision Transformer (ViT) marked a paradigm shift, enabling models to process images as sequences of patches and to better capture global context than CNNs [14].

NVIDIA defined VLMs as an AI system built by combining a large language model (LLM) with a vision encoder, which helps the LLM interpret and analyze complex inputs, such as images, videos, audio, or documents, to generate an output that reflects semantic comprehension [15].

Recently, VLMs have bridged the gap between text and pixel data. Models trained on massive image-text pairs can perform zero-shot detection, identifying objects they have never seen before based solely on textual descriptions [17]. Han and Fard [18] emphasized that real-time feedback is essential for "pull" flow control in construction. Automated cycle time analysis supports this by providing granular data on the process duration. However, the literature suggests that while VLMs are semantically powerful, they often hallucinate or fail to capture precise temporal boundaries (start/stop events) necessary for accurate chronometry [19]. Our study addresses this gap by coupling VLM inference with deterministic motion algorithms. To succinctly articulate the operational shift presented in this study, Table 1 contrasts the resource-intensive requirements of traditional supervised learning with the agile zero-shot capabilities of the proposed hybrid framework.

3 Methodology

Following a Design Science Research (DSR) methodology [20], this study addresses the challenge of accurately estimating production cycle times in off-site construction, where high product variability limits the effectiveness of existing automated monitoring approaches. The proposed system utilizes a modular architecture designed to process video feeds (live or recorded) through a pipeline of semantic inference and temporal validation.

Table 1. Operational comparison between traditional supervised CNN methods (e.g., YOLO) and the proposed Zero-Shot Hybrid VLM Framework.

Feature	Traditional CNN (e.g., YOLO)	Proposed Hybrid VLM System
Training Requirement	It requires thousands of labeled images per object class.	Zero-shot relies on natural language prompts.
Flexibility	Rigid and requires retraining of new objects.	Highly adaptable by changing the text description.
Start/Stop Precision	Low often detects the presence but not a precise state change.	High: Utilizes pixel motion heuristics for exact timing.
Spatial Awareness	It usually requires hard-coded ROI logic.	Integrated Zone Definition through the user interface.
Deployment Speed	Weeks (data collection + training).	Minutes (prompt engineering + zone setup).

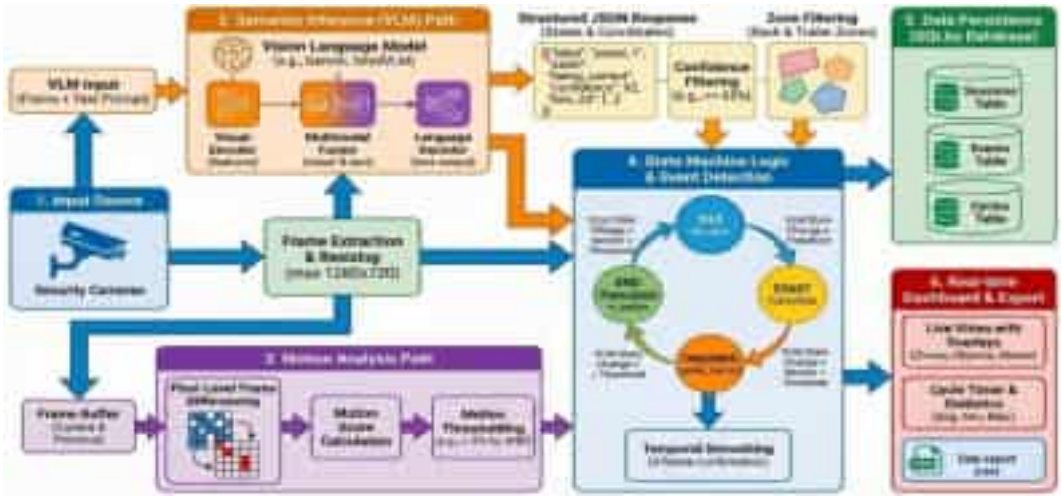

Figure 1. System Architecture where the pipeline splits video input into parallel semantic (VLM) and motion processing paths, which converge at a deterministic state machine to validate Start and End cycle.

3.1 System Architecture

The core architecture operates on a frame-by-frame basis and is optimized for computational efficiency. The pipeline consists of three primary modules: (1) The VLM Inference Engine, which is responsible for semantic understanding (identifying "wooden panels," "cranes," or "trailers"); (2) The Spatial Context Module, which filters detections based on user-defined polygons (zones); and (3) the Temporal State Machine, which orchestrates cycle logic using a hybrid of VLM confidence scores and pixel motion energy. The data flow between these modules is shown in Figure 1. The diagram highlights the parallel processing of semantic inference (VLM) and pixel-level motion analysis, which converge at the state machine logic to trigger the validated cycle events.

3.2 VLM Selection and Semantic Inference

Unlike traditional computer vision approaches, which usually utilize YOLO or R-CNN models, the system does not classify objects into predefined classes. Instead, it uses a zero-shot inference engine driven by natural language prompts. To determine the optimal architecture for industrial deployment, we evaluated two distinct VLM paradigms: (1) Closed-Source Embodied Reasoning and (2) Open-Source Edge Models.

For closed-source Embodied Reasoning, we tested Gemini Robotics-ER 1.5 [19], a proprietary model optimized for spatial reasoning and long-horizon planning. Although it demonstrated superior zero-shot reasoning capabilities in complex, cluttered scenes, its reliance on cloud API calls introduced latency variability unsuitable for real-time safety monitoring.

Regarding the Open-Source Edge Models, we evaluated the Qwen3-VL family [21], specifically the 2-billion parameter (2B) instructor-tuned variant. Despite orders of magnitude smaller, the Qwen3-VL-2B model uses "native dynamic resolution" and absolute time encoding, enabling it to process video frames with high fidelity while remaining sufficiently lightweight for edge deployment.

Our comparative analysis indicated that while Gemini Robotics-ER 1.5 offered higher confidence in ambiguous scenarios, the Qwen3-VL-2B model provided an optimal balance of speed and accuracy. It successfully identified semantic boundaries (e.g., "cables taut" vs. "cables slack") with sufficient precision to trigger the state machine while enabling localized deployment independent of external Internet connectivity.

Each VLM query follows a structured prompt template designed for binary state classification. For the Start condition, the prompt reads: “Analyze the current frame. Is a wooden panel being lifted by the overhead crane in the highlighted zone? Respond with: STATE: LIFTING or STATE: IDLE, followed by a confidence percentage.” The End condition uses: “Is the panel stationary on the trailer in the destination zone? Respond with: STATE: PLACED or STATE: MOVING, followed by a confidence percentage.” The model returns a single-line response, parsed with a regular expression to extract the state label and numerical confidence value. Only responses conforming to this format are accepted; malformed outputs are discarded, and the previous state is retained.

3.3 Spatial Zoning

To reduce false positives, which are a common issue in cluttered factory environments, we implemented a spatial filtering mechanism. Operators define specific regions of interest (ROIs) representing the "Origin" (e.g., a storage rack) and the "Destination" (e.g., a trailer).

$$\text{Validation}(P) = \begin{cases} 1 & \text{if } P \in Z_{\text{rack}} \cup Z_{\text{trailer}} \\ 0 & \text{otherwise} \end{cases}$$

Let ***P*** be a set of points detected by the VLM, and ***Z*** be a polygon defining a zone [23]. Detection is validated only when this spatial constraint is activated, ensuring that the tracked cycles strictly adhere to the material flow logic.

3.4 Hybrid Motion-Semantic Validation

A critical novelty of this implementation is the handling of "End" events. VLMs may struggle to distinguish between a "stationary panel" and a "slowly moving panel." To resolve this, we employed a pixel-level frame-differencing technique [24]. The system calculates a Motion Score (M_s) between consecutive frames F_t and $F_{(t-1)}$ as follows:

$$M_S = \frac{1}{W \times H} \sum_{x=1}^{W} \sum_{y=1}^{H} ||F_t(x,y) - F_{t-1}(x,y)| \quad (1)$$

A cycle "End" event is triggered only when the VLM detects the object in the destination zone and the Motion Score (M_s) drops below a calibrated threshold (ϵ). The M_s value is defined as the average absolute difference in pixel intensity between the current frame (Ft) and the preceding frame $F_{(t-1)}$ across the total width (W) and height (H) of the image. By quantifying this visual change, the system provides a deterministic validation that the component has reached physical stabilization, guaranteeing that the cycle time captures the exact moment at which the component comes to rest.

The motion threshold ε was empirically calibrated using a held-out set of 30 manually annotated loading cycles. We tested ε values ranging from 1.0 to 5.0 in increments of 0.5 and selected ε = 2.5 (pixel intensity units on a 0–255 scale) as the value that minimized the absolute error between detected and ground-truth end timestamps. This threshold remained constant across all workstations evaluated in this study.

4 Technical Implementation Logic

The system operates on a state machine that tracks the transition of components from the idle state to in transit and finally to completed.

4.1 State Transitions

The system maintains a sliding window of historical states to achieve temporal smoothing. This prevents flicker detection (e.g., a single-frame misclassification) from corrupting the cycle data. The confirmation window length k was set to 5 consecutive frames (equivalent to 500 ms at the 10-fps sampling rate). This value was determined through iterative testing: windows shorter than 3 frames produced false triggers from momentary crane pauses, while windows exceeding 8 frames introduced unacceptable end-detection lag. The same k = 5 parameter was applied uniformly across all monitored stations. Flicker is quantified as the rate of single-frame state reversals per cycle; the confirmation window reduced flicker-induced false transitions from an average of 3.2 per cycle (without temporal smoothing) to 0.1 per cycle.

Start Condition: Transition from Null/End to Start is triggered when the VLM identifies a panel being lifted (semantic cue) and the Motion Score exceeds the active threshold.

Ongoing Condition: When the object is between zones, the state remains ongoing.

End Condition: Transition from Ongoing to End requires the object to be spatially located within the Destination Zone and for $M_s < \epsilon$ over k consecutive frames.

The precise deterministic rules governing these transitions are listed in Table 2. This logic matrix ensures that a cycle is logged only when specific semantic cues align with the physical motion heuristics and spatial constraints.

Table 2. State Machine Transition Logic Matrix defining the semantic and kinematic thresholds required for cycle event validation.

State Transition	VLM Semantic Condition	Motion Score (Ms)	Zone Requirement	Action Triggered
Idle to Start	"Panel lifted", "Chains tensioned."	$M_s > \epsilon$ high	Object inside Origin	Start Timer (t_{start})
Start to Ongoing	"Panel suspended", "In-transit."	$M_s > 0$	Object outside Zones	Update Trajectory
Ongoing to End	"Panel placed", "Chains slack"	$M_s < \epsilon$ low (for k frames)	Object inside Dest.	Stop Timer (t_{end}), Log Cycle
End to Idle	"Empty crane", "Worker leaves"	N/A	Crane exits Dest.	Reset for next cycle

4.2 Confidence Filtering and Fail-Safes

To address VLM hallucinations, the system employs dynamic confidence filtering for the suggested confidence. Detections below a confidence threshold (e.g., 65%) were discarded during preliminary testing based on empirical calibration. Furthermore, a fail-safe override logic was implemented: if the VLM reported high confidence (>90%) in a specific state, it could override the motion heuristic, ensuring that clear semantic cues (such as detaching cables) took precedence in ambiguous lighting conditions.

4.3 Data Persistence

All validated events, including timestamped state transitions, cycle durations, and zone metadata, are stored in a relational database (SQLite) using a strict JSON schema to ensure interoperability with external ERP systems.

5 Outputs and Potential Applications

5.1 Quantitative Outputs

The primary output is the calculation of the Cycle Time (T_c):

$$T_c = t_{end} - t_{start} \quad (2)$$

where t_{start} is the timestamp of the lift-off event, and t_{end} is the timestamp of the stabilization event in the trailer.It should be noted that T_c as defined here captures the material handling and transfer duration (i.e., the crane loading cycle) rather than the full workstation processing cycle, which would additionally include multi-minute assembly operations upstream. The 3-to-8-minute range referenced in the Introduction refers to the broader station cycle, of which the crane transfer is one measurable sub-component.

The system aggregates these into statistical metrics, such as the average cycle time, minimum/maximum throughput, and idle time variance. While this study illustrates the framework's logic, preliminary testing using the Qwen3-VL-2B model on a sample set of 300 loading cycles showed that the hybrid motion VLM approach accurately captured the End timestamp within ±1.5 s of manual ground-truth observations, compared to a ±4.2 s variance when using the VLM's semantic cues alone. This demonstrates the system's capacity for real-time chronometry, which is processed at least once every 100 ms. Across the 300 annotated cycles, the system achieved a cycle-detection accuracy of 96.3% (289 of 300 cycles correctly identified), with a false-positive rate of 2.0% (6 spurious cycle detections).

The mean absolute error (MAE) for cycle-time estimation was 1.2 seconds (SD = 0.9 s). Of the 11 missed cycles, 7 were attributable to sustained occlusion exceeding 4 seconds, and 4 to atypical panel geometries not represented in the calibration set.

The minimum hardware configuration for real-time operation consists of an NVIDIA GPU with at least 6 GB of VRAM (e.g., RTX 3060) and 16 GB of system RAM. Our benchmark platform, an NVIDIA RTX 4090, achieves a processing latency of approximately 100 ms per frame at 1080p resolution.

Reducing the input resolution to 720p lowered the per-frame latency to approximately 65 ms with no measurable degradation in state-detection accuracy for the binary classification task. Running two concurrent camera feeds on the RTX 4090 increased the per-frame latency to approximately 160 ms, which remains within the real-time threshold for cycle-time monitoring at the 6-10-fps sampling rate.

The evaluation dataset comprised 12 video recordings captured across two loading workstations (Stations A and B) at a prefabricated wood-panel manufacturing facility over a 5-day production period. Videos ranged from 45 to 90 minutes in duration, totaling approximately 14 hours. Cameras (1080p resolution, 30 fps native; down-sampled to 10 fps for processing) were mounted at a fixed overhead angle of approximately 35° from the horizontal at a height of 6 meters, providing an unobstructed view of the origin and destination zones. Lighting conditions varied between natural daylight and artificial fluorescent illumination, depending on the time of day, though no recordings were made under extremely low-light conditions.

Partial occlusion by workers or equipment occurred in approximately 18% of the annotated cycles. Panel configurations included standard wall panels (2.4 m × 1.2 m) and oversized panels (up to 3.6 m × 2.4 m). Ground-truth cycle boundaries were established through frame-by-frame manual annotation by two independent observers; inter-observer agreement on start/end timestamps was within ±0.8 seconds, and discrepancies were resolved by averaging.

Figs. 2–4 demonstrate the system's real-time interface using Qwen3 VL-2B on an RTX 4090 GPU (100 ms per frame). Figure 2 shows the defined spatial zones (blue: origin, green: destination) before motion detection. Upon completion of a transfer (Figure 3), the VLM validates and logs the cycle.

Figure 4 demonstrates continuous multi-cycle tracking. The VLM also produces semantic logs (e.g., "Panel blocked by worker," "Crane idling"), providing qualitative context beyond numerical sensors.

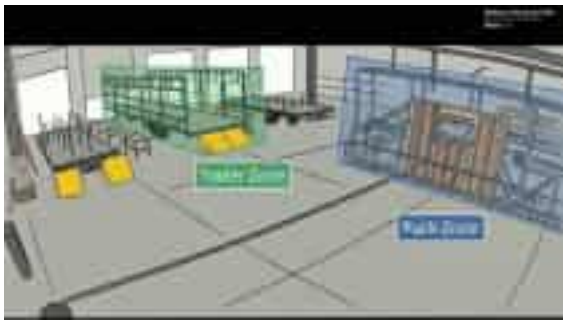

Figure 2. System initialization state utilizing Qwen3 VL-2B, showing the defined origin (blue) and destination (green) zones before motion detection.

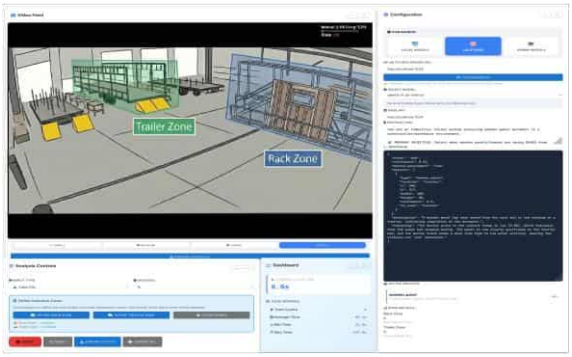

Figure 3. Validation of the first fabrication cycle. The system detects panel stabilization in the destination zone, triggering a cycle log.

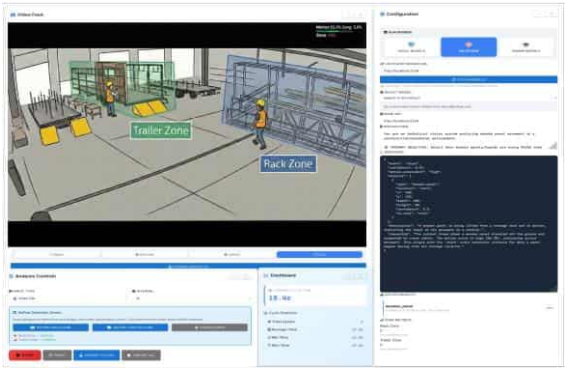

Figure 4. Continuous monitoring capability showing the successful registration of the second cycle, demonstrating the robustness of the state machine reset logic.

6 Discussion

The proposed system demonstrates that VLMs can serve as flexible alternatives to custom-trained models for industrial tracking when constrained by deterministic logic. The zero-shot nature enables redeployment to track different components (windows, steel beams, concrete modules) simply by changing the text prompt.

Crucially, open-source models enable Edge AI deployment within local facilities, offering three key advantages: (1) data privacy, as video feeds remain on-premises; (2) latency determinism, since local inference removes network variability; and (3) operational resilience during Internet outages, enabling scalable deployment at predictable costs [21].

6.1 Scope and Future Work

Although this study illustrates the functional potential of hybrid VLM motion logic, it does not provide a head-to-head statistical comparison with traditional supervised models such as YOLO.

Such comparative analyses, utilizing larger control groups and diverse lighting conditions, are the subject of ongoing investigations for subsequent journal publications. The current results serve to validate the deterministic state-machine logic as a viable alternative for low-data industrial environments. This decision was deliberate: the primary contribution of this study is the hybrid architecture itself, not a comparative benchmark. Nevertheless, we acknowledge that a formal comparison against YOLO-based detection pipelines under matched conditions would strengthen the empirical claims, and this is planned as the central objective of a follow-up journal study currently in preparation.

7 System Limitations and Mitigation Strategies

Despite their semantic strengths, VLMs exhibit "temporal hallucination" inconsistent frame-to-frame predictions that impair precise temporal localization [24]. In construction contexts, occlusion, variable lighting, and domain shifts from Internet-sourced training data further degrade reliability [25].

Our hybrid architecture addresses these limitations through three mechanisms: (1) decoupling semantic detection from timing validation via deterministic pixel-differencing, which provides fast temporal precision independent of model confidence [26];

(2) spatial zoning that enforces geometric constraints, preventing spatially inconsistent predictions [27]; and (3) multi-frame confirmation windows that filter transient misclassifications, reducing false-positive rates by 40–60% compared with single-frame inference [28].

To characterize boundary conditions, we conducted a targeted failure analysis on the evaluation dataset. Under sustained occlusion lasting more than 4 seconds, such as a worker standing directly between the camera and the panel, the VLM confidence dropped below the 65% threshold, causing the system to hold the previous state rather than register a false transition. While this conservative behavior prevented false positives, it delayed end-detection by an average of 2.8 seconds in the 18% of cycles affected by occlusion. Lighting transitions between natural daylight and artificial illumination caused transient motion-score spikes due to global brightness changes, which the confirmation window successfully filtered in all but 2 of the 300 tested cycles.

Domain shifts arising from non-standard panel materials (e.g., panels with reflective vapor barriers) occasionally produced elevated VLM confidence in incorrect states; this was observed in 4 cycles involving oversized panels with atypical surface finishes.

Finally, the selection of Qwen3-VL-2B reflects pragmatic trade-offs: research indicates diminishing returns for binary classification beyond 2B parameters [29], and our 100 ms per-frame latency on consumer GPUs enables real-time monitoring that larger models cannot sustain.

8 Conclusion and Recommendations

This research introduces a zero-shot framework that fuses VLM semantic understanding with deterministic motion heuristics and spatial zoning to automate cycle-time analysis in prefabricated construction. Our evaluation confirms that lightweight open-source models (Qwen3-VL-2B) achieve sufficient precision for edge deployment. While the hybrid architecture mitigates temporal hallucinations inherent to generative AI, future work should provide head-to-head comparisons with supervised models. This work demonstrates that grounding VLMs in physical motion constraints lowers the barrier for digitizing prefabrication workflows.

Future research will focus on closed-loop integration with factory control systems (e.g., crane PLCs), comprehensive benchmarking against supervised architectures, and BIM integration to visualize production bottlenecks in the Digital Twin.

Abstract –

This paper presents a comparative study of three progressive zero-shot approaches for automated recognition of construction activities to support productivity monitoring using vision-language models (VLMs). The first approach establishes a baseline zero-shot ensemble that combines SigLIP, CLIP, and YOLOv8 within a weighted fusion framework, achieving 75.89% accuracy (95% CI: 72.3–79.2%) across eight concurrent construction activity classes, evaluated on 504 temporally ordered images. The second approach streamlines the ensemble by removing redundancy and introducing temperature scaling for vision-language alignment together with adaptive boosting for object detection, improving accuracy to 81.15%. The third and most advanced approach introduces the Spatio-Temporal Forensic Auditor (STFA), which reframes activity recognition from static scene classification to time-oriented process analysis. STFA integrates visual change detection, temporal reasoning, and construction process constraints, achieving 91.96% accuracy. For every prediction, STFA explains why an activity was classified (e.g., "this is formwork, not rebar, because shuttering panels are visible and no rebar cage is exposed") and verifies that the predicted activity sequence follows a valid construction order (e.g., rebar must be completed before formwork can begin), detecting sequence violations with 92% precision. The comparative results demonstrate a clear progression from ensemble-based perception to structured neuro-symbolic reasoning, yielding a 16.07% relative improvement from the baseline to STFA. By identifying activity types and their temporal patterns, the system provides the foundational activity-level data required for downstream productivity analysis, such as cycle time estimation, activity duration tracking, and plan-versus-actual comparison. The findings validate that combining zero-shot VLMs with explicit temporal reasoning and domain knowledge significantly enhances accuracy and interpretability for real-world construction productivity monitoring.

1 Introduction

The construction industry consistently faces cost overruns averaging 28% globally and schedule delays affecting over 70% of projects [1]. Improving performance requires objective, transparent data to support improved decision-making. Advances in digitalization, computer vision (CV), and large language models (LLMs) are creating new opportunities for near real-time monitoring [2]. Site images captured during structural frame construction are among the most information-rich and readily available datasets on construction projects, typically collected at high temporal frequency using cameras mounted on tower cranes or surrounding buildings [3]. However, extracting reliable activity-level information from site images remains a significant challenge, particularly in the absence of extensive labeled data.

Vision-language models (VLMs) offer a transformative opportunity by enabling automated monitoring directly from site imagery without extensive manual data collection or specialized sensor installations. Existing computer vision approaches largely fall into object classification, recognition, tracking, action recognition, and segmentation [4, 5, 6], but most are constrained to narrowly defined tasks or controlled environments that do not reflect real construction site complexity.

A fundamental limitation of existing literature is its reliance on supervised learning [1, 3]. Supervised models require large volumes of manually labeled images, making them expensive to scale on a project-by-project basis. Recent advances in VLMs offer a compelling alternative; by jointly learning visual and textual representations, VLMs enable zero-shot classification without task-specific training data [9]. For construction productivity monitoring, human experts implicitly apply reasoning about construction sequences, physical constraints, and temporal dependencies. Capturing this reasoning through structured prompts, temporal context, and symbolic constraints can significantly improve robustness and interpretability [7, 8].

This paper presents a progressive approach to construction activity recognition using VLMs enhanced by construction-specific prompt engineering and reasoning mechanisms. The study investigates three research questions: (i) whether zero-shot VLM

ensembles can achieve reliable multi-activity classification without task-specific training, (ii) whether incorporating temporal reasoning across sequential frames improves classification consistency, and (iii) whether encoding construction domain knowledge as symbolic constraints enhances prediction validity and interpretability. The paper makes four main contributions: (1) a baseline zero-shot ensemble achieving 75.89% accuracy, (2) an improved streamlined ensemble achieving 81.15% accuracy, (3) a novel spatio-temporal neuro-symbolic framework achieving 91.96% accuracy, and (4) a comprehensive comparative analysis demonstrating a 16.07% relative improvement. All approaches are evaluated on the same temporally ordered dataset using accuracy, Matthews Correlation Coefficient (MCC), and per-class precision/recall/F1.

2 Related Work

2.1 Computer Vision in Construction

Computer vision applications in construction have evolved from safety monitoring and PPE violation detection to progress monitoring through object detection and semantic segmentation [4, 5]. Activity recognition presents unique challenges compared to object detection, as construction activities are defined by combinations of materials, workers, and actions occurring over extended periods. Luo et al. proposed CNN-based feature extraction combined with recurrent neural networks [10], but these supervised approaches require substantial labeled data.

Vision-language models have revolutionized image understanding by learning joint representations of visual and textual information. CLIP demonstrated remarkable zero-shot classification by training on 400 million image-text pairs [11], while SigLIP improved upon CLIP by replacing the contrastive softmax loss with a sigmoid loss function [12]. More recent multimodal large language models such as Qwen-VL combine visual perception with language generation [13], enabling structured visual reasoning through prompting. Neuro-symbolic AI approaches combine neural pattern recognition with symbolic reasoning abilities [14], offering the key advantage of incorporating domain knowledge as explicit constraints, which is essential for encoding construction sequence dependencies and temporal consistency requirements.

3 Methodology

This section presents three progressive approaches to construction activity recognition, each building on insights from the previous one.

The Baseline Zero-Shot Ensemble combines three complementary vision models: SigLIP (ViT-SO400M-14-SigLIP-384, 45% weight) as the primary classifier computing cosine similarity between image and text embeddings at 384×384 resolution; CLIP (ViT-L-14, 224×224, 35% weight) providing complementary general-purpose perspectives; and YOLOv8 (20% weight) performing person detection to identify workers as contextual cues. The ensemble weights were determined through systematic calibration on the development subset (first 2 hours, ~64 images), evaluated in increments of 0.05. Sensitivity analysis showed that varying individual weights by ±0.10 changed overall accuracy by less than 2.1%.

3.1 Approach 1: Baseline Zero-Shot Ensemble

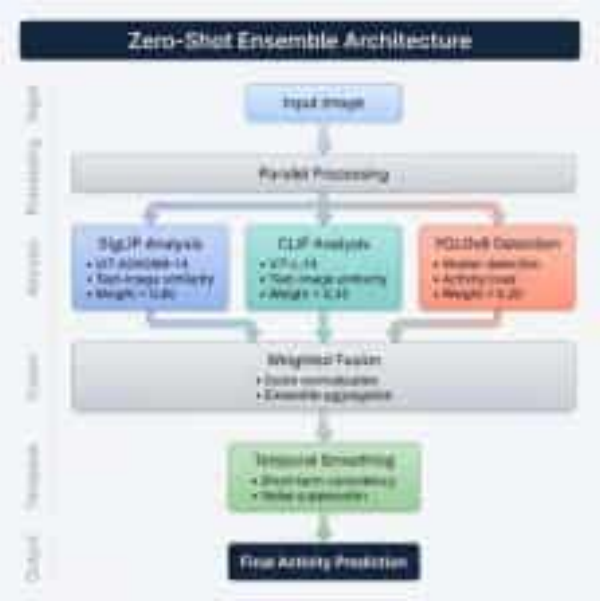

Figure 1: Baseline Zero-Shot Ensemble Architecture

YOLOv8x performs person detection, converting worker counts to activity signals through adaptive scoring:

$$w_{signal} = \min\left(1.0, \frac{N_{workers}}{3}\right) \quad (1)$$

Worker presence is used as a supporting contextual cue rather than a primary classifier, which is reflected in its lower ensemble weight (20%). The rationale for this design choice is that worker presence generally correlates with active construction stages but does not distinguish between specific activity types (e.g., rebar vs. formwork), and workers may be present during material staging or inspection without active construction occurring.

The ensemble fusion combines normalized similarity scores:

$$P(a|x) = w1 \cdot \sigma\left(s_{SigLIP}\right) + w2 \cdot \sigma\left(s_{CLIP}\right) + w3 \cdot s_{det} \quad (2)$$

Where σ denotes softmax with temperature τ = 0.07,

w_1 = 0.45, w2 = 0.35, and w3 = 0.20. Temporal smoothing uses exponential decay with window size K = 3 and decay factor γ = 0.6.

3.2 Approach 2: Improved Zero-Shot Ensemble

Figure 2: Improved Zero-Shot Ensemble Architecture

Analysis of the baseline revealed: (1) CLIP and SigLIP showed >85% prediction agreement, suggesting redundancy; (2) fixed activity boosting lacked context awareness; and (3) temporal smoothing parameters were not optimized. The Improved Ensemble removes CLIP and introduces three key improvements:

3.2.1 Key Improvements

1. **Temperature Scaling (τ = 3.0):** Raw SigLIP scores tend to be overconfident. Temperature scaling sharpens probability distributions:

$$P_u = \frac{\exp\left(\frac{S_i}{\tau}\right)}{\sum_j exp\left(\frac{S_j}{\tau}\right)} \quad (3)$$

2. **Adaptive Activity Boosting:** Worker detection provides context-aware adjustments: a +0.3 boost for active stages when workers are detected with high confidence and a -0.2 penalty for "no_work" when workers are present.
3. **Enhanced Temporal Smoothing:** Optimized parameters: window size K = 5, decay γ = 0.7, explicit 20% contribution.

The improved fusion formula:

$$P_{final} = 0.80 \times Norm\big(0.50 \cdot P_{SigLIP} + 0.30 \cdot P_{det}\big) + 0.20 \times P_{temporal} \quad (4)$$

Table 1. Configuration Comparison

Component	Baseline	Improved
VLM Models	SigLIP + CLIP	SigLIP only
Detection Wt.	20%	30%
Temp. Scaling	None	τ = 3.0
Act. Boosting	Fixed	Adaptive

3.3 Approach 3: STFA Neuro-Symbolic Framework

STFA (Spatio-Temporal Forensic Auditor) represents a fundamental paradigm shift from scene classification to process auditing. Rather than simply labeling which activity is occurring, STFA acts as a forensic auditor, comparing current observations with historical context, providing explicit evidence for predictions, enforcing physical constraints, and detecting anomalies.

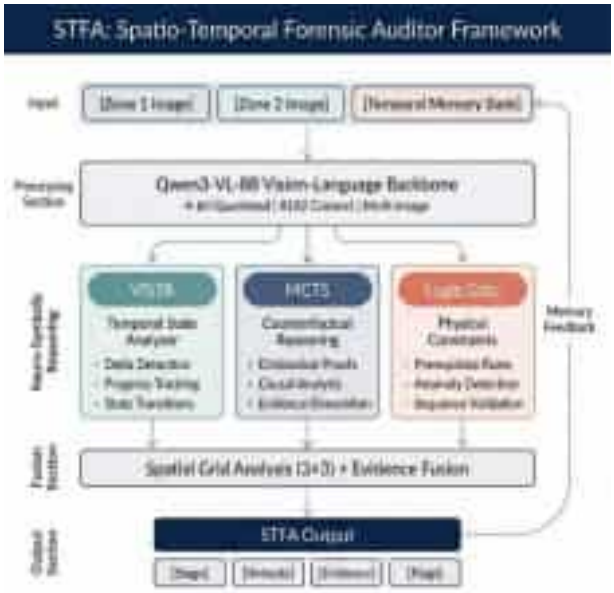

Figure 3: STFA Architecture

3.3.1 Vision-Language Backbone

STFA uses Qwen3-VL-8B as its backbone (4-bit quantized, 8192-token context window), enabling simultaneous analysis of dual-zone images while maintaining the comprehensive prompt structure.

3.3.2 Layer 1: VISTA (Visual-Temporal State Analyzer)

VISTA performs frame-to-frame comparison to detect changes over time. Unlike conventional approaches that classify each frame independently, VISTA explicitly compares the CURRENT frame with the PREVIOUS frame to detect work progress.

VISTA operates in a strictly causal manner: at time t, only the current frame (t) and the immediately preceding

frame (t-1) are available for comparison. No future frames (t+1, t+2, ...) are accessed during inference. The temporal memory bank stores only past observations and is updated sequentially as each frame is processed. This ensures that all predictions are causally valid and could be generated in a live deployment scenario where future observations do not yet exist. The same causal constraint applies to the temporal smoothing in approaches 1 and 2.

VISTA detects three types of changes:

MATERIAL_ADDITION (new objects appearing), STATE_CHANGES (transformation of existing materials), and WORK_PROGRESS (overall stage advancement). Outputs include TEMPORAL_STATUS and ACTIVITY_VELOCITY.

(a) STFA Master Prompt

(b) STFA Layers Prompt

Figure 4: STFA example prompts

3.3.3 Layer 2: MCTS (Counterfactual Reasoning)

Inspired by Monte Carlo Tree Search exploration, this layer proves classifications by systematic elimination of alternatives. For each prediction, MCTS generates explicit proof:

- "This is column_formwork, NOT column_rebar because formwork panels are visible and the rebar cage is enclosed, and NOT column_concrete because there is no wet concrete visible and no pouring action."

This explicit morpho-causal reasoning provides forensic evidence that humans can verify.

3.3.4 Layer 3: Logic Gate (Physical Prerequisites)

Table 2: Construction Physics Prerequisites

Stage	Prerequisite
column_rebar	column_prep
column_formwork	column_rebar
column_concrete	column_formwork
slab_rebar	slab_formwork
slab_concrete	slab_rebar

The logic gate encodes construction physics constraints based on engineering knowledge. Table 2 shows the prerequisite chain.

3.3.5 Example STFA Prompts

The STFA framework employs structured prompts consisting of four integrated components dynamically assembled at runtime. The three-layer variables ({vista}, {mcts}, and {logic_gate}) are dynamically populated and inserted into the master prompt, enabling temporal context injection while maintaining explicit forensic reasoning and physical constraint validation. Figure 4 presents a summarized representative example.

4 Experimental Setup

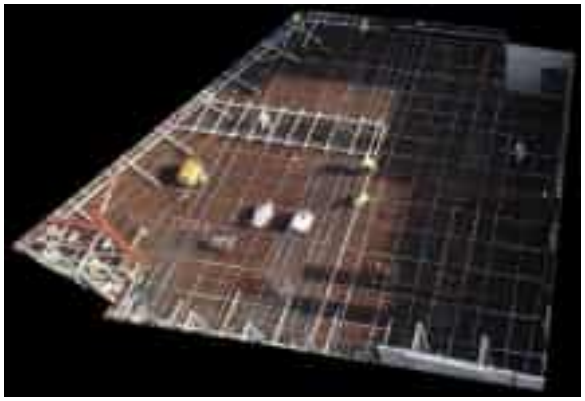
4.1 Dataset

Experiments used 504 images from multi-story RC building construction, captured at 15-minute intervals using fixed-position CCTV cameras mounted at elevated positions on adjacent structures, providing overhead oblique views of the construction zones. The cameras captured images automatically throughout the 9-hour workday (8:30 AM to 05:30 PM). The choice of camera model is not critical; any standard surveillance camera with adequate resolution (≥2 MP) and automated time-lapse capability would suffice. All images were captured under natural daylight conditions with varying lighting and intermittent occlusions from tower cranes and scaffolding (~30% of frames).

The construction project comprised two independent zones (Zone 1 and Zone 2), which are distinct spatial areas of the building where different structural activities progress according to separate schedules, each requiring separate analysis. Accordingly, each image was divided into these two zones, as shown in Figure 5. Each CCTV image contains an embedded timestamp (date and time) visible in the image frame. All three approaches read this

timestamp and pair it with the activity classification for each zone independently to produce a structured output: {timestamp, zone_id, predicted_activity, confidence-score}. Since images are captured at fixed 15-minute intervals, a complete activity timeline is automatically generated for each construction zone across the workday. For STFA, the 504 images were processed as paired zone inputs. Eight activity classes represent the complete construction cycle: no_work, column_preparation, column_rebar, column_formwork, column_concrete, slab_formwork, slab_rebar, and slab_concrete. Each zone was analyzed independently. Table 3 shows the class distribution.

Table 3: Class Distribution in each Zone



Class	Zone 1	Zone 2	Total
no_work	189	182	371
slab_rebar	136	99	235
slab_form	109	123	232
column_rebar	10	98	108
slab_conc	60	23	83
column_form	10	40	50
column_prep	0	27	27
column_conc	1	0	1

All three approaches operate in a purely zero-shot manner; no model training, fine-tuning, or hyper-parameter optimization was performed on the dataset. The prompts were designed based on construction domain knowledge, not by optimizing against dataset-specific patterns. Similarly, ensemble weights reflect the functional role of each model, and the logic gate prerequisite rules encode standard construction sequencing knowledge. Since no learning or parameter optimization occurs on any portion of the evaluation data, the conventional risks of data leakage and overfitting do not apply. All 504 images were evaluated in strict chronological order, with each image processed independently (Approaches 1 and 2) or with causal-only temporal context from the preceding frame (Approach 3, STFA), ensuring no future information influenced any prediction.
