4.2 Evaluation Matrices

All metrics are computed at the per-image, per-zone level, with each zone receiving an independent activity prediction. Therefore, each of the 504 images yields two predictions, resulting in 1,008 total classification instances for evaluation. For STFA, each zone's prediction may incorporate temporal context from the same zone's previous frame, but predictions across zones remain independent. Models were evaluated using standard classification metrics as given below:

- Overall Accuracy: Percentage of correctly classified images.
- Multiclass MCC (Matthews Correlation Coefficient): The MCC is computed as a balanced measure that accounts for all four confusion matrix categories (true positives, true negatives, false positives, and false negatives). MCC ranges from -1 (complete disagreement) to +1 (perfect prediction), with 0 indicating random prediction.
- Per-Class Precision, Recall, and F1-Score.

(a) Zone 1: slab_rebar stage

(b) Zone 2: slab_formwork stage

Figure 5: Example paired zone images showing simultaneous but different construction activities

4.3 Implementation Details

All experiments were conducted on a workstation equipped with an NVIDIA RTX 6000 Ada Generation (48 GB VRAM), Intel Core i9-14900K CPU, and 64 GB RAM, running Linux 5.15.153.1 – Microsoft standard WSL2 with CUDA 12.1 and PyTorch 2.5.1.

Table 4: Implementation Requirements Comparison

Component	Baseline	Improved	STFA
Framework	PyTorch	PyTorch	Transformers
GPU Mem.	~8 GB	~6 GB	~12 GB
Inf. Time	~2.5s/pair	~1.8s/pair	~3.2s/pair

5 Results and Evaluation

5.1 Overall Performance Comparison

Results demonstrate clear progression. Improved Ensemble achieves an absolute improvement of 5.26% over Baseline. STFA achieves a 16.07% relative improvement over baseline, validating that neuro-symbolic reasoning with temporal memory significantly enhances construction activity recognition. Table 5 presents the overall performance comparison across all three approaches.

Table 5: Overall Performance Summary

Approach	Accuracy	MCC
Baseline	75.89%	0.7024
Improved	81.15%	0.7532
STFA	91.96%	0.8948

To quantify uncertainty, we performed bootstrap resampling (n=2000) to compute 95% confidence intervals for all reported metrics:

Table 6: Overall Performance Summary with 95% Confidence Intervals

Approach	Accuracy (95%CI)	MCC (95%CI)
Baseline	75.89%	0.7024
	(73.2%–78.5%)	(0.669–0.733)
Improved	81.15%	0.7532
	(78.8%–83.5%)	(0.722–0.784)
STFA	91.96%	0.8948
	(90.2%–93.7%)	(0.872–0.916)

The non-overlapping confidence intervals between all three approaches confirm that the performance differences are statistically significant. Additionally, we analyzed temporal variability by computing accuracy across four time blocks throughout the workday as shown in Table 7. STFA exhibits the most stable performance across time blocks (±3.0% variation), compared to the Baseline (±4.1%) and Improved Ensemble (±6.1%). This suggests that STFA's explicit temporal reasoning provides greater robustness to the varying lighting conditions and activity patterns that occur throughout a workday.

Table 7: Temporal variability throughout the workday

Component	Baseline	Improved	STFA
(8:00–10:00)	79.2%	82.1%	88.1%
(10:00–12:00)	76.8%	74.6%	91.1%
(12:00–15:00)	78.2%	79.8%	92.6%
(15:00–18:00)	71.1%	86.8%	94.1%
Max variation	±4.1%	±6.1%	±3.0%

The column_concrete class has only 1 instance (0.1% of 1,008 zone-level instances), resulting in zero precision and recall across all three approaches. This extreme underrepresentation reflects a genuine characteristic of the construction process; column concrete pouring is a short-duration activity (typically 10–15 minutes per column) that frequently falls between the 15-minute capture intervals. We retain this class for transparency but report results both with and without it (Table 8). The negligible difference (<0.1% accuracy, <0.002 MCC) confirms that conclusions are not artifacts of this underrepresented class.

Table 8: Performance with/without column_concrete

Approach	Accuracy (8 cls)	Accuracy (7 cls)	MCC (8 cls)	MCC (7 cls)
Baseline	75.89%	75.97%	0.70	0.70
Improved	81.15%	81.23%	0.75	0.75
STFA	91.96%	92.06%	0.89	0.90

The baseline ensemble achieves 75.89% overall accuracy with strong performance on visually distinct classes (slab_concrete: 82%+ precision, slab_formwork: 87% precision) but lower performance on visually similar classes (column_rebar vs. column_preparation). The improved ensemble achieves 81.15% accuracy, with temperature scaling reducing overconfident predictions, adaptive boosting correctly identifying active work stages, 40% faster inference due to CLIP removal, and enhanced temporal smoothing reducing prediction jitter.

Table 9: STFA Per-Class Performance

Class	Prec	Rec	F1	Spec	MCC
no_work	0.93	0.94	0.94	0.96	0.90
column_prep	1.00	1.00	1.00	1.00	1.00
column_rebar	1.00	0.59	0.74	1.00	0.75
column_form	1.00	0.60	0.75	1.00	0.77
column_conc	0.00	0.00	0.00	1.00	0.00
slab_form	0.98	0.95	0.97	1.00	0.96
slab_rebar	0.82	0.97	0.89	0.94	0.86
slab_conc	0.96	0.98	0.97	1.00	0.97

STFA achieves 91.96% accuracy, a relative 16.07% improvement over baseline. Table 9 shows STFA per-class performance. STFA additionally provides capabilities beyond classification: sequence violation detection at 92% precision (22 of 24 flagged violations confirmed as true violations), temporal consistency at 89% frame-to-frame, and evidence generation in 100% of predictions. It additionally provides capabilities beyond classification. Table 10 summarizes these.

Sequence Violation Detection: A sequence violation is defined as a predicted activity transition that contradicts the physical prerequisite chain (Table 3). The Logic Gate flagged 24 potential violations; manual review confirmed 22 as true violations (92% precision). The 2 false positives occurred due to rapid activity

transitions within a single 15-minute interval.

Temporal Consistency (89% frame-to-frame): Measured as the percentage of consecutive frame pairs where the predicted activity either remained the same or transitioned to a valid successor activity, compared against ground truth transitions.

Table 10: STFA Additional Capabilities

Capability	Performance
Overall Accuracy	91.96%
Multiclass MCC	0.8948
Sequence Violation Detection	92% precision
Temporal Consistency	89% frame-to-frame
Evidence Generation	100% (always)

5.2 STFA Ablation Study

To isolate the contribution of each STFA component, we conducted an ablation study:

Table 11: STFA Ablation Study

Configuration	Accuracy	MCC
Qwen3-VL	83.41%	0.8012
+ VISTA	87.27%	0.8456
+ MCTS	90.03%	0.8734
+ Logic Gate	91.96%	0.8948

Each component contributes meaningfully: VISTA +3.86%; MCTS +2.73%; and Logic Gate +1.96%.

6 Discussion

6.1 Key Findings

Finding 1: VLM Ensemble Redundancy. SigLIP and CLIP show >85% correlation in predictions when using similar prompts. This proves that multiple VLMs with overlapping pre-training provide diminishing returns. The Improved Ensemble's decision to remove CLIP maintained accuracy while reducing computational cost.

Finding 2: Temperature Scaling Impact. Temperature scaling (τ = 3.0) significantly improved confidence calibration. Raw VLM similarity scores tend to be overconfident, and sharpening the distribution helps distinguish between visually similar classes, such as column_preparation and column_rebar.

Finding 3: Temporal reasoning is critical. The 10.81% accuracy gap between Improved Ensemble (81.15%) and STFA (91.96%) demonstrates the value of explicit temporal reasoning over simple smoothing. STFA's VISTA layer detects material changes between frames, providing stronger classification signals.

Finding 4: Domain knowledge improves robustness. The Logic Gate's enforcement of construction physics constraints catches errors that pure pattern recognition misses. When the VLM predicts an impossible sequence, the explicit rules flag the anomaly for human review.

Finding 5: Explainability enables trust. STFA's counterfactual reasoning not only improves accuracy but fundamentally changes system utility. By explaining 'why X and not Y,' STFA provides auditable predictions that construction managers can verify.

6.2 Limitations

- Computational requirements: STFA requires ~12 GB GPU memory and 3+ seconds per frame pair.
- Single project evaluation: Results may not generalize to different construction types.
- Prompt sensitivity: Zero-shot performance depends on prompt engineering quality.
- Occlusion handling: All approaches struggle with partially obscured activities.

6.3 Future Work

This work is exploratory in nature and demonstrates the feasibility of zero-shot VLM-based activity recognition. Several steps are needed to advance these methods toward practical deployment:

- **Multi-site validation:** The current evaluation is limited to a single RC building project. Validating the framework across diverse construction types (steel structures, infrastructure, and renovation) and site conditions is essential to establish generalizability.

- **Computational efficiency:** STFA requires ~12 GB GPU memory and ~3.2 seconds per image pair. For real-time site monitoring, model distillation or edge-optimized architectures are needed to reduce inference time and hardware requirements.

- **Schedule integration:** The system currently classifies activities at 15-minute intervals. Integrating these classifications with project scheduling data (e.g., Primavera, MS Project) to automatically compute plan-versus-actual deviations represents a key integration step toward actionable productivity analytics.

- **Scalable activity vocabularies:** While the framework assumes a fixed set of eight activity classes, real projects involve a wider variety of activities. Developing methods to dynamically extend the activity vocabulary, potentially through ontology-guided prompt generation, would increase practical applicability.

- **Human-in-the-loop refinement:** Incorporating user corrections into a feedback loop could progressively refine prompt strategies and confidence thresholds without requiring full model retraining, preserving the zero-shot advantage while improving site-specific accuracy.

7 Conclusion

This paper presented a comprehensive study of three progressive approaches for zero-shot construction activity recognition. Starting with a baseline ensemble combining SigLIP, CLIP, and YOLOv8 (75.89% accuracy), we achieved improvements through model optimization and adaptive boosting, yielding an improved ensemble (81.15% accuracy). The STFA neuro-symbolic approach achieved state-of-the-art 91.96% accuracy while providing unprecedented interpretability through counterfactual reasoning, temporal tracking, and construction physics validation.

The key insight is that construction activity recognition benefits significantly from moving beyond pure pattern recognition to incorporate domain knowledge. STFA demonstrates that combining deep learning perception with symbolic reasoning yields systems that generate auditable reasoning artifacts, enabling construction managers to verify and understand the basis for each prediction. We note that this work primarily contributes to automated activity recognition, the foundational data layer required to support productivity analysis. Integrating these outputs with project scheduling data and resource allocation records would enable formal productivity estimation, which we identify as an important direction for future work.

Abstract –

Classification of three-dimensional (3D) point clouds is fundamental to semantic labelling and scene understanding in bridge inspection and management. However, accurate classification of bridge components remains challenging due to their complex geometries and high inter-class geometric similarity. To address these challenges, this study explores the potential of incorporating prior knowledge into a bridge point cloud classification model. Motivated by the distinctive spatial distribution of bridge components, we introduce a bridge-wise batching training strategy that treats all clusters within each bridge as a single training unit. The distribution of various components in the vertical direction is designed as a hard constraint to guide both training and inference. The proposed approach was validated on a bridge dataset covering four representative Reinforced Concrete (RC) girder bridge types. The results show that integrating prior knowledge consistently outperforms the PointNet baselines, yielding higher classification accuracy and more stable convergence during training. Overall, the findings highlight the effectiveness and promise of integrating prior knowledge into the point cloud classification task of bridge components.

Bridge point cloud; Prior knowledge; Point cloud classification; Physics-informed; Structural knowledge

1 Introduction

Point cloud data has been increasingly adopted in bridge engineering due to its superiority in capturing as-is conditions with high spatial fidelity and resolution [1]. Generated by Light Detection and Ranging (LiDAR) or photogrammetry, point clouds preserve fine-scale shape, enable precise measurement without meshing, and naturally support change detection through repeat acquisitions [2]. Thus, point clouds have been widely utilised for various tasks across the bridge lifecycle, including Quality Assurance (QA), construction progress monitoring, and damage assessment [3].

A variety of learning-based tasks have been proposed to facilitate 3D understanding of point clouds, including point cloud semantic segmentation, instance segmentation, classification, and point cloud completion [1,4,5]. Among them, point cloud classification has been widely used to assign semantic meaning to 3D data and enable higher-level scene understanding. By mapping unstructured point sets to semantic categories, classification facilitates a wide range of downstream tasks across multiple domains, including urban mapping, Building Information Modelling (BIM), industrial Facility Management (FM), and autonomous inspection.

Point cloud classification is particularly critical for semantic labelling in bridge Scan-to-BIM. Specifically, traditional geometry-based methods often rely on point cloud clustering or region growing to partition raw scans, followed by heuristic or feature-based classification to identify structural elements [6,7]. More recently, emerging foundation models and vision language models, such as the Segment Anything Model (SAM), have been explored for bridge point cloud pre-segmentation by operating on projected images or videos [8]; however, these approaches typically generate over-segmented or unlabelled point cloud clusters and still require reliable point cloud classification for semantic assignment. Although previous research has developed classification methods for a small number of component types, these methods tend to introduce higher uncertainty when applied to multi-component classification. No existing efforts have been found that could assign semantic labels reliably for bridges with diverse component types.

To address this challenge, this study proposes a prior knowledge-enhanced point cloud classification strategy for RC girder bridges with various component types. Building on existing deep learning architectures, we

introduce a bridge-wise batching training strategy that treats all clusters within each bridge as a single training unit, rather than a collection of independent patches from different bridges. Based on bridge-wise batching, prior knowledge is incorporated as explicit constraints to guide both model training and prediction. After embedding prior knowledge into the classification model, it can produce highly accurate classifications of multi-component types, thereby facilitating downstream tasks.

2 Literature review

2.1 Point cloud classification

Point cloud classification aims to assign semantic labels to 3D samples represented as unstructured point sets, enabling 3D scene understanding in Euclidean space [9]. Compared with images defined on regular pixel grids, point clouds are irregular and unordered, which makes feature extraction more challenging. In recent years, deep learning has become the dominant method for point cloud classification. Deep learning-based approaches can be broadly grouped into (i) voxel-based methods that rasterise points onto sparse 3D grids for 3D convolutions, (ii) multi-view methods that render point clouds into 2D images for Convolutional Neural Network (CNN) processing, and (iii) point-based methods that learn features directly from raw point sets [10]. Although voxel- and projection-based strategies benefit from mature convolutional operators, converting from 3D to grid/image representations may result in the loss of critical 3D spatial information. Consequently, point-based methods have become the mainstream strategy for point cloud segmentation and classification.

Representative point-based architectures include PointNet [11], along with subsequent advances such as graph-based message passing [15] and attention mechanisms [12]. With the growing adoption of point cloud data in infrastructure scenes, learning-based point cloud classification has been widely applied to label a variety of infrastructure objects, such as bridge damage [13], road components [14] and building materials [15]. Accurate point cloud classification, therefore, plays a crucial role in infrastructure-level 3D scene understanding, facilitating downstream applications such as Scan-to-BIM integration and infrastructure condition assessment.

2.2 Physics-guided neural networks

In recent years, Machine Learning (ML) has shifted from purely data-driven paradigms toward knowledge-data dual-driven methods, in which prior knowledge is explicitly encoded into data-driven models to improve robustness, accuracy, and reliability. These approaches are often referred to as physics-guided neural networks (PgNNs) [16]. By integrating prior knowledge and mathematical models into network training, PgNNs not only minimise data-driven loss but also enforce feasibility and consistency constraints imposed by known physics [17]. When such prior knowledge is formalised as governing differential equations, such as ordinary differential equations (ODEs) or partial differential equations (PDEs), together with associated boundary and initial conditions and embedded into the loss function, the resulting framework is commonly termed physics-informed neural networks (PINNs) [16].

The infrastructure domain offers rich priors and well-validated physical laws; accordingly, PgNNs and PINNs have been increasingly applied across the infrastructure life cycle, such as design, post-design analysis, construction, and maintenance/structural health monitoring. Representative studies span physics-based surrogate modelling for early-stage structural design [18], physics-consistent response inference for real bridge systems using limited measurements [19], and physics-informed damage identification and long-term response prediction for bridges [20].

Overall, existing research suggests that embedding prior knowledge into neural networks can substantially enhance data efficiency, interpretability, and generalisation, enabling learning models to tackle complex and nonlinear engineering problems in the real world.

3 Methodology

3.1 Training strategy

This section presents a knowledge-enhanced training strategy for point cloud classification of bridge components, in which prior knowledge information is encoded as hard, rule-based constraints during both training and inference. Conventional approaches typically obtain batches for each training and testing by randomly sampling instances from different bridges. However, these point cloud instances are sampled from different bridges and randomly contain different bridge component types, posing a challenge for leveraging topology-aware priors in the same bridges.

To address this, we propose bridge-wise training and inference via bridge-wise batching: each optimisation step uses all clusters from one bridge, with an adaptive batch size equal to that bridge's number of clusters. This batching strategy enables these constraints, derived from prior knowledge, to be effectively imposed on these components in the same bridges. To validate the proposed training strategy and the effectiveness of prior knowledge, the pioneering point-based learning model, PointNet [11], is adopted for its established reputation

and superior performance in point cloud classification. The main framework for the proposed bridge-wise point cloud classification model with rule-based constraints is illustrated in Figure 1, which includes the strategy of utilising rule-based constraints in both the training and inference stages.

3.1.1 Bridge-wise training

As shown in Figure 1(a), for each iteration, all point cloud clusters from a single bridge are grouped into one batch and passed through PointNet to extract point-wise features. These features are then fed into fully connected layers to produce a score matrix $S \in \mathrm{R}^{C \times K}$, where C is the number of classes and K is the number of clusters in the bridge. Based on the score matrix, prior knowledge is compiled into a hard mask $M \in \{0, 1\}^{C \times K}$, as defined by Equation (1), where zeros mark infeasible prediction results based on the pre-defined prior knowledge (e.g., piers must have a component above). Before computing the loss, infeasible entries are masked by mapping them to -∞ and cross-entropy is evaluated on the masked scores $\tilde{S}$. This forces gradients to flow only through prior-consistent constraints, preventing the network from spending capacity on structurally impossible labels.

$$\tilde{S}_{ck} = \begin{cases} S_{ck}, & M_{ck} = 1 \\ -\infty, & M_{ck} = 0 \end{cases} \tag{1}$$

3.1.2 Bridge-wise inference

As shown in Figure 1(b), inference follows the same bridge-wise setting: all clusters of a bridge are processed together. For cluster i, the network outputs raw scores $S_{i\text{-}k}$. Then, the hard masks are applied to the raw scores, marking infeasible predictions as **False**. The final label is chosen from the prior-admissible set, as defined in Equation (2). This two-stage logic yields predictions that are simultaneously data-driven and structurally admissible, preventing violations of the pre-defined priors and propagating topological consistency across all clusters within the same bridge.

$$\hat{y}_{i\text{-}k} = \arg \max_{C:\, M_{ck}=1} \tilde{S}_{i\text{-}k} \tag{2}$$

3.2 Elevation-based hierarchical priors

Bridge structures exhibit a strong vertical layout characteristic due to their mechanical design [7], as illustrated in Figure 2. For example, components with lower location, such as piers and abutments, transfer gravity and other loads to the ground. Pier caps, if present, connect the piers and girders and transmit loads from the superstructure to the piers. Within the superstructure, the components also follow a consistent bottom-to-top order, from girders to decks to parapets, while diaphragms, if present, are distributed between the girders.

To leverage this observation for point cloud classification, we encode this knowledge as Elevation-based Hierarchical Priors (EHP). For each point cloud cluster, we compute a relative elevation to capture its vertical position. Based on the observed distribution of bridge components along the vertical axis, we then define several elevation bands. For each band, we specify a subset of component types that are admissible at that height. This prior is implemented as a hard mask on the logits, so classes that violate the hierarchy are removed from the feasible set during both training and inference.

To achieve this, for each point cloud instance in raw point coordinates, such as instance i, we first compute a robust vertical bounding box by taking lower and upper quantiles of the z-coordinates (Z_i), $Z^i_{\min}$ and $Z^i_{\max}$, as defined by Equation (3). The instance-level elevation is then represented by the midpoint Z^i_{mid}.

$$\begin{cases} Z^i_{\min} = \mathrm{quantile}\left(Z_i, q_{\mathrm{low}}\right) \\ Z^i_{\max} = \mathrm{quantile}\left(Z_i, q_{\mathrm{high}}\right) \\ Z^i_{\mathrm{mid}} = \dfrac{1}{2}\left(Z^i_{\min} + Z^i_{\max}\right) \end{cases} \tag{3}$$

Because the model is trained with bridge-wise batching, we further normalise elevations at the bridge level. For each bridge, we compute the bottom level $Z_{\min}$ and top level $Z_{\max}$ by taking the minimum of all $Z^i_{\min}$ and the maximum of all $Z^i_{\max}$ across the whole bridge, as defined by Equation (4). Then, the effective vertical range (Z_{r}) of bridges can be calculated.

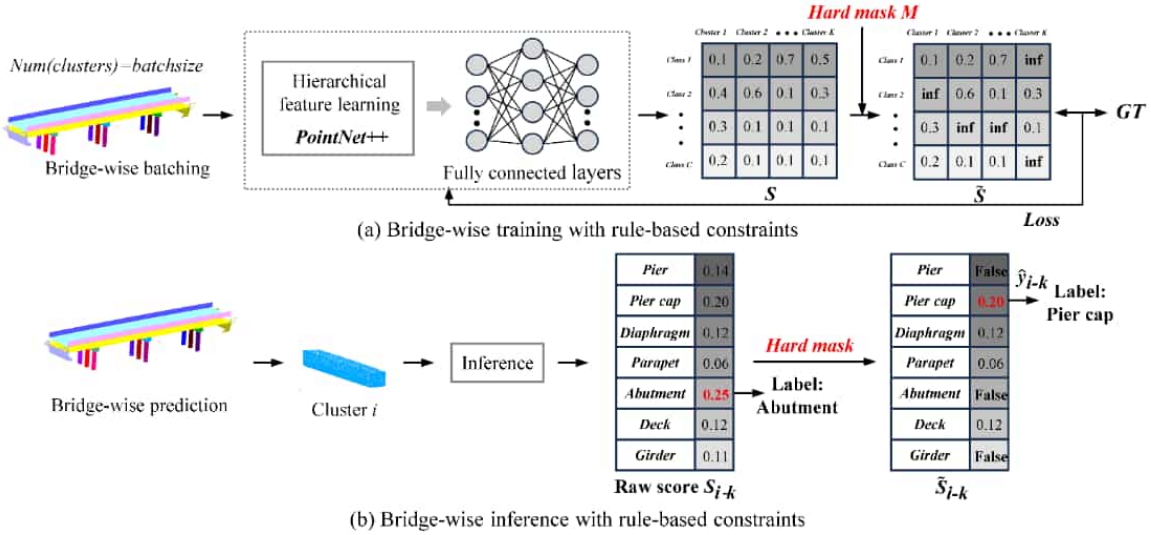

Figure 1. Bridge-wise point cloud classification model with rule-based constraints, (a) bridge-wise training and (b) bridge-wise inference.

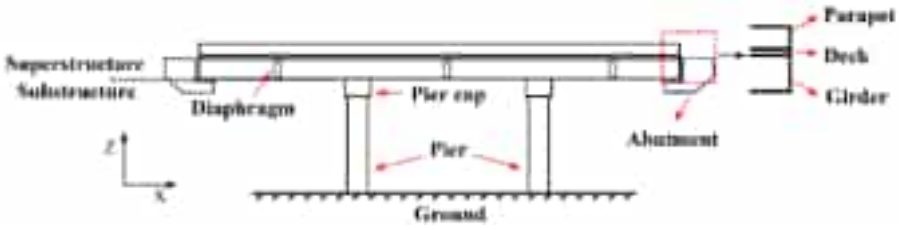

Figure 2. Component distribution of typical RC girder bridges in the vertical direction.

$$\begin{cases} Z_{\min} = \min\limits_{i} Z^{i}_{\min} \\ Z_{\max} = \max\limits_{i} Z^{i}_{\max} \\ Z_{r} = Z_{\max} - Z_{\min} \end{cases} \tag{4}$$

For each cluster i, we define a relative $Z^{i}_{ele} \in [0,1]$ by normalising the midpoint Z^{i}_{mid} within this bridge, as defined in Equation (5). This normalisation removes absolute elevation and makes the prior comparable across different bridge structures.

$$Z^{i}_{ele} = \frac{Z^{i}_{mid} - Z_{\min}}{Z_{r}} \in [0,1] \tag{5}$$

Based on the observed distribution of components in the vertical direction, we then define a small number of elevation bands. For each band, we specify a subset of component types that are admissible at that height, and implement this prior as constraints during model training and testing. Table 1 summarises the band definition. The vertical range is partitioned into four bands using thresholds (Z_{lo}, Z_{mid} and Z_{hi}), corresponding to "bottom", "lower-middle", "upper-middle", and "top" regions. Each band is matched to the component types that typically exist at that height range, consistent with the normal vertical arrangement of the bridge substructure and superstructure. Specifically, the bottom band allows only piers, indicating that the primary substructure occupies the lowest elevations. The lower-middle band allows for abutment, pier, and pier cap, representing the transition from the foundation/substructure to the pier caps. The upper-middle band is a broader superstructure zone that permits abutment, pier cap, girder, diaphragm, deck, and parapet. The top band is restricted to the deck and parapet, which typically occupy the highest elevations.

Table 1. Definition of vertical band for elevation-based prior constraints.

Bands	Definition	Permitted components
Bottom	$Z^{i}_{ele} < Z_{lo}$	Pier
Lower-middle	$Z_{lo} \le Z^{i}_{ele} < Z_{mid}$	Pier, pier cap, abutment

Upper-middle	$Z_{mid} \leq Z^{i}_{ele} < Z_{hi}$	Abutment, pier cap, girder, deck, diaphragm, parapet
Top	$Z_{hi} \leq Z^{i}_{ele}$	Deck, parapet

In this study, the three thresholds Z_{lo}, Z_{mid} and Z_{hi} are set to 0.3, 0.7, and 0.9, respectively, based on a statistical analysis of the normalised vertical positions of components in our bridge dataset. These values should be regarded as empirical reference thresholds rather than universal constants. They can be updated based on statistical analyses of more typical RC girder bridges in the real world. More importantly, when defining the four elevation bands, we deliberately chose relatively broad and soft intervals to accommodate the complexity and variability of real bridge design, rather than introducing many narrow bands that would attempt to separate every component type, which could harm the model's generalisability.

4 Experiment and results

4.1 Data preparation

The dataset used in this study comprises 34 bridge point clouds, covering slab-beam bridges, single or multi-box girder bridges, and T-girder bridges. Among them, 24 bridge point clouds are generated from 3D BIM models, while ten bridge point clouds are obtained from real-world laser scanning data provided by Lu et al. [21]. As the real scanned data primarily consist of slab-beam bridges, additional synthetic models are incorporated to enhance structural diversity within the dataset, including 8 T-girder bridges, 8 multi-box girder bridges, and 8 slab/single-box girder bridges. For synthetic point clouds from 3D BIM models, the Heidelberg LiDAR Operations Simulator (Helios++) [22] is adopted to generate more realistic bridge point clouds. All point clouds are first aligned along the longitudinal axis via principal component analysis (PCA) and subsequently levelled using the deck as a reference plane. After point cloud generation, each bridge point cloud is manually annotated into different component point clouds for model training and prediction.

4.2 Implementation details

All experiments were conducted in PyTorch on Ubuntu 20.04, utilising an Intel Xeon Gold 6242R CPU and a single NVIDIA Quadro RTX 5000 (16 GB). We evaluated 34 bridges with a 7-fold cross-validation. Different RC girder bridges were randomly assigned to folds, enabling each fold to contain all four RC bridge types and real-world bridge data. Each model was trained for 100 epochs with bridge-wise batching. The input point number was set to 4096, and seven bridge component types were considered in the classification results. Bridge-level dynamic class weight was utilised to mitigate class imbalance. Data augmentation, following standard point cloud practice, was applied, including random point dropout, isotropic scaling, and translation.

4.3 Evaluation metrics

Performance was evaluated using overall accuracy (OA) and mean class accuracy (mAcc), as defined by Equations (6) and (7).

$$\mathrm{OA} = \frac{\sum_{c=1}^{C} TP_c}{N} \tag{6}$$

$$\mathrm{mAcc} = \frac{1}{C}\sum_{c=1}^{C} \frac{TP_c}{N_c} \tag{7}$$

where C is the number of classes and N is the total number of labelled instances. TP_c is the component that is correctly labelled with class c.

To assess both performance and training stability, we evaluate OA and mAcc over epochs using two criteria: $\mathrm{BestAcc}_{\mathrm{last30}}$ (the highest test accuracy in the last 30 epochs) and $\mathrm{WorstAcc}_{\mathrm{last30}}$ (the lowest test accuracy in the last 30 epochs). Focusing on the final 30 epochs ensures the model has sufficiently trained and provides a reliable estimate of the learned representation for classification.

4.4 Results and evaluation

Figure 3 shows the average training accuracy of PointNet with or without prior knowledge for seven-fold cross-validation, including training accuracy (left), test OA (middle), and test mAcc (right). Across all views, models augmented with prior knowledge consistently achieve higher accuracy and reach high accuracy earlier than the baseline models. Importantly, the baselines exhibit significant fluctuations, even in later epochs, indicating unstable convergence. This behaviour is largely due to the presence of many repeated components in bridge point clouds. Once a specific component type is misclassified, the error tends to propagate across numerous similar instances, leading to significant fluctuations in overall performance. After introducing prior knowledge, the constraints effectively improve the classification results, and the training curves become steadier, with consistent high accuracy.

Furthermore, Table 2 and Table 3 present the quantitative evaluation results under seven-fold cross-validation. For the $\mathrm{BestAcc}_{\mathrm{last30}}$ (peak capability), across the seven folds, introducing prior knowledge yields clear gains in peak performance. Specifically, our model reaches 100% OA in four of the seven folds. The average $\mathrm{BestAcc}_{\mathrm{last30}}$ increases from 96.0% OA and 94.0% mAcc

(Baseline) to 99.3% OA and 98.6% mAcc (Ours).

For $\text{WorstAcc}_{\text{last30}}$ (stability and convergence), the stability benefits are more noticeable. The average $\text{WorstAcc}_{\text{last30}}$ rises from 85.7% OA and 78.0% mAcc (Baseline) to 97.4% OA and 94.5% mAcc (Ours). The improvements are especially large on the difficult fold (e.g., Fold 1, the OA increased from 74.1% to 96.4%).

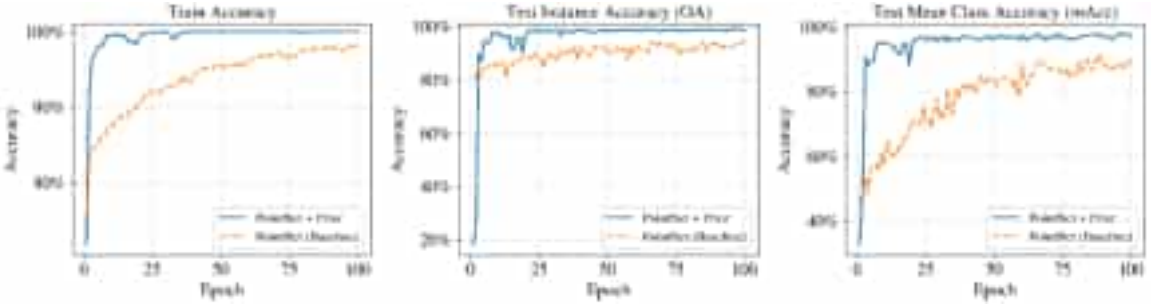

Figure 3. Comparison of PointNet (top) with or without prior knowledge, including training accuracy (left), test OA (middle), and test mAcc (right).

Table 2. $\text{BestAcc}_{\text{last30}}$ under different folds.

Fold		Fold 1	Fold 2	Fold 3	Fold 4	Fold 5	Fold 6	Fold 7	Avg.
Baseline	OA	90.6	98.9	96.9	96.5	100.0	90.0	99.4	96.0
	mAcc	80.4	97.0	91.1	97.3	100.0	93.0	99.5	94.0
Our	OA	97.8	99.6	97.9	100.0	100.0	100.0	100.0	99.3
	mAcc	96.1	98.6	95.6	100.0	100.0	100.0	100.0	98.6

Table 3. $\text{WorstAcc}_{\text{last30}}$ under different folds.

Fold		Fold 1	Fold 2	Fold 3	Fold 4	Fold 5	Fold 6	Fold 7	Avg.
Baseline	OA	74.1	96.4	91.4	83.9	78.4	80.0	96.0	85.7
	mAcc	67.5	80.0	75.9	82.4	81.9	77.3	81.1	78.0
Our	OA	96.4	98.2	95.4	100.0	98.1	95.7	98.3	97.4
	mAcc	93.3	92.9	88.7	100.0	95.7	94.6	96.0	94.5

Table 4 further reports per-class accuracies, and Figure 4 display the corresponding confusion matrices for the best and worst epochs over the last 30 epochs.

It can be observed that the PointNet baseline exhibits noticeable fluctuations for deck (from 91.2% $\text{BestAcc}_{\text{last30}}$ to $\text{WorstAcc}_{\text{last30}}$ 55.9%), girder (from 85.3% $\text{BestAcc}_{\text{last30}}$ to $\text{WorstAcc}_{\text{last30}}$ 64.7%), and abutment (from 84.6% $\text{BestAcc}_{\text{last30}}$ to $\text{WorstAcc}_{\text{last30}}$ 70.8%), indicating unstable convergence during model training.

The confusion matrix in Figure 4 further reflects this instability. For $\text{BestAcc}_{\text{last30}}$, the dominant errors in the PointNet baseline are: abutments are incorrectly labelled as pier caps and diaphragms; piers are incorrectly labelled as abutments and diaphragms; and diaphragms are incorrectly labelled as abutments and piers. For $\text{WorstAcc}_{\text{last30}}$, a similar error pattern is observed, but the misclassification becomes substantially more severe. For example, a markedly larger number of diaphragm samples are wrongly predicted as piers and abutments.

After incorporating prior knowledge into model training, the model achieves 100% $\text{BestAcc}_{\text{last30}}$ for pier, girder, diaphragm, deck, and parapet, and also improves the classification accuracy for abutment (from 84.6% to 95.4%). In the $\text{WorstAcc}_{\text{last30}}$, the model keeps the diaphragm at 100%. However, similar misclassification problems can still be found for abutments and pier caps.

Table 4. Class-wise classification result.

Class		Pier	Pier cap	Abutment	Girder	Diaphragm	Deck	Parapet
$\text{BestAcc}_{\text{last30}}$	baseline	96.7	93.5	84.6	85.3	99.1	91.2	97.1
	Our	100.0	93.5	95.4	100.0	100.0	100.0	100.0
$\text{WorstAcc}_{\text{last30}}$	baseline	92.9	95.2	70.8	64.7	88.4	55.9	91.2
	Our	99.5	91.9	75.4	97.1	100.0	97.1	98.5

5 Conclusion

To enhance the point cloud application in bridge scenes, this study proposed a prior knowledge-enhanced point cloud classification model. In our method, we designed a bridge-wise batching training strategy to encode prior knowledge, and then proposed elevation-based priors for model training and prediction. The proposed method was validated using components from 34 RC girder bridge point clouds, covering four typical girder types. The results revealed that introducing prior knowledge yields clear gains in peak performance, as indicated by $\text{BestAcc}_{\text{last30}}$, and stability for convergence, as indicated by $\text{WorstAcc}_{\text{last30}}$. The average $\text{BestAcc}_{\text{last30}}$ improves from 96.0% OA and 94.0% mAcc (PointNet baseline) to 99.3% OA and 98.6% mAcc (Ours).

However, the proposed method is not intended to be a universal solution. Although the bridge-wise batching strategy is potentially applicable to different bridge types, its thresholds still need to be adjusted based on statistical analyses of component distributions for specific bridge categories. Meanwhile, further investigation is still required to validate the applicability of the proposed method to diverse real-world bridge scenarios. In future work, we will focus on: (i) validating the framework on RC girder bridges with more diverse component inventories, while further developing more effective structural priors and refining hyperparameters to improve robustness; and (ii) extending the methodology to other bridge types (e.g., arch and cable-stayed bridges) and infrastructures by designing corresponding structural priors.

Abstract –

This paper presents FloorPlan2Nav, a framework that transforms architectural floor plan images into topological navigation graphs serving as prior maps for mobile robots. The framework combines deep learning-based semantic segmentation with contour-based instance extraction, where majority voting within geometrically accurate contours corrects boundary errors in pixel-wise predictions. A connectivity graph constructed from labelled instances enables hierarchical path planning. Graph-guided planning determines the sequence of rooms and connectors, while local A* computes trajectories within each segment in parallel. Experiments on the ResPlan dataset demonstrate 98.16% instance-level segmentation accuracy and 56.89% reduction in planning time compared to global A*. Simulation also confirms that floor plans provide sufficient geometric constraints to correct positional drift, enabling successful navigation without SLAM-based exploration.

Keywords –

Floor Plan Parsing; Connectivity Graph; Hierarchical Path Planning; Mobile Robot Navigation; Prior Map

1 Introduction

Autonomous indoor navigation requires environment maps for path planning and localisation. Conventional approaches rely on SLAM to construct such maps, but the robot must first explore the environment before it can begin operation. Recent studies have explored using prior maps derived from building documentation to reduce this exploration effort. BIM-guided frameworks construct navigation maps from IFC data [1], [2], and visual SLAM systems have incorporated BIM constraints to reduce trajectory drift [3]. These approaches are effective when BIM models are available, but many buildings do not have such documentation. Floor plan images are far more accessible. They can be found in real estate listings, facility archives, and evacuation signs, and they contain the geometric information about walls, rooms, and doors needed for navigation. However, unlike BIM or IFC data, floor plan images are unstructured, and the spatial information is embedded in pixels rather than represented as geometric entities with semantic labels. Hence, a method that can automatically parse floor plan images into structured navigation maps would enable prior map-based indoor navigation in a wider range of buildings.

This paper presents FloorPlan2Nav, a framework that transforms floor plan images into topological navigation graphs. The framework combines semantic segmentation with contour-based instance extraction to identify functional spaces and connectors such as doors, windows, and front doors with precise boundaries. These instances are organised into a connectivity graph that can be adapted to different robot types by enabling edges according to their traversal capabilities. Path planning operates hierarchically, i.e., graph-guided planning first determines the sequence of rooms and connectors, then local A* computes trajectories within each segment in parallel, which significantly reduces planning time. The framework is evaluated on the ResPlan dataset [4] and validated in simulation. Results demonstrate improved planning efficiency and show that floor plans can also serve as geometric reference to correct positional drift during navigation.

2 Related Work

Floor plan understanding has been extensively studied using deep learning methods. Datasets such as CubiCasa5K [5] and ResPlan [4] provide thousands of annotated floor plans covering various room types and architectural styles. ResPlan is particularly relevant to this work as it includes explicit room adjacency graphs alongside vector representations, enabling both geometric and topological analysis. Using these datasets, segmentation networks can effectively learn to classify walls, rooms, doors, and windows at the pixel level [5], [6]. However, navigation relies on topological graphs where spatial adjacency is typically detected through

morphological operations on segmented masks. Pixel-wise accuracy is unable to guarantee correct topology, because predictions often overflow or fall short of true boundaries. Such errors lead to incorrect adjacency relationships, which is problematic for downstream path planning.

Prior map-based navigation has been explored using structured building data. Chen et al. [7] developed a BIM-integrated path planning framework using IFC-based layered mapping and adaptive A* for ground robots. Blum et al. [8] proposed LiDAR localisation in 3D building models using semantic filtering and ICP registration. Gao and Kneip [9] achieved drift-free localisation using CAD-based floor plans as reference maps. More recently, graph-based representations have gained attention for their efficiency and semantic expressiveness. Zhu et al. [10] demonstrated that connectivity graphs constructed from IFC data enable efficient pathfinding by exploiting spatial relationships rather than dense geometry. Ayanzadeh and Oates [11] explored using large language models (LLMs) to parse floor plan images into spatial knowledge graphs for navigation assistance.

While these methods advance prior map-based navigation, they rely on structured building data such as BIM, IFC, or CAD, or require robots to pre-explore environments to construct spatial representations. However, in practice, such digital documentation or pre-exploration is often unavailable. By contrast, floor plan images are readily accessible from real estate listings, evacuation signs, and facility archives. This paper aims to address the challenge of automatically generating navigation-ready topological graphs from floor plan images, thereby bridging the gap between readily available architectural imagery and robot navigation systems.

3 Methodology

The proposed FloorPlan2Nav framework transforms architectural floor plan images into topological navigation graphs through three main stages: semantic segmentation with instance extraction, connectivity graph construction, and hierarchical path planning.

3.1 Semantic Segmentation and Instance Extraction

The input to our framework is a blank architectural floor plan without any semantic annotation. Semantic segmentation is employed to transform the raw drawing into a coloured semantic map. A DeepLabV3+ network trained on the ResPlan dataset [4] learns the visual and geometric patterns of residential floor plans and predicts pixel-wise labels for walls, rooms, doors, windows, and other architectural elements. However, pixel-wise segmentation often suffers from local boundary errors where predicted masks overflow beyond true room boundaries or fall short of them, leaving small gaps. To obtain geometry-accurate instances, we perform contour-based extraction directly on the original floor plan drawing. The image is binarised to isolate structural drafting lines that depict walls and boundaries. These lines naturally partition the plane into enclosed regions. Connected-component labelling identifies all enclosed regions that do not touch the image boundary, and a contour-tracing algorithm extracts the precise boundary of each region (see Figure 1).

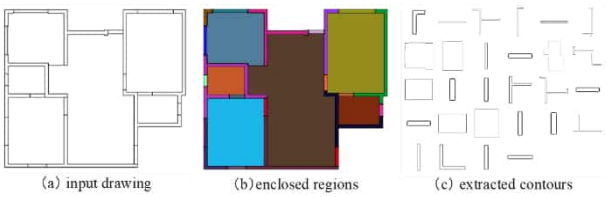

Figure 1 Instance extraction from floor plan

With all instances extracted, the semantic label of each instance is determined through majority voting over the predicted pixel labels within its contour. This effectively corrects local boundary errors in the raw semantic predictions. As shown in Figure 2, when the semantic mask falls short of the true boundary or overflows into adjacent regions (indicated by dashed boxes), the majority vote still assigns the correct label based on dominant predictions inside the geometrically accurate contour. This hybrid approach combines the semantic recognition capability of deep learning with precise geometric boundaries guaranteed by contour-based extraction, which is required for correct graph construction.

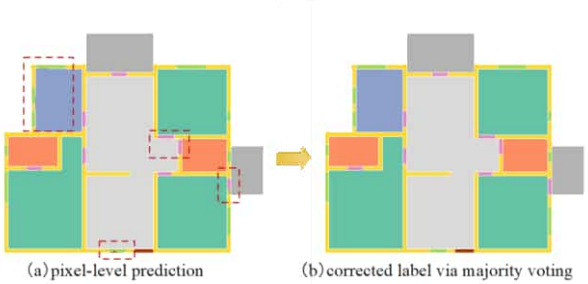

Figure 2 Semantic label assignment

3.2 Connectivity Graph Construction

The annotated floor plan is converted into a connectivity graph for navigation. Nodes correspond to segmented instances grouped into functional spaces (living rooms, bedrooms, bathrooms, kitchens) and

connectors (doors, windows, front doors, and open balconies). Walls are excluded as they represent barriers rather than navigable connections. Spatial adjacency is detected by applying morphological dilation with kernel size k to each instance mask. Overlapping dilated boundaries indicate potential connections, and since each instance is processed independently, this operation can run in parallel. However, not all overlaps represent valid connectivity. Two adjacent doors may overlap after dilation but do not form a traversable path. Semantic filtering removes such connector-to-connector links and retains only space-to-connector relationships (see Figure 3).

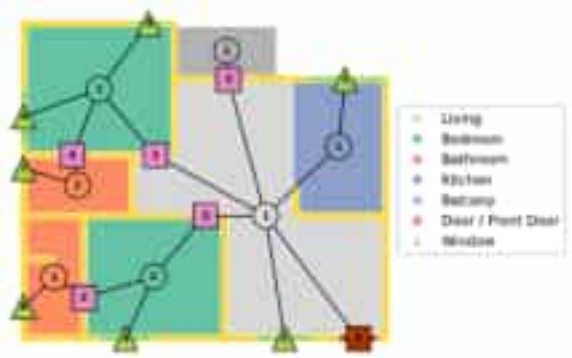

Figure 3 Connectivity graph construction

Which connectors are traversable depends on the robot's physical capabilities. Ground robots can only pass through doors and front doors. UAVs can additionally traverse windows and open balconies, enabling exterior routes along the building facade. Edge weights can further encode traversal costs such as penalties for stairs or narrow passages, making the graph adaptable to different robot types.

3.3 Hierarchical Path Planning

The connectivity graph enables a two-stage planning approach. Global path planning searches the graph to determine the sequence of rooms and connectors the robot should traverse. Figure 4 illustrates alternative routes from balcony to front door for different robot types. Ground robots (a) can only pass through doors, while UAVs (b) can also traverse windows and fly along the building exterior.

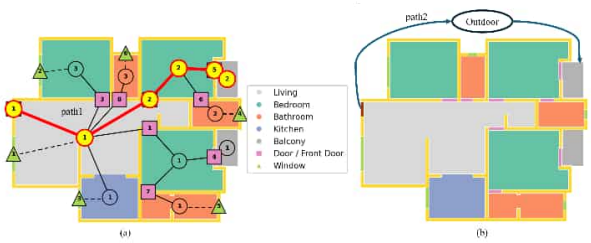

Figure 4 Path alternatives: (a) ground robot, (b) UAV

With the path determined, local path planning computes the trajectory within each segment using A*. Connector centroids are used as waypoints to ensure safe passage through doorways. Since segments between consecutive connectors are independent, local planning runs in parallel (see Figure 5), and computational savings increase with the number of segments, making the approach scalable to larger and more complex floor plans.

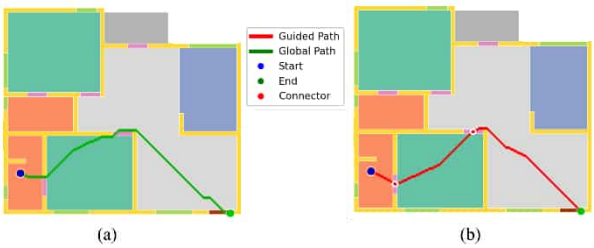

Figure 5 Path planning: (a) global A*, (b) segment-based parallel approach

4 Experiment

4.1 Experiment Setup

We evaluate our framework on the ResPlan dataset, which contains 17,107 residential floor plans with pixel-level annotations for 10 semantic classes: background, living room, bedroom, bathroom, kitchen, balcony, wall, door, window, and front door. The dataset is split into training, validation, and test sets with a ratio of 8:1:1. For semantic segmentation, we employ DeepLabV3+ [12] with Xception-65 backbone pre-trained on PASCAL VOC 2012. The network is trained for 100 epochs using SGD with momentum 0.9, learning rate decaying from 7×10^{-3} to 7×10^{-5} with cosine annealing, and input size of 512×512 pixels. The dilation kernel size k for graph construction is set to 5 pixels. Path planning experiments are conducted on Intel Core i7-11800H (2.30GHz) with 16GB RAM.

4.2 Segmentation Results

We evaluate the model's ability to predict semantic labels from blank floor plan drawings. The DeepLabV3+ model achieves 95.86% mean IoU and 99.54% pixel accuracy. After majority voting within instance contours, instance-level classification reaches 98.16% accuracy across 55,065 instances from 1,711 test images. Table 1 shows results grouped by category. Functional spaces and walls achieve over 99% F1 score. Connectors show lower accuracy due to visual confusion among door, window, and front door. However, for navigation the key requirement is distinguishing connectors from non-traversable elements rather than differentiating connector types. Table 2 shows that when treated as a binary classification, connector detection reaches 99.75% precision and 99.60% recall.

Table 1 Instance-level segmentation results

Category	Precision	Recall	F1
Functional spaces	99.21%	99.03%	99.12%
Connectors	96.48%	96.03%	96.25%
Wall	99.34%	99.56%	99.45%
Background	96.11%	97.93%	97.01%
Overall	98.00%	98.16%	98.08%

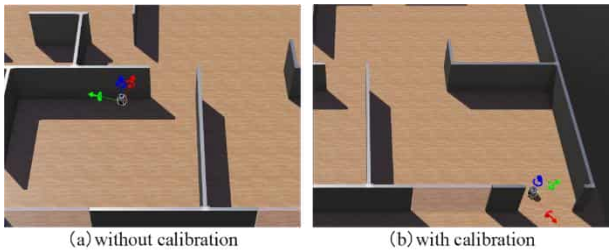
Table 2 Connector confusion matrix

GT \ Pred	Connector	Others
Connector	23,882	97
Others	61	31,025

4.3 Path Planning Efficiency

We compare the proposed graph-guided approach against global A* on path planning efficiency. 100 floor plans are randomly selected from the test set, and 10 start-goal pairs are generated for each floor plan by randomly sampling functional spaces, yielding 1,000 navigation tasks in total. Table 3 reports the average performance across all tasks.

The graph-guided method reduces planning time by 56.89% and explores 58.13% fewer nodes compared to global A*. The path cost increases by 7.34% because routing through door centres produces slightly longer trajectories than paths that cut close to door edges. In practice, this difference is negligible since robots adjust trajectories dynamically during execution.



While the absolute time savings are small for these residential layouts, the hierarchical design is valuable because of how it scales. Global A* must search across the entire map grid, so planning time increases as the floor plan grows larger. In contrast, graph-guided planning only searches within individual room segments, each of which stays small regardless of overall building size. Since these segments are computed in parallel, planning time does not accumulate as the number of rooms increases. Therefore, the advantage is greatest in larger commercial or institutional floor plans.

4.4 Simulation Validation

We conduct simulation experiments in Webots to test navigation using the floor plan as a prior map. Webots is an open-source robot simulator that provides realistic physics and sensor models. We use a simulated TurtleBot3 Burger equipped with LDS-01 LiDAR (360° FOV, 0.12-3.5m range). The setup assumes no discrepancy between the floor plan and physical environment, and rooms are empty. The robot follows waypoints generated from the connectivity graph. To simulate realistic localisation drift, Gaussian noise (σ=20mm per timestep) is injected into XY odometry while yaw is assumed accurate from IMU. Without using the floor plan for position correction, cumulative drift causes the robot to deviate and collide with walls (Figure 6a). With periodic calibration, the robot completes the trajectory successfully (Figure 6b).

Table 3 Path planning performance comparison

Metric	Global A*	Graph-guided (ours)	Improvement
Planning time (ms)	23.42	10.09	-56.89%
Nodes explored	2,231	934	-58.13%
Path cost (px)	85.29	91.57	7.34%

(a) without calibration (b) with calibration

Figure 6 Navigation results in Webots simulation

Calibration is triggered every five waypoints. The robot extracts line segments from LiDAR scans and matches them against visible wall contours from the floor plan. Matching candidates are filtered by segment orientation (horizontal or vertical) and validated by distance and angular proximity relative to the robot. Since residential layouts are typically axis-aligned, corrections are decoupled along orthogonal directions: horizontal segments refine Y position and vertical segments refine X.

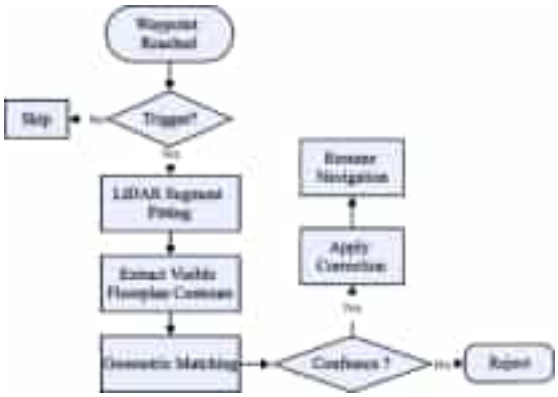


Figure 7 LiDAR calibration flowchart

The matching process and calibration results are illustrated in Figures 8 and 9. Figure 8 shows the segment matching at four waypoints, where segments extracted from LiDAR scans (solid lines) are matched against wall contours from the floor plan (dashed lines). The number of matched pairs varies depending on visible walls. Figure 9 shows the corresponding calibration results. After position correction, the robot position (blue) moves consistently closer to ground truth (green) compared to the drifted estimate (red), confirming that floor plan geometry provides adequate reference for odometry compensation.

Figure 8 Segment matching at four waypoints

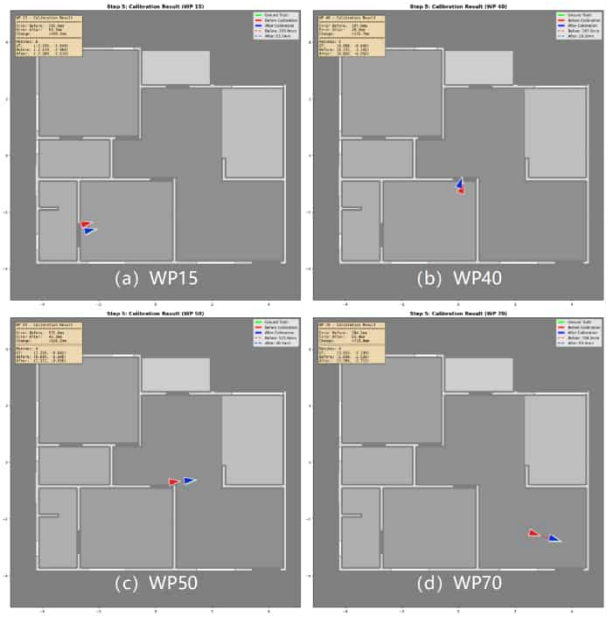

Figure 9 Calibration results at four waypoints

5 Discussion

This work has several limitations. Firstly, the simulation assumes no discrepancy between the floor plan and physical environment, which may not hold for older buildings with undocumented renovations. Secondly, the calibration scheme relies on axis-aligned wall geometry and accurate yaw from IMU. Rooms are also assumed to be empty without furniture that could occlude walls or block paths. The framework also

operates on 2D floor plan images only and does not incorporate three-dimensional information such as floor slopes, door sill heights, or elevation changes. Addressing these factors would require additional elevation data or depth sensing, which is beyond the scope of this work.

The pipeline relies on accurate segmentation, and the sensitivity of navigation to segmentation errors has not been analysed. The contour-based instance extraction and majority voting correct minor pixel-level errors, but more severe failures such as a missed door or a merged room boundary could disrupt the connectivity graph. Furthermore, floor plan segmentation is a well-studied problem, and high accuracy has been demonstrated on both furnished and unfurnished floor plans [13]. The 98.16% instance accuracy on the ResPlan test set is consistent with this. A systematic robustness analysis is left for future work.

Future work will address building discrepancies through probabilistic matching methods that handle geometric deviations. Another direction is vision-language navigation (VLN), where the connectivity graph serves as spatial knowledge rather than a source of precomputed waypoints. Instead of relying on precise geometric matching, the robot observes its surroundings, matches what it sees against the expected layout from the floor plan, and moves toward the next connector by visually identifying doors and walls in real-time, allowing the robot to handle environmental changes and partial occlusions. In this setting, the floor plan serves not as a geometric reference for contour matching, but as a semantic map providing spatial knowledge such as room types and connectivity.

6 Conclusion

This paper presents FloorPlan2Nav, a framework that transforms blank floor plan images into navigation-ready representations for mobile robots. The floor plan is utilised at three stages. Semantic segmentation combined with contour-based instance extraction converts the raw drawing into labelled functional spaces and connectors, where majority voting within geometrically accurate contours corrects boundary errors in pixel-wise predictions. A connectivity graph constructed from these instances enables hierarchical path planning, i.e., global planning on the graph determines the sequence of rooms and connectors, while local A* computes trajectories within each segment. Since each segment is independent, they can be computed in parallel, and the efficiency gain scales with building complexity. The floor plan also serves as a prior map for localisation during navigation, which allows robots to correct odometry drift by matching LiDAR observations against known wall geometry.

Experiments on the ResPlan dataset demonstrate 98.16% instance-level segmentation accuracy with 99.60% connector detection recall. The graph-guided planning achieves 56.89% reduction in computation time compared to global A*. Simulation in Webots confirms that floor plan-based calibration effectively corrects accumulated drift and enables successful navigation without SLAM-based exploration.

Abstract – Road construction consumes large quantities of virgin aggregates and asphalt, while circular-economy (CE) strategies, such as using reclaimed asphalt pavement (RAP) and recycled aggregates, remain underutilized due to quality uncertainties, logistical constraints, and limited digital integration. Existing simulation tools are predominantly linear and single-site, which prevents the realistic evaluation of CE strategies across demolition (DEM), mixing (MIX), and construction (CON) operations. This paper introduces a distributed simulation framework based on the High-Level Architecture (HLA) that links DEM, MIX, and CON federates to model dynamic, multi-site and closed-loop material flows. A conceptual CE framework, a set of simulation requirements, and a literature-based gap analysis are developed. A proof-of-concept implementation demonstrates federate connectivity and quantifies CE effects: recycled flows supply 544 t of RAP and 7,500 t of mineral recyclates, reducing virgin-material demand by roughly 25 %. The results demonstrate that distributed simulation offers a feasible and extensible framework for analyzing CE strategies under realistic operational constraints, thereby supporting sustainable, smart, and lean road-construction planning through network-level logistics, environmental indicators, and scenario-based optimization.

Keywords – circular economy; road construction; distributed simulation; high level architecture; material flow

1 Introduction

Road construction is a highly material-intensive sector that relies on large quantities of aggregates, asphalt, and concrete, among other materials [1], [2]. At the same time, the industry faces increasing pressure to reconcile traditional project objectives – cost, quality, and time – with growing ecological requirements and resource scarcity [3]. Achieving an economically viable, specification-compliant pavement while simultaneously reducing environmental impacts creates an inherent conflict of goals for contractors, agencies, and material suppliers [4]. These competing objectives intensify the need for more resource-efficient, data-driven, and operationally integrated methods capable of supporting future-ready road-construction workflows. Circular Economy (CE) principles offer substantial potential for addressing these challenges [5], [6]. Strategies such as incorporating reclaimed materials demonstrate clear potential [1], [2], [7]. However, CE adoption in practice remains limited. Key barriers include uncertainties in the properties of reclaimed materials [2], [8], logistical constraints across demolition, production, and paving operations [9], [10], restrictive specifications, and limited digital integration among stakeholders [8], [9]. Despite increasing political attention to circular construction, practical operational models for implementing CE principles in road construction are still lacking [10]. Existing modeling tools offer limited support for CE integration. Most simulation approaches remain linear, isolated, and focused on single sites [11], [12]. Road-construction networks involve dynamic material exchanges among demolition (DEM) sites, mixing plants (MIX), and construction (CON) sites that are spatially separated and temporal in nature [12], [13], [14]. Current models cannot represent multi-site material availability, quality-dependent blending, or the temporal coordination required to evaluate recycling feasibility [13], [15]. As a result, they cannot generate system-level CE indicators such as recycled content or virgin-material substitution [16], [17]. To address these limitations, this paper proposes a distributed simulation framework based on the High-Level Architecture (HLA). The framework links three federates – DEM, MIX, and CON – to represent multi-site interactions and circular material flows, with the option to add and remove more sites to ensure fidelity with real-world project schedules. The aim is to demonstrate that distributed modeling enables detailed site-specific process representation, realistic and scalable multi-site material exchange, and explicit

closed-loop modeling (DEM-MIX-CON). The main contributions of this paper are:

1. A conceptual and technical framework combining CE principles with distributed simulation.
2. Integration of discrete process simulation with material-flow and Sankey-based CE visualization.
3. A requirement set (R1–R7) for CE-oriented simulation in road construction.
4. A systematic literature comparison covering simulation in construction and their relevance to CE in road construction.
5. A proof-of-concept federated HLA implementation linking DEM, MIX, and CON.

The remainder of the paper is structured as follows: Section 2 reviews related work across CE, material-flow modeling, construction simulation, and distributed simulation. Section 3 introduces the conceptual framework and federation design. Section 4 presents the implementation and proof-of-concept demonstration. Section 5 discusses implications and challenges, and Section 6 concludes with an outlook for future research.

2 Background and Related Work

This section presents a review of CE concepts, material flow modeling techniques, and construction simulation methods, with the aim of specifying requirements and identifying knowledge gaps for creating realistic and scalable simulations of road construction circularity. Together, these perspectives highlight the need for more integrated and digitally coordinated approaches to support future resource-efficient construction workflows.

2.1 Circular Economy in Road Construction

CE principles, such as reduce, reuse, recycle, provide a strategic foundation for improving resource efficiency and reducing environmental impacts in pavement engineering [18]. Strategies such as substituting virgin materials with reclaimed ones, using rejuvenators, or improving end-of-life recovery can substantially reduce material extraction and emissions [1], [2], [7], [16]. However, CE implementation remains limited due to quality variability of reclaimed materials, aging effects, and contamination that complicate mix design [2], [19]. Logistical issues, such as transport distances and timing mismatches between demolition and production, further constrain practical feasibility [20], [21]. Standards often restrict the use of recycled content, and digital tools for coordinating material flows across organizations are still scarce [8], [9], [22]. Despite increasing policy attention, most CE studies in pavement engineering remain material-centric and do not address the dynamic, process-level, and network-level considerations required for operational CE integration [13], [17].

2.2 Material Flow Modeling

Material Flow Analysis (MFA) provides a quantitative framework for assessing inputs, outputs, and stocks of materials within a defined system boundary [15]. In road construction, MFA is used to represent material requirements for pavement layers and the material flows [1], [22]. MFA enables transparent reporting of circularity indicators such as recycled content, virgin substitution, and diversion rates [16]. Sankey diagrams are widely used to visualize these flows, offering an intuitive representation of how materials move through the system and where losses or inefficiencies occur [23]. Such visualizations are effective communication tools, particularly for comparing linear and circular system configurations. However, MFA is inherently static. It does not account for temporal aspects such as scheduling, process durations, capacity constraints, or quality-dependent blending decisions [15]. For road construction, these temporal dynamics are crucial: DEM output may not align with MIX demand; materials may degrade during storage; and transport times may disrupt planned operations [7], [13], [19]. Consequently, MFA alone cannot determine whether CE strategies are operationally feasible or economically beneficial under realistic process conditions. A dynamic model is needed that can integrate temporal, spatial, and operational constraints across the network. This motivates the development of CE-oriented dynamic simulation approaches.

2.3 Simulation in Construction Processes

In contrast to the static nature of Sankey diagrams, discrete event simulation (DES) offers a convenient method to analyze the dynamics of construction operations through explicit modeling of activity sequencing logic, resource flows, and uncertainties in duration and quantities involved. These properties enable simulation to overcome the limitations of real-world experimentation (expensive and unfeasible) and static analytical modeling (which make overly simplifying assumptions about the underlying system) to provide an objective means of analyzing and optimizing construction operations [11], [24]. Prior work that showcases the applicability and generalizability of DES to construction operations in general include tunnel boring [25], pipe-spool module assembly [26], modular construction ([27], disaster recovery [28], and asphalt paving operations [29]. However, despite these strengths of DES for modeling construction operations, it has some significant limitations that hinder its ability to model circularity in roadway construction: (1) the DES current focuses on modeling only single sites, which makes it

unsuitable to model multiple sites in a region; (2) it is difficult to model the temporariness of projects as they would occur in the real world, as DES tends to focus on modeling operations from start to finish for a single operation on a single site; (3) current DES methods do not enable the transfer of resources between models in a time-synchronized manner, which is necessary to model material transfer between sites for circular roadway construction. These limitations are overcome in this research by adopting the HLA for distributed simulations using the ConStrobe simulation engine, as will be described in Section 3.

2.4 Requirements for CE-oriented simulation in road construction

Based on the gaps identified in the previous sections, a simulation framework intended to support CE in road construction must satisfy several functional requirements that exceed the capabilities of traditional MFA or isolated discrete-event models.

1. R1 – Scalable Multi-Site System Representation: Road construction CE requires modeling interactions among multiple DEM, MIX, and CON sites operating concurrently within a distributed network [12], [20], [21].
2. R2 – Dynamic Material Flow Tracking: The simulation must track material batches over time, including their quantities, origins, and quality attributes, since recycling feasibility depends on temporal and compositional alignment [13], [15].
3. R3 – Circular Material Feedback Loops: Closed-loop flows must be modelled to quantify circularity indicators such as recycled content, virgin-material reduction, and diversion rates [16], [18].
4. R4 – Process-Level Operational Detail: The model must capture operational constraints (e.g., queueing, capacity limits, availability, and process times at DEM, MIX, and CON sites) [11], [12].
5. R5 – Inter-Model Communication and Modularity: Given the heterogeneity of DEM, MIX, and CON processes, the simulation must support independent models that communicate through standardized interfaces, as enabled by the HLA [30], [31].
6. R6 – Scalability to Network-Level Decisions: To evaluate CE strategies at the project or regional level, the simulation must scale to multiple sites and varying process configurations [14], [21].
7. R7 – CE Indicators and Visualization: The framework must generate CE-relevant metrics and support visualization through flow diagrams such as Sankey charts [16], [23].

Together, these requirements form the basis for a CE-capable simulation architecture, demonstrating the need for a distributed modeling approach that integrates multi-site material flows and operational dynamics.

2.5 Requirement-Based Evaluation of Existing Simulation Approaches

To assess the suitability of existing construction-simulation research for CE-oriented modeling, the requirements defined in Section 2.4 (R1–R7) were used as evaluation criteria. The DES-focused literature discussed in Section 2.3 represents the dominant modeling approaches in construction operations and offers mature capabilities in activity sequencing, equipment modeling, and queue-based resource interaction. However, these studies remain fundamentally constrained by their single-site scope and linear process assumptions. Table 1 summarizes the comparison between representative DES studies and the CE-oriented requirements. Conventional DES models generally satisfy process-detail requirements (R4) but lack mechanisms for multi-site coordination (R1, R6), dynamic material-quality tracking (R2), circular flow modeling (R3), inter-model communication (R5), and CE indicator generation (R7). All reviewed works are limited to single-site, linear processes and do not represent interdependent DEM–MIX–CON systems, circular material feedback loops, or closed-loop mass tracking.

Overall, no existing DES study fulfills more than two CE-relevant requirements. No prior work combines multi-site process modeling, dynamic material-flow tracking, and circularity assessment, highlighting a clear research gap that directly motivates the distributed HLA-based simulation framework presented in Section 3.

3 Conceptual Framework and System Design

This section presents the conceptual foundation for modeling circular material flows across demolition, mixing, and construction activities, as modeled by the corresponding federates. The framework integrates CE principles with a distributed, multi-site simulation perspective, directly operationalizing the requirements derived in Section 2.4. The framework enables transparent tracking of material origins, quality-dependent transformation steps, and batch-level allocation across the distributed DEM–MIX–CON system. The modeling approach mirrors the physical organization of road-construction processes and provides the basis for evaluating recycling and substitution effects under realistic operational constraints.

3.1 System Boundary and Material Loop

The framework encompasses the entire material cycle associated with demolishing and constructing a 1 km-long and 7 m-wide road section. All materials extracted during demolition, as well as those required for constructing the surface, base, and frost layers, are included. The process is decomposed into three domains:

- **DEM** – milling and excavating surface, base, and frost layers; asphalt-bound and mineral materials.
- **MIX** – classification, crushing, screening, and production of asphalt and granular mixes.
- **CON** – placement and compaction of the new road.

The analysis encompasses all materials generated from DEM and all materials necessary for CON. While this models a single life-cycle iteration, the structure supports multi-cycle CE assessments by allowing CON outputs to re-enter future DEM processes or even introduce maintenance activities as a combination of the DEM and CON federates.

3.2 Pavement Structure, Material Composition and Machinery

The pavement consists of three layers: surface, base, and frost, each with distinct material compositions and recycling potentials.

Table 2: Pavement layers, material composition, and machinery

	Primary Materials	DEM Machines	CON Machines
Surface	Asphalt(1)/RAP(2), Bitumen(3), Crushed Stone(4), Filler(5)	Milling Machine	Asphalt Paver, Roller
Base	Asphalt(1)/RAP(2), Concrete(6), Crushed Stone(4), Gravel(7)	Excavator, Wheel Loader	Grader, Roller, Wheel Loader
Frost	Concrete(6), Crushed Rock(8), Gravel(7)		

3.3 Reference Material Flows and Sankey-Based CE Representation

The Sankey diagram in Figure 1 forms the quantitative backbone of the conceptual framework. It depicts the complete flow of materials from DEM to MIX for all pavement layers, identifying the recoverable asphalt components, the mineral fractions suitable for reuse, and the unavoidable losses resulting from fines, contamination, or mechanical degradation. The recyclable materials are depicted in light green.

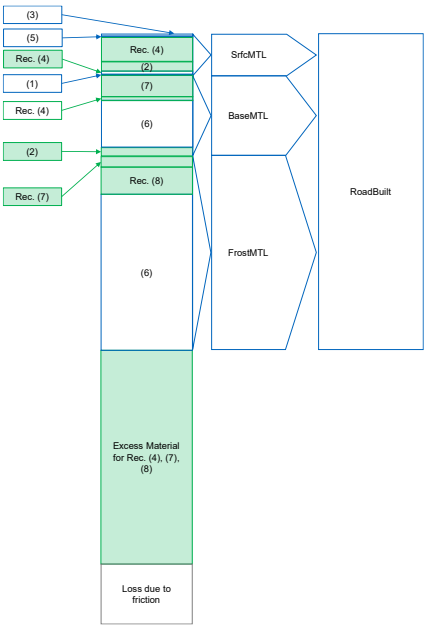

Figure 1: Sankey diagram of material flows across DEM-MIX-CON

The underlying values are derived from an estimation model calibrated using real project data and validated through expert interviews. DEM generates three primary material streams corresponding to the original pavement structure: approximately 1,314 t from the surface layer, 2,533 t from the base layer, and 6,131 t from the frost/sub-base layer. These streams sum to 9,979 t and are decomposed into asphalt-bound components, recoverable granular fractions, and non-recoverable losses. In the surface layer stream, 308 t of material are recovered as high-quality RAP (approximately 90 % of the asphalt content), 777 t are recycled as mineral

fractions (around 80 % of the unbound portion), and 229 t are lost due to processing-related degradation. The base layer yields 236 t of RAP, 1,818 t of recycled mineral aggregates, and 462 t of losses. The frost/sub-base layer, containing no asphalt binder, contributes the largest volume of mineral recyclate, with 4,905 t recovered and 1,226 t lost. In total, the CE potential amounts to 544 t of RAP and 7,500 t of reusable mineral aggregates, whereas 1,916 t of material must be virgin inputs. These flows define the theoretical upper bound of substitution in the CON process and establish quality and mass constraints governing decisions in MIX.

3.4 Material Transformation Logic from DEM to MIX to CON

The transformation logic governs how materials move through the DEM–MIX–CON chain, ensuring that the simulation reflects realistic process behavior and CE constraints. DEM produces heterogeneous batches characterized by material type, grain-size distribution, asphalt content, binder ageing (for RAP), moisture, and contamination. These properties determine their eligibility for high-quality RAP production or mineral recycling pathways. Once transferred to MIX, the batches undergo screening, crushing, composition analysis, and RAP-quality evaluation before being sorted into dedicated stockpiles. MIX thus transforms DEM output into three categories: RAP suitable for asphalt mixtures in surface or base layers, recycled aggregates for base and frost layers, and reject fines, representing the loss streams in the Sankey diagram. CON consumes the processed materials according to the structural requirements of each layer. The surface layer relies on bitumen, high-quality aggregates, filler, and a controlled RAP share. The base layer accommodates a wider mix of RAP and recycled minerals, while the frost/sub-base layer can incorporate nearly all available mineral recyclates. When recycled supply is insufficient or fails to meet quality requirements, virgin materials are introduced to maintain mass balance and ensure layer specifications are met. In this way, the simulation can evaluate both the theoretical CE potential and the operational feasibility of recycling outcomes.

3.5 Distributed Simulation and HLA

Given the limitations of conventional DES to model multiple spatially and temporally distributed demolition sites, construction sites, and mixing plants that form the dynamic system for which circularity is being considered, this research proposes the use of distributed simulations that is enabled through the IEEE 1516 HLA standard for creating distributed, time-synchronized simulations. In this framework, individual simulation models are referred to as federates, and they join a federation through a Runtime Infrastructure (RTI), which facilitates time synchronization and data exchange between the individual federates. AbouRizk (2010) has previously identified HLA as a promising direction for construction simulation and has developed the Construction Synthetic Environment (COSYE) for the Simphony simulation system. This research utilizes the CERTI HLA framework [32] for the RTI and the ConStrobe simulation system [33] to provide individual federates for the various demolition, construction, and mix plant sites within the road network. A schema of this distributed simulation framework is shown in Figure 2.

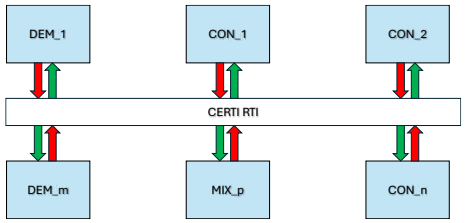

Figure 2: HLA Architecture

The light blue boxes represent HLA-compliant ConStrobe models that represent any of the different DEM, CON, or MIX sites, which act as federates and publish and subscribe to data from other federates through the CERTI RTI. They interact through a shared Federation Object Model that defines material batches using attributes such as mass, material type, RAP fraction, binder properties, grain-size class, timestamp, and federate origin. Time management services coordinate the execution order and ensure synchronized access to material stocks and process events. The modularity of the architecture enables the integration of extended scenarios, such as additional recycling facilities, alternative pavement designs, or network-level simulations, without requiring modifications to existing federates.

3.6 Circularity Indicators and Model Outputs

The distributed simulation generates CE-relevant performance measures, including RAP utilization in asphalt production, mineral substitution rates across all layers, total recycled versus virgin material, and mass balance consistency across federates. Temporal indicators, such as synchronization between DEM supply and CON demand, further support the evaluation of CE strategies under realistic scheduling and capacity constraints. Together, the outputs translate static Sankey-derived potentials into dynamic operational CE metrics.

4 Implementation and Demonstration

This section presents the prototype implementation of

the distributed simulation framework and demonstrates the feasibility of linking DEM, MIX, and CON through HLA. The implementation follows a modular design, in which each federate operates as an independent simulation unit, utilizing a simplified DES logic.

4.1 Model Description

Each federate is implemented with DES-like process logic, supporting queueing, batching, and resource-driven processing. DEM generates material batches corresponding to the layer-specific flows defined in the Sankey diagram, assigning attributes such as mass, material type, RAP fraction, and binder quality. MIX applies simplified processing steps, mapping DEM outputs to the recycling categories defined in Section 3.4. Figure 3 depicts DEM as an exemplary federate.

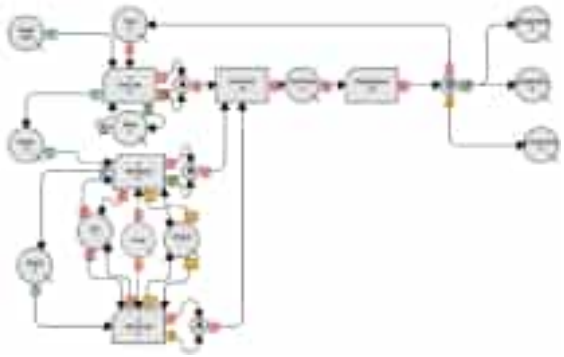

Figure 3: DEM federate in ConStrobe

CON receives processed materials and allocates them to surface, base, or frost layers according to their specification requirements. Several simplifying assumptions enable a clear proof-of-concept demonstration without overburdening the model:

- Machinery resources are represented through processing-time proxies rather than detailed equipment behavior.
- Transport between DEM–MIX–CON is modelled using deterministic travel times.
- MIX capacity is assumed sufficient for the given scenario, avoiding queue overflow.

These assumptions preserve focus on inter-federate communication, CE mass flows, and model extensibility.

4.2 Federate Connections and HLA Synchronization

The three federates communicate through the RTI using object and interaction classes defined in the Federation Object Model. DEM publishes MaterialBatch objects, which include mass, type, timestamp, and origin. MIX subscribes to these objects and publishes corresponding ProcessedBatch objects after transformation. CON then consumes these batches through MaterialRequest and MaterialDelivery interactions. Time-stepped HLA time management is used to ensure logical causality. All federates advance simulation time in synchronized increments. This mechanism ensures that the distributed model remains consistent with the temporal dynamics of real-world construction operations, where material availability constrains production and placement.

4.3 Demonstration Scenario

The demonstration uses the case introduced in Section 3. The DEM federate generates batches totalling 9,979 t, decomposed by layer origin. MIX processes these batches into RAP, recycled mineral aggregates, and residual losses, applying the CE transformation logic defined in Section 3.4. CON then sequentially constructs the frost, base, and surface layers by requesting and receiving materials in accordance with their layer-specific specifications. Through the demonstration run, the federates successfully exchange materials, update inventories, and maintain time-synchronized execution. The resulting simulation logs capture all material transformations and serve as the basis for deriving a dynamic Sankey diagram that mirrors Figure 1.

4.4 Results: Connectivity and Material-Substitution Effects

The proof-of-concept implementation confirms that DEM, MIX, and CON federates can be reliably linked through HLA. All federates exchanged material batches without message loss, and synchronized time advancement preserved correct causal ordering of production, processing, and consumption events. This demonstrates the technical feasibility of distributed, multi-site simulation for road construction processes.

Table 3: Material substitution results for linear vs. circular scenarios

	Linear scenario	CE-enabled scenario
Total material [t]	9,979	9,979
Virgin material [t]	9,979	7,519
RAP used [t]	-	544
Recycled mineral aggregates used [t]	-	7,500
Virgin material reduction [t]	-	2,460

Beyond connectivity, the simulation quantifies the impact of circular material flows on demand for virgin materials. In a linear reconstruction scenario, the full 9,979 t of pavement material is supplied from virgin

sources. When CE pathways are enabled, recycled outputs from DEM and MIX provide 544 t of RAP and 7,500 t of recycled mineral aggregates, reducing virgin material demand by approximately 2,460 t (~25 %). Substitution effects are strongest in the frost and base layers, while surface-layer reductions are limited by RAP quality requirements. These results show that CE performance depends not only on theoretical recycling potential but also on the operational synchronization of DEM–MIX–CON federates.

5 Discussion

The proof-of-concept demonstrates that distributed simulation is a viable approach for modeling CE-oriented material flows across DEM, MIX, and CON operations. Using HLA enables modularity and interoperability, allowing heterogeneous process models to exchange material batches through a shared, synchronized representation and to dynamically generate CE metrics (e.g., RAP utilization and virgin-material substitution), rather than relying on aggregate assumptions. Key implementation challenges remain. Consistent data structures across federates require careful FOM design, particularly when introducing additional material types or quality attributes. Interoperability issues may arise when federates operated by different organizations use incompatible internal models. Differences in temporal and spatial granularity between DEM, MIX, and CON also require harmonization strategies to maintain causal consistency. Overall, the framework provides a basis for extending the federation to multi-site networks, comparing recycling configurations (e.g., mobile vs. stationary), and integrating additional indicators such as CO_2 emissions or energy use.

6 Conclusion and Outlook

This study presented a distributed simulation framework that links DEM, MIX, and CON processes through HLA to evaluate CE-oriented material flows in road construction. The proof-of-concept demonstrated reliable federate synchronization and batch exchange, enabling dynamic assessment of recycling and substitution effects under operational constraints. A key result is that synchronized DEM–MIX–CON interactions reduced virgin material demand by ~25 % compared with a linear scenario. Future work can enhance model fidelity by integrating spatial data (BIM/GIS) to account for transport and network effects and coupling the simulation with environmental and economic assessment modules to support informed decision-making for circular infrastructure planning. By enabling digitally connected, resource-efficient, and operationally synchronized construction processes, the proposed framework contributes to constructing the future of road infrastructure that is sustainable, smart, and lean.

Abstract –

BIM design workflows involve complex multi-step interactions with professional software, limiting the direct use of large language models (LLMs). This paper proposes an LLM-agent-driven BIM design assistant that enables natural-language-based BIM design and visualization through reliable tool invocation. First, a two-layer Revit interface function library is designed to bridge LLM agents and BIM software, providing secure, extensible, and fine-grained model manipulation capabilities. Based on the ReAct paradigm, an agent framework is developed that integrates dialogue history management, structured prompt engineering, and step-by-step reasoning to support long-horizon and multi-turn BIM tasks. An agent-oriented BIM benchmark is constructed to evaluate the system, covering querying, visualization, modification, and deletion tasks with varying difficulty. Experiments with three representative LLMs show that high-performance models can reliably act as BIM design assistants within the proposed framework, achieving up to 90% task accuracy. The results demonstrate the feasibility of LLM-driven BIM design assistance.

Keywords –

Building Information Modeling; Revit; Large language models; Agent

1 Introduction

Building Information Modeling (BIM) has become a key data-driven approach across the building lifecycle [1]. By integrating project data into a unified model, it improves collaboration and information management efficiency [2]. However, as BIM models become more complex, tasks such as model manipulation, information retrieval, and modification still rely heavily on manual interaction with tools like Autodesk Revit [3], increasing barriers for non-expert users and reducing efficiency in repetitive multi-step operations.

More recently, advances in natural language processing and large language models (LLMs) have stimulated growing interest in language-driven BIM interaction [4]. Existing work has investigated LLM-based methods for NLP-based information extraction and analysis [5,6,7], knowledge acquisition [8,9], BIM question answering [10], and building information modeling [11]. However, most of these approaches focus on semantic-level tasks where LLMs mainly support information understanding or text generation. Their capability to execute design operations within BIM software environments remains limited.

The emergence of LLM-based agents provides a potential solution by enabling models to reason and interact with external tools [12,13]. In the BIM domain, this development suggests a shift from passive language assistance toward active task execution. For example, Ying et al. proposed a ReAct-based agent for design checking that can interpret requirements and retrieve BIM data [14]. Jang et al. explored natural-language-driven architectural detailing assistance [15]. However, these studies either rely on predefined task rules or support only limited BIM operations, and they do not establish a general framework for reliable natural-language-driven BIM design interaction.

To address this limitation, this study develops a BIM design assistant driven by LLM agents to enhance BIM-assisted design and visualization tasks. The main contributions are threefold: (1) a two-layer BIM interface architecture that converts low-level Revit APIs into structured tools callable by LLM agents; (2) an agent-based interaction framework integrating ReAct reasoning, prompt engineering, and dialogue history management for multi-step BIM operations; and (3) a benchmark containing 100 BIM tasks across querying, visualization, modification, and deletion to systematically evaluate the proposed framework. Although the present implementation is developed in Autodesk Revit, the proposed framework is not entirely Revit-specific. The platform-dependent components are the BIM operation layer, which includes low-level Revit functions and composed Revit Interfaces. By contrast, the two-layer architectural organization, the ReAct-based planning and execution workflow, etc., are platform-agnostic at the

methodological level. Therefore, transferring the framework to other BIM platforms mainly requires replacing the low-level tool layer with interfaces built on the corresponding software APIs.

2 Design and Implementation of an LLM-Oriented Revit Interface Library

To enable real-time BIM model manipulation, a structured Revit interface library is developed using the official Revit API in C#, exposing core modeling operations to LLM agents and supporting safe agent-based BIM interaction.

2.1 Overall Design

Given the broad functional scope of Revit, this study focuses on structural design tasks and targets common operations such as element retrieval, modification, deletion, parameter configuration, and visualization.

To support these operations efficiently and safely, we design a two-layer interface architecture, as illustrated in Figure 1. The lower layer, Revit Functions, encapsulates low-level BIM model operations and directly interfaces with the Revit. While the upper layer, Revit Interfaces, composes basic functions into higher-level, agent-facing operations, enabling more expressive manipulation.

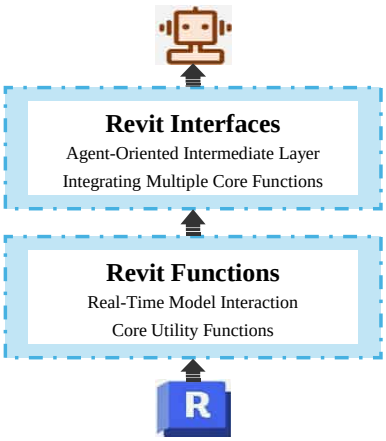

Figure 1. Two-layer interface architecture

This layered design allows shared functionality to be implemented once at the lower level while supporting diverse, integrated operations at the upper level, thereby improving extensibility and development efficiency. Moreover, since all model modifications in Revit are managed through transaction mechanisms, potentially unsafe operations are isolated at the lower layer and exposed to the agent only under controlled conditions at the upper layer. Structured input-output descriptions further accompany each Revit interface to facilitate accurate tool selection and invocation by LLM agents.

2.2 Design of Revit Functions

Revit Functions form the low-level interaction layer that directly and safely operate on the BIM model, comprising nine core functions that provide essential modeling capabilities, as illustrated in Table 1.

Table 1. Core Revit functions

Function Name	Description
Convert Unit	Converts parameter value between user and internal unit
Create Element Filter	Builds filters for element selection
Delete Object	Deletes specified model element
Get Category	Retrieves built-in element categories
Get Parameter Unit	Retrieves internal parameter unit
Retrieve Object	Retrieves elements matching given filters
Retrieve Object Params	Retrieves parameters of a specified element
Set Element Parameter	Sets values of editable element parameter
Show Elements	Highlights selected element

When composed appropriately, these core functions are sufficient to support all target operations while providing controlled access to internal model data. And they are designed to be extensible, enabling future tool integration without altering the core framework.

2.3 Design of Revit Interfaces

While Revit Functions provide low-level capabilities, their API-specific data types are not suitable for direct LLM interaction. Therefore, a higher-level layer, Revit Interfaces, composes multiple functions into integrated operations with simplified inputs (e.g., text and numeric values) for agent invocation (Figure 2). These interfaces also return structured execution feedback for reasoning. Eight interfaces are implemented to support the target BIM operations (Table 2).

Table 2. Core Revit interfaces

Function Name	Description
Delete Element	Deletes elements specified by IDs. Return deleted element IDs or the failure cause
Retrieve Element	Return elements matching given filters or the failure cause
Retrieve All Parameters	Return all parameters of a specified element in a structured format or the failure cause
Retrieve	Return a specific parameter using

Parameter With Built-In Id	its built-in ID in a structured format, or the failure cause
Retrieve Parameter With Parameter Name	Return parameters matching a given name in a structured format or the failure cause
Set Parameter With Built-In Id	Sets parameter values by built-in IDs with validity checks. Return parameter IDs and value changes, or the failure cause
Set Parameter With Parameter Name	Sets parameter values by name with validity checks. Return parameter IDs and value changes, or the failure cause
Show Elements	Highlights specified elements in the 3D view. Return displayed elements' IDs, or the failure cause

By leveraging these, the agent can manipulate BIM models through textual inputs. Moreover, the Revit Interfaces layer is designed to be extensible, allowing additional interfaces to be incorporated.

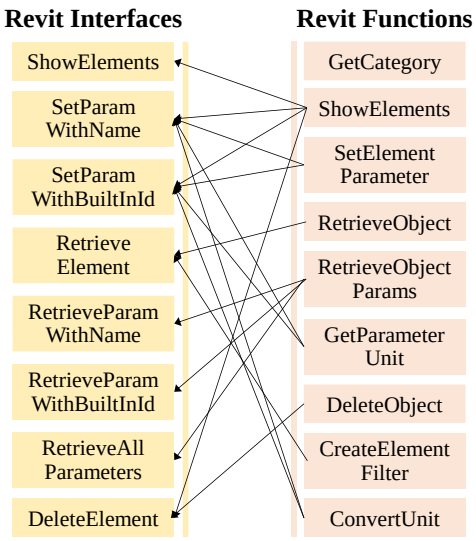

Figure 2. Dependencies between Revit Interfaces and Revit Functions

2.4 Interface Descriptions for LLM-Based Agents

LLM-based tool invocation relies on explicit interface descriptions. Accordingly, each Revit Interface is accompanied by a standardized description consisting of four components: interface name, functionality, input parameters, and output definitions. The interface name serves as the identifier for agent invocation, while the functionality provides a concise summary of the interface behaviour. Input parameters specify the semantics and data types required for correct execution, and output definitions describe the format and meaning of returned information, which supports subsequent agent reasoning and decision-making. These descriptions are assembled during agent-user interactions to support accurate tool selection and execution, as illustrated in Figure 3.

{
"**Interface name**": DeleteElement
"**Functionality**": This interface deletes element(s) from the Revit project given their element ID(s)
"**Input parameters**": The requirements and meanings of the input parameters of this interface are as follows: elementIdStrings: A list of string representations of element IDs of all elements to be deleted
"**Output definitions**": This interface outputs a string message indicating whether the deletion was successful. If failed, a message showing the failure information is returned.
}

Figure 3. Interfaces descriptive information

3 Design Agent Development Based on ReAct and Prompt Engineering

This study adopts the ReAct Think-Act-Observe paradigm as the core framework for BIM-assisted agent development and designs key components based on this paradigm. To ensure the correct interpretation of Revit-specific context, a curated prompt library is incorporated to support reliable multi-turn reasoning and execution.

3.1 Multi-Turn Agent Component Design

Complex BIM design tasks typically require multi-turn interactions with users or the system rather than being completed in a single operation. This necessitates mechanisms for managing dialogue history, controlling the interaction process, and coordinating real-time communication between the agent and Revit interfaces. To meet these requirements, the agent's functionalities are decomposed into modular components that together support a complete conversational workflow.

Specifically, five agent components are designed to collaboratively construct the interaction framework, supporting instruction parsing, task planning, tool invocation, execution, and user feedback, as shown in Figure 4. A dialogue history management system and a planning and execution algorithm form the core of the framework, orchestrating the interaction flow and coordinating other components. Tool invocation is handled by an executor that maps parsed commands to Revit Interfaces, while LLM interaction is supported by a prompt library and LLM APIs for context-aware prompt assembly and response retrieval. The following describes these five components in detail.

1. Dialogue history management system: BIM tasks typically involve long, multi-step interactions,

requiring the LLM to retain awareness of prior actions and dialogue context. To avoid excessive context growth and degraded model performance, we implement a selective history management mechanism that appends only semantically essential dialogue content while discarding auxiliary prompt information. This design preserves core contextual semantics with significantly reduced input length, enabling longer interaction horizons. Dialogue entries are further annotated with role identifiers to ensure compatibility with standard LLM APIs.

2. Planning and execution algorithm: Following the ReAct paradigm, the agent iteratively performs Think-Act-Observe cycles to complete tasks, interacting with the Revit environment and using execution feedback to guide subsequent actions. The algorithm also determines appropriate task termination and governs the overall interaction workflow, as detailed in Section 3.2.
3. Executor: Parsed agent commands are converted into a structured JSON format and passed to the executor for interface invocation. Serving as an intermediary between the agent core and the Revit interface library, the executor parses inputs, calls the corresponding Revit Interfaces, and returns execution results to the agent core as part of the dialogue.
4. Prompt library: To guide LLM reasoning and execution, two categories of prompts are designed, each combining core instructions, response formats, examples, and interface information. The prompt library is detailed in Section 3.3.
5. LLM APIs: Due to the high resource cost of local deployment, this study adopts an API-based approach to access remote LLMs. The OpenAI API is used for its compatibility with the C# environment in Revit, enabling prompt submission and response retrieval within the agent workflow.

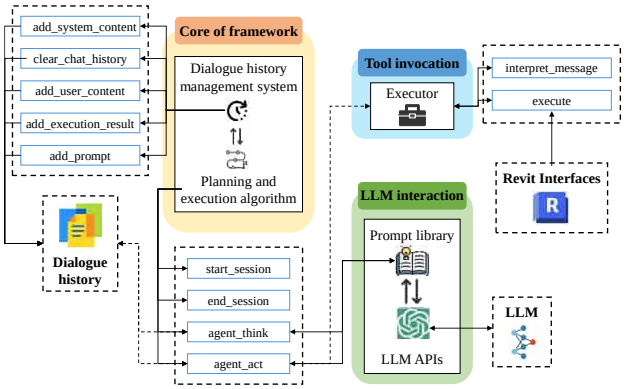

Figure 4. Interaction among the main agent components

3.2 Core of framework Design Based on ReAct

The operation of the agent requires coordinated management of multiple components and proper handling of user-agent dialogue logic. To this end, a ReAct-based core of framework is designed to govern the overall interaction workflow of the Revit Agent, which is executed at the start of each user session. The algorithm is organized into three main stages: initialization, dialogue, and termination, with execution actions conditionally triggered during the dialogue stage, as shown in Figure 5.

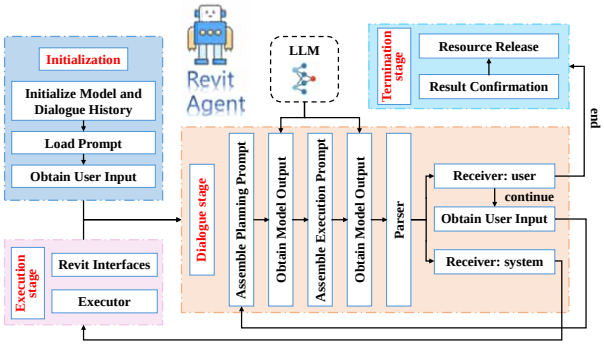

Figure 5. Core of framework design based on ReAct

During initialization, the LLM instance, dialogue history manager, and prompt library are initialized, and users may select different LLM backbones supported by the OpenAI API through configuration settings. The dialogue history manager creates a new history container and populates it with system prompts and synthetic agent-user exchanges that simulate background inquiry, preparing the agent for subsequent multi-turn interaction. Interface-related information is embedded into the dialogue history to support later tool invocation. Finally, the user provides a task description, which serves as the primary objective for the subsequent interaction process.

During the dialogue stage, the algorithm guides the agent through multi-turn interaction following the ReAct Think-Act-Observe paradigm. In each turn, a Think Prompt from the prompt library is first combined with the dialogue history to generate a new prompt, and the LLM produces an unstructured response to plan subsequent actions. Then an Act Prompt that enforces a structured JSON output defined as a Message. The generated JSON is parsed into a C# Message object, enabling executable control flow, as illustrated in Figure 6. Based on the Receiver field in the message, two execution paths are defined. If the receiver is the user, the algorithm evaluates the End flag to determine whether to terminate the interaction or proceed to the next dialogue turn after receiving user input. If the receiver is the system, the

algorithm enters the execution stage, where the executor parses the Call and Args fields to invoke the corresponding Revit Interface. The execution result is then appended to the dialogue history, and the algorithm proceeds to the next interaction cycle.

```
{
"Receiver": system
"Call": RetrieveElement
"Args":{
        "elementIdStrings": null,
        "builtInCategoryName": "OST_Walls",
        "className": null,
        "familyIdString": null,
        "familySymbolIdString": null,
        "levelIdString": null,
       "isElementType": false,
       "parameterFilterArgs": null
   }
}
```

Figure 6. Example of a message class object

The termination stage indicates that the agent determines the task to be completed or infeasible. All executed actions are subject to user confirmation, and any rejected actions are rolled back to ensure BIM model data integrity. Finally, all allocated resources are released, and the dialogue session and task execution are concluded.

3.3 Prompt Design with Multi-Information Integration

LLM outputs are highly sensitive to prompts, making prompt engineering essential. To ensure correct understanding of Revit-specific context and appropriate action generation, instructions, Revit background information, and interface descriptions are integrated into structured prompts. These prompts are organized into three types: Think Prompts, Act Prompts, and Interface Information Prompts.

1. Think Prompts: Consist of core instructions and response examples. The core instructions guide the agent to plan subsequent actions based on the dialogue history, while the examples illustrate reasonable planning responses.
2. Act Prompts: Include core instructions, response examples, and summarized interface information. The core instructions require the agent to generate a structured Message according to a predefined format. While the schema constrains the output format, the examples illustrate correct interface selection and parameter usage. The interface summary briefly lists available interfaces and their functionalities to mitigate LLM forgetting.
3. Interface Information Prompts: Provide complete interface descriptions, including interface names, functionalities, and input-output specifications. Due to their length, these prompts are only injected during the initialization stage.

```
{
"Name": Think Prompt
"Instruction": Based on the task requirements I've presented, and taking into account the historical conversation information, please think in an organized way about what should be accomplished next, what Revit interfaces should be called, or what necessary information you need me to add. If the task has been completed, please think about how you should report and summarize the results to me. Please note that what you think about at this stage will not be executed, you can simply reply in natural language.
"Example": The user wants to get the IDs of all wall instances and the user has given the built-in category ID of the wall as \"OST_Walls\". Among the interfaces provided, the \"RetrieveElement\" interface can filter the eligible element instances by the built-in category. So next, we can call this interface and set the input parameter \"builtInCategoryName\" to \"OST_Walls\", set \"isElementType\" to false and the remaining parameters to null.
}
```

```
{
"Name": Act Prompt
"Instruction": Based on the task requirements and the contents of your thinking above, please reply in JSON format. You can choose to reply to the Revit system to call a specific Revit interface to continue completing the task, or reply to me to ask for more necessary information or report the results after the task is completed. The two types of replies have different format requirements.
"Example": {
        \n Receiver = "system", \n Call = "RetrieveElement", \n Args = {\n { "elementIdStrings", null }, \n
        { "builtInCategoryName", "OST_Walls" }, \n { "className", null }, \n { "familyIdString", null }, \n
        { "familySymbolIdString", null }, \n { "levelIdString", null }, \n { "isElementType", false }, \n { "parameterFilterArgs", null \n }}
   }
}
```

Figure 7. Prompt examples

4 Benchmark for Agent-Based BIM Design Assistance Tasks

4.1 Manually Annotated Test Dataset

Due to the lack of publicly available datasets for Revit-based BIM design tasks, the benchmark dataset is manually collected and annotated to ensure reliability and evaluation relevance. All tasks supported by the current interfaces are categorized into four types: information querying, model visualization, component modification, and component deletion. Tasks are designed for each category based on a reference BIM model and real-world design scenarios, with multiple difficulty levels introduced according to operational complexity.

Each task is accompanied by a manually written reference answer describing the correct execution outcome or feasible interface invocation. In total, 100 English test tasks with annotated answers are constructed to ensure balanced evaluation across different LLMs, with task statistics shown in Table 3.

Table 3. Task statistics

Task Categories	Quantity
Information querying	52
Model visualization	18
Component modification	20
Component deletion	10

4.2 Evaluation Criteria

In practical BIM design and visualization tasks, users primarily focus on the correctness of final results rather than execution details. Accordingly, this study adopts an outcome-oriented evaluation strategy using two metrics: task completion rate and task accuracy.

The task completion rate measures whether the agent successfully completes a task and reports the result, while task accuracy evaluates whether the completed task produces correct outcomes consistent with user requirements. Both metrics are computed as the ratios of completed or accurate tasks to the total number of tasks. Evaluation is conducted by manually comparing the agent's outputs and execution results against annotated reference answers.

5 Experiment

To assess the reliability of the proposed agent system and the impact of different LLM capabilities, three representative models from the GLM series, GLM4-flash, GLM4-plus, and GLM-Zero-Preview, are evaluated. These models respectively represent mid-level general-purpose performance, flagship general-purpose capability, and reasoning-oriented models with strong logical inference ability.

To facilitate a more detailed analysis of LLM performance, results are reported by task category and difficulty level in addition to overall performance. Tasks are grouped into information querying, model visualization, component modification, and component deletion, while difficulty is defined by the minimum number of interaction turns required for completion ($\leqslant$2, 3-4, and $\geqslant$5 turns for Levels 1-3, respectively). This criterion reflects increasing reasoning complexity and dialogue history length.

5.1 Overall Results

Table 4 summarizes the results on the test dataset. The results show that GLM4-plus achieves the best performance, reaching 90% accuracy, which exceeds prior LLM-assisted BIM methods such as BIMS-GPT [16] under zero-shot prompting. It should be noted that, due to differences in tasks and datasets, the comparison with prior studies should be interpreted as a qualitative reference rather than a strictly equivalent benchmark. GLM-Zero-Preview and GLM4-flash show similar accuracy but lower performance than GLM4-plus, while GLM-Zero-Preview exhibits a notably lower completion rate despite high correctness on completed tasks. This is mainly due to its tendency to request additional information when handling complex interface calls. Overall, the results indicate that GLM4-plus enables more reliable BIM-assisted design and visualization within the proposed agent framework.

Table 4. Overall results

Model	Context Limit (K)	Completion rate (%)	Accuracy (%)
GLM4-flash	128	70	93
GLM4-plus	128	90	99
GLM-Zero-Preview	16	71	71

5.2 Performance Across Task Categories

Across task categories, the three LLMs exhibit distinct strengths, as shown in Figure 8-9. GLM4-plus achieves near-perfect completion and 100% accuracy in component modification and deletion, with consistently high performance across all tasks. GLM4-flash performs well in information querying and component deletion but is less effective in model visualization and component modification. GLM-Zero-Preview excels in component modification, while its identical completion and accuracy rates indicate that all completed tasks are correct and all failures result from incomplete execution, mainly due to incorrect judgments about required task information rather than interface invocation errors.

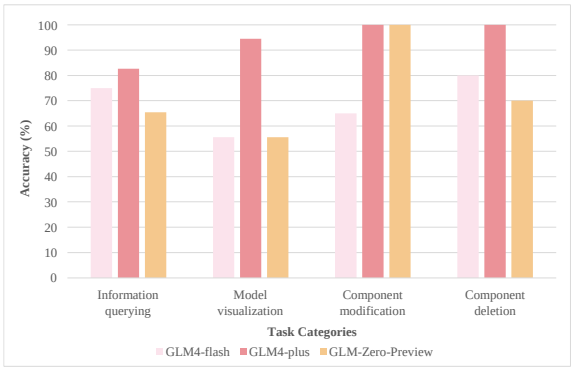

Figure 8. Classification accuracy

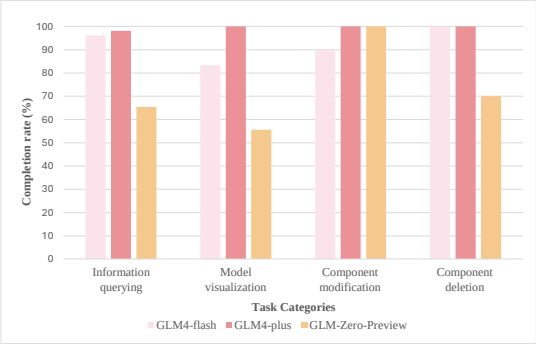

Figure 9. Completion rate

5.3 Performance Across Task Difficulty Levels

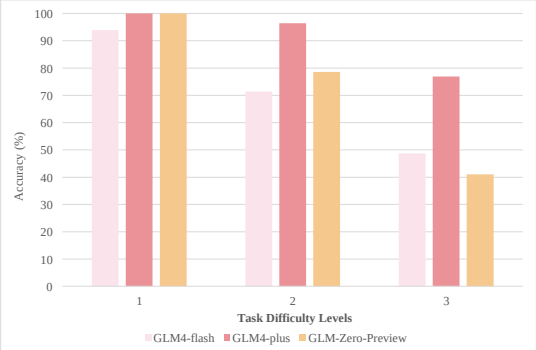

Figure 10. Classification accuracy

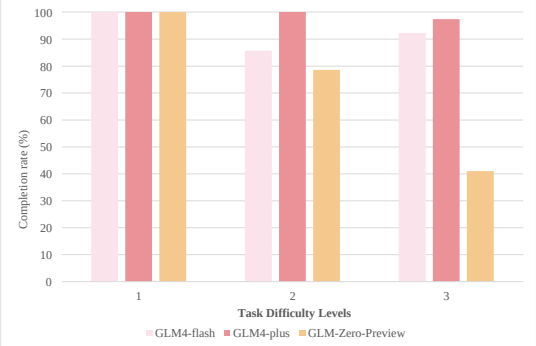

Figure 11. Completion rate

The benchmark includes 33 Level-1, 28 Level-2, and 39 Level-3 tasks, yielding a balanced difficulty distribution. As expected, both accuracy and completion rate decrease with increasing difficulty for all models. While all LLMs perform well on Level-1 tasks, accuracy for GLM4-flash and GLM-Zero-Preview drops sharply on Level-2 and Level-3 tasks, reflecting increased reasoning complexity with longer interactions.

Completion rate analysis further shows that GLM4-flash behaves more aggressively by attempting task completion at all difficulty levels regardless of correctness, while GLM-Zero-Preview adopts a more conservative strategy, frequently requesting additional user input when confidence is insufficient, leading to a higher rate of incomplete tasks.

Figure 12 presents an end-to-end example of a GLM4-plus–based agent successfully completing a task in the model visualization category (difficulty level 2). The task is to display all door instance elements on Level 2 in the Revit 3D view. As shown, the agent first retrieves the corresponding elements using the RetrieveElement interface and then invokes ShowElements based on the returned element IDs. By sequentially using system responses to guide subsequent interface calls, the agent accurately completes the task.

Figure 12. An end-to-end example

6 Conclusion

This study presents a BIM design assistant driven by LLM agents and implements a reliable prototype within the Autodesk Revit environment The main contributions are as follows:

1. A two-layer interface architecture is designed and implemented, accompanied by structured interface descriptions. This design enables real-time manipulation of Revit BIM models by the agent and ensures efficient and accurate interface invocation for seamless BIM interaction.
2. A BIM design agent is developed based on ReAct and Prompt Engineering. By integrating dialogue history management, ReAct-based reasoning, and structured prompt engineering, the agent is endowed with step-by-step reasoning capability, allowing it to handle complex tasks and long-

horizon interactions effectively.

3. An agent-oriented BIM-assisted design benchmark is constructed, introducing task completion rate and task accuracy as evaluation metrics. A total of 100 manually annotated test tasks are created to systematically evaluate the reliability and accuracy of the proposed system.

Experimental results show that high-performance general-purpose LLMs, represented by GLM4-plus, can reliably act as BIM design assistants within the proposed framework, accurately completing tasks of varying types and difficulty levels with an accuracy of up to 90%. These findings demonstrate that, when combined with appropriate agent architectures and domain-specific interfaces, LLM-driven design assistants can provide reliable and practical support for BIM-assisted design and visualization.

Abstract –

Onshore wind power plays a critical role in sustainable energy development. However, its deployment is often constrained by complex construction-stage logistics, particularly the planning and design of access roads. During the early-stage evaluation of onshore wind projects, construction road layout design and earthwork estimation remain labor-intensive due to terrain and engineering constraints.

This study proposes an automated optimization framework for the design of hierarchical access roads during onshore wind farm construction. The framework integrates high-resolution terrain data with parametric road modeling and constrained optimization to generate geometrically feasible road alignments. Key engineering constraints, including longitudinal gradient limits, deviation ratio from wind turbine locations, and cut-and-fill earthwork requirements, are explicitly incorporated into the optimization process. By formalizing road layout planning as a solvable computational problem, the proposed method transforms a process into an automated decision support workflow.

The applicability of the proposed framework is illustrated through an example, demonstrating its capability to generate feasible access road alignments while satisfying engineering constraints. The automated workflow supports rapid construction cost estimation during the planning stage.

Wind turbine access roads; Road alignment optimization; Earthwork optimization; Engineering constraints

1 Introduction

Wind energy has become a critical pillar of the global renewable energy portfolio, driven by the increasing demand for clean and sustainable power sources [1]. Despite challenges related to technology deployment, environmental constraints, economic feasibility, and social acceptance [2,3], onshore wind power continues to attract substantial investment and accounts for a significant share of the global energy market [4]. As global decarbonization targets accelerate, the efficient development of onshore wind farms remains essential for meeting future energy demands [5,6].

From a construction perspective, the deployment of onshore wind projects involves a multi-stage process. Typical workflows include candidate site selection based on wind resource assessment, for instance, by NEDO [7], wind turbine layout optimization considering terrain conditions, and construction planning and cost estimation. Among these stages, construction access road planning encompassing route selection, geometric design, and earthwork quantity estimation, represents a major bottleneck in practical project implementation. This stage is inherently complex and resource-intensive, as it must account for diverse land-use classifications, junction design between turbine platforms and access roads, the integration of disaster prevention facilities, and detailed construction cost calculations.[8] In practice, these tasks rely heavily on manual expertise and iterative trial-and-error processes, leading to high labor demands and prolonged project timelines. For example, even when multiple candidate plans satisfy the same preliminary conditions, a comparative evaluation is still required, as these plans may differ in design priorities. [8-10].

To address this challenge, this study proposes a computational approach that formalizes construction access road planning as an automated optimization problem. A geometric optimization framework is developed using high-resolution point cloud data to generate geometrically feasible road alignments and gradients under engineering constraints. By transforming a traditionally experience-driven task into an automated decision support workflow, the proposed method streamlines construction stage planning and facilitates more efficient and reliable construction cost estimation for onshore wind farm projects.

2 Problem Definition and Design Constraints

2.1 Road Design for Wind Turbine Access Roads

Road design is a critical aspect of civil engineering, particularly for access infrastructure in complex terrain. It involves alignment planning, longitudinal gradients, and earthwork operations, including excavation, embankment formation, grading, and compaction, to ensure adequate drainage, structural stability, and construction feasibility.

In the specific context of wind turbine access roads, road geometry and earthwork quantities are strongly coupled. Longitudinal gradients and alignment continuity govern the feasibility of transporting heavy construction vehicles and oversized turbine components. In addition, road design must account for heterogeneous land use conditions, such as agricultural land, forest areas, and developed zones. Consequently, earthwork requirements, road geometry, land use, and environmental considerations must be addressed in an integrated manner to ensure the overall feasibility and performance of wind turbine access road design.

2.2 Engineering Design Constraints

Engineering design must satisfy a set of interrelated constraints to ensure construction feasibility, operational safety, and regulatory compliance. In this study, the following key design constraints are incorporated into the optimization framework.

2.2.1 Wind Turbine Siting Constraints

Wind turbine locations are treated as predefined inputs in the access road planning process. Turbine siting is determined based on wind resource assessments, environmental regulations, and geotechnical feasibility, and is assumed to be fixed prior to construction road design. Each turbine location therefore acts as a mandatory destination that access roads must connect to, subject to geometric and constructability requirements.

2.2.2 Longitudinal Gradient Constraints

Longitudinal gradients of access roads are constrained to ensure the safe transportation of heavy construction vehicles and oversized turbine components. Maximum allowable gradients are specified according to engineering standards and vehicle performance limitations, typically less than 12% [11], also depending on site conditions. In the proposed framework, gradient constraints are enforced along the entire road alignment and directly interact with earthwork requirements.

2.2.3 Connectivity to Existing Roads and Forest Trails

Access road layouts must ensure appropriate connectivity to existing public roads and forest trails to support construction logistics and long-term site accessibility. Feasible connection locations are constrained by traffic safety requirements, visibility conditions, environmental regulations, and land-use limitations. In the optimization framework, access road alignments are restricted to connect through predefined candidate access points while satisfying geometric and constructability requirements.

2.2.4 Cut-and-Fill Earthwork Constraints

Cut-and-fill earthwork constraints are introduced to control excavation and embankment volumes along access road alignments. Excessive imbalance between cut and fill increases construction costs, material transportation demands, and environmental impacts, and may compromise slope stability. Accordingly, earthwork constraints are formulated to promote balanced material utilization. In practice, cut and fill volumes are not exchanged on a 1:1 basis due to soil bulking and compaction effects. In this study, however, the influence of bulking and shrinkage factors on the relative comparison among candidate routes is expected to be limited. Thus, earthwork quantities are used for comparative evaluation of alternative routes, and these effects are therefore not explicitly considered.

2.2.5 Horizontal Curvature Constraints

Horizontal curvature constraints are imposed to accommodate the maneuverability of construction and maintenance vehicles, particularly those transporting large wind turbine components. In practice, these constraints are expressed as minimum allowable turning radii to ensure safe vehicle operation and compliance with design standards. In the present study, however, horizontal curvature is treated as a general alignment consideration rather than an explicit minimum turning-radius constraint.

2.3 Optimization Problem Overview

Based on the engineering considerations described above, access road planning is addressed as a multi-objective optimization problem within an optimization framework. The objective aims to identify road configurations that achieve a favorable balance between construction-related effort, such as earthwork quantities, and road accessibility, while satisfying the prescribed engineering requirements. Meanwhile, soft performance is also taken into account through penalty terms. The detailed representation and solution strategy are described in the subsequent chapter.

3 System Framework and Modeling Approach

3.1 Overall System Architecture

To address the challenge of construction access road optimization under complex terrain conditions, this study proposes an automated framework composed of three primary components: (1) ridge detection for terrain feature extraction, (2) primary access road selection, and (3) secondary access road selection. These components are supported by two core computational modules, namely parametric road model creation and cut-and-fill earthwork volume calculation. Within the framework, terrain data are first processed to identify ridge features and generate initial road profiles, which are subsequently refined through road modeling and earthwork evaluation. By integrating these elements, the proposed framework enables the systematic selection of main and branch access road alignments that balance construction cost, earthwork demand, and accessibility requirements. An overview of the proposed framework is illustrated in Figure 1.

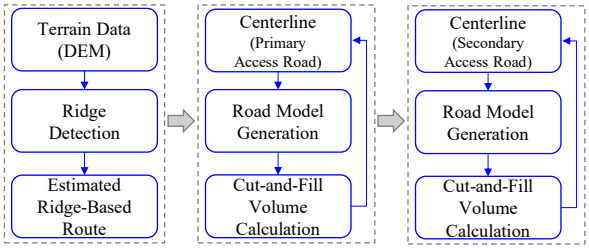

Figure 1. Framework overview

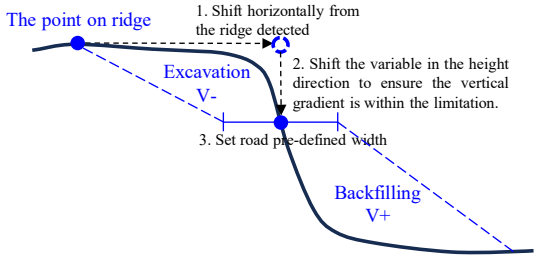
3.2 Ridge Detection and Terrain Feature Extraction

Ridge detection is employed to support access road planning for wind turbine construction, as routing roads along ridge lines generally minimizes earthwork demand and reduces construction costs. In this study, mountain ridges are identified using a watershed-based terrain analysis approach, where ridges are defined as topographical boundaries separating adjacent drainage catchments. The target terrain is first represented as a Digital Elevation Model (DEM), which is then processed using a watershed algorithm to extract ridge features. In this procedure, the DEM is treated as a surface subjected to a simulated flooding process initiated from local minima. As water levels rise uniformly within individual catchment basins, watershed boundaries are formed at the interfaces where adjacent basins meet. These boundaries constitute a network of watershed lines that correspond to mountain ridges. The extracted ridge features provide terrain-aware guidance for generating initial access road profiles, forming the basis for subsequent road modeling and optimization. The overall concept of ridge detection using the watershed approach is illustrated in Figure 2.

Figure 2. Watershed-based detection concept [12]

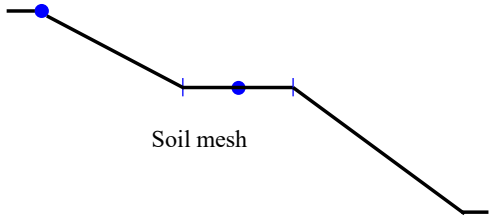
3.3 Parametric Road Modeling

The road model creation module generates an integrated mesh representation of access roads, including the road surface and associated cut-and-fill slopes. The module requires three primary inputs: road width, side batter width, and the prescribed cut-and-fill slope angle. As illustrated in Figure 3(a), the process begins with a parametric calculation that determines the initial road profile location. At this location, a horizontal road surface with a predefined width is generated. The outer edges of the road surface are then extended at the specified slope angle to form cut-and-fill side slopes. For each edge, the model automatically determines whether a cut or a fill operation is required by comparing the edge elevation with the existing terrain surface. If the edge lies below the terrain, a cut slope is generated upward until it intersects the ground surface; if the edge lies above the terrain, a fill slope is generated downward until ground intersection is achieved. The resulting road-and-slope mesh as shown in Figure 3(b) provides a geometrically consistent representation of the road cross-section and is subsequently passed to the earthwork calculation module for cut-and-fill volume estimation.



3.4 Cut-and-Fill Earthwork Calculation

The final earthwork volumes are computed by spatially comparing the modified terrain mesh incorporating the road model with the original terrain mesh. The volumetric difference between these two surfaces represents the total cut-and-fill earthwork required for access road construction. In the proposed framework, earthwork volumes are calculated by evaluating the vertical differences between the two meshes over their shared horizontal projection. Regions



where the modified road mesh lies above the original terrain are classified as fill volumes (V+), corresponding to material that must be placed, whereas regions where the modified mesh lies below the original terrain are classified as cut volumes (V-), corresponding to material that must be excavated. These cut and fill volumes are computed independently and aggregated over the entire road alignment, providing quantitative inputs for construction planning, earthwork balancing, and cost estimation within the automated workflow.

3.5 Optimization Formulation and Solution Strategy

A hierarchical optimization approach is adopted to balance construction cost and road accessibility in access road planning. Although numerous researchers have proposed a wide range of multi-objective optimization algorithms [13-15], evaluating candidate road networks in this study requires computationally expensive geometric modeling and earthwork calculations, which makes conventional population-based methods inefficient for large-scale exploration. Considering the large-scale nature of the problem and the objective of preliminary estimation rather than detailed design, a surrogate-assisted multi-objective optimization strategy based on Radial Basis Functions (RBFMOpt) is employed. Different objective functions are formulated at different stages, and RBF-based surrogate models are used to approximate these objectives, reducing the number of expensive evaluations while enabling efficient exploration. This solution strategy enables efficient optimization within the proposed automated framework and is well suited for construction-stage decision support under complex terrain conditions.

4 Route Optimization Methodology

4.1 Computational Environment and Modeling Tools

The proposed optimization framework is implemented within the Rhino–Grasshopper computational environment. Rhino [16] is used for precise three-dimensional geometric modeling, while Grasshopper [17] provides a visual programming interface that enables flow-based logic control of geometric operations without conventional text-based coding. This environment allows direct integration of geometric road modeling, terrain processing, and optimization workflows, making it well suited for construction-stage access road planning. In addition, Grasshopper's extensive ecosystem of community-developed plugins provides tools for terrain analysis, parametric modeling, and multi-objective optimization, enabling seamless integration of the geometric modeling modules and optimization solvers required by the proposed automated framework.

4.2 Terrain Data Preparation

The terrain data used in this study are based on 5-meter-high-resolution open-source Digital Elevation Model (DEM) data provided by Geoscience Australia [18]. The DEM serves as the topographic foundation for watershed-based ridge detection and subsequent access road planning. In the proposed workflow, the DEM is imported into the Grasshopper environment as a mesh using a module from the Bison package [19], with input parameters defining the file path, sampling factor, and spatial resolution in the horizontal directions, as shown in Figure 4(a). A square site with plan dimensions of 495 m × 495 m was selected as the illustrative case study area, with elevations ranging from 376.82 m to 596.02 m, as illustrated in Figure 4(b).

The terrain geometry and turbine layout are visualized in both top and perspective views within the Rhino–Grasshopper environment, as shown in Figure 5. The terrain is represented as a continuous mesh surface derived from the DEM, while the wind turbine locations are overlaid as discrete points distributed across the site. As the same time, ten wind turbine locations were randomly generated within the study area and treated as fixed constraints in the subsequent access road alignment optimization, also as shown in Figure 5.

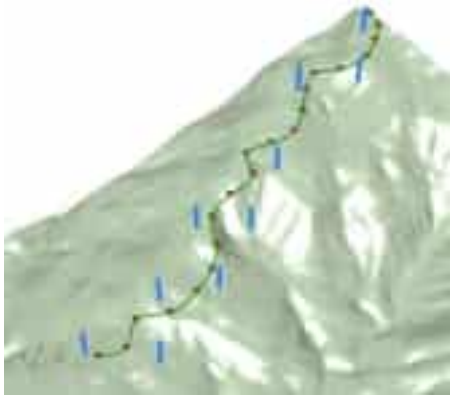
4.3 Optimization of Primary Access Roads

4.3.1 Ridge-Based Initial Route Estimation



Initial candidate routes for the primary access road are generated based on the Digital Elevation Model, as illustrated in Figure 6(a). Ridge lines identified through watershed-based analysis provide elevated paths that generally minimize earthwork demand. To improve geometric continuity and constructability, the rough alignment is subsequently smoothed through interpolation. In this study, as shown in Figure 6(b), the initial alignment was discretized into approximately 20 segments, and an interpolated curve was generated to form a continuous and refined initial route that serves as the starting point for further optimization.

4.3.2 Local Optimization Under Gradient Constraints

Although the initial alignment was obtained, as shown in Figure 6(b), several segments did not satisfy the longitudinal gradient requirement for this illustrative case (20%), when the alignment was discretized into 20 segments. Consequently, these non-compliant segments were extracted for further processing.

(a) Extracted ridge features

(b) Smoothed ridge-based alignment

Figure 6. Ridge-based alignment extraction

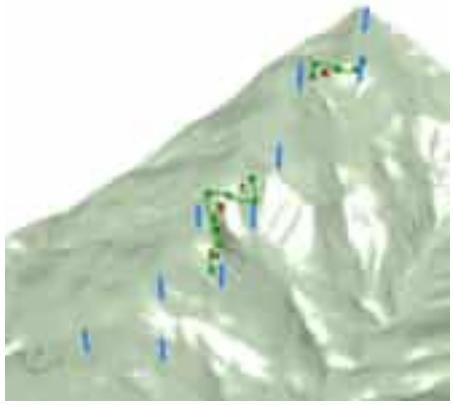


Figure 7. Local optimization under longitudinal gradient constraints

To address this issue, the maximum longitudinal gradient was treated as a strict engineering constraint rather than a conventional objective function. Specifically, the maximum longitudinal gradient was subject to an upper-bound constraint, and, even when this constraint was satisfied, it was still incorporated into the algorithm as a penalty term to encourage alignments with smaller gradient values. For each non-compliant segment, a midpoint was introduced to increase segment resolution, as indicated by the red crosses in Figure 7. The midpoints were then allowed to move in the *Y*-direction within the *XY* plane, while the corresponding longitudinal gradients were recalculated. Once all segments satisfied the prescribed gradient constraint, one of the optimized alignments was obtained, as illustrated by the green alignment in Figure 7.

4.3.3 Global Horizontal Alignment Optimization

Following the local optimization under vertical gradient constraints, an initially optimized main route alignment is obtained in the vertical plane. At this stage, the optimization only considers the maximum longitudinal gradient and does not account for additional geometric and planning factors. In the subsequent step, road length and deviation ratio *R* were treated as bi-objective functions, and RBFMOpt was used to generate Pareto-optimal candidate solutions. The final alignment was selected by minimizing road length among solutions satisfying an acceptable *R* threshold, without introducing weighting factors. As shown in Figure 8, the resulting alignment had a total road length of 1103.66 m and a maximum longitudinal gradient of 17.41%.

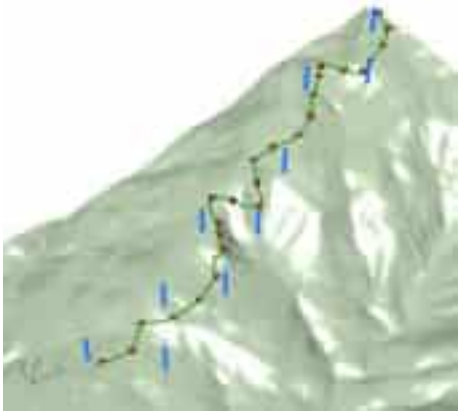

Figure 8. Local optimization under vertical gradient and total road length constraints

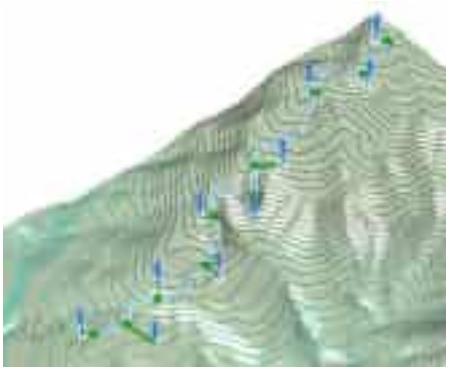
4.3.4 Global Vertical Alignment Optimization

Finally, global vertical alignment optimization is performed with earthwork volume introduced as an additional objective function. In this step, the first point of the main route is fixed, and subsequent points are iteratively adjusted in the negative vertical *Z*-direction to evaluate corresponding earthwork volumes. The earthwork volume consists of both cut and fill, which are calculated for each trial alignment. The resulting alignment under optimal conditions. In this case, as the Table 1 shown, the cut volume was 21,449.46 m^3, the fill volume was 83,846.15 m^3, and the total earthwork volume, defined as the sum of absolute cut and fill, was 105,295.61 m^3. The additional volume associated with cut-fill imbalance was 62,396.69 m^3. Through this procedure, the final main route alignment is determined hierarchically, with earthwork objectives optimized within the feasible space defined by prior gradient constraints.

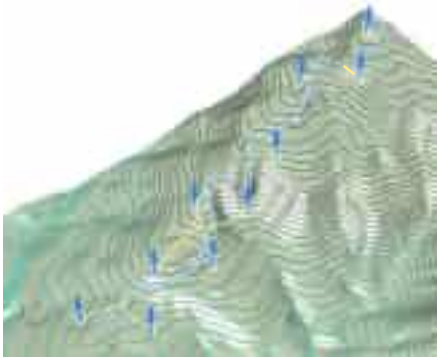
Table 1. Mass balance of primary road earthworks

Earthwork	Cut (-) [m^3]	Fill (+) [m^3]	Mass balance [m^3]
Volume	21,449.46	83,846.15	62,396.69



4.4 Optimization of Secondary Access Roads

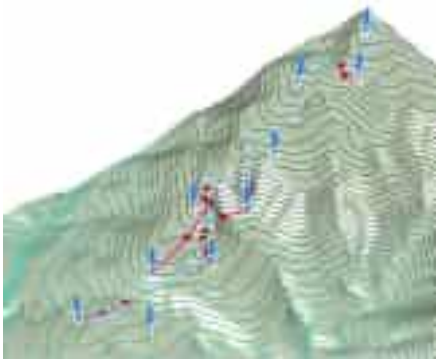
4.4.1 Network-Level route selection



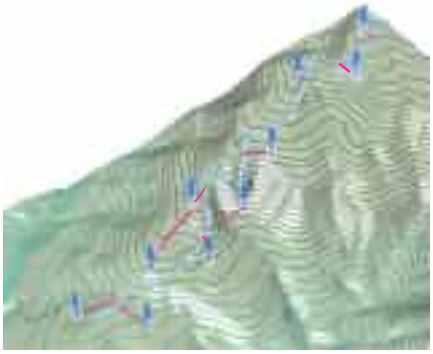
The network-level selection of secondary access roads connecting wind turbines to the primary route follows a systematic procedure. For each wind turbine, the closest point on the primary route alignment is first identified, and an initial straight-line connection between the turbine location and this point is generated, as shown in Figure 9(a), where contour lines with a 5 m interval are overlaid for visualization purposes. The straight-line branch is then divided into three equal sub-segments, and the vertical gradient of each sub-segment is evaluated. If all sub-segments satisfy the allowable gradient threshold, the straight line is retained as a candidate branch road. If any sub-segment violates the gradient constraint, the corresponding branch is selected for further refinement.

In this refinement step, the branch remains represented as a straight line, while the connection point on the primary route is iteratively adjusted to minimize branch length, subject to satisfying the prescribed gradient constraint for all sub-segments. By combining the resulting branch roads with the primary route, an initial configuration of the access road network is obtained.

Among the generated branches as shown in Figure 9(b), those serving turbines 0, 2, 3, 4, 5 and 8 were identified for subsequent secondary optimization, as no feasible connection point along the primary route can satisfy the gradient constraint through network-level adjustment alone. The remaining branches correspond to routes accepted at the initial network-level selection stage.



(a) Initial straight-line connection roads



(b) Network-level selected branch roads

Figure 9. Network-level branch road selection

(a) Optimization of non-compliant branch roads

(b) Final optimized branch roads

Figure 10. Local optimization of secondary access roads

4.4.2 Local Optimization Under Gradient Constraints

Local optimization under vertical gradient constraints was subsequently performed for the branch roads serving turbines 0, 2, 3, 4, 5 and 8. For each branch, a midpoint is inserted into the initial straight-line segment while the two endpoints remain fixed. This midpoint is allowed to move within the *XY* plane to reduce excessive vertical gradients along the branch. A smooth curve is then fitted using the two endpoints and the midpoint to generate the optimized branch alignment, as illustrated by the pink curves and control points in Figure 10(a). The maximum longitudinal gradient was treated as a constraint, and the optimization aimed to obtain feasible alignments rather than balance multiple objectives.

The final branch alignments are shown in Figure 10(b). The corresponding earthwork quantities are summarized in Table 2, with a total cut volume of 137,064.47 m³, a fill volume of 129,647.73 m³, and a volume balance of −7,416.74 m³.

Table 2. Mass balance of secondary roads earthworks

Earthwork	Cut (-) [m^3]	Fill (+) [m^3]	Mass balance [m^3]
Volume	137,064.47	129,647.73	-7,416.74

5 Conclusion and Future Work

5.1 Conclusions

This study proposed an automated optimization framework for construction-stage planning of access road networks in onshore wind farm projects. The framework integrates terrain-aware analysis, parametric road modeling, earthwork evaluation, and stage-wise optimization into a unified computational workflow. Both primary and secondary access roads are generated through a hierarchical optimization strategy that incorporate practical engineering constraints, including longitudinal gradient limits, road geometry, deviation control from turbine locations, connectivity requirements, and cut-and-fill earthwork characteristics.

Through an illustrative example, the proposed framework demonstrates its capability to generate construction-feasible access road networks under complex terrain conditions. The results show that the framework can systematically support early-stage route selection, earthwork estimation, and network configuration, providing quantitative information for construction planning and decision support. The optimization process combines constraint enforcement (e.g., gradient limits) with local objective-based refinement, enabling efficient solution generation without relying on global weighting factors. The proposed approach is particularly suited for preliminary evaluation and scenario exploration rather than detailed design.

5.2 Future Work

Future work will further extend the current framework beyond the illustrative 495 × 495 m case to larger-scale terrains, with particular attention to computational efficiency and scalability. This extension will also enable systematic comparison with expert-designed road alignments to evaluate the practical performance of the proposed framework. In this context, data-driven approaches, such as reinforcement learning, could be explored to enhance cost-oriented optimization under more complex conditions.

In addition, more realistic earthwork modeling can be considered by introducing non-unity cut–fill conversion factors. The current interpolation-based approach may also be refined by incorporating explicit geometric constraints, such as minimum turning radius.

Abstract

The digitization of building codes is critical for Automated Compliance Checking (ACC) within the BIM paradigm, yet faces challenges such as unstructured text, semantic ambiguity, and deep logical nesting. Traditional hard-coding lacks flexibility, while reliance solely on Large Language Models (LLMs) is prone to hallucinations and offers limited BIM integration. This study proposes a multi-stage framework integrating Domain-Specific Languages (DSL), hybrid Knowledge Graphs, and LLMs to automate the formalization of computational design rules from textual codes. Using the Code for Design of Residential Buildings (GB 50096-2011) as a case study, we parse and classify regulatory provisions into four categories , Numerical, Logical, Topological, and Fuzzy and employ Prompt Engineering to guide LLMs in generating structured DSL JSON. A hybrid storage architecture (Neo4j, PostgreSQL, Drools) forms a queryable knowledge base that bridges natural language regulations and executable logic, enabling automated reasoning and direct interoperability with BIM models for compliance verification.

Domain Specific Language ; Large Language Model; Building Code Digitization; Knowledge Graph; Automated Compliance Checking.

1 Introduction

Building Information Modeling technology supports structured representation of building information across the full lifecycle through the Industry Foundation Classes (IFC) data format, transforming design deliverables into semantically rich, computer-readable data objects and establishing a foundation for interoperability. However, a core bottleneck in Automated Compliance Checking remains the digitization of building codes, which are predominantly available as unstructured natural language texts. Current reliance on manual review is not only inefficient and and prone to errors but also leads to inconsistent enforcement, ultimately affecting building safety and approval efficiency.

Research on ACC spans half a century, aiming to replace manual checking with automated solutions [1, 2]. BIM and IFC provide structured information models for ACC [3]. Recent studies have explored ontologies, semantic web technologies, and knowledge graphs. Anastasiya et al. [4] formalized compliance requirements via ontologies, though manual construction remains inefficient [5]. Peng et al. [6] used NLP to transform code clauses into formats readable by machines, and so did Lu Jia et al. [7] combined semantic web with IFC for improved checking.

Artificial intelligence technologies, including deep learning, NLP, and large language models (LLMs), are increasingly applied to rule extraction and semantic understanding. Li et al. [8] developed ontologies and deep learning models for building standard labeling. Wang et al. [9] proposed an NLP-based ACC system for spatial relationship review. Domain-Specific Languages (DSLs) offer tailored syntax and semantics for domain specific tasks [10], enabling domain experts to formalize problems without deep programming knowledge [11]. DSLs have been applied in parametric design [12], generative AI integration [13, 14], and construction robotics [15, 16].

Despite these advances, ACC faces key challenges. First, knowledge formalization remains labor-intensive and lacks scalability, struggling with implicit logic and regional variations. Second, a semantic gap persists in translating ambiguous natural language provisions into computable rules. Third, LLMs, while promising, are prone to hallucinations, affecting reliability. Finally, DSL application in ACC is still nascent and warrants further exploration.

To address these challenges, this paper proposes a framework based on BIM with multiple stages that integrates DSL, hybrid knowledge graphs, and LLMs to automate the formalization of design rules from building codes. The framework converts regulatory

texts into structured, executable knowledge through a dedicated DSL, reducing semantic ambiguity and interpretability risks. A hybrid storage architecture combining graph, relational, and rule based databases enables efficient management of numerical, logical, topological, and vague clauses, establishing a verifiable foundation for automated compliance checking integrated with BIM.

2 Parsing and Transformation Technology

While standard Large Language Models can perform general semantic parsing, their inherent stochasticity often leads to hallucinations and inconsistent extraction of complex building codes. The methodological innovation of this section lies in a twofold advancement: a multidimensional guided parsing strategy and a four tier DSL schema. First, in the parsing phase, we propose a “deconstruct then extract” strategy that uses prompt engineering to force the LLM to perform semantic role labeling identifying subject, constraint, and condition thereby minimizing linguistic ambiguity before data extraction. Second, in the transformation phase, we introduce an original four tier DSL schema that acts as a semantic safety buffer. By enforcing this constrained intermediary grammar, the framework decouples nondeterministic AI outputs from deterministic IFC data structures. This dual layered approach ensures that unstructured clauses are systematically transformed into a verifiable, machine readable format, providing logic stability and traceability that existing end to end LLM methods lack (Figure 1).

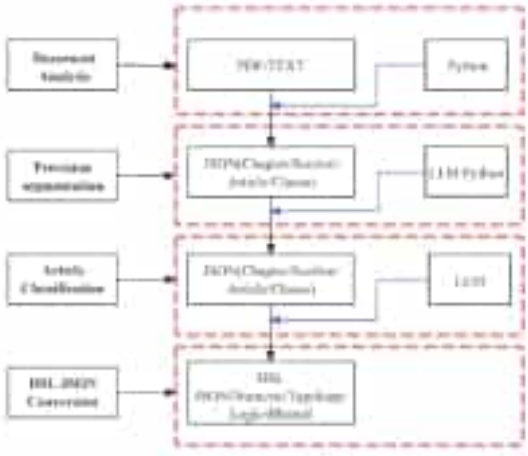

Figure 1: Technical Pathway Diagram

2.1 Document Preprocessing

To support the integration of design rules with BIM, this paper designs a parsing workflow that transforms semi-structured code documents into machine readable hierarchical data objects aligned with BIM entities. The process involves three core steps. First, raw documents undergo text cleaning and standardization to remove formatting artifacts. Second, a parsing algorithm using regular expressions recognizes the hierarchical structure (e.g., chapter, section, article, clause) and reorganizes text into a nested tree. Concurrently, metadata such as code name and effective date are extracted. Finally, structured content and metadata are encapsulated into standardized JSON objects, providing a foundation for subsequent clause atomization and mapping to BIM component attributes.

2.2 Clause Segmentation

The clause segmentation process deconstructs complex regulatory sentences into minimal, machine executable constraint units enabling precise mapping to BIM components. The process includes three steps. First, syntactic parsing identifies logical boundaries to split long sentences. Second, LLMs perform semantic completion to resolve coreferences, ensuring each atomic clause contains complete “object, attribute, constraint” semantics relevant to BIM properties. Finally, a keyword algorithm detects modality terms (e.g., “shall”, “should”) and assigns mandatory or optional labels, producing a standardized set of candidate rules ready for formalization and execution integrated with BIM (Figure 2).

Figure 2: Detailed Processing Procedure for Article Segmentation

2.3 Multidimensional data classification

To implement differentiated digitalization strategies for different types of code clauses, this paper establishes a multi-dimensional data classification mechanism after clause atomization. Atomic clauses are precisely classified into four categories(Table 1):

1. Numerical Constraint Clauses: Identified by comparative operators, extracting specific quantitative indicators such as area and height.

2. Logical Constraint Clauses: Based on conditional sentence patterns, locking the dependency relationship between preconditions and subsequent requirements in building scenarios.
3. Topological Constraint Clauses: Focusing on spatial predicates such as "adjacent to," "connected to," and "contained within," defining geometric positional relationships between components.
4. Vague Constraint Clauses: Targeting qualitative descriptions like "should," "reasonable layout," and "aesthetic," identifying guiding principles that are difficult to quantify directly.

Table 1 Clause Classification Criteria

Type	Keywords	Process	Mandatory
Numerical	≥, ≤, greater than, not less than	DSL	True
Logical	When... shall; If... then...	DSL	False
Topological	connected to, near	DSL	False
Blurred	Reasonable,s hould	DSL	False

2.4 DSL Semantic Transformation Based on LLM

To bridge the semantic gap between natural language regulations and executable logic within the BIM environment, we designed a Domain-Specific Language Schema adapted to the characteristics of building codes and aligned with common BIM data structures. This Schema includes fields such as target entity, check attribute, operator, and priority. Leveraging the semantic understanding capabilities of LLMs, we designed specific prompts to guide the model in transforming atomic natural language clauses into structured DSL JSON format. This process includes a "manual verification" step to ensure the accuracy and BIM integrability of the generated formal rules.

2.4.1 DSL Transformation for Logical Clauses

Logical clauses, characterized by conditional patterns such as "When… shall…" or "If… then…", define mandatory or recommended requirements under specific building scenarios. The core formalization challenge lies in accurately separating conditions from conclusions and establishing their logical mapping within a BIM aware framework.

To support this, the DSL Schema includes a structured conditions array, where each condition object describes a premise using fields like parameter (often mapped to a BIM property), operator, and value. The conclusion is defined by target entity (linked to a BIM component type), check attribute, and operator. For instance, the clause "When a bedroom is located underground, a ventilation shaft shall be provided" is transformed into a rule where the condition checks location == "underground" and the conclusion targets the bedroom entity for ventilation facility provision."

This transformation leverages LLMs for semantic parsing and is followed by manual verification to ensure logical accuracy and alignment with BIM semantics. The output provides unambiguous if then rules ready for execution against BIM model data.

Figure 3: DSL Transformation for Logical Clauses

2.4.2 DSL Transformation for Numerical Clauses

The core feature of numerical clauses is the quantitative constraint on attributes (e.g., area, height, distance) of building spaces or components through specific numbers and comparison operators. To transform them into machine executable rules, this method designs a targeted DSL Schema and prompt engineering strategy.

The transformation is achieved using LLMs. By constructing prompts containing clear instructions, output format examples, and domain knowledge, the LLM is guided to accurately parse and map clauses like "bedroom area shall not be less than 12 square meters" to corresponding fields in the Schema. For instance, the LLM needs to correctly identify "not less than" as the operator ">=" and extract the pure number "12" and unit "square meters." A manual verification step is set in this stage. Verification focuses include: whether the value and unit correspond accurately; whether prerequisite conditions in conditional statements are fully captured and transformed into the conditions field; and whether the priority field for recommendatory clauses is

correctly marked as lower priority (Figure 4).

Figure 4: DSL Transformation for Numerical Clauses

2.4.3 DSL Transformation for Topological Clauses

Topological clauses regulate the relative position and connection relationships between building spaces or components, such as "adjacent to," "connected to," "contained within." These clauses are crucial for ensuring functional flow and spatial rationality but are highly challenging to formalize due to complex spatial semantics and geometric relationships. To achieve their transformation into machine executable rules, this paper specially designs an extended DSL Schema.

Addressing the characteristics of topological constraints, fields such as topology type, source entity, spatial relation operator, and target entity are added to the basic DSL Schema. A standardized set of topological operators is predefined in the Schema, including "adjacent to," "contains," "connected to," and "separate from." Secondly, the semantic reasoning capability of LLMs is utilized to accurately extract spatial features from clauses. Through prompt engineering, the model is guided to identify keywords like "immediately adjacent to," "abutting," "accessed via..." and map them to normalized DSL operators.

To ensure the geometric checkability of generated rules, strict manual verification is required after transformation. Verification focuses include: whether the relation predicate accurately reflects the original clause intent(Figure 5).

Figure 5: DSL Transformation for Topological Clauses

3 Database Construction

While existing ACC systems typically store rules in a single database format, this study proposes a hybrid storage architecture that matches storage paradigms to clause types a design choice that directly addresses the heterogeneous nature of building codes. The key innovations are: (1) a “ metadata rule body ” separation pattern that decouples code version management from rule logic; (2) clause type specific storage strategies relational for numerical rules requiring efficient quantitative queries, rule engine for logical rules needing condition triggered reasoning, and graph database for topological rules requiring spatial relationship traversal; and (3) a unified knowledge graph that captures cross clause dependencies , enabling traceability and impact analysis beyond simple compliance checking.The database construction in this paper takes the structured DSL output from Chapter 2 as input, directly addressing the need for machine executable code clauses within a BIM supported environment. Based on the structured JSON data after DSL transformation, we designed a hybrid database architecture and a code knowledge graph to organize and manage rule knowledge in a manner aligned with BIM data structures and query requirements (Figure 6).

Figure 6: Database construction process

3.1 Database Structure

To achieve precise traceability and version management of code clauses, the database table structure adopts a "metadata rule body" separation design pattern.

1. Metadata Layer: Establish a specification index table to store global attributes of codes, including code name, version number, applicable region, and effective time. This design supports the system in quickly filtering applicable code sets based on project attributes.
2. Rule Body Layer: The core compiled rules table stores atomized rules. Field designs include: clause id, original text, target entity, dsl content, and, most importantly, executable code.

3.1.1 Database Construction for Numerical Clauses

For the numerical DSL JSON, this study employs Python scripts to import clauses into a PostgreSQL database. A relational hybrid storage architecture is implemented, organizing data into two BIM integrated dimensions. The structured dimension maps check targets, operators, and limit values to dedicated SQL columns, directly corresponding to BIM component attributes for efficient evaluation. The semistructured

dimension uses PostgreSQL ’ s JSONB type to store applicability conditions, which are often linked to BIM project parameters. A GIN index is applied to the JSONB field to enable fast, contextaware rule retrieval across extensive clause sets, ensuring performant interoperability with BIM model queries.

3.1.2 Database Construction for Logical Clauses

For logical clauses, the system converts them into Drools rule language for storage, enabling checks to be triggered only when relevant BIM objects satisfy specific preconditions, thereby optimizing computation within the BIM context. A Python based translator parses the condition triggers and check logic from the DSL JSON, mapping them to Drools' MVEL language. At the data level, a dynamic Design Entity fact object is used, storing variable component attributes in an attributes Map to flexibly accommodate diverse BIM component schemas.

The generated drl files employ a “violation pattern matching” strategy, transforming code requirements into negative capture patterns. When a violating BIM component is matched, the system instantiates a Validation Result object, automatically injecting traceable metadata. This enables millisecond-level logical reasoning with full compliance traceability. Finally, the rule files are deployed to Business Central and exposed as a remote service for BIM integrated compliance checking (Figure 7).

Figure 7: Related functional files and deployment on remote servers

3.1.3 Database Construction for Topological Clauses

For complex topological rules involving spatial adjacency, vertical stacking, and circulation connectivity, this study utilizes Neo4j to construct a code meta-knowledge graph.

Storage Architecture and Meta graph Construction: Based on the DSL JSON structure, the graph adopts a “Entity Type, Constraint Edge, Entity Type” triple pattern for storage.

1. Semantic Node Abstraction: Defines code objects like "bedroom" and "exhaust duct" as Entity Type nodes, establishing mapping anchors to the IFC entity classification standard via the code field.
2. Graphical Representation of Constraint Logic: Stores clause logic as relationship edges with properties. Core properties include relation type and constraint level. This design makes each edge an independent, traversable logical unit.

3.1.4 Database for Vague Clauses

For the numerous subjective clauses in codes that cannot be quantitatively calculated, such as "reasonable layout" and "harmonious with the environment," this study constructs a lightweight knowledge base based on local CSV storage and semantic retrieval.

3.2 Knowledge Graph Database Construction

To manage complex relationships between clauses (Figure 8), such as parameter dependencies and potential conflicts, we constructed a Neo4j knowledge graph encompassing all clauses.

Node Design defines four core node types to structurally store code knowledge: Specification, Clause, Entity,Parameter.

Relationship Design defines directed connections between nodes to express logic and dependencies.

Figure 8: Dependency Relationships Between Clauses

4 Case Study

To validate the effectiveness of the proposed method, we selected the Residential Design Code GB 50096-2011 as the experimental subject, performing a full-process digitalization of its clauses.

4.1 Data Processing Results

To ensure reproducibility, the rule extraction and formalization process was standardized using the Qwen-Max model with fixed generation parameters:

temperature = 0.1, top_p = 0.95, and max_tokens = 2048. Consistent prompt templates were used for Numerical, Logical, Topological, and Fuzzy clauses. This systematic approach enables replication following the DSL specifications and prompt logic detailed in this study. After preprocessing, 338 atomic rule clauses were extracted (Table 2).

Table 2: Clause Segmentation Results

Type	Quantity	Percentage
Numerical	123	36.4%
Logical	159	47.0%
Topological	45	13.3%
Blurred	11	3.3%
Total	338	100%

4.2 DSL JSON Transformation and Code Base Construction

After completing the document preprocessing and clause atomization of *GB 50096-2011*, this study obtained 338 semantically independent and structurally clear atomic clauses. To achieve their transformation from natural language to machine executable rules, this stage focused on two core tasks:

Phase 1: Automated DSL JSON Generation. The core of this study lies in the "LLM+DSL" semantic transformation paradigm. First, we designed refined DSL Schemas for the three types of "clear clauses" (numerical, logical, topological), specifying the data type and semantic boundary of each field (as described in Section 2.4). Subsequently, for each atomic clause, we constructed highly customized prompts containing the following key elements:

1. Role Definition: Explicitly instructing the LLM to act as a "building code digitalization expert."
2. Task Instruction: Clearly requiring the LLM to transform the input natural language clause into a JSON object strictly adhering to the specified Schema.
3. Output Format Example: Providing correct transformation examples for the same type of clause to guide the model in learning the mapping pattern.
4. Domain Knowledge Constraints: Embedding lists of domain-specific entities and operators to constrain the model's output space and reduce hallucination risk.

By calling the LLM API, the system automatically transformed the 338 atomic clauses into structured DSL JSON objects one by one. To ensure transformation quality, all automatically generated JSON objects underwent a manual verification step.

Phase 2: Hybrid Database Construction and Storage. This study abandons the generic storage approach of a single database, adopting instead a "allocate on demand, each performing its own function" hybrid storage architecture to maximize the processing efficiency for different rule types.

1. Numerical Clauses: Verified numerical DSL JSON was batch-parsed by Python scripts and imported into the PostgreSQL relational database. The scripts mapped key fields like check attribute, operator, and value to standard SQL columns, while storing complex applicability conditions in the applicability conditions field in JSONB format. A GIN index was established to support efficient contextual retrieval.
2. Logical Clauses: Logical DSL JSON was fed into a specially developed rule translator. This translator accurately compiled the condition and conclusion logic from the JSON into drl files recognizable by the Drools rule engine. These rule files were then deployed to the Drools Business Central platform and encapsulated as remote service interfaces for on demand calling by the compliance checking system, enabling complex condition triggered reasoning.
3. Topological Clauses: Topological DSL JSON was used to construct the code meta knowledge graph in the Neo4j graph database. Scripts created nodes for source entity and target entity and stored information like spatial operator and constraint level as properties of relationship edges (Figure 9).

Figure 9: Relationships Among Topological Clauses in Neo4j (Partial GB 50096-2011 Examples)

4. Vague Clauses: For vague clauses like "reasonable layout" that cannot be quantified, their original text, associated chapter, and related entity information were structured and stored in a local CSV file.

4.3 Error Analysis and Accuracy Testing

During automated DSL JSON generation, the LLM occasionally produced incorrect outputs despite prompt engineering. Manual verification identified seven failure patterns, accounting for 22 erroneous outputs out of 338 atomic clauses. These included: misinterpretation of comparative operators (4), where “not less than” became “>” instead of “>=”; incomplete condition capture in logical clauses (3), omitting premises when conditions appeared mid sentence; entity role reversal in topological clauses (3), swapping source and target; unit inconsistency (2), extracting values without units or confusing millimeters with meters; target entity mismatch (3), assigning incorrect BIM entity types; missing optional/recommendation flag (2), failing to map “should” to the priority field; and fuzzy clause not recognized (5), misclassifying qualitative clauses as logical or numerical. We built a test set containing 100 BIM model fragments as test cases to ensure that the provisions in the database can be retrieved.

For numerical clauses, we created multiple test cases, stored them in a temporary SQL table, and used Python scripts to call the SQL database for compliance checking. The checking process first matched the check objects in the cases with the clauses, performing compliance checks only if the preconditions of the clauses (e.g., building completion year, location, object type) were satisfied (Figure 10).

Figure 10: Partial Test Cases (Numerical)

For logical clauses, we similarly stored cases in a temporary SQL table, then used Python scripts to call the deployed Drools remote server for compliance checking. We also inserted test cases for clauses into Business Central to verify whether our drl code rules were invoked (Figure 11).

Figure 11: Checking if drl Files are Invoked in Business Central

For topological clauses, we stored cases in a temporary SQL table and used Python scripts to call the deployed Neo4j for compliance checking.

4.4 Application Value of the Knowledge Graph

The constructed knowledge graph, designed to support BIM based analysis, contains over 300 nodes and 500 relationships. Graph analysis reveals strong couplings between design entities such as “Bedroom” and performance parameters including “Daylight Factor” and “Ventilation Opening Area.” In a typical BIM aided design scenario, if a designer modifies a window size, the system can utilize the graph’s path-search algorithms to not only evaluate compliance with daylighting standards but also proactively surface related clauses involving “façade aesthetics” or “cost indicators.” This demonstrates the potential of the graph to enable multidimensional, rule aware correlation analysis within the BIM workflow.

5 Scalability and Limitations

The proposed framework demonstrates strong generalizability across building codes from different regions and domains. The DSL Schema decouples logical structure from natural language, enabling systematic migration to other regulatory documents such as the International Building Code (IBC), European construction standards, and domain specific fire safety regulations without reconstructing the core architecture. Since the four category classification (numerical, logical, topological, fuzzy) covers the vast majority of regulatory provisions encountered in typical building codes, core prompt templates require no modification when adapting to new codes. Adaptation follows a calibration workflow: prepare 20 – 30 annotated clauses as few shot examples, feed them into the LLM to learn new terminology and patterns, validate output quality, then process the full code with manual verification only for ambiguous cases. This calibration takes 2-3 hours per new code, demonstrating the framework’s automation efficiency for large scale code digitization.

Compared to existing LLM, rule based, or ontology approaches which suffer from hallucinations, manual effort, or limited scalability our hybrid framework integrates LLM semantic understanding with DSL precision. This enables verifiable rule extraction and provides a modular architecture for rapid reconfiguration across diverse building codes.

Nevertheless, the current system has limitations. It relies on manual verification to ensure semantic

accuracy, preventing full end to end automation. This manual step, while necessary to eliminate LLM hallucinations and guarantee correct DSL generation, represents a bottleneck in achieving a fully automated pipeline for rule formalization.

6 Conclusion

This paper proposes a complete technical pathway for transforming building codes into a structured digital knowledge base within a BIM oriented framework. Using GB 50096-2011 as a case study, the resulting hybrid database and knowledge graph form a reasoning capable rule system that can serve as the core engine for BIM based automated compliance checking. The system supports automated verification of numerical, logical, and topological clauses and provides auxiliary decision support via a vague clause knowledge base.

Future work will focus on enhancing BIM integration through multidimensional IFC parsing for richer semantic and geometric data, automated version comparison, DSL schema refinement, and automating manual verification in the DSL pipeline via three strategies: a retrieval augmented generation mechanism with few shot examples, a rule based post-processor for recurring errors, and a self consistency validation loop using bidirectional translation. These enhancements will reduce manual effort while maintaining accuracy, strengthening end to end automation and deployability, alongside a scalable compliance-checking application on Dify.

Abstract

Adoption of Artificial Intelligence (AI) is growing across the construction industry, but its use remains uneven. While AI is being increasingly adopted for information management workflows, its application to construction scheduling remains limited. It is a critical gap because construction scheduling is inherently dynamic and must respond to disruptions such as workforce constraints, procurement delays, coordination issues, and changing site conditions. Although traditional scheduling approaches have improved over time, they remain limited in supporting adaptive decision-making under uncertainty. To address this gap, this study proposes a trajectory-based learning approach for construction scheduling. A technical simulation environment was developed by modelling construction actions as trajectories. The proposed framework is demonstrated through a case study of ductwork installation in a six-story building. A dataset of 50 trajectories with 577 steps of thought-action-observation was constructed to capture diverse execution scenarios. An In-Context Learning (ICL) approach leveraging large language models (LLMs) was adopted to learn from training trajectories and predict subsequent construction actions. Zero-shot and few-shot prompting strategies were evaluated comparatively. The initial next-action prediction task was further extended with an additional experiment on predicting short sequences of future actions to better reflect real-world construction operations. Results show that Llama 3B achieved 76% accuracy in next-action prediction under the 5-shot setting, while GPT-5.4 demonstrated stronger reasoning capability in the extended experiment. This study highlights the potential of trajectory-based learning as an on-site decision-support mechanism and provides a preliminary foundation for future intelligent construction scheduling agents.

Construction; In-context learning; Large language models; Scheduling; Trajectory learning

1 Introduction

Despite technological advancements and applications in the industry, accurate construction scheduling remains a critical challenge. This is basically due to the inherent complexity and dynamic nature of construction work. In addition, other influencing factors such as labour, material and equipment availability, weather, change orders and economic fluctuations also contribute to unrealistic scheduling. Traditional scheduling approaches range from the Critical Path Method (CPM) to construction scheduling software like MS Project and Primavera which remain deterministic with poor reasoning capability [1]. Research has also focused on applying Artificial Intelligence (AI) and Machine Learning (ML) to construction scheduling in terms of predicting completion percentages and evaluating project performance [2]. Moving forward, current research has applied Large Language Models (LLMs) to construction scheduling in terms of capturing delay causes and automatic schedule generation [3]. Additionally, integration of digital technologies like Digital Twins (DTs) with LLMs can be seen in enhancing robots for dynamic task allocation in construction [4]. Some studies have developed LLM-based frameworks for construction with the integration of robotics by leveraging Industry Foundation Classes (IFC) [5]. These frameworks have been successful in guiding robots to perform tasks like brick-laying and 3D printing [5]. Despite these advances, existing approaches remain limited in their ability to handle construction uncertainties in an adaptive manner. Most AI and LLM-based scheduling approaches depend on predefined methods offering deterministic schedule generation instead of learning through sequential behaviours. This highlights a research gap in developing scheduling approaches that can reason under uncertainties and better address current industry needs. To address this gap, this study introduces an agentic approach for construction scheduling that learns sequencing behaviour from trajectories under uncertainty.

LLMs are transformative technologies with applications not only in construction but also in other sectors like finance and manufacturing [6]. In-context

learning (ICL) is a mechanism through which LLMs perform a task by learning from instructions and examples given directly in the prompt. ICL eliminates the need for complex fine-tuning which frequently acts as a bottleneck in existing ML approaches [7]. Hence, an ICL method was applied in this study leveraging LLMs, using training trajectory data as the context for the user prompt. This study demonstrates HVAC (Heating, Ventilation, and Air Conditioning) installation as a case study where both positive (successful) and negative (unsuccessful) trajectories were provided as in-context examples. Dynamic construction interactions which include task dependencies, rework and coordination between site personnel were incorporated to infer decision patterns. Ultimately, this study examines whether ICL enables LLMs to reason over construction scheduling trajectories.

2 Methodology

2.1 Trajectory data

This study models the interaction between the agent and the environment as trajectories which provides the structural representation used for learning. Trajectories capture the complete or partial execution of a construction task over time through a sequence of decisions and outcomes. In this study schedule related operations are represented as thought-action-observation (t-a-o) trajectories, where thought denotes what needs to be done, action denotes the managerial or operational decision taken, and observation denotes the resulting outcome (Figure 1) [8].

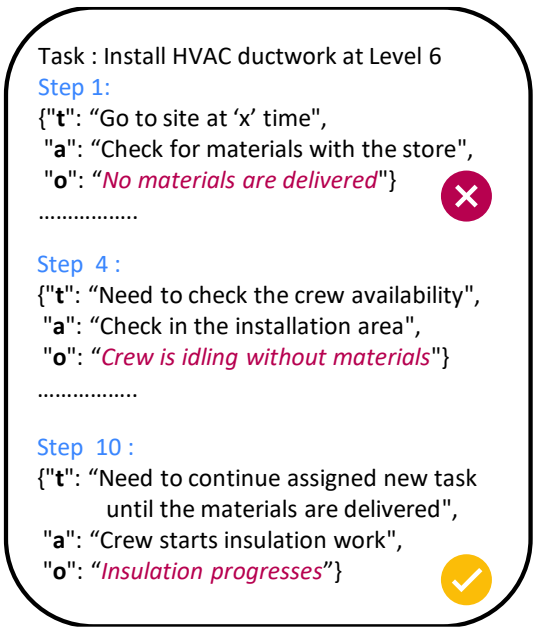

Figure 1. Trajectory representation

Dynamic scheduling factors such as crew availability, safety hazards, material delivery delays, and environmental conditions are embedded explicitly at the step level within the observation component. This enables the trajectories to capture real-world construction uncertainties and intermediate decision consequences. These trajectories are encoded into the task environment in a structured order, where the state space ($\mathcal{S}$) describes the context at a given step and the action space ($\mathcal{A}$).

This study used an open-source time-motion dataset which includes a long chain of events resulting from video footage [9]. It captures the activities of MEP (Mechanical, Electrical, and Plumbing) workers in a six-storey multifamily building in Finland which showed elevated levels of wasted efforts. A total of 50 trajectories were constructed for the HVAC installation task, including 12 positive trajectories and 38 negative trajectories. Positive trajectories contain correct execution steps throughout the full sequence. Negative trajectories include either trajectories with an unsuccessful final outcome, or trajectories with a successful final outcome but incorrect intermediate steps. Negative trajectories were included since the process of human learning not only involves observing successful executions but also includes experiencing failures [10].

2.2 ICL approach

ICL was adopted to evaluate LLMs for construction action prediction in schedule decision support. Instruction-finetuned open-source LLMs, namely Llama-3.2-3B-Instruct and Qwen 2.5-3B-Instruct were used in this study. These models were selected because they represent relatively lightweight and practically deployable LLMs suitable for early-stage evaluation of on-site decision-support scenarios. These models were accessed through a Hugging Face API token [11]. Training trajectories were given as contextual examples within the user prompt enabling models to learn scheduling patterns. Data were split based on the 80/20 rule. The held-out test trajectories served as the ground truth with the original t-a-o construction sequences.

During ICL, LLMs analysed unseen test trajectories and predicted the next action under uncertainty. However, this decision is solely based on the given trajectories of different scenarios. Zero-shot and few-shot prompting approaches were incorporated for comparative evaluation. In the zero-shot setting, the model receives no in-context trajectory examples, whereas in the few-shot setting, it learns from a small number of example trajectories provided in the prompt. Factors like the diversity and quality of examples shown in the in-context demonstrations may improve the quality of model output [7]. To assess the capability of ICL in distinguishing trajectory patterns, two conditions were studied: positive only and mixed positive-negative trajectory contexts.

Prompt was designed as using positive trajectory and (positive + negative) trajectory contexts to predict the next best action. Regarding example selection, few-shot examples were re-sampled for each run, and each model was evaluated across all test trajectories. The prompt was specified to generate only positive outcomes. For each condition, zero-shot, 1-shot, 5-shot and 10-shot prompting configurations were examined. Final reward was computed based on the Outcome Reward Model (ORM). ORM uses binary labels with "1" representing successful task completion and "0" for uncompleted tasks [12]. This study assigns a reward of "1" if the ground-truth label is "positive", whereas it assigns a value of "0" if the ground-truth label is "negative". Evaluation was conducted at the trajectory level by aggregating step-level rewards across each predicted trajectory and computing the average reward against the ground-truth trajectory. To evaluate whether the system can differentiate positive and negative trajectories, accuracy and a confusion matrix were computed, including true positives (TP) and true negatives (TN). Model outputs were evaluated over multiple runs, and accuracy was recorded. Subsequently, accuracy for each shot configuration was calculated by taking the average accuracy across all runs.

In real-world construction processes, scheduling decisions often involve not only the next action but also a short sequence of subsequent actions. To better reflect this practical need, the ICL setup for next-action prediction was extended with an additional experiment that evaluates the prediction of future action sequences with prior trajectory actions as input context. In addition

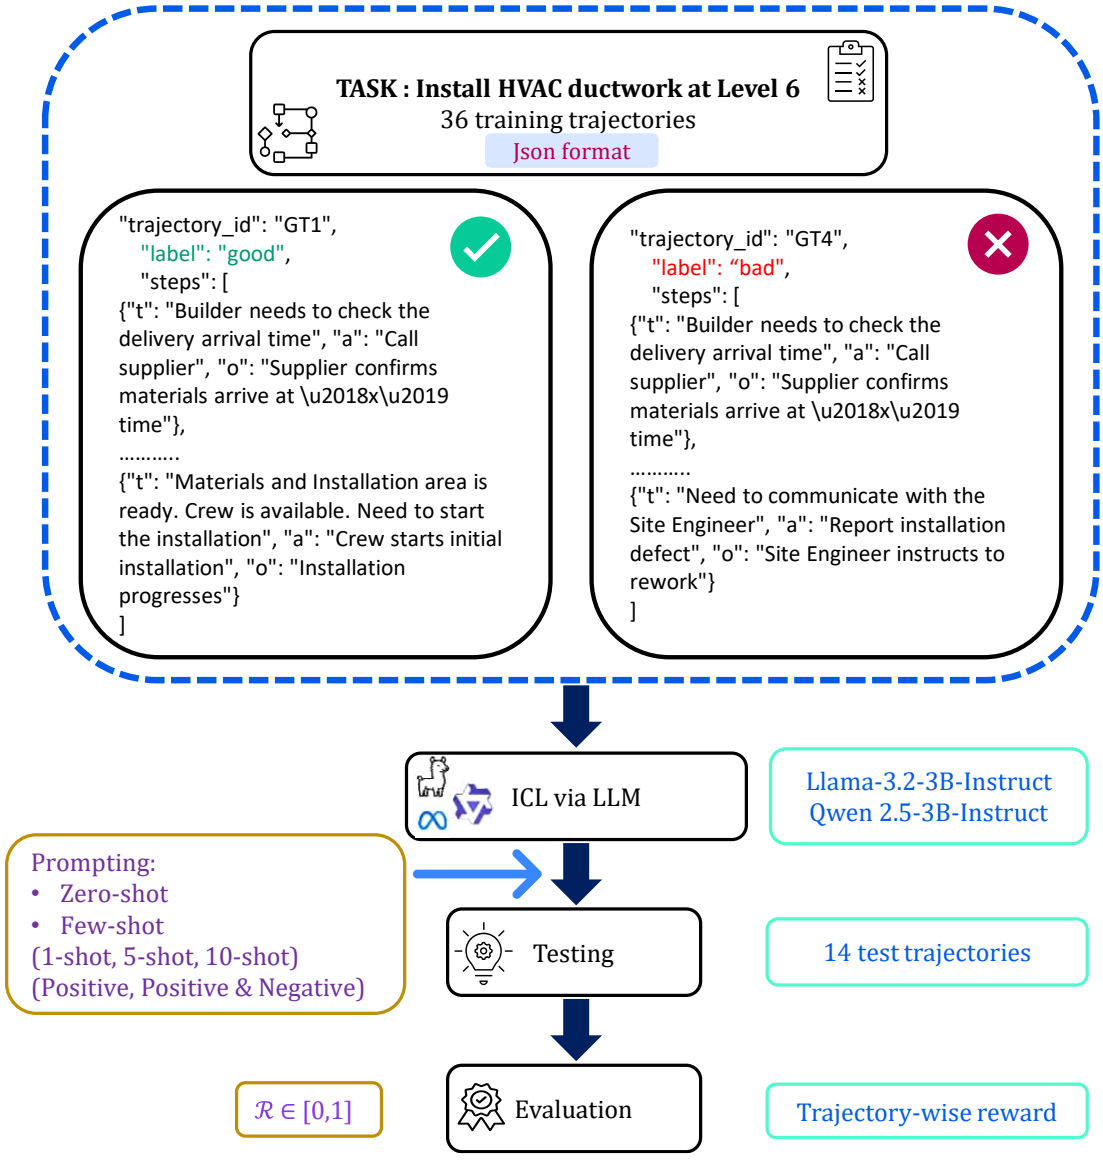

Figure 2. Methodology for preliminary ICL approach

to Llama and Qwen, this experiment included Mistral-7B-Instruct-v0.2, GPT-4o-mini, and GPT-5.4 to compare performance across both open-source and API-based models. Predicted trajectories were assessed manually.

3 Results and discussion

When the same unseen trajectory was tested with LLMs under positive and negative conditions the following outputs were obtained as indicated in Table 1.

Table 1. Accuracy levels of positive-negative trajectory context

Prompt	Qwen 2.5-3B-Instruct	Llama 3.2-3B-Instruct
Zero-shot	30%	40%
1-shot	76%	66%
5-shot	60%	76%
10-shot	58%	70%

Table 1 shows that neither model performed well under the zero-shot setting. Qwen achieved its best performance under the 1-shot configuration, with an accuracy of 76%, compared with 66% for Llama. In contrast, Llama performed better at the 5-shot and 10-shot settings, suggesting that it benefited more from additional in-context examples. However, both models showed lower performance at 10-shot than at 5-shot, indicating that adding more examples did not necessarily improve prediction accuracy. This suggests that excessive in-context examples may introduce less relevant or distracting context, reducing the models' ability to use the prompt effectively. Overall, Qwen performed best in the 1-shot setting, whereas Llama achieved its strongest performance in the 5-shot setting.

One possible reason for the variation in few-shot performance is output truncation. As the number of few-shot examples increases, the prompt becomes more complex and consumes more tokens during inference. Since each trajectory contains around 10 steps on average, larger few-shot settings increase both prompt length and response complexity. To manage this, generation was limited to 500 output tokens. As a result, the study mainly evaluated action prediction accuracy rather than the quality of the generated explanation. Example explanations are presented only for illustration, and their content may vary depending on the number and similarity of the in-context examples. An example from the 5-shot Llama setting is shown in Figure 3.

In addition to comparing different LLM architectures, an ablation study was conducted to examine the effect of model scale within the same model family by comparing Qwen 2.5-7B-Instruct and Qwen 2.5-3B-Instruct. As shown in Figure 4, the 7B model achieved higher accuracy than the 3B model in most settings, except for the 1-shot configuration. Zero-shot performance was nearly twice as high for the 7B model, suggesting stronger instruction-following capability. The 7B model also performed better under the 5-shot and 10-shot settings, indicating improved use of multiple in-context examples. These results suggest that increasing model scale may improve robustness to noisy context and strengthen the use of trajectory examples.

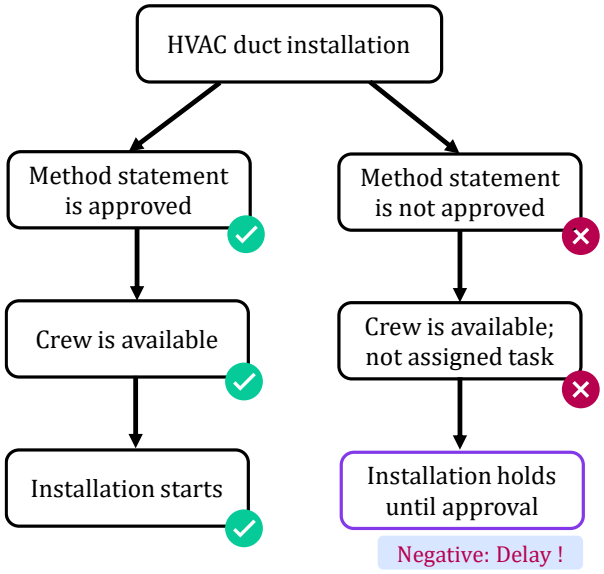

Figure 3. Next action prediction (5 shot Llama setting)

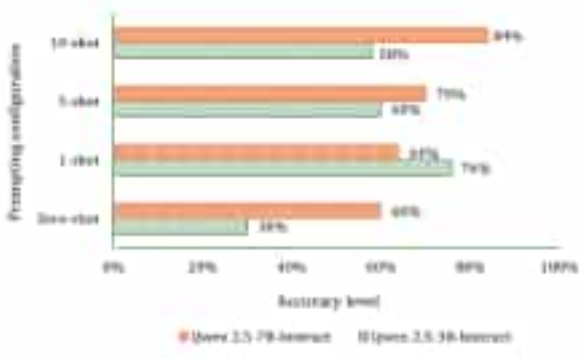

Figure 4. Accuracy levels of the ablation study

Figure 5 presents the cosine similarity values obtained in the extended experiment on predicting future action sequences across different LLMs and prompting configurations. Qwen and Llama showed patterns generally consistent with the next-action prediction results from the previous experiment, while Mistral performed at a similar level with slight variation across prompt settings. GPT-based models showed stronger performance than the open-source models, suggesting that trajectory-prediction performance may improve with model scale. Figure 6 shows an example future trajectory prediction generated by GPT-5.4.

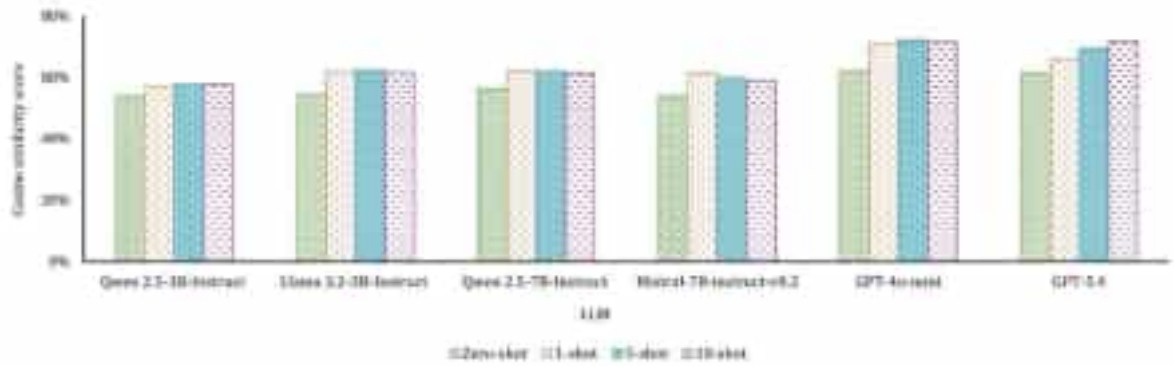

Figure 5. Cosine similarity scoring of different LLMs

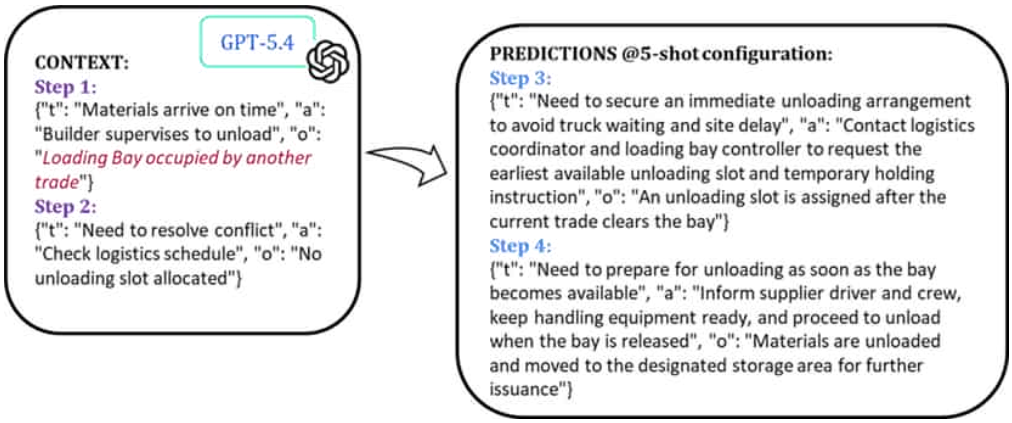

Figure 6. Prediction of trajectory using GPT-5.4

This study presents a trajectory-based ICL approach for construction scheduling. Rather than replacing conventional scheduling tools, the proposed method is designed as a decision-support mechanism that helps site teams interpret evolving situations and identify feasible follow-up actions. This work contributes to contrastive learning from positive and negative trajectory patterns, including intermediate-step failures that are often overlooked in conventional deterministic schedules.

One of the key limitations is the limited number of trajectories which limits the diversity of decision patterns available for unseen scenarios. Hence, it is recommended to train the model with a considerably bigger dataset, covering a wide range of cascading scenarios under uncertainty.

As an initial step towards developing a scheduling agent, this study provides a basis for future development. The next step is to advance this work towards an LLM-based scheduling agent by incorporating stepwise rewards and a mixed post-training method that includes supervised instruction fine-tuning and reinforcement learning. It would also be valuable to include larger scale LLM baseline models in future evaluations.

4 Conclusion

Timely project completion remains a persistent challenge in the construction industry adhering to its inherent complex nature and uncertainty. The proposed approach is designed to support adaptive scheduling decisions under disruptions by predicting future action sequences from prior trajectory context.

This study leads to the following key findings. First, the performance of ICL is influenced by both the number and quality of the in-context examples. Despite the small dataset, ICL appears to offer a practical alternative in settings where construction scheduling data are scarce. Additionally, Llama showed stronger performance in next-action prediction at the preliminary stage, while commercial LLMs such as GPT-5.4 performed better in the extended future-trajectory prediction experiment. This suggests that model architecture and scale may influence trajectory-learning performance.

This paper presents an exploratory study towards such a system, in which the agent learns construction sequences from both positive and negative trajectories and is evaluated on its ability to predict subsequent actions and short future trajectories. In practical terms, the contribution of the approach lies in its potential to support schedule adjustment under disruptions by recommending feasible next actions that reduce delay.

Abstract –

Design for manufacturing and assembly (DfMA), extended through more generic Design for X (DfX) is an important component for realising the benefits of modular and industrialised construction. This requires balancing heterogeneous objectives derived from diverse, often fragmented data sets. In the absence of a unified data model, designers often resort to bespoke solutions on a per-case basis, missing the opportunity for optimally mass-customised solutions. Semantic web technologies have proven the capability to unify diverse data sources through the formalisation and re-use of knowledge across lifecycles and projects. But its application within modular construction has remained limited. This paper proposes the Modular Building Components Ontology (MBCO) to formally represent components' hierarchy in line with Linked Building Data (LBD) and DfX principles. The Ontology 101 methodological framework is adopted. It reuses and aligns high-level vocabularies like Building Topology Ontology (BOT) to enhance interoperability. It provides a modular core structure with optional extensions to further knowledge (like environmental indicators, constructability, mass customisation, etc.) without bloating the schema. Reasoning-based checks and SHACL shapes ensure consistency and data quality. We illustrate feasibility through a case study that populates a residential modular unit and show how SPARQL queries and lightweight rules can extract objective metrics like component commonality and production-assembly constraints directly from the graph. The results show that such an ontology can facilitate automated simultaneous multi-objective optimisation using diverse data sources, thereby operationalising DfX in modular construction.

Keywords –

Modular Buildings; Ontology; Linked Building Data; Design for X

1 Introduction

Modular and industrialised building construction has promised a huge potential with the recent advancements in the architecture, engineering, and construction (AEC) industry. The benefits realisation, however, has remained limited due to several challenges, design being one of the foremost. This is because the industrialised construction process largely relies upon modular design properties to achieve benefits through mass customisation. The disjointed process of offsite production and onsite assembly makes the consideration of downstream requirements within design more important, giving rise to the Design for Manufacturing and Assembly (DfMA) philosophy. More recently, this has been replaced by a notion of Design for X (DfX) [1], where the considerations are expanded to sustainability, modular suitability, etc. Multi-objective design optimisation, akin to the manufacturing domain, has thus gained momentum to address this gap [2]. The problem with that, however, is the fragmented nature of information linked to multiple objectives. For example, components' environmental data, manufacturing process, module transportation requirements, and crane assembly constraints all have different standards for representing information, and real-time inclusion to support the designer is often difficult, if not absent at all [3,4]. Semantic web technologies provide a mechanism to unify such information into a consistent model through the Linked Building Data (LBD) initiative for the AEC domain [5]. Existing applications within modular construction have primarily focussed on standardising the DfX-based design review process. However, the automation of optimal design generation promises wider benefits in view of the recent AI-based methods. These methods heavily rely on the representation of design, with graph-based methods showing promising results [6]. However, no formalisation of a graph-based modular building component structure could be found which would

streamline these efforts and exploit the benefits of standardisation. A need, thus, arises to formalise a core representation of modular buildings within the LBD context, based on which the requirements for automated design generation may be uniformly defined.

This paper tries to address this gap through the development of a core ontology to represent modular building component structure, aligned with existing efforts and allowing for subsequent extensions to support a unified design optimisation workflow. Ontology development 101 methodological framework provides a comprehensive, step-by-step guide for this process, and has been utilised for the current work. The Web Ontology Language (OWL) is used for the specifications, and it works on the Resource Description Framework (RDF) data model. The proposed ontology is meant to be positioned as middle-to-upper level, formalising domain-specific concepts, while aligning with existing high-level definitions like Building Topology Ontology (BOT) [7] for building context and spatial containment, and Ontology for Property Management (OPM) [8] for component properties. Core classes like Volumetric Module, Planar Module, etc. extend BOT concepts, while allowing for further domain extensions to suit multiple DfX criteria. Similarly, a set of minimal attributes are associated with the classes, which may be easily extended to capture details like geometry, materials, manufacturer details, etc. A modular architecture is employed to define a core structure, which is extendable through Linked Data hooks to external knowledge bases, without bloating the schema. Manufacturability and Mass Customisation based DfX criteria definitions are further constructed to demonstrate usability and automated reasoning across domains. Shapes Constraints Language (SHACL) has been used to define rules for consistency and manufacturability to ensure data quality and real-world applicability. The feasibility is illustrated through populating a residential modular building in line with the ontology and computing objective values of multiple criteria like component commonality, module dimensions, and weight limits from the RDF graph.

2 Background

The current work focusses on two primary theoretical foundations to develop the case for this research – (1) Design within modular buildings and the various considerations required for achieving the promised benefits of modular construction; (2) The application of semantic web and linked data technologies within modular construction to implement the proposed design principles.

2.1 Design in Modular Construction

Based on the requirements for design in modular construction, two distinct considerations can be pointed out – DfMA and Mass Customization.

DfMA involves incorporating downstream manufacturing and assembly requirements during design and originated in manufacturing. In AEC, its integration with BIM has been shown to improve process flow, although regulatory, cultural, and knowledge-related barriers remain [9]. These have also identified DfMA's potential for autonomous design and construction manufacturing, while demonstrating that existing work places greater emphasis on design review than on the a priori inclusion of design requirements, consistent with Lee et al. [1]. A broader Design for X (DfX) approach has further been proposed, where "X" may represent criteria such as modularity, sustainability, commonality, variety, production cost, transportability, etc. In this form, DfX aligns more closely with mass customisation as compared to DfMA.

Mass customisation seeks to combine the efficiencies of mass production with a desired level of variety. It is commonly enabled through product platform architectures and the customer-oriented design decoupling point model. Jensen [10] identified four modular construction platform strategies based on the decoupling point: engineered-to-order, modify-to-order, configured-to-order, and select-variant-to-order, in increasing order of standardisation. This trade-off between standardisation and customisation is central to DfX. The present work addresses its formalisation through design representation.

2.2 Linked Data for Modular Buildings

Semantic web and linked data technologies have shown promise in addressing information fragmentation in AEC, leading to standard knowledge dictionaries for representing spatial topology, product structure, geometry, and element properties [7,8,11]. For modular buildings, however, although product-based structuring has been recognised at a high level, domain-specific formalisation remains limited. Early efforts include the Product Semantic Representation Language (PSRL) and semantic web-based component catalogue representations highlighting the need for standardised components [12]. Subsequent studies proposed semantic support for DfMA-based design, manufacturing integration, and cost estimation [13]. Lee et al. [1] similarly aimed to standardise DfX review for modular buildings, but focused on process concepts without adequately representing the design artefact itself.

Other work has linked DfMA with mass customisation through client-engagement modelling [14], or proposed ontologies for constructability and mass customisation [15,16]. However, these approaches are either too component-centric for inter-domain DfX use or limited to lower-level product library descriptions

Table 1: Comparison of MBCO with existing efforts for formalised graph-based modular building representation. MLE=Modular, Lightweight, and Extensible Ontology Structure

References	Ontology Proposed	LBD Alignment	MLE Structure	DfX Criteria Inclusion	Abstraction Level
Gan [7]	No	No	No	Multi	-
IfcOwl [18]	Yes	Yes	No	No	All
DfX [1,14,15,20]	Yes	No	No	Single	Middle
Cao et al. [20]	Yes	Yes	No	Single	Lower
Rasmussen et al. [18]	Yes	Yes	Yes	No	Lower
MBCO	Yes	Yes	Yes	Multi	Middle

despite alignment with ifcOWL [17,18]. Further ontology-based manufacturability studies [19,20] define core component concepts, but do not adequately capture module–element compositional relationships or align well with existing linked building data ontologies. A lean, comprehensive, and standardised cross-domain design representation is therefore still lacking.

2.3 Research Gaps

The following research gaps can be summarised based on existing literature:

1. There is no standard ontology for representing modular buildings' component hierarchy concepts. Particularly, an alignment with upper-level ontological frameworks like BOT, BPO, etc. is missing.
2. There is a lack of a middle-level domain specific ontology definition for modular buildings. The existing efforts on modular building ontologies target the lower-level definitions, often based on individual cases or specific component instances, aligning more with the definition of a knowledge graph rather than an ontology. This also limits the multi-domain reasoning capability for DfX as each study defines all definitions based on its own singular criterion (e.g., manufacturability [19], constructability [15], cost assessment [13], etc.).
3. Most work on ontology-based DfX for modular buildings is focussed on the design review process [1], and not on design generation process, which limits the automation of design.

To address these gaps, this study develops the Modular Building Component Ontology (MBCO) as a federated extension to BOT in the domain of modular construction, aligning with the principles of domain extensible shared ontology [21], and Linked Data deployment scheme. This is meant to compliment the work of LBD Community Group[1] of the World Wide Web Consortium (W3C) in the direction of modular buildings. Table 1 compares MBCO with existing efforts aimed at formalising a graph-based representation for modular buildings across five dimensions. Here, LBD alignment assesses the reuse of existing ontologies. The modular, lightweight, and extensible (MLE) criterion assesses the ontology structure against linked open data principle of defining ontologies as light-weight modules which are easy to maintain and extend as required.

The positioning of the current study relative to the wider ontology development efforts within the AEC domain is illustrated in Figure 1. In this context, MBCO is meant to be a bridge connecting upper-level AEC domain ontologies with lower-level ontologies built for specific objectives.

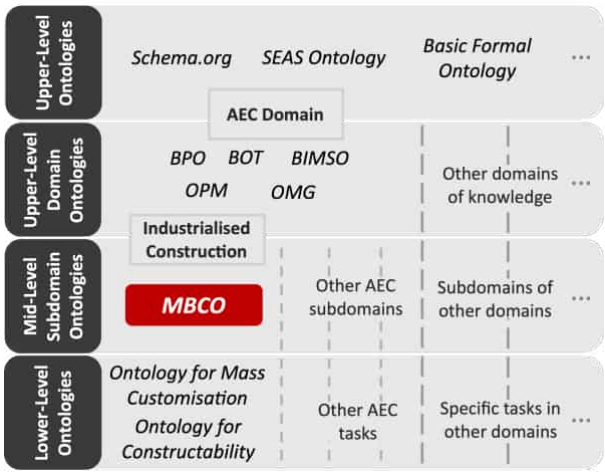

Figure 1. Positioning of MBCO among the wider ontology development efforts.

3 Methodology

The development of the proposed ontology follows a six-step process. This is guided by the Ontology Development 101 framework [22]. This method was selected because of its widespread use within

[1] https://www.w3.org/community/lbd/

construction applications and the provision of a tool-supported, step-by-step procedure incorporating best practices for ontology building [4,22]. This includes: (1) the definition of domain, scope, and competency questions, (2) reuse and alignment with existing ontologies, (3) enumerating key terms, (4) defining classes, (5) class properties & their types, and (6) creating instances and evaluation of ontology. Protégé is an open-source tool recommended by Ontology Development 101, and is used here, with Web Ontology Language (OWL) based reasoning to verify logical consistency and inferred classifications. The resulting ontology is organised in a modular manner – a lean core schema for component hierarchy and connectivity, with optional extensions to external datasets (like environmental indicators, etc.) to avoid over-complicating the core vocabulary while enabling multi-domain reasoning workflows.

4 Modular Building Component Ontology

4.1 Domain, Scope & Competency Questions

MBCO is developed to provide a core formal, reusable representation of modular building component hierarchy that supports design reasoning and automation, and which can be extended with specialised DfX ontologies. Here we use the term component in a loose definition to refer to any part of a modular building.

The scope of the ontology is restricted to defining (i) a core modular component decomposition structure, and (ii) a minimal set of extendable attributes for multi-criteria DfX incorporation. To further clarify the scope, the following competency questions (CQs) are developed:

CQ1. What are the types and numbers of all modules that constitute a given modular building?
CQ2. What smaller modules and/or elements are contained inside a larger module?
CQ3. What modules are adjacent to or intersecting with a given module?
CQ4. How to assign metadata to modules, elements, or their connections?
CQ5. How to assign attributes to constituents of a modular building to serve a given DfX criterion?
CQ6. How can attributes of modules/elements be reused across multiple DfX criteria?

Further, separate modular ontologies can be integrated for each DfX criterion that needs to be considered. Here, we show this by the examples of manufacturability and mass customization used in combination with the core MBCO. For example, competency questions for assessing mass customisation criteria using MBCO may be considered as follows:

CQ7. Which components are reused across multiple modules and with which properties?
CQ8. What is the aggregated manufacturing cost based on a given modular composition of a building?

4.2 Reuse of Existing Ontologies

Reuse of and alignment with existing ontologies and knowledge definitions is one of the key principles of linked data implementation [22]. To avoid duplicate effort, existing libraries of reusable ontologies like Linked Open Vocabularies[2], DAML[3], and Ontobee[4] were searched for terms related to modular buildings, industrialised construction, prefabrication, and design. Further, Scopus [5] database was searched for relevant works of a non-ontological nature, or which might not be published as open use ontologies. Although some recent efforts have tried to implement ontology-based design representations for DfX [15,19], but no effort was found providing a core, reusable modular building structure, in-line with W3C linked data deployment scheme which is reusable across multiple DfX criteria.

To ensure interoperability with the LBD ecosystem, MBCO reuses and aligns established vocabularies rather than redefining generic building concepts related to topology, products, or geometry. BOT is adopted to represent building topology, including zones, elements, and their containment and adjacency relationships. This caters to partially address CQ2, CQ3, and CQ4. Further, BPO is aligned to represent part-whole assembly relationships addressing CQ2. For the core concepts of MBCO, the product decomposition taxonomies from [6,23] and ontology concepts from [15,19,20] are reused to varying extents to address CQ1 through CQ6, as explained below. To attach metadata, we utilise concepts from ontology for property management (OPM) and ontology for manging geometry (OMG) to address CQ4.

4.3 Enumerating Important Terms

Important terms related to modular buildings' component hierarchy have been identified through knowledge sources including textbooks , articles, and open-source data dictionaries describing modular design [23–25]. Continuing from the scope definition, the important terms for MBCO may be viewed from two interlinked perspectives – (i) terms representing the core modular product decomposition structure in view of CQ1 through CQ4, like modular building, volumetric module, planar module, framing element, connection, interface, material, geometry, typology, sub-components, etc., and (ii) terms allowing for multiple DfX criteria inclusion in

[2] https://lov.linkeddata.es/dataset/lov
[3] https://www.daml.org/ontologies/
[4] https://ontobee.org/
[5] https://www.scopus.com/

view of CQ5 and CQ6, like DfX criterion, DfX performance indicator, etc.

4.4 Defining Classes and Class Hierarchy

The classes and their hierarchy are defined based on the enumerated concepts and the reused ontologies. A combination development process [22] is employed, which starts with the description of the most salient concepts like *VolumetricModule* and *PlanarModule*. These are then generalised (bottom-up) into a *Module* class and are specialised (top-down) into *ModuleType* class. *ModuleType* is introduced here as a generic concept to distinguish modules at any level of hierarchy. For example, *PlanarModule* may be specialised into Exterior wall, Interior wall, Slab, Framing, etc., or *VolumetricModule* may be specialised into Bathroom pod, Kitchen pod, or Balcony module, etc. But these concepts are left to be decided by the user, in this case, the designer or manufacturer. This is in line with addressing CQ1 and CQ6 and maintaining MBCO as a middle level domain ontology. *VolumetricModule* is then aligned as a subclass of *bot:Zone*, while *PlanarModule* is specified under *bot:Element*. The BOT classes allow the topological expressivity to address CQ2 and CQ3. Additionally, *mbco:ModularBuilding*, a subclass of *bot:Building* is deemed necessary to allow for building level attributes specific to modular buildings. Base attributes of a *Module* like material, geometry, etc. are supported directly through *opm:Property* class, which may further be linked to *omg:Geometry* class [11], addressing CQ4. Similarly, the types of connections between modules, elements, and modules and elements play an important role in defining the component breakdown structure in modular buildings, often influencing design choices related to mass customisation, cost, and constructability. *Connection* class has been defined here to specify these requirements as a subclass of *bot:Interface*. Further, *ConnectionType* class is defined in relation to *Connection* class to fully address the needs for CQ4.

Similar process is repeated for defining the DfX related classes addressing CQ5 and CQ6, where *DfXCriterion* represents a given module's DfX criterion under assessment, like manufacturability, constructability, etc. *DfXIndicator* class further encapsulates the performance indicators for individual DfX criteria like dimensional constraints for manufacturability, lifting constraints for constructability, typology constraints for mass customisation, etc. of a given module or element. These classes need to be utilised in combination with the task-specific ontologies extending the MBCO for realising comprehensive assessments.

4.5 Defining Properties and their Types

Properties describe the internal structure of the classes and are essential to realising the competency questions [22]. Object properties link classes to other classes, while datatype properties link classes to specific values as necessary. To operationalise the class model in MBCO, we define a small set of object properties deemed essential to answer the competency questions, as summarised in Table 2:

1. Modular decomposition across building levels is anchored in BOT. *mbco:hasModule* links a *bot:Storey* to any *mbco:Module*, while *mbco:hasVolumetricModule* specialises this for *mbco:VolumetricModule* and is declared a subproperty of both *mbco:hasModule* and *bot:containsZone*; similarly, *mbco:containsPlanarModule* is a subproperty of *mbco:hasModule* and *bot:hasElement*, enabling query-compatible retrieval while preserving BOT semantics.
2. *mbco:hasProperty* connects a *Module* to *opm:Property* definition for allowing attributes like

Table 2: Summary of object properties in MBCO (all entities defined in *mbco:* domain except specified otherwise)

Competency Addressed	Object Properties	Sub-Property of	Domain	Range
CQ3, CQ4	*connectionOf*	*bot:interfaceOf*	*Connection*	*Module, bot:Element*
CQ1, CQ2	*containsPlanarModule*	*hasModule, bot:hasElement*	*bot:Zone*	*PlanarModule*
CQ4	*hasConnectionType*	-	*Connection*	*ConnectionType*
CQ5, CQ6	*hasDfXCriterion*	-	*ModularBuilding, Module*	*DfXCriterion*
CQ5, CQ6	*hasDfXIndicator*	-	*DfXCriterion*	*DfXIndicator*
CQ1	*hasModule*	-	*bot:Storey*	*Module*
CQ1	*hasModuleType*	-	*Module*	*ModuleType*
CQ4	*hasProperty*	*seas:hasProperty*	*Module*	*opm:Property*
CQ1, CQ2	*hasVolumetricModule*	*hasModule, bot:containsZone*	*bot:Storey*	*VolumetricModule*

material, geometry, etc. Where the extended hierarchy of properties is not required, *props* predicates can be directly used from IFC models as done by the IFC-to-LBD convertor [26].

3. Inter-module connectivity is captured via *mbco:connectionOf* to represent realised interfaces between modules.
4. Explicit type assignment relations are provided using *mbco:hasModuleType* and *mbco:hasConnectionType*. These properties support integration with controlled vocabularies (e.g., manufacturer catalogues, platform families, standard connection taxonomies). In practice, *ModuleType* and *ConnectionType* can evolve into enumerated classes or be aligned to higher level concept schemes (like *skos:Concept*), depending on whether strict logical typing or flexible terminological tagging is desired.
5. DfX assessment is modelled using *mbco:hasDfXCriterion* and *mbco:hasDfXIndicator*, creating a structure for computable multi-criteria evaluation as envisioned by [1].

No datatype properties are introduced yet to keep the core ontology lightweight and easily extensible. Quantitative or logical DfX assessment values (e.g., costs, embodied carbon, commonality scores, constraint checks, etc.) can be added later either through task-specific extension modules or external vocabularies. A total of 9 classes and 9 object properties comprise the final core structure of MBCO, as illustrated in Figure 2.

5 Case Study – Creating Instances and Evaluation

To illustrate how MBCO can be used in practice, we model a minimal modular building design (Figure 3) consisting of two volumetric modules and eight planar modules: six wall panels (three solid walls and three opening walls) and two slabs. The goal is to show (i) how a designer can quickly create a consistent instance graph using the MBCO relationships, and (ii) how the same instance data can be evaluated using lightweight, executable checks and computations. The capabilities of CQ1 through CQ6 are utilised for realistic design applications. In this case study, *SolidWall*, *OpeningWall*, *Slab*, *BathroomPod*, and *KitchenPod* are represented as module types (instances of *mbco:ModuleType*). Module properties were attached using IFC-to-LBD-style [26] *props:* predicates so that wall and slab dimensions could be queried directly in a manner consistent with IFC-derived linked data. Additionally, a total of nine connections were instantiated: five of type-1 between volumetric modules and walls, and four of type-2 between walls. The graph thus becomes capable of reasoning over interactions between the modules along with the decomposition structure. The resulting instance graph includes 28 named nodes and 120 RDF triples (i.e. relationships), a part of which is illustrated in Figure 4.

Ontology evaluation ensures logical consistency and testing for fitness for the purpose. In this study, automated consistency checking is done using Protégé HermiT reasoner due to its speed and ease of implementation. It showed no error, confirming the consistency of the ontology. Further, basic task-based evaluation checks are conducted as follows: (i) a lower-level commonality [27] score is computed using the dimensions, types, and connections of planar modules retrieved using SPARQL queries on the populated RDF graph, (ii) manufacturability checks are done on all wall panels to ensure they do not exceed a production line maximum allowable length (set to 8m), and (iii) constructability checks are performed using gross weight of volumetric modules against a crane lifting capacity (set to 4500kg), using SHACL shapes for reasoning.

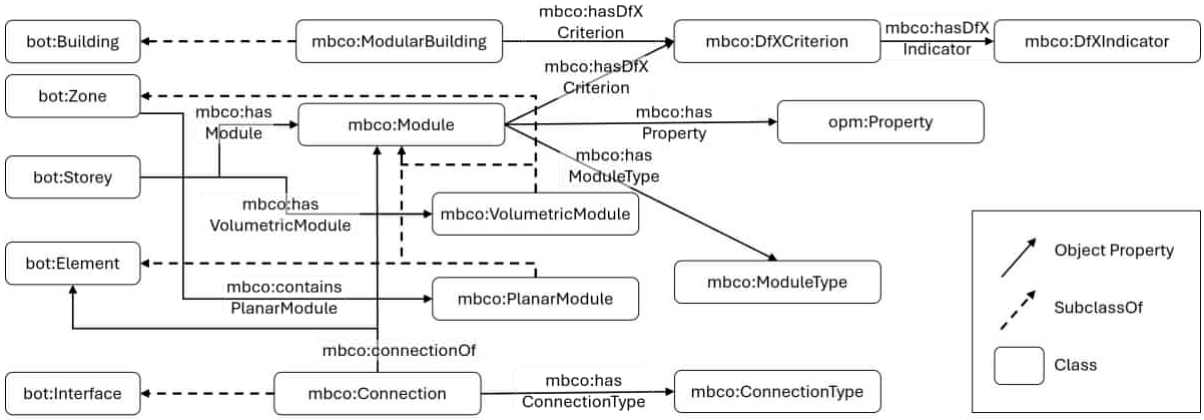

Figure 2: The Modular Building Component Ontology (MBCO)

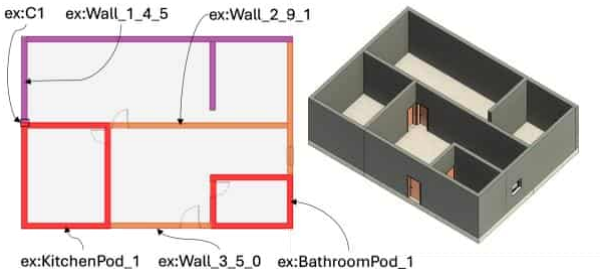

Figure 3. Simple Modular Building Example Case

The computed commonality value of each element and the SHACL reasoning results are populated back into the instance graph using *DfXCriterion* and *DfXIndicator* instances. The SHACL reasoning checks both missing values and values exceeding capacity. Two walls (13.3m and 9.1m) are flagged as being too long against the line limit of 8m. The kitchen pod is flagged as being too heavy against the crane lifting capacity. This demonstrates how MBCO can support the workflow from instance creation through to executable manufacturability and constructability checking and graph-native commonality evaluation.

6 Conclusion

This paper presented the Modular Building Component Ontology (MBCO) as a core, lightweight, interoperable semantic foundation for representing modular buildings in early-stage design. By positioning MBCO as a middle "core" layer aligned to established building ontologies (notably BOT), the ontology captures essential modular concepts like volumetric and planar modules, their containment relationships, and realised interfaces while remaining extensible to downstream task ontologies and external datasets. The case study demonstrated how a simple modular plan can be instantiated efficiently and then evaluated using executable mechanisms: a SPARQL-based commonality metric to quantify reuse across planar modules, and SHACL rules to validate manufacturability and constructability constraints such as production-line length and crane lifting weight limits for various modules. Together, these examples show how MBCO supports a practical workflow from structured representation to computable assessment without embedding project-specific constraints into the core schema. MBCO therefore provides a reusable bridge between modular building semantics and DfX-style decision support, enabling more consistent data integration, automated checking, and possibility for graph-based optimisation. Future work will expand the type catalogues and connection semantics, introduce optional lower-level extension ontologies for performance attributes, and validate the approach on richer industrial case studies integrating BIM/IFC pipelines and multi-objective design optimisation. The data from this research is available at https://github.com/khansalik/MBCO.

Abstract

In the field of Facility Management (FM), the increasing complexity of operations and the demand for Environmental, Social, and Governance (ESG) compliance require strategic, lifecycle-oriented data management. However, current practices often suffer from information fragmentation and a lack of integration between spatial and FM data. This study addresses these issues by developing a cloud-based Building Information Modeling (BIM)-FM integration system that offers decision support to 2 specific real estate ownership forms: Corporate Real Estate (CRE) and Real Estate Investment Trust (REIT). By defining distinct management requirements for each type, we constructed a system using Autodesk Platform Services (APS) that dynamically links 3D BIM models with external management databases without overburdening the BIM files. The proposed system was verified through a prototype applied to office buildings in Tokyo. The results indicate that the system improves operational efficiency in CRE by visualizing cost sources and enhances governance in J-REITs by providing investors and asset managers with transparent, real-time access to granular property data. This approach establishes a practical model for utilizing BIM in the maintenance phase to maximize real estate value.

Keywords –

BIM; Cloud; CRE; Digital Twin; Decision Support System; FM; REIT

1 Introduction

1.1 Research Background

In recent years, facility maintenance and construction management operations have become increasingly complex due to the extension of facility lifespans and multifunctionality. Additionally, there is a growing demand for strategic management that considers the entire building lifecycle, including responses to Environmental, Social, and Governance (ESG) management and carbon neutrality. This has heightened the importance of management methods that capture various tasks cross-sectionally and handle information continuously, going beyond preservation and operation.

On the other hand, information handled in these operations often remains recorded on paper or managed individually by departments, causing information fragmentation, update delays, and personalization, which hinders rapid decision-making. Building Information Modeling (BIM) is an effective means to solve these issues.

BIM functions as a database integrating spatial and attribute information, enabling unified management throughout the lifecycle.

Nevertheless, most existing research and practices regarding BIM focus on information sharing during the design and construction phases, and concrete operational models for the facility management phase have not been established. In particular, sufficient consideration has not been given to the fact that the quality of decision-making and necessary data granularity differ depending on the purpose of real estate ownership.

Therefore, this study classifies real estate ownership forms into CRE and REIT and constructs a BIM-FM

integration system based on their respective management requirements. The purpose is to contribute to the maximization of real estate value in a stock-based society.

1.2 Previous Research

Previous research [1] attempted to construct an environment where facility managers without specialized skills could intuitively utilize BIM data. Specifically, a prototype of the system was developed using Autodesk Platform Services (APS). Figure 1 illustrates the platform developed in the previous study.

Figure 1. System developed in the previous study

In that study, targeting existing office buildings in Tokyo, a data linkage method was established to associate different forms of FM data—such as power consumption, seat usage, and repair records—with room IDs and seat IDs on the BIM model. This system enabled the visualization of energy consumption and spatial occupancy rates for each floor as a heatmap on a web browser without requiring specialized BIM software. This demonstrated the utility of the system as an integrated visualization system for building information by reducing the technical barriers to BIM utilization.

1.3 Research Objectives

The prototype constructed in previous research focused on the technical verification of 3D data visualization. However, it didn't sufficiently examine the lack of sustainability in update operations due to reference data relying on local environments, nor did it assess its suitability for decision-making processes in actual real estate management. In particular, sufficient consideration was not given to the fact that the requirements and judgment indicators sought by managers differ fundamentally depending on the form of real estate ownership.

Therefore, this study inherits the technical foundation of the previous research while securing operational sustainability by fully migrating the data management infrastructure to the cloud and newly introduces management requirements based on real estate type. The objective is to develop a more practical decision-making support model by implementing specific business logic into the system—such as operational efficiency in CRE and profitability evaluation in REIT—going beyond information visualization.

1.4 Research Methodology

This study is divided into the following three-stage process. First is the definition of management requirements based on real estate types. Target properties are selected from CRE and REIT, and the data granularity and technical requirements necessary for decision-making in each category are clarified.

Second is the construction of a BIM-linked system. Based on the cloud visualization technology developed in previous studies, a database structure and ID linkage logic satisfying the defined requirements are implemented.

Third is verification and evaluation. The developed system is applied to medium-sized office buildings in Tokyo, representing both CRE and REIT. The utility of the system for decision support and operational efficiency is verified in scenarios from both CRE and investor perspectives. Table 1 shows the chapter structure and content of this paper.

2 Requirements Definition

2.1 Classification od Real Estate Types and their Domestic Asset Scale

According to the Cabinet Office's Annual Report on National Accounts (FY2023 estimates) [2], the total value of "non-financial assets" (real assets including land, buildings, and structures) in Japan's national wealth has reached approximately 3,065 trillion yen. Based on the ownership entity, these assets are broadly classified into three categories: "Households," "Public Real Estate (PRE)," and "CRE".

Their ownership forms are broadly classified into two categories: PRE and CRE. In this study, grasping the asset scale of each category is important for estimating the social ripple effects of system implementation.

1. PRE
   This refers to assets owned by the national or local governments, such as government buildings, public housing, and educational facilities. The estimated asset scale is approximately 769 trillion yen. However, as the management principle is public welfare, this is excluded from the scope of this study.
2. CRE (broad defined)
   This refers to real estate owned by private enterprises. According to the Cabinet Office data, the total asset scale reaches approximately 786 trillion yen. In this study, we further classify this broad CRE into two types based on the purpose of ownership:

   - Operational Assets (narrow defined)
     Real estate owned for business activities (headquarters, factories, logistics, etc.). This accounts for the majority of the stock (approx. 762 trillion yen), where cost optimization is the primary goal.

   - Investment Assets (REIT)
     Real estate operated for rental income or capital gains. While the asset scale of J-REITs is approximately 24 trillion yen, this sector requires high transparency and accountability to investors.

In this study, we specifically target CRE, which has a large asset scale and high ripple effects on economic activities, and REIT, which is a growth area, to construct a BIM linkage model optimized for their respective management requirements.

2.2 Issues in Existing Real Estate Management Operations

2.2.1 Scope and Issues of Real Estate Management in CRE

CRE management operations consist of business processes that circulate within the enterprise. Issues and reports extracted from the site are aggregated to the property administration and FM departments and are processed as optimization measures for management resources, such as cost management and layout planning. The business content is broadly divided into the following three categories:

1 Management and Administrative Tasks:
Contract management, quality control, office receipts and disbursements, and complaint handling.

2 Operational Tasks:
Energy management, parking management, FFE (Furniture, Fixtures, and Equipment) management, environmental hygiene and cleaning, and general information and security.

3 Maintenance Tasks:
Equipment maintenance, exterior maintenance, building maintenance, construction planning and supervision.

Based on the organization of these tasks, there are two primary issues in CRE real estate management.

The first issue is the fragmentation of information and increased management costs. As mentioned above, tasks such as contract management, energy management, and equipment maintenance differ in nature, and in many cases, the departments in charge or the outsourced vendors are also compartmentalized. Consequently, data such as repair history, energy usage, and contract conditions are scattered, creating a situation where unified management is difficult. As a result, this becomes a factor in delaying judgments regarding cost reduction and quality maintenance from an overall optimization perspective.

The second issue is the personalization of maintenance operations. At building and equipment maintenance sites, there is a strong tendency for decisions to be made based on the empirical rules of skilled personnel. Since know-how regarding anomaly detection and preventive maintenance is not formalized as data, there is an inherent risk that operational quality will decline due to staff turnover or retirement. Furthermore, the shortage of Building Management (BM) personnel due to the declining birthrate and aging population may also contribute to the deepening of this issue.

2.2.2 Scope and Issues of Real Estate Management in REIT

J-REIT operations have a multi-layered structure consisting of the Site (PM), Operation (AM), and Investors. The business content is broadly divided into the following three categories:

1 Management and Financial Tasks
Lease contract management, tenant contract management, deposit management, budget and balance management, billing and payment management, and fund planning.

2 Operational Tasks
Energy management, parking management, FFE management, and environmental hygiene and cleaning management.

3 Maintenance Tasks
Equipment maintenance, exterior maintenance, building maintenance, construction planning and

supervision.

Regarding the issues in REIT management, information fragmentation, delayed decision-making, and the personalization of tasks—identified in the previous section on CRE—are considered common challenges. However, a specific issue unique to REIT is the limitation of reporting operations to the AM. In conventional paper-based monthly reports, vast amounts of operational data generated on-site were aggregated on a monthly basis and submitted in static media such as PDFs. However, the lack of direct access to raw data and means of verification prevents AMs and investors from objectively evaluating the validity of Capital Expenditure (CAPEX) and operating costs. Under increasingly sophisticated disclosure requirements, this hinders the ability to logically and immediately prove the effectiveness of investments or their contribution to improving asset value.

2.3 System Requirements Definition

2.3.1 Requirements Definition for CRE

Based on the previous section, we defined the specific system requirements for CRE.

1 Operational Workflow Transformation

In the conventional operational flow, different departments such as General Affairs, Property Administration, and Accounting managed data in their respective ledgers. For a Facility Manager to grasp the current status, a lot of man-hours were required to collect Excel files and drawings from these vertically segmented departments and to manually cross-reference them. After the introduction of this system, data from different sources is automatically integrated via spatial information; therefore, manual data verification becomes unnecessary, enabling operational efficiency and a transition to a higher standard of management.

2 Data Integration Requirements

- Power Consumption
  Time-series data of electricity usage recorded every 15 minutes on each floor from BEMS or smart meters.
- Construction and Repair Data
  Past repair history, costs, construction details, and long-term repair plans.
- Seat Occupancy Rate
  Utilization status per seat extracted from existing office seat reservation systems.

3 Key Functions:

- Cost Heatmap
  Visualizes the density of power and repair costs by color-coding them on the space to identify areas of energy waste.
- Occupancy Monitoring
  Identifies dead spaces with low usage frequency based on seat occupancy data to provide decision-making material for layout changes.

2.3.2 Requirements Definition for J-REIT

Based on the previous section, we defined the specific system requirements for REIT.

1 Operational Workflow Transformation

In conventional PM operations, basic data reported from the sites such as inspection records, repair history, and energy performance—were scattered without being linked to physical spatial information. Consequently, when PMs reported asset status to Asset Managers (AMs), it was difficult to quantitatively demonstrate the causal relationship between profitability and physical condition. Therefore, explaining equipment deterioration risks and life-extension effects—the basis for CAPEX proposals—required significant man-hours to manually re-aggregate dispersed data and supplement the logical structure. After the introduction of this system, the flow shifts to one where data in diverse formats from BM is automatically integrated on the cloud via common spatial information. This allows PMs to immediately visualize the factors causing fluctuations in Net Operating Income (NOI) in correlation with repair history and equipment status. Consequently, it makes an environment for fulfilling accountability at a higher level, enabling PMs to present risk avoidance effects and return on investment of CAPEX to AMs logically and with high resolution.

2 Data Integration Requirements

- Power Consumption
  Monthly meter reading data used for tenant billing.
- Construction/Repair Data
  Detailed construction order history including CAPEX/OPEX classification, and long-term repair plans.
- Contract Information
  Rent roll (rent, contract period, tenant information, security deposits, etc.).

3 Key Functions

- Construction Planning and Budget Management
  Visualizes construction results that caused budget variances and future repair plans in 3D space to support judgments on the validity of construction implementation.

- Contract Information Visualization

Visualizes vacancy information in 3D space to visually grasp vacant sections or sections approaching contract expiration, thereby supporting leasing activities.

In this study, we adopted a unified system architecture that satisfies these distinct requirements using a single platform foundation. The specific design of this common platform is detailed in the next chapter.

3 System Construction Methodology

3.1 Overall System Design and Architecture

To address the detailed technical design and operational workflow, a comprehensive schematic of the system architecture, database schema, and data update workflows is provided in Figure 2. As illustrated, the architecture consists of four layers. The Database Layer (Google Cloud BigQuery) stores the spatial master and operational records in separate tables, managed with key identifiers such as Spatial Object ID. The Backend API Layer (Node.js/Express) exposes endpoints (e.g., GET /api/construction/projects, GET /api/rooms/all) to process requests from the frontend layer. The BIM model is updated only during major renovations, while the Property Manager uploads financial and operational data (e.g., rent, energy, repair logs) on a regular basis, such as monthly or annually.

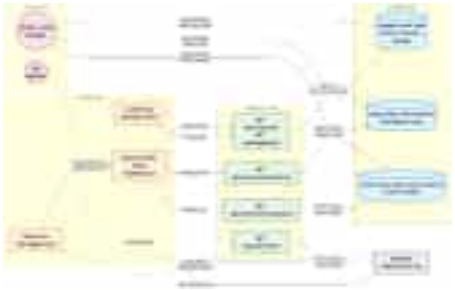

Figure 2. Comprehensive system architecture, database schema, and update workflows

3.2 Database Composition

3.2.1 Master Data Design

In designing the master data, the policy was adopted to limit the information held within the BIM model to the minimum IDs necessary for linking with the external database. Previous research has attempted methods of inputting management attributes and some non-geometric information into properties within the BIM model. However, updating frequently fluctuating information on BIM software each time requires specialized licenses and operational skills, which becomes a major factor causing update delays and discrepancies with actual conditions during the operation phase. To avoid this issue and minimize the future editing burden on the BIM model, this system uses BIM schedules to extract only the Spatial Object ID. These are defined as the primary keys for the spatial master in the system-side database. Fluid management information such as rent unit price, contract period, and tenant name is entirely managed on the cloud database side and dynamically linked via the Spatial Object ID. This establishes an environment where attribute information updates that do not involve shape changes can be executed immediately and inexpensively from a web browser without going through the BIM model.

3.2.2 Spatial Object ID Scheme

To accurately link spatial elements within the BIM model with management information in an external database, a unique identifier is essential. Previous BIM implementation case studies [3] have cited inconsistent tagging as a factor that hinders asset data integration, demonstrating the effectiveness of an ID scheme that hierarchically combines physical location and system classification.

Based on these findings, this system adopts a spatial ID naming rule consisting of the following five levels, hereafter referred to as "room_id" in this study, designed to optimize spatial identification and filtering efficiency in database queries. Table 2 summarizes the detailed definitions and examples of this scheme.

Table 2 Spatial Object ID Naming Levels

Object ID Naming Levels	Description
Level 1: Floor Code	Floor level indication where the space is located. (e.g., "2F" for Second Floor)
Level 2: Large Zone Name	AreaName: Functional classification of the major zone. (e.g., "OfficeZone", "Staircase")
Level 3: Large Zone Number	Two-digit number identifying specific major zones. (e.g., "01", "02")

Formatted Table

Formatted: Font: 8 pt

Formatted: Font: 9 pt

Formatted: Font: 8 pt

Formatted: Font: 9 pt

Formatted: Font: 8 pt

Formatted: Font: 9 pt

Level 4: Small Zone Name	Descriptive name of the specific functional unit. (e.g., "MeetingRoom", "Workspace")
Level 5: Small Zone Number	Two-digit number identifying specific zones. (e.g., "01", "02")

The codes for each level are jointed using underscores (_) as delimiters to construct the final format as follows:

[Floor]_[LargeZoneName]_[LargeZoneNumber]_[SmallZoneName]_[SmallZoneNumber]

In this study, this room_id is assigned based on structural spans to serve as a unchanging spatial unit. In the database, tenant contracts and other management data are managed as a collection of these associated room_id units. To ensure the continuity of historical data during floor plan changes caused by contract renewals or interior reconfigurations, the system responds by updating the assignment of these persistent room_id units to the corresponding management records. This room_id is stored as a Revit instance parameter, functioning as the primary key for external database integration.

3.2.3 Data Formatting

Raw data imported from accounting systems or PM reports are lists of numbers that do not possess spatial coordinates. In this system, a data formatting pipeline using SQL join processing was constructed to assign the ~~IfcGuid~~ DBID to this data via the spatial master defined in the previous section. The DBID is an internal integer identifier generated by APS, which is strictly required to select, color, or manipulate specific 3D objects within the web viewer. Specifically, queries were designed to execute joins against the spatial master table extracted from BIM, using floor information and section names contained in the raw data as foreign keys. Through this processing, for example, for a construction record such as "2024-Month X, AC Repair Cost, Office 1", the ~~IfcGuid~~ DBID corresponding to Office 1 is automatically mapped. In the event of a mismatch between the room_id and the external data due to input errors in the raw data, the DBID returns a null value. Since it is only necessary to verify these data matching errors during the initial stage of defining the spatial model, these missing data are not displayed on the dashboard. However, these null values can be checked in the frontend console.

3.3 Data Visualization Algorithm

The role of the visualization algorithm is to convert values in the database into visual attributes perceptible to the user. Internally, the system utilizes the aforementioned DBID to match the retrieved database records with specific 3D objects in the APS Viewer, rendering them based on the following logic. For coloring spatial objects on the BIM model, two methods are used depending on the nature of the data: Discrete Value Mapping and Continuous Value Mapping.

1 Discrete Value Mapping
  Applicable Data:
  Contract status, construction status (planned/completed), etc.
  Logic:
Determines whether the data string perfectly matches a specific condition.

2 Continuous Value Mapping
  Applicable Data:
  Power consumption, rent unit price, etc.
  Logic:
  Normalizes numerical values to a range of 0.0 to 1.0 based on maximum and minimum values and maps them to a color hue circle.
The calculation is performed using Equation (1).

$$x_{norm} = \frac{x_i - x_{min}}{x_{max} - x_{min}} \qquad (1)$$

x_{norm}: The normalized value (ranging from 0.0 to 1.0).
x_i: The individual data value of the target object.
x_{min}: The minimum value within the dataset.
x_{max}: The maximum value within the dataset.

The calculated normalized value *x(norm)* is substituted into the color ramp function *f(x)* to determine the RGB value.

4 Verification

4.1 Case Study for CRE

4.1.1 Overview of Target Facility

To verify the utility of the proposed system, a prototype system was constructed and applied to two representative office buildings in Tokyo, each corresponding to a different ownership form.

In this study, we verified the system's effectiveness in solving the issues of information fragmentation and difficulty in status grasping faced by CRE. The target facility is a medium-sized office building located in Minato-ku, Tokyo, selected to simulate a typical corporate asset. Details of the building are below.

Formatted: Font: 8 pt
Formatted: Font: 9 pt
Formatted: Font: 8 pt
Formatted: Font: 9 pt

- Scale: B1/10F
- Total Floor Area: Approx. 7,800 m²
- Structure: Steel (partly CFT)

4.1.2 Verification of Effectiveness Scenario

The system's effectiveness was verified through a scenario integrating energy management and maintenance tracking. First, Figure 3 shows that selecting a specific date on the dashboard simultaneously displays electricity usage and seat occupancy rates for each floor. This visualization allows facility managers to immediately identify inefficient zones where energy is consumed despite low occupancy. In the context of CRE, this directly supports space optimization decisions, such as identifying target areas for layout coordination or adjusting HVAC operational hours, thereby fulfilling the primary goal of operational cost minimization.

Figure 3. Visualization of energy consumption data

Second, regarding repair history, floors were color-coded by repair frequency in the 3D viewer. As illustrated in Figure 4, it was confirmed that selecting a specific floor displayed a list of past construction records, and clicking a record immediately highlighted the corresponding section while showing detailed specifications. This seamless transition from macro-level status grasping to micro-level detail verification demonstrates the system's capability to resolve information fragmentation and significantly reduces the time required for cause identification.

Figure 4. Visualization of repair history and details

4.2 Case Study for REIT

4.2.1 Overview of Target Facility

In the second case study, we verified the system's effectiveness in solving the issues of untransparent information and accountability faced by REIT management. The target facility is an existing office building located in Shinjuku-ku, Tokyo, selected to simulate an investment property under asset management. Details of the building are as below.

- Scale: 9F
- Total Floor Area: Approx. 6,000 m²
- Structure: SRC

4.2.2 Verification of Effectiveness Scenario

The system's effectiveness was verified through a scenario where PM and AM utilize a unified information environment. First, operational data such as electricity usage and construction history trends were visualized on the management dashboard. Figure 5 shows the management dashboard for construction history and KPIs. This interface enables intuitive tracking of the building's physical condition and budget status over time. For REIT management, this bridges the gap between physical deterioration and financial impact, enabling AMs and investors to make data-driven decisions regarding the validity of CAPEX proposals and to prioritize renovations that directly contribute to maintaining asset value and maximizing NOI.

Figure 5. Visualization of construction history data

Furthermore, regarding leasing management, contract

status was mapped directly onto the 3D model. Figure 6 shows the visualization of contract data and specific section details. In this view, it was confirmed that users could visually identify vacancy risks and, by clicking specific sections, immediately access detailed contract terms.

Figure 6. Visualization of contract data and specific section details

4.3 Summary of Verification Results

To evaluate the accuracy of the ID linkage method, the mapping results from both case studies are summarized in Table 3. ~~Finally, the verification results for both case studies are summarized in Table 4.~~

A total of 665 operational records for CRE and 259 for REIT were mapped to the spatial objects extracted from their respective BIM models. As a result, the system achieved a 100% success rate across all categories.

Table 3. The mapping results from both case studies

		Valid Records	Successfully Linked	Success Rate (%)
CRE	**Energy & Contract**	189	189	100%
	Construction History	429	429	100%
	Construction Plan	47	47	100%
REIT	**Energy & Contract**	147	147	100%
	Construction History	52	52	100%
	Construction Plan	60	60	100%

Furthermore, the practical verification results for both case studies are summarized in Table 4, which outlines the key issues and main outcomes for each scenario.

Table 4 Summary of verification results

Case	Issue	Main Outcome
Case 1: CRE	Data Fragmentation	Demonstration of streamlined workflows for identifying cost sources and analysing space usage.~~Reduced time for identifying cost sources and analyzing space usage.~~
Case 2: REIT	Information Asymmetry	Provision of a unified platform to support explanation capability and transparent decision-making.~~Improved explanation capability and transparent decision-making.~~

5 Conclusion

5.1 Summary

In this study, we developed a prototype system that integrates BIM and financial data on a web browser to address the issues of information fragmentation and reporting opacity in real estate management. Through a case study applied to office buildings in Tokyo, we technologically verified the system's effectiveness in two specific aspects: accelerating the identification of cost sources for CRE and ensuring data transparency and accountability for REITs. The results demonstrated that dynamically linking spatial information with management data via the cloud is a valid technical approach for supporting decision-making and resolving information asymmetry. However, this research is currently limited to functional verification within specific scenarios. Establishing measurable baselines to quantitatively evaluate the actual reduction in operational time and the degree of improvement in decision-making remains a subject for future research.

5.2 Future Outlook

5.2.1 Expansion to Portfolio Management

The current system targets the visualization of a single property, but operational practices require unified management of the entire portfolio consisting of dozens to hundreds of properties. As a future outlook, we aim to extend this system to support multi-asset management and implement functions to cross-sectionally compare and analyze the operation status and repair risks of multiple properties. This enables decision-making support from a management perspective, such as maximizing NOI for the entire portfolio.

5.2.2 Application to Investor Relations (IR) and Improvement of Market Evaluation

We are also considering utilizing this system for information disclosure to external investors. To achieve this, it is necessary to select the information to be disclosed and design data access restrictions. Since the primary objective of investors is to manage asset value and cash flow, the data is provided at a different level of granularity while sharing the same underlying data source as the PM. Although the contracts, energy usage, construction history, and construction plans visualized in this study remain the subjects of visualization, to protect tenant privacy and confidential information, the system will visualize large-scale renovations exceeding a certain threshold and display general floor-by-floor energy costs, occupancy rates, and rent-based revenue trends using heatmaps. Additionally, access restrictions are enforced at the frontend presentation layer. When accessing the application, the JavaScript side checks the user's login role. If the role is an investor, the frontend converts the view and restricts the rendering of detailed data tables.

Abstract -

Construction code retrieval is a recurring bottleneck in AEC compliance workflows, where decisions require clause-addressable evidence and cross-discipline reference completion under incomplete project attributes. We present a clause-centric retrieval-augmented generation (RAG) pipeline that treats retrieval as auditable evidence discovery and enforces an evidence-bounded selection contract: outputs may cite only clause identifiers from the candidate set C_k with evidence spans anchored to retrieved text for mechanical validation. A trigger-based multi-agent orchestrator invokes an arbiter only under expert disagreement or validation flags. Experiments on a labelled query set (dev200/test100/all300) over a 600-code corpus (141681 clause units) show that, at the original top-10 operating point on dev200, dense retrieval reaches Hit@1=0.550 versus 0.210 for BM25. A retrieval-budget sensitivity analysis over $k \in \{1, 3, 5, 10\}$ further shows that dense gold-in-C_k rises from 0.550/0.500 at $k = 1$ to 0.935/1.000 at $k = 10$ on dev200/test100, while post-hoc feasibility audits of archived selector and arbitration outputs indicate non-linear downstream gains as candidate pools deepen. Under identical evidence inputs, evidence-bounded selection favours cost-efficient models (Qwen-plus Hit@1=0.430; USD 0.896 per 1K queries) over higher-cost alternatives (GPT-4o Hit@1=0.345; USD 5.763 per 1K queries). On held-out tests, arbitration is triggered in 37% of cases and revises the majority decision in 32.4% of triggered cases. The resulting clause packages link design decisions to regulatory clauses with auditable evidence, improving accountability and reducing manual clause hunting. Prototype code and experimental data are released at `https://github.com/bruce0210/RagConstructionAssistant`.

Keywords -

Construction Codes; Clause-Level Retrieval; RAG; Evidence-Bounded Generation; Multi-Agent Arbitration

1 Introduction

Construction code clause retrieval is a routine step in design review and compliance checking [1]. Reviewers typically need clause-addressable evidence, an explicit statement of scope and exceptions, and a compact bundle of cross-referenced clauses that can span multiple disciplines. When project attributes that govern applicability are missing, reliable practice favours an auditable set of candidate clauses with stated assumptions, rather than a single confident answer.

Large language models (LLM) and RAG offer a natural interface for code look-up, but many AEC assistants remain answer-centric: retrieved passages are used as supporting material, and citations are not enforced as mechanically verifiable links to a bounded evidence pool [2, 3, 4]. Moreover, missing scope attributes and cross-discipline coupling can yield multiple plausible clauses; deployment therefore needs governance that surfaces disagreement and evidence gaps for triage instead of hiding them in a single response.

To address these constraints, a clause-centric RAG pipeline is introduced that treats retrieval as evidence discovery and keeps downstream reasoning evidence-bounded. Codes are unitised into clause evidence objects with stable identifiers and provenance; retrieval returns a fixed candidate set C_k; discipline experts produce structured clause packages with applicability labels and evidence spans; and an arbiter is invoked only under explicit disagreement or evidence-quality violations. Figure 1 overviews the end-to-end pipeline.

The pipeline is evaluated on a labelled six-discipline query set with clause-identifier ground truth. Tables 3–5 summarise fixed-point retrieval, selection, and arbitration results at the original $k = 10$ operating point, while Section 5.5 and Figure 4 report retrieval-budget sensitivity and post-hoc feasibility audits for archived downstream outputs.

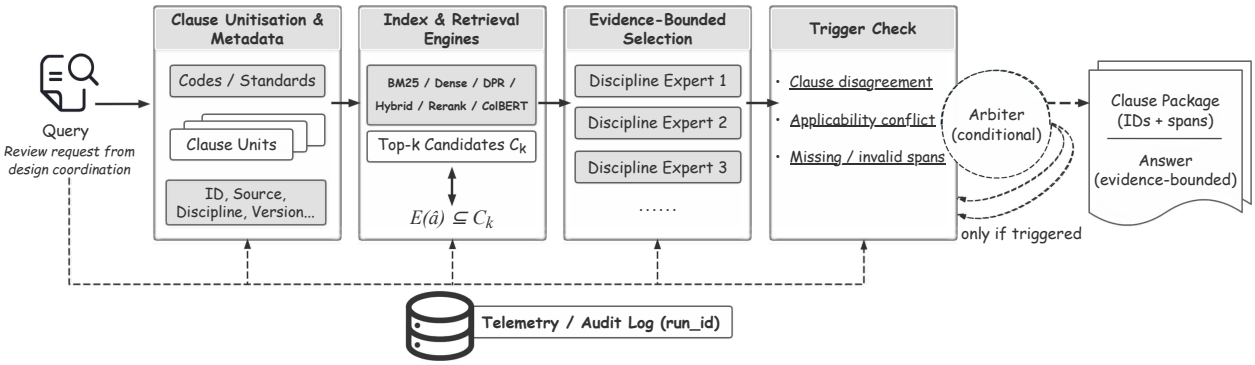

Figure 1. Auditable clause-centric RAG pipeline

The contributions are threefold. First, a clause-centric retrieval unit is defined for construction code retrieval and compliance checking, where each candidate is a citeable clause with stable identifiers and provenance metadata for plan-checking, design coordination, and cross-discipline review. Second, an evidence-bounded clause-selection contract (Formula 1) is enforced through structured validation: returned clause IDs must lie in C_k, and evidence spans must map to retrieved text. Third, a trigger-based multi-agent arbitration mechanism addresses cross-discipline ambiguity by invoking an arbiter only when experts disagree on clause/applicability or evidence is missing; trigger rates and outcomes are reported on dev200/test100/all300.

2 Literature Review

Construction code consultation sits at the intersection of regulatory knowledge management and decision support. Unlike general information seeking, the expected output is reviewable evidence traceable to specific clauses and defensible under audit [5]. This section therefore reviews clause-oriented compliance support, RAG for AEC knowledge services, and reliability and governance for LLM-assisted decision support.

2.1 Clause-Level Evidence Traceability

Digital compliance support in AEC has long recognised that regulatory text is structured by scopes, exceptions, and cross-references that affect applicability [6]. Traditional rule-checking approaches often rely on formalised representations aligned with building models [7], which can be effective when attributes are complete and scope is well specified, but usually require substantial authoring effort and remain brittle to code updates and local interpretations [8].

For practical construction retrieval, engineers need to locate the governing clause, confirm scope and exceptions, and assemble a minimal evidence bundle for review. The main bottleneck is therefore evidence traceability at clause granularity. Document-level retrieval or paragraph-level quoting can obscure the exact normative unit supporting a decision and complicate both evaluation and review workflows [9]. This motivates clause-addressable evidence units with stable identifiers and provenance, making the evidence object explicit, mechanically checkable, and easier to cite and track in review.

2.2 RAG for AEC Knowledge Services

RAG-style systems have been explored for AEC knowledge search over project documents, specifications, standards, and BIM-linked information [2, 3, 10]. They improve topical relevance and reduce reliance on parametric memory, but construction codes expose two limitations of generic RAG patterns: the review-relevant unit is usually a clause or subclause rather than an arbitrary chunk, and retrieval must account for applicability under scope conditions and cross-discipline coupling. Large passages can mask these constraints, while small chunks without stable identifiers struggle to provide review-ready citations.

2.3 LLM Reliability and Governance

Reliability in LLM-assisted decision support is often addressed with citations, structured outputs, and verifier-style checks, but compliance consultation requires a stronger guarantee than merely "having citations": cited evidence must remain restricted to, and traceable within, a bounded retrieved pool. This motivates a mechanically checkable evidence boundary (Formula 1) and span-level evidence tied to concrete text. Multi-agent designs are most useful here as governance rather than blanket ensembling: disagreement and evidence-quality violations should surface as operational risk signals that trigger conditional scrutiny, consistent with engineering review workflows and judge-style arbitration frameworks [11].

2.4 Summary of Gaps

Existing AEC compliance support and RAG systems rarely provide review-ready, clause-addressable evidence packages. Many rely on document or chunk retrieval and allow models to cite beyond a fixed retrieved pool, which weakens verifiability and auditability [4]. Ambiguity from missing scope attributes and cross-discipline coupling is also often absorbed into a single response, obscuring failure modes and governance needs under cost and latency constraints.

These gaps motivate the clause-centric evidence design, evidence-bounded selection contract, and trigger-based arbitration protocol introduced in Section 3.

3 Methodology

This section specifies a clause-centric RAG workflow for construction-code clause retrieval in compliance review, treating retrieval as auditable evidence discovery and constraining clause selection with an evidence-bounded contract. Figure 1 summarises the end-to-end pipeline.

3.1 Overview and Evidence-Bounded Formulation

Given a natural-language query q, retrieval returns a bounded candidate set of code clauses $C_k = \{c_1, \ldots, c_k\}$ from a clause-indexed corpus, and a selector produces the final clause set supporting the response. An evidence-bounded contract is enforced: the generated answer $\hat{a}$ may cite only clauses inside C_k. Let $\mathcal{E}(\hat{a})$ be the set of clause identifiers cited as evidence in $\hat{a}$, then

$$\mathcal{E}(\hat{a}) \subseteq C_k. \tag{1}$$

This constraint makes citations verifiable and bounds uncontrolled generation when project attributes are underspecified. Applicability in construction codes is shaped by scope conditions, exceptions, and cross-references; accordingly, clause unitisation provides citeable units with stable identifiers and provenance metadata, expert outputs include applicability labels and evidence spans anchored in C_k, and arbitration is triggered only when clause/applicability disagreement or invalid evidence spans indicates elevated ambiguity.

3.2 Clause Unitisation and Corpus Schema

Instead of treating each standard as an unstructured document, the corpus is represented as clause units [12]. Each clause unit stores (a) its canonical text, (b) a stable internal identifier (clause_id) used for indexing and evaluation, and (c) structured metadata such as clause number (clause_no), source document identifier, and optional media references (e.g., figures extracted from the source). This representation supports clause-addressable citations and allows downstream components to operate on comparable evidence granularity across different codes and disciplines. Clause boundaries are produced by a lightweight rule-based structural parser that detects clause-numbering patterns and common chapter/article/appendix markers, then normalises numbering and merges continuation lines to form a single clause unit. Unitisation can introduce noise in cases of inconsistent numbering, scanned layouts, or table/figure regions; therefore, raw source text is retained as provenance and spot checks are used to validate clause_id–text alignment.

3.3 Candidate Retrieval for Auditable Evidence

The retrieval stage maps q to a bounded candidate set C_k by ranking clause units using one or more retrieval engines. Each candidate $c_i \in C_k$ is packaged as an evidence item with its clause_id, clause_no, source, and a minimal text span sufficient for inspection. This evidence packaging is the only admissible evidence pool for downstream selection under the contract in Formula 1.

Construction-code queries commonly combine domain terminology with scope constraints, exceptions, and cross-discipline coupling; therefore, retrieval is framed as evidence discovery rather than a single best-match search.

3.4 Evidence-Bounded Clause Selection

Given q and C_k, each discipline expert performs clause selection and returns a structured clause package rather than free-form text. The output is defined as $o_j(q) = (S_j, A_j, \Sigma_j)$, where S_j is a short ranked list of selected clause identifiers, A_j is an applicability label for the query as stated, and Σ_j are evidence spans anchored in the retrieved candidate texts. Requiring Σ_j operationalises the evidence-bounded contract in Formula 1 and supports mechanical checks (e.g., whether cited spans fall inside C_k and whether a claimed selection is backed by explicit text), providing governance signals for downstream arbitration and error analysis.

3.5 Trigger-Based Arbitration and Governance

Arbitration serves as a governance step for ambiguity-prone cases rather than a default refinement stage, and it is invoked if the parameter-free trigger $\tau(q) = 1$ in Formula 3 holds: experts disagree on clause IDs or applicability, or schema/evidence checks fail ($\nu_j(q) = 0$). For example, if experts return $c_a \in C_k$ with applicability "yes" and $c_b \in C_k$ with "no", the arbiter stays within C_k, rejects any package whose clause IDs or spans fail validation, and then retains the package whose anchored span more directly supports the queried scope condition or exception. Thus, a scope-aligned clause may replace the majority top clause while keeping the final package

evidence-bounded; see Table 6 for an arbiter-changed example. Given $\{o_j(q)\}$, the arbiter outputs a final clause package by prioritising evidence-supported clauses, resolving cross-discipline references, and discarding selections not anchored to C_k, keeping the decision evidence-bounded and auditable.

$$m(q) = \text{mode}\big(\{s_j(q)\}_{j=1}^{M}\big), \tag{2}$$

$$\tau(q) = \mathrm{I}\Big[(\exists\, j,l:\ s_j(q) \neq s_l(q)) \vee (\exists\, j,l:\ a_j(q) \neq a_l(q)) \vee (\exists\, j:\ \nu_j(q) = 0)\Big], \tag{3}$$

$$\chi(q) = \mathrm{I}[s^*(q) \neq m(q)], \tag{4}$$

where $\mathrm{I}[\cdot]$ is the indicator function and $s^*(q)$ is the arbiter-selected clause when $\tau(q) = 1$. Formulas 2–4 define the majority top clause, trigger indicator, and arbiter-change flag.

3.6 Evaluation Protocol and Metrics

Evaluation adopts dev200 for calibration and test100 for final reporting. For each query q with a gold set of relevant clause identifiers $G(q)$, retrieval quality is measured by Hit@k on identifiers, together with MRR and nDCG@k. For the multi-expert stage, the majority selector is compared with the trigger-based arbiter output; Hit@1 is reported overall and on the triggered/changed subsets, and the arbitration accuracy delta is defined as $\Delta\text{Hit@1} = \text{Hit@1}_{arb} - \text{Hit@1}_{maj}$ (overall and triggered) under the same evidence pool. Governance rates over a query set Q are defined in Formula 5.

$$\begin{aligned} \text{TrigRate} &= \frac{1}{|Q|}\sum_{q\in Q}\tau(q), \\ \text{ChangeRate} &= \frac{1}{|Q|}\sum_{q\in Q}\tau(q)\chi(q), \\ \text{Change} \mid \text{Trig} &= \frac{\sum_{q\in Q}\tau(q)\chi(q)}{\sum_{q\in Q}\tau(q)}. \end{aligned} \tag{5}$$

4 Prototype Implementation

This section describes a working prototype that operationalises the methodology in Section 3. The implementation emphasises auditability, reproducibility, and modular replacement of retrieval and model components. Figure 2 shows the system architecture and data flow.

4.1 System Architecture and Data Flow

A query q enters the pipeline as a retrieval request. The retrieval layer ranks clause units and returns a bounded candidate set C_k as a packaged evidence bundle (clause identifiers, source references, and minimal inspectable text spans). The orchestration layer applies the evidence-bounded selector under Formula 1; if trigger conditions indicate clause/applicability disagreement or evidence violations, arbitration is invoked with q, C_k, and expert outputs. The system returns a clause-addressable package and a concise explanation bounded to cited evidence, while emitting structured telemetry keyed by a run identifier for replay and error analysis, as shown in Figure 2.

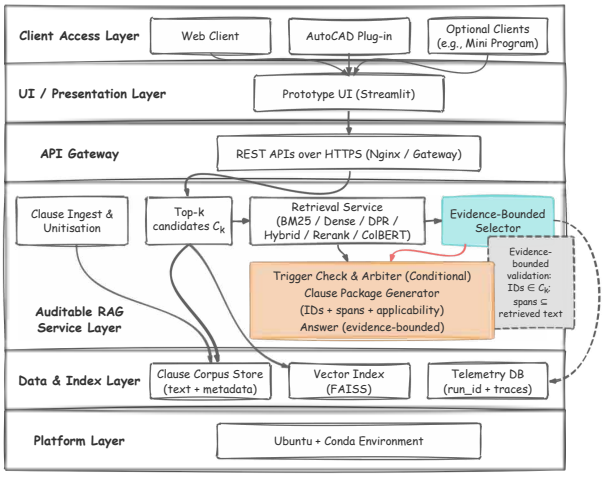

Figure 2. System architecture of the auditable clause-centric RAG prototype. Evidence-bounded validation checks that cited clause IDs belong to C_k and evidence spans are anchored to the retrieved clause text; violations raise governance triggers.

4.2 Web Interface and Telemetry Logging

The web UI prioritises evidence inspection: retrieved candidates are rendered with clause identifiers and provenance, and the final output is a clause package with explicit clause IDs and evidence spans for rapid cross-checking. All stages are recorded in a relational telemetry store for replay and audit, capturing the query, retrieval configuration, candidate-set hashes, model settings, and the final clause package. Table 1 summarises the core telemetry entities captured for reproducible experiments.

4.3 Arbitration Service and Prompt Orchestration

The orchestration layer separates multi-agent expert selection from arbitration under strict input-output schemas. A lightweight validator enforces the evidence-bounded contract by checking that cited clause identifiers belong to C_k and that evidence spans align with the returned candidate texts; arbitration is invoked only when the trigger rules

Table 1. Telemetry artifacts captured for auditable runs

Artifact	Stored in	Audit role
Run record	`trace_logs` (PostgreSQL)	Groups a run and links query, configs, and outputs via `run_id`.
Candidate pool	`*_details.jsonl`	Reproduces retrieval candidates for offline metrics and error analysis.
Expert outputs	`*.agents.jsonl`	Inspects discipline votes, applicability labels, and evidence spans.
Arbitration trace	`*.adjudication.jsonl`	Explains trigger reasons and produces the final clause package.

in Section 3.5 are satisfied. Prompts use a shared schema containing the query, minimal context, bounded candidates C_k (clause id/provenance/spans), and a fixed output contract (selected IDs, applicability, anchored spans). When triggered, the arbiter receives q, C_k, and the expert clause packages, and returns a final clause package with clause identifiers, aligned evidence spans, and an applicability judgement.

4.4 CAD Integration Entry Point

To integrate construction-code clause retrieval into drawing production and coordination, the prototype provides a lightweight CAD entry point for embedded consultation inside AutoCAD. A practitioner can invoke the custom command `"RAGCA"` during drafting to query relevant code clauses without leaving the drawing environment. The server-side pipeline returns the same evidence bundle and clause package as the web interface, keeping results auditable under the evidence-bounded contract and supporting compliance checking during drawing-based coordination. Figure 3 illustrates the within-CAD consultation flow.

5 Experiments and Results

This section reports fixed-point retrieval, selection, and arbitration results at the original $k = 10$ operating point, and then adds a retrieval-budget sensitivity analysis to examine how stricter candidate budgets affect reachability and downstream decision feasibility.

5.1 Datasets and Experimental Setup

Evaluation uses a labelled six-discipline query set (architecture, structure, heating, ventilation, and air conditioning (HVAC), plumbing, electrical, fire), with dev200 for calibration, test100 for held-out assessment, and all300 for their union. Retrieval operates over a clause-indexed corpus of 600 construction codes (141681 clause units); within each comparison, all methods share the same candidate budget k to ensure comparable evidence inputs.

Table 2. Dataset statistics and split configuration. Primary discipline is used for each query. "Cross" denotes integrated multi-discipline scenarios. Single-discipline queries = $\#Q - \#Cross$.

Split	#Q	#Cross	Arch.	Str.	HVAC	WSD	Elec.	Fire
Dev200	200	36 (18.0%)	31	30	35	29	39	36
Test100	100	24 (24.0%)	19	20	15	21	11	14
All300	300	60 (20.0%)	50	50	50	50	50	50

Abbreviations: Arch.=Architecture; Str.=Structure; WSD=Water supply and drainage; Elec.=Electrical; Fire=Fire protection.

Table 3. Clause retrieval results under a fixed top-10 candidate budget (dev200, $n = 200$)

Method	Hit@1	Hit@5	Hit@10	nDCG@10
Dense	**0.550**	**0.850**	**0.935**	**0.691**
Hybrid	0.385	0.725	0.820	0.504
Rerank	0.315	0.600	0.760	0.414
DPR	0.305	0.585	0.685	0.370
ColBERT	0.290	0.535	0.660	0.351
BM25	0.210	0.460	0.565	0.267

Main selector and arbitration comparisons use top-k candidates with $k = 10$ as the original operating point. This supports controlled comparison but does not by itself characterise retrieval-depth sensitivity. Increasing k would generally improve upper-bound recall, but also increases evidence inspection cost and can dilute top-rank precision. Section 5.5 therefore analyses $k \in \{1, 3, 5, 10\}$ using exact dense gold-in-C_k rates on dev200/test100 and post-hoc audits of archived $k = 10$ selector/arbitration outputs under stricter prefix pools C_k. Table 2 summarises split statistics and discipline coverage.

5.2 Retrieval Baseline Comparison

Retrieval baselines rank clause units to form the bounded evidence pool for downstream selection. Stronger retrieval raises the upper bound of evidence-bounded selection, although final correctness still depends on accurate clause selection.

Table 3 reports retrieval effectiveness on dev200 under a fixed top-10 candidate budget. Dense retrieval achieves Hit@1=0.550 and nDCG@10=0.691, versus 0.210 and 0.267 for BM25. Hybrid improves over BM25 on Hit@1 (0.385) and nDCG@10 (0.504) but remains below Dense under the same budget, suggesting that score fusion can still elevate lexically similar yet scope-mismatched clauses when attributes are underspecified.

5.3 Evidence-Bounded Selector Comparison

Evidence-bounded clause selection is evaluated with the same candidate budget ($k = 10$) to test whether a selector can identify the correct clause from a bounded evidence pool; dev200 is used because this stage is sensitive to prompt calibration and output-schema valida-

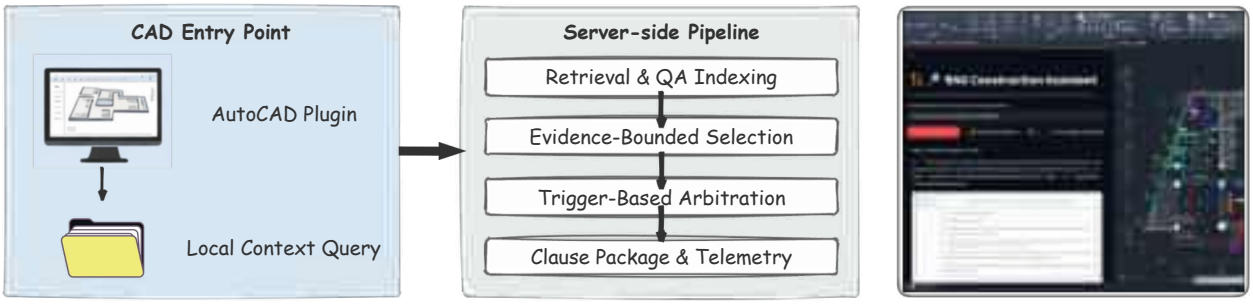

Figure 3. Within-CAD consultation flow reusing the server-side evidence pipeline

Table 4. Evidence-bounded selector results under a fixed top-10 candidate budget (dev200, $n = 200$). Cost is reported as USD per 1K queries.

Selector	Hit@1	MRR	Latency (s/query)	Cost
Qwen-plus	**0.430**	**0.523**	1.418	0.896
Qwen-max	0.395	0.501	2.498	2.944
GPT-4o	0.345	0.470	4.063	5.763
GPT-4o-mini	0.335	0.471	2.145	0.353

tion. Schema checks reject 1.0% of Qwen-plus outputs (2/200) due to out-of-candidate IDs, while other selectors have 0% invalid outputs; rejected cases are counted as misses. Table 4 compares API-based selectors under identical evidence inputs: Qwen-plus achieves Hit@1=0.430 (MRR=0.523) with 1.42 s/query and USD 0.896 per 1K queries, whereas GPT-4o achieves Hit@1=0.345 (MRR=0.470) with 4.06 s/query and USD 5.763 per 1K queries. Section 5.5 complements this fixed-point comparison with a post-hoc budget-feasibility audit of the archived Qwen-plus top-1 outputs under stricter prefix candidate pools.

5.4 Multi-Agent Arbitration Outcomes

Conditional arbitration is assessed on test100 to quantify when multi-agent expert disagreement indicates elevated ambiguity and how often arbitration revises majority selections under the fixed $k = 10$ evidence pool. Governance rates follow Formula 2 and Formula 5: arbitration triggers for 37% of queries and changes the majority top clause for 12% overall (32.4% among triggered cases). On test100, the main benefit concentrates on triggered queries: Hit@1 improves from 0.243 to 0.297 when arbitration is activated, while the overall gain is smaller (0.280 to 0.300) because non-triggered cases are already handled by the majority selector. Clause-ID disagreement accounts for all triggered cases (37/37 cases); applicability disagreement appears in 16 triggered cases as an additional signal, and no span-invalid triggers are observed in this benchmark (Table 5). Section 5.5 further audits how the archived final arbiter decisions remain feasible under stricter retrieval budgets.

Table 5. Arbitration statistics on test100 ($n = 100$). Trigger categories may overlap. Change is measured as whether the final arbiter-selected clause differs from the majority-voted top clause.

Split	Trig. rate	Change rate	Change|Trig.
Test100	37/100 (37.0%)	12/100 (12.0%)	12/37 (32.4%)

Split	Clause disagr.	Appl. disagr.	Span inv.
Test100	37	16	0

Notes: Trig.=arbiter invoked (computed from experts' top-1 clause outputs under the fixed $k = 10$ evidence pool); Change|Trig.=changes among triggered cases; Clause disagr.=experts select different clause IDs; Appl. disagr.=applicability conflict; Span inv.=missing/invalid evidence spans. Categories may overlap.

5.5 Retrieval-Budget Sensitivity and Post-hoc Feasibility Audit

To examine retrieval-depth sensitivity, Dense retrieval is analysed at $k \in \{1, 3, 5, 10\}$ using archived traces on dev200 and test100. Figure 4(a) shows that gold-in-C_k rises monotonically: on dev200, 0.550, 0.765, 0.850, and 0.935; on test100, 0.500, 0.820, 0.890, and 1.000 for $k = 1, 3, 5, 10$, respectively. The largest gain occurs between $k = 1$ and $k = 3$, with smaller gains thereafter, indicating diminishing marginal returns from deeper candidate pools.

Because the archived Qwen-plus selector and multi-agent arbitration runs in Tables 4 and 5 were executed at $k = 10$, downstream sensitivity is assessed through post-hoc feasibility audits under stricter prefix pools C_k. Figure 4(b) shows the results for the archived Qwen-plus run on dev200. Selected top-1 feasibility rises from 0.430 ($k = 1$) to 0.575 ($k = 3$), 0.660 ($k = 5$), and 0.740 ($k = 10$); all 86 correct top-1 decisions already correspond to retrieval rank 1. Figure 4(c) shows the results for the archived arbitration run on test100. The final arbiter-decision feasibility rises from 0.220 to 0.400, 0.620, and 0.880, while feasibility among the 30 correct final arbiter decisions rises from 43.3% to 60.0%, 83.3%, and 100.0%, respectively. Retrieval depth therefore increases reachability, but downstream gains are not linear in k: many correct selector and arbiter decisions are concentrated in highly

ranked candidates, whereas a smaller subset depends on deeper evidence pools.

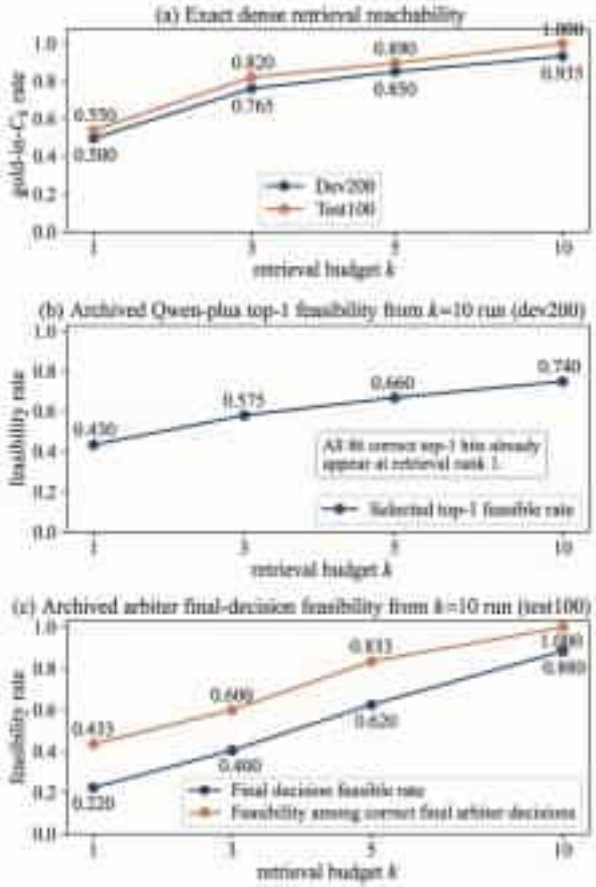

Figure 4. Retrieval-budget sensitivity and post-hoc feasibility audit over $k \in \{1, 3, 5, 10\}$. (a) Exact dense gold-in-C_k rate on dev200 and test100. (b) Post-hoc feasibility of archived Qwen-plus top-1 outputs from the $k = 10$ dev200 run under stricter prefix candidate pools. (c) Post-hoc feasibility of archived final arbiter decisions from the $k = 10$ test100 run under stricter prefix candidate pools.

5.6 Qualitative Case Studies

Two case studies illustrate auditable clause packaging and triggered arbitration under underspecified or cross-discipline conditions. Each reports the query, retrieved top-k clause IDs, the final clause package, and the arbitration trace when triggered; Table 6 provides the compact reporting template. Case B shows that arbitration corrects the majority choice under underspecified hazard-zone attributes by selecting an evidence-aligned clause within the retrieved pool, rather than a topically relevant but scope-mismatched alternative.

Table 6. Compact case study reporting for two representative queries on test100. Top-10 clause IDs are retrieved under a fixed candidate budget; the final clause package records the selected clause and an evidence span (translated excerpt).

Case A (no arbitration)	
Split / qid	Test100 / qid=12
Query	What is the minimum required clear width for a residential building corridor (passage)?
Retrieved top-10 clause IDs	`25429,3683,125838,76891,60520,60519,12735,11011,76499,37937`
Final clause package (ID + evidence span)	25429: "The clear width of a corridor passage shall not be less than 1.20 m."
Applicability (final)	yes
Trigger flags	–
Arbiter change (vs. majority top clause)	No (not triggered)
Case B (arbiter changed)	
Split / qid	Test100 / qid=230
Query	For Zone 20 in a hazardous (explosive) atmosphere, how should electrical equipment be selected per code requirements?
Retrieved top-10 clause IDs	`29097,71780,88188,122388,39587,71781,69799,101799,35034,39588`
Final clause package (ID + evidence span)	71781: "The explosion-proof class/group of equipment shall not be lower than that of the explosive gas mixture present in the environment."
Applicability (final)	yes
Trigger flags	clause disagreement; applicability disagreement
Arbiter change (vs. majority top clause)	Yes (71780→71781)

6 Discussion

Section 5 suggests that reliability in construction-code clause retrieval improves when evidence is bounded and disagreement is treated as a governance signal, rather than resolved through unconstrained generation. Dense retrieval raises the evidential ceiling by placing correct clauses earlier in C_k, while clause-level units keep verification tied to citeable clauses with stable identifiers. The retrieval-budget sensitivity analysis further qualifies the fixed-point results: reachability rises sharply from $k = 1$ to $k = 5$ and then slows, so $k = 10$ should be read as an operating point rather than a universal optimum. Post-hoc audits likewise show that downstream gains are not linear in k: many correct selector and arbiter decisions are already supported by highly ranked candidates, whereas a smaller subset depends on deeper evidence pools. The evidence-bounded selection contract keeps grounding mechanically checkable by requiring cited clause identifiers and evidence spans to remain traceable to retrieved text. For deployment, this supports a low-cost default selector with conditional arbitration for elevated-ambiguity cases. Residual failure sources remain missing scope attributes, long cross-references, and cross-edition drift. Reference-aware retrieval and lightweight attribute elicitation remain practical directions for improving robustness on tightly coupled multi-discipline queries.

7 Conclusion

This paper presented a clause-centric RAG pipeline for building construction code retrieval, where retrieval is treated as auditable evidence discovery and downstream models operate under an evidence-bounded clause-selection contract. By representing standards as clause-level evidence units with stable identifiers and provenance metadata, the system produces clause-addressable evidence bundles for rapid review and mechanical validation.

Experiments across multiple disciplines show that improving top-ranked evidence raises the ceiling for evidence-bounded selection, but that ceiling grows non-linearly with retrieval budget. Exact dense-retrieval sensitivity over $k \in \{1, 3, 5, 10\}$ shows strong reachability gains from $k = 1$ to $k = 5$, with smaller gains thereafter; post-hoc audits of archived $k = 10$ selector and arbitration outputs further show that many correct downstream decisions are already concentrated in highly ranked candidates, while a smaller subset depends on deeper evidence pools. Conditional multi-agent arbitration further serves as a governance layer by concentrating additional reasoning effort on high-risk cases identified through disagreement and evidence-quality triggers.

Together, these design choices support practical deployment under latency and cost constraints while keeping outputs traceable to explicit clause identifiers. Future work will focus on structured elicitation of missing project attributes and systematic handling of cross-standard cross-references for tightly coupled multi-discipline queries.

Abstract -

Rapid informal urban expansion in high-slope terrains presents a critical challenge for disaster risk management, particularly where foundational digital documentation is absent. This study proposes an automated framework for quantifying urban growth and geodynamic hazard exposure by integrating UAV photogrammetry with a Scan-to-BIM workflow. By processing high-resolution point clouds through noise reduction and normal vector calculation to segment horizontal roof planes, building footprints were extracted and converted into Industry Foundation Classes (IFC) models at a volumetric massing level using IfcOpenShell. Longitudinal analysis revealed a substantial rise in dwelling density across the study periods, with the total built-up area expanding significantly. Critically, spatial intersection with terrain models demonstrated that the most aggressive expansion occurred on the steepest slope categories, highlighting increased population exposure to rockslides according to national risk standards. While the study identifies limitations in detecting irregular geometries and unconventional materials, the proposed framework establishes a reproducible, interoperable BIM–GIS bridge that overcomes the temporal and spatial limitations of traditional monitoring in undocumented urban territories.

Keywords -

Urban Digitalization; UAV Photogrammetry; Scan-to-BIM; Informal Settlements

1 Introduction

The process of urbanization at the global level has experienced rapid growth over the last century. In 1990, only 15% of the urban population lived in urban areas [1]. However, this trend increased significantly during the 20th century. For example, in 2018, more than 58% of the world's population lived in urban areas. Current projections indicate that by 2050, more than approximately 75% of the world's population will live in urban areas [1].

In Peru, given that the formal housing supply has failed to meet demand and due to a lack of urban planning, informal settlements have become the main form of urban growth as massive migration from rural to urban areas [2].

Informal settlements refer to the organization of people in search of housing who occupy vacant lots and take collective action to resolve their urban and social organization problems themselves [3]. In cities such as Lima, the capital of Peru, these settlements have expanded into hillside areas, which are typically by unfavorable geographical conditions and, as a result, are exposed to natural hazards[4].

Currently, multitemporal analysis of urban growth based on remote sensing techniques, including 3D change detection [5], time series analysis of land use [6], and advanced approaches such as multitemporal mergers and segmentation using fuzzy logic [7], has become a high-level tool for monitoring informal urban growth at the regional and metropolitan scale using optical satellite and radar images. However, its application in dense informal contexts has some limitations.

One of the main limitations of using optical satellite images is cloud cover, which affects the acceptance of solar radiation reflected by the surface, reducing the quality of the spectral information available and limiting continuous multitemporal analysis. For example, in Lima, persistent cloud cover for several months of the year makes it difficult to capture clear and consistent images over time [2].

In addition, the construction characteristics of informal settlements may introduce additional challenges. The predominant materials used in housing roofs, such as concrete and dry wood, have spectral signatures similar to those of bare soil, which causes spectral confusion in classification processes and makes it difficult to accurately delimit building footprints. This spectral similarity, combined with high building density and the absence of separation between dwellings on a single block, makes it difficult to delimit building footprints. As a result, urban footprint maps created using spectral signatures have unsatisfactory levels of accuracy [8]. In contexts such as in Lima, characterized by desert conditions and exposed soil surfaces, the spectral similarity between housing roofs and soil is intensified [2], increasing the uncertainty of urban footprint extraction.

Although satellite radar images overcome some limitations associated with cloud cover and dependence on solar radiation, gaps remain in relation to spatial and temporal

scale and geometric distortions present in informal urban monitoring [4]. In particular, there is no consensus on the optimal spatial and temporal resolution needed to adequately capture rapid informal urbanization processes [9]. This limitation is evident in studies such as [4], which use Sentinel-1 SAR images to monitor informal growth in areas such as Morro Solar and Lomo de Corvina, where the analysis is based on a set of 14 images acquired between December 2020 and May 2021. This temporal resolution is insufficient to capture rapid changes in real time, while the spatial resolution of 10 m restricts the analysis to estimating occupied areas, without allowing for direct quantification of the number of dwellings.

On the other hand, in informal contexts, the availability of BIM models is practically non-existent, and creating them manually is tedious, costly, and time-consuming [10]. However, generating BIM models from point clouds in these environments can be highly beneficial for gathering information on current conditions, designing interventions, communicating proposals, and raising awareness among residents about environmental issues [11]. Studies such as [12] have shown that the integration of BIM models, visualized on Geographic Information System (GIS)-based platforms, improves the efficiency of urban monitoring and enables applications such as risk assessment in buildings and roads, as well as the development of early warning systems.

In this context, there is a clear need for alternative approaches that allow high-resolution spatial information to be captured with greater temporal flexibility, capable of characterizing the configuration of informal settlements and generating BIM models, particularly those located on slopes exposed to natural hazards.

To address this gap, this study proposes an automated framework for digitizing informal urban environments, integrating data acquired using Unmanned Aerial Vehicle (UAV) with Scan-to-BIM techniques. This approach allows for the automatic extraction of building footprints from point clouds, the generation of BIM models, and the multitemporal quantification of informal housing across different analysis periods. The methodology was applied in hillside areas exposed to rockfalls and landslides, enabling the assessment of informal urban growth and its relationship with the associated hazards, and providing detailed spatial information that can support urban planning and disaster risk management processes. Furthermore, the integration of BIM and GIS provides conceptual support for the representation and analysis of multiscale urban information, aligned with the principles of City Information Modeling and smart cities [13].

2 Related Work

Recent studies have explored the use of data acquired through UAVs and photogrammetric techniques for monitoring informal buildings in urban environments. In [14, 15], the use of oblique photogrammetry with drones was proposed to generate three-dimensional models of the urban environment, allowing the creation of Digital Surface Models (DSM), orthophotographic maps, and 3D models. By analyzing differences between DSMs, they were able to automatically extract and quantitatively analyze informal constructions. Similarly, in [16], a methodology was developed for detecting urban changes by combining differences between dense DSMs and true orthophoto maps (TDOM) generated from aerial images. This approach made it possible to identify changes in both floor plan and height, overcoming the limitations of conventional methods through the use of advanced techniques such as Semi-Global Matching (SGM) and Multi-View Stereo (MVS), and demonstrating high spatial accuracy at the regional scale.

On the other hand, various studies have used synthetic aperture radar (SAR) images and multitemporal approaches for urban growth analysis. In [17], a methodology was presented for the automatic detection of urban changes based on the integration of SAR time series and multispectral data, evaluating the performance of different optical and radar sensors. In the Peruvian context, [2] used SAR images acquired by the Sentinel-1 constellation since 2017 to identify concentrations of urban growth in the Lima metropolitan area, complementing the analysis with high-resolution optical images for the visual identification of informal settlements. Complementarily, in [3], time series of Sentinel-1 SAR images were applied to map the extent of recent occupations in areas with unfavorable soil conditions in the face of seismic events, demonstrating the potential of radar for urban monitoring in vulnerable contexts.

Although these approaches have proven effective for monitoring and detecting informal urban growth, most studies focus on two-dimensional analyses or identifying general patterns of urban expansion. They also have limitations in terms of the precise delimitation and individual quantification of informal dwellings, as well as the automated generation of three-dimensional models that can be integrated into BIM environments, particularly in hillside areas exposed to the risk of rockfalls and landslides.

3 Methodology

Figure 1 illustrates the proposed methodology, which consists of three main components. First, UAV technology is used to efficiently acquire high-resolution data across different analysis periods. These images are processed us-

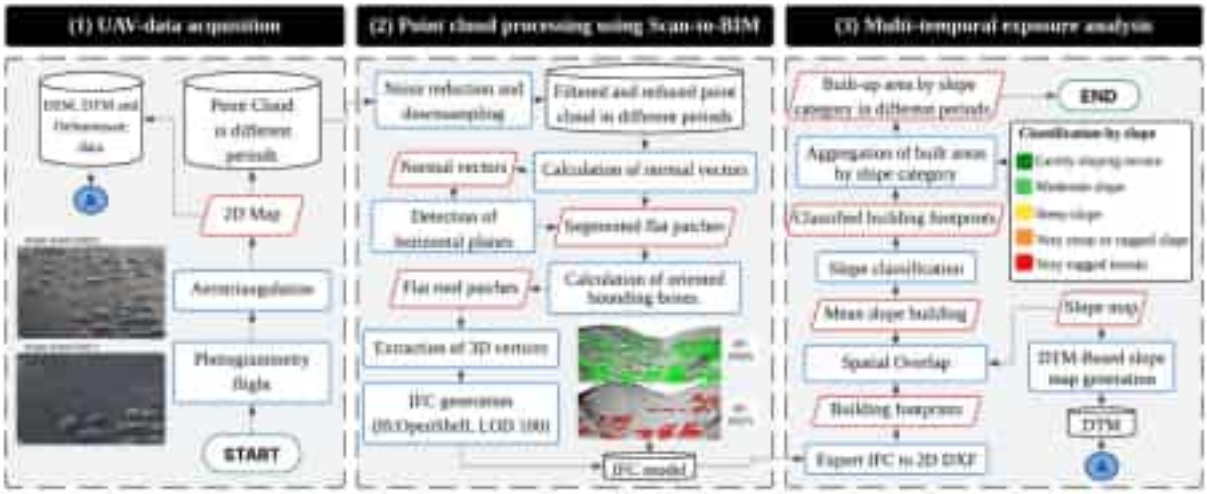

Figure 1. Proposed framework for quantifying exposure in informal urban settlements using UAVs and Scan-to-BIM.

ing photogrammetric techniques to generate point clouds, orthomosaics, and Digital Terrain Models (DTM), which form the geometric and topographic basis of the study.

Second, the generated point clouds are processed using an automated Scan-to-BIM workflow. This process includes noise reduction, normal vector calculation, and the detection of horizontal planes associated with the roofs of the houses. From these geometries, the footprints of the buildings are extracted and BIM models are generated in IFC format using IfcOpenShell, allowing for the digital representation of the houses in the absence of previous documentation.

Finally, the multitemporal analysis is carried out. The IFC models are exported to DXF format to obtain the footprints of the dwellings in a two-dimensional environment, which are intersected with slope maps derived from the DTM. Each footprint is assigned an average slope value, which is then classified into the five ranges of slope established by the National Center for Disaster Risk Estimation, Prevention and Reduction (CENEPRED) of Peru. The aggregation of areas by slope level for each period allows for a temporal comparison of urban occupation based on its exposure. This classification characterizes the terrain's susceptibility to geodynamic hazards, such as rockslides [4] . Finally, the aggregation of residential areas by slope level for each analysis period allows for a temporal comparison of urban occupation, assessing its exposure to hazards associated with highly susceptible terrain.

3.1 Study area

The district of Comas (Figure 2b), located in the province of Lima (Figure 2a), department of Lima, Peru, covers a total area of 48.75 km2 and has 14 zones and 32 urbanizations, with a population density of 9,989.3 inhabitants per square kilometer [18] (see Fig. 2). This study focuses on the Año Nuevo settlement, Zone A (Figure 2c), and covers an area of approximately 0.7 km² [4].

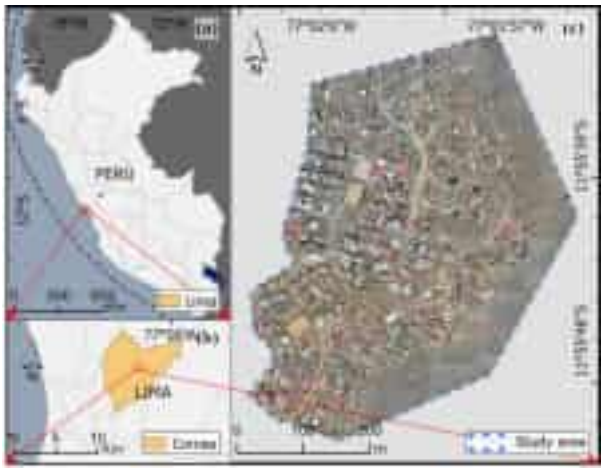

Figure 2. Location map of the study area.

3.2 UAV data acquisition

Data acquisition for the generation of point clouds and 2D maps was performed using photogrammetry for the periods of 2017 and 2025. The flight parameters are pre-

sented in Table 1, which summarizes the specifications of the UAV flights implemented.

Table 1. Technical specifications of UAV flights.

Data	2017 Flight	2025 Flight (%)
UAV model	DJI Phantom 3	DJI Mavic 3 Enterprise (M3E)
Sensor	Integrated RGB camera, FC300X model	High-resolution integrated RGB camera
Camera resolution	12 MP (4000 × 3000 px)	20 MP (5280 × 3956 px)
GSD	7.7 cm/pixel	4.5 cm/pixel

3.3 Scan-to-BIM workflow

The photogrammetric data was processed using DJI Terra 5.1.1, from which the main photogrammetric products were generated, including the DSM, DTM, orthomosaic, and the dense point cloud. Based on the generated point cloud, the Scan-to-BIM methodology was used to produce as-built BIM models of existing buildings, enabling digital documentation and geometric representation of the built environment in areas where no previous BIM information existed [19, 20].

3.3.1 Point cloud preprocessing

The raw datasets for 2017 and 2025 were subjected to noise reduction and spatial downsampling at a 0.05 m resolution. This resolution was selected as a compromise between computational efficiency and the preservation of geometric features relevant for roof segmentation, as finer resolutions did not significantly improve segmentation results while substantially increasing processing cost. This preprocessing balanced computational efficiency with geometric fidelity, significantly reducing the point density while preserving the structural features necessary for morphological analysis (see Tab. 2).

Table 2. Point cloud preprocessing parameters for the 2017 and 2025 datasets.

Dataset	Raw Points	Processed Points	Reduction (%)
2017	30,313,508	11,413,767	62.3%
2025	41,380,614	11,170,087	73.0%

3.3.2 Automated roof detection and segmentation

Roof surfaces were identified by detecting horizontal planes within the processed point clouds. Using the Open3D library, surface normals were estimated via KD-tree–based nearest-neighbor searches. Planar patches were segmented using the Oriented Bounding Box (OBB) method, supported by covariance analysis and local density criteria.

This simplification was guided by the study area, where roofs are predominantly flat or near-horizontal, making them the most reliable feature for building detection. While effective in this context, it may limit applicability in areas with more complex roof geometries. This process identified 1,659 horizontal planes for the 2017 dataset and 1,908 for 2025, forming the geometric basis for the building models.

3.3.3 Semantic alignment and interoperability strategy

The segmented point cloud data were transformed into a structured digital environment by extracting the 3D vertices of detected roof planes to define individual building contours. These geometries were converted into parametric BIM entities at LOD 100, representing the general volumetric massing of the dwellings. The reconstruction process was automated using IfcOpenShell, enabling a reproducible workflow for the generation of longitudinal models for 2017 and 2025.

The workflow was designed to comply with the FAIR principles for geospatial data [21] and to support BIM–GIS integration. The use of IFC as a native data structure enables direct integration with IfcOpenShell for geometry generation, attribute handling, and standardized data exchange, ensuring reproducibility and compatibility with established BIM processing tools [22, 23]. Although each dwelling corresponds conceptually to a single building, the geometry was instantiated as IfcSpace entities as a pragmatic modeling simplification within the implemented workflow. We acknowledge that this choice does not comply with IFC spatial hierarchy conventions, and that each entity should be assigned to an IfcBuilding according to IFC 4.3.

To reduce reprojection errors and information loss during IFC–CityGML transformations, global georeferencing was embedded directly within the IFC output [23]. By adopting LOD 100, the methodology supports efficient processing of high-density informal settlements while enabling standardized and interoperable BIM model generation despite irregular urban morphologies [24, 25].

This approach demonstrates that the absence of prior documentation or the irregular morphology of the built environment does not preclude the creation of standardized, interoperable BIM models [26].

3.3.4 Multitemporal Analysis

Multitemporal analysis was performed to evaluate the evolution of urban occupation in hillside areas between 2017 and 2025, based on the relationship between built-up areas and terrain slope. The main input used was the footprints of the dwellings extracted from the IFC models generated using the Scan-to-BIM methodology, which made it possible to represent urban occupation in a homogeneous environment for both periods.

The footprints of the buildings were integrated with slope maps obtained from the digital terrain model (DTM), allowing each built unit to be assigned a representative average slope value using zonal statistical methods. These values were then classified into the five slope levels established by CENEPRED. Finally, the built-up areas were aggregated by slope level for each period of analysis, enabling a temporal comparison of urban growth based on the topographical conditions of the terrain.

3.3.5 Quantitative Accuracy Evaluation

Numerical validation was performed by comparing the extracted features with a manual ground truth using pixel-by-pixel confusion matrices. The 2025 results show solid performance (precision: 0.919; F1 score: 0.703), thanks to the high resolution and precision of the DJI Mavic 3 drone camera, which minimizes noise. In 2017, although precision was 0.900, the F1 score dropped to 0.384. This lower precision is attributed to a more dispersed and noisy point cloud, resulting from lower-resolution sensors and a higher flight altitude, which, combined with unconventional surface materials, increased false negatives. This evaluation quantifies the reliability and limitations of the proposed automation system in the face of variations in the density and accuracy of the source data.

Table 3. Performance metrics for automated building footprint extraction.

Year	Raw Accuracy	Precision Points	Recall	F1 Score (%)
2017	0.9	0.432	0.345	38.4
2025	0.919	0.578	0.896	70.3

4 Results and discussions

The Scan-to-BIM workflow successfully transformed spatial point cloud data into georeferenced, interoperable BIM models in IFC format. By extracting building footprints and altitudes from detected horizontal planes (roofs), volumetric representations of the informal settlement were generated for the years 2017 and 2025.

4.1 Longitudinal modeling analysis

The automated reconstruction process identified a clear increase in the number of reconstructed dwellings over the eight-year study period.

- 2017 Dataset: Around 1000 dwellings were reconstructed as parametric IfcSpace entities, representing the spatial distribution and volumetric configuration of the settlement at the baseline year (Fig. 3).
- 2025 Dataset: Using identical reconstruction parameters, almost 1600 dwellings were generated. This corresponds to an increase of 682 dwellings, or around 60%, relative to 2017, providing a quantitative indicator of built-up expansion and informal growth within the study area (Fig. 4).

Figure 3. Reconstructed dwelling distribution for the 2017 dataset.

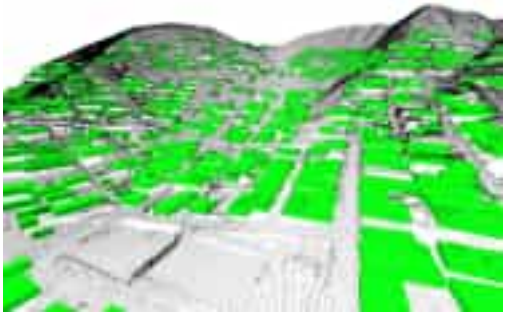

Figure 4. Reconstructed dwelling distribution for the 2025 dataset.

4.2 Multitemporal analysis

The multitemporal analysis made it possible to generate thematic maps of urban occupation for the years 2017 and 2025, as shown in Figures 5 and 6, which represent the footprints of buildings within the study area, each footprint associated with an average slope value and classified into five levels according to the ranges established by

CENEPRED, which allowed for the spatial visualization of the area where the dwellings are located in relation to the topographical conditions of the terrain.

In addition, summary tables were prepared that quantify the total area occupied by dwellings for each slope level and for each analysis period, as shown in table 4. These results made it possible to compare urban occupation between the two years, revealing differences in the spatial distribution of built-up areas according to slope level.

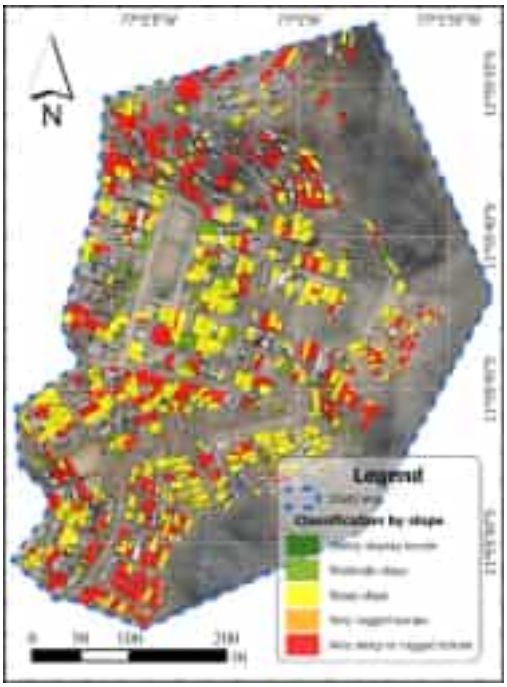

Figure 5. Map of building footprints in 2017 classified by terrain slope levels.

Table 4. Distribution of built-up area by terrain slope level, 2017 and 2025.

Classification by slope	**Slope**	**Area 2017** (m^2)	**Area 2025** (m^2)
	< 5º	173,75	416,25
	5º - 15º	4.005,75	6.287,25
	15º - 25º	21.737,25	21.813,75
	25º - 45º	76,25	924,75
	> 45º	18.766,75	33.142,75
Total area (m^2)		44.759,75	62.584,75

5 Conclusions

This study proposes an automated framework for quantifying the exposure of informal urban settlements over

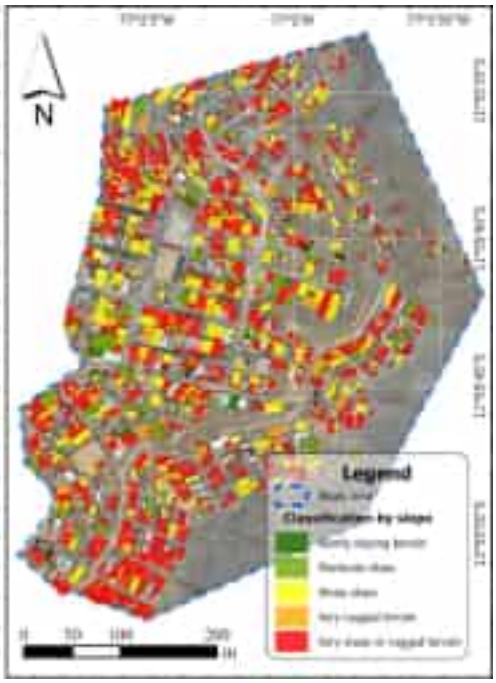

Figure 6. Map of building footprints in 2025 classified by terrain slope levels.

different time periods using UAVs and Scan-to-BIM. The results suggest that the proposed approach allows for: (1) automated digitization of building footprints, (2) generation of BIM models in LOD 100 and their export in IFC format, and (3) multitemporal analysis of urban growth and exposure to hazards. In this sense, the methodology reduces some of the limitations associated with the spatial and temporal resolution of traditional satellite image-based approaches, by providing high-resolution spatial data with greater temporal flexibility. It also minimizes the need for manual and repetitive processing of point cloud data and geospatial analysis.

Despite these advantages, the study also highlights limitations related to the accurate detection of informal dwellings, especially in cases where roof geometries are not flat or are irregular. The presence of unconventional roofing materials, such as corrugated iron and wood, as well as the lack of minimum separation between dwellings, affected the correct delimitation of building footprints. In addition, high noise levels in the point cloud led to the misclassification of surfaces that do not correspond to dwellings, which influenced the accuracy of urban occupation estimates. In this context, it is suggested that future research incorporate automated tools for the detection of non-flat surfaces, as well as methods for automatic classification and noise reduction in the point cloud.

Abstract

Structural Health Monitoring (SHM) systems installed on bridges are increasingly being used to analyze traffic parameters. This includes estimating the gross vehicle weight and may be referred to as Weigh-in-Motion (WIM) methods. However, current research relies predominantly on numerical analyzes, whereas available field experiments are typically performed under quasi-controlled conditions. Such studies often assume that a single vehicle is moving along the predefined path at a known speed. In contrast, real-world traffic is inherently non-deterministic, often making it impossible to precisely define all initial conditions. This article presents the SHM system installed on a network arch bridge in Wolin, Poland. Strains induced by passing vehicles are measured using fiber-optic sensors based on Fiber Bragg Grating (FBG) technology. A neural network (NN) algorithm, whose architecture was optimized using Particle Swarm Optimization (PSO), is then used to estimate vehicle weight, with particular emphasis placed on robustness to traffic-related uncertainties. The system directly incorporates the structural specificity of the bridge and involves multi-gate weight estimations by strain values recorded by a minimal number of sensors. To evaluate the performance of the proposed approach, various tests were performed using real-world traffic experiments, involving multiple vehicles and varying speed. The system achieved a mean absolute percentage error of 4.6%, also for several vehicles on the bridge, complex traffic scenarios, and dynamic effects included.

Keywords –

Structural Health Monitoring; Bridge Weigh-in-Motion; Machine Learning

1 Introduction

Structural Health Monitoring (SHM) is currently one of the fastest growing fields, combining engineering, science, and information technology. These systems integrate various measurement techniques and are widely applied to different types of structures. In bridge engineering, SHM has been increasingly used to estimate road traffic load in the form of Weigh-In-Motion (WIM) systems. It should address the issues associated with the non-deterministic nature, uncertain positioning, and variety of traffic scenarios. The available studies in the literature confirm that WIM is still evolving and remains an important area of industrial research [1].

However, existing WIM applications are subject to several limitations. A significant part of studies are based solely on numerical analyzes [2], while available field experiments are often conducted under quasi-controlled or laboratory conditions [3], [4]. Consequently, this study extends the WIM method, demonstrating the possibility of utilizing the structural specificity of the bridge and allowing the number of sensors required to be reduced. Furthermore, by using three independent measurement gates, the proposed method enables the determination of vehicle weight under unconstrained traffic conditions. The presented approach is resistant to random impact of multiple vehicles and dynamic effects while maintaining a high level of accuracy.

2 Literature review

In many cases, experiments assume the exact position and speed of the vehicle [5], [6]. In reality, traffic flow is inherently random, and therefore the results of such studies may not be fully representative of real-world traffic conditions. For example, Brzozowski et al. [7] investigated the influence of various external factors on the accuracy of weight estimates. Their results show that the vehicle traffic path is one of the most significant contributors to measurement error. For lateral load displacements of up to 50 cm, the total weight prediction

error was approximately 10%, while for displacements exceeding 170 cm, the error increased dramatically to almost 30%.

Furthermore, many current WIM solutions require the definition of specific preconditions [8],[9], distributed measurements, or a large number of sensors, especially the influence line-based applications [10]-[13]. Although a higher level of accuracy can be achieved, the requirement to define input parameters such as the number, spacing of axles, or vehicle speed is often difficult to satisfy in real-world traffic. Moghadam [14] presented an example of the Nothing-on-Road (NOR) WIM application, which assumes the time delay between the strain peaks caused by the traversing axles. The study was conducted using numerical data under controlled conditions. Similarly, Wang et al. [15] proposed a method to estimate vehicle parameters using the vehicle-bridge interaction. In this approach, additional input data was defined in the form of roughness of the road surface, which was estimated using a particle filter. Moreover, the analysis was limited to two-axle vehicles and scenarios involving only a single vehicle. Under these assumptions, the maximum weight estimation error was 11.9%.

Consequently, WIM methods still lack experimental validation in which vehicle position, speed, and traffic composition are not known a priori. The method shown in this paper estimates vehicle weight in unconstrained traffic using three independent measurement gates and a limited number of sensors, while remaining accuracy in random multi-vehicle scenarios.

3 Methodology

3.1 Bridge case study description

This study introduces an SHM system installed on a network arch bridge in Wolin, Poland, in which one of the objectives is the detection of the gross weight of vehicles. The bridge analyzed is a steel structure with a theoretical span of 165.0 m. Its total width is 16.9 m and the height of the arch is 24.0 m (Figure 1).

3.2 System description

The system consists of a network of sensors in which data is acquired and processed using Machine Learning (ML) algorithms. The specificity of the bridge influenced the selection of the sensors, as the most significant feature of the structure is the local nature of the influence area of the crossbeams. Consequently, the increase in the strain in the crossbeams is specifically caused by vehicles located in their immediate vicinity. This ensures that the readings are not affected by vehicles farther away. To improve the robustness of the system and reduce the probability of two vehicles moving side by side in two lanes at the same, three consecutive measurement gates, each consisting of three sensors, are designed, located at 1/4, 1/2, and 3/4 of the span. This configuration allows for estimation of vehicle weight by three independent measurements recorded in different places along the bridge. The network is supplemented with two additional sensors located in the middle of the tie-beams. (Figure 2).

Figure 1. Analyzed arch bridge in Wolin, Poland

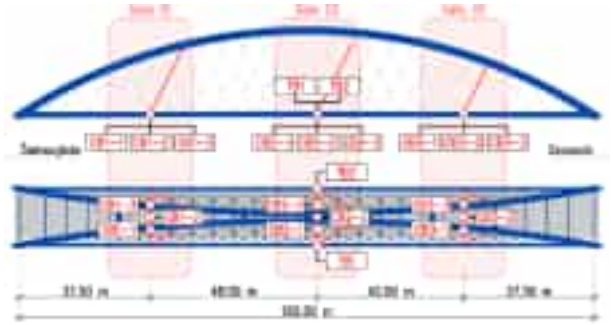

Figure 2. Distribution of the sensors on the bridge

The sensors were spot-welded directly to the surface of the element after the paint layer had been ground off. The sensors on the crossbeams are placed on the top surface of the bottom flange, whereas those on the tie-beams are installed underside of the section. The sensors were subsequently protected against corrosion using a non-hardening, high-adhesion masking sealant. Finally, they were covered with a 0.05 mm thick aluminum foil coated with a 3 mm layer of kneadable putty (Figure 3). The system enables synchronous acquisition of data from all channels allowing for time-correlation analysis.

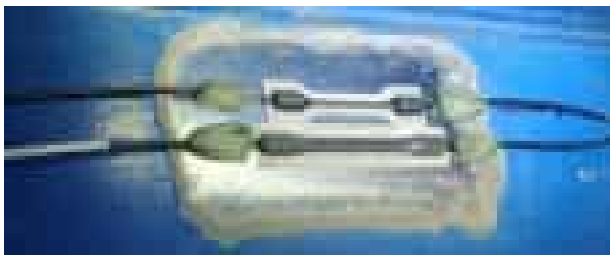

Figure 3. Example configuration of the sensor

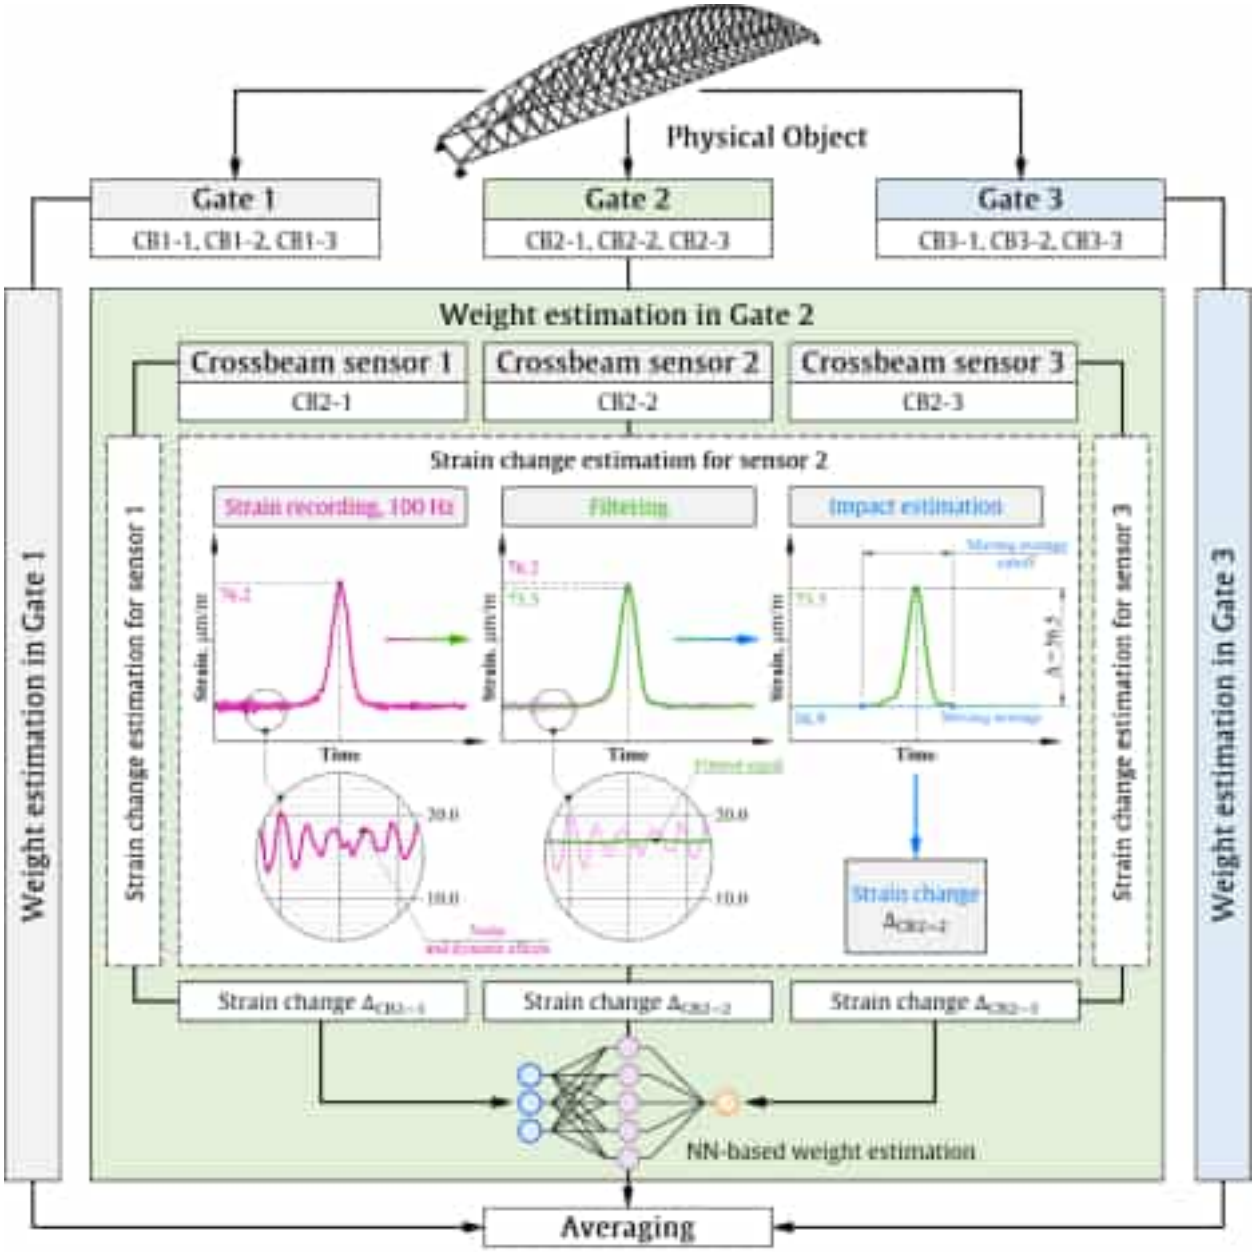

Figure 4. Overview of the proposed weight estimation methodology

The overview of the weight estimation methodology is shown in Figure 4. Each of the nine sensors records the strain with a frequency of 100 Hz. The time-series data are processed by an Infinite Impulse Response (IIR) Butterworth filter. It applies the low-pass design and processes the signal forward and backward to achieve zero-phase distortion. Using the processed signal, the moving average is calculated for each of the sensors independently, excluding outliers that usually indicate the beginning of the load impact. The moving average serves as a base against which the maximum strain value is compared to estimate the strain change due to vehicular load. The strain increases recorded by the sensors are grouped by timestamp and gate and, as such, are passed to the neural networks for weight estimation.

The proposed design incorporates three independent neural networks, each assigned to the specific gate and consisting of three input units. The networks are trained using data obtained through Finite Element (FE) simulation. An important part of the current procedure is an updated bridge FE model, calibrated on the basis of the static load test results. It involved minimization of the difference between the measured and simulated response, including strains and deflections due to a known and precisely arranged load.

The procedure of the FE model calibration involved the results of static load tests with nine trucks positioned in various scenarios, including three loading schemes above each of the measurement gates, individually, and two asymmetrical cases with trucks aligned to the left and right edges of the road. A Genetic Algorithm (GA) was applied, with the objective of minimizing the difference between the strains measured by the SHM system and those predicted by the FE model. The GA consisted of 20 generations of 150 candidates and reached convergence in the last generations. The input parameters of the GA were the elastic moduli of all structural elements with the assumed limit values of 160 – 240 GPa for steel and 5 – 45 GPa for concrete elements. Although the elastic moduli boundaries include values that exceed the standard values for structural steel and concrete, it was assumed that they should reflect different factors that affect the overall stiffness. The effects in question may include, but are not limited to, assembly clearances, inaccuracies in geometrical, material, and structural properties, and stiffness of the non-structural elements like pavement, caps, curbs, barriers or railings.

3.3 Optimization of the NN architecture

Choosing an appropriate neural network architecture is crucial to achieving high accuracy in estimating the gross weight of vehicles. This process involves defining the number of layers, the number of neurons in each layer, the activation function, and the learning rate, and can be formulated as a classical optimization task.

One of the most widely used optimization algorithms is the Particle Swarm Optimization (PSO), which is inspired by the behavior of a herd of animals cooperating to find an optimal solution. In PSO, a population of particles iteratively moves through the solution space, adjusting their position based on their individual best experience and the best position in the entire swarm.

Adopting appropriate values for the coefficients and inertia weight is a crucial element of the PSO algorithm and directly influences the accuracy of the results obtained. In order to balance global exploration and local exploitation, the inertia weight ω was dynamically updated at each iteration of the algorithm (Equation (1)).

$$\omega^{t+1} = \omega_{\max} - \left(\frac{\omega_{\max} - \omega_{\min}}{t_{\max}}\right) \cdot t \qquad (1)$$

where, t_{max} denotes the maximum number of iterations, and t the current iteration. The inertia weight value was assumed in the range between of $\omega_{\min} = 0.4$ and $\omega_{\max} = 0.9$.

To determine the appropriate NN architecture for weight prediction, each PSO particle was represented in a 5-dimensional solution space. This consisted of: the number of layers ranging from 1 to 5, the number of neurons in the first hidden layer, the reduction factor for number of neurons applied to subsequent layers, the learning rate, and the activation function used, encoded in the numerical form: 0: ReLU, 1: leaky ReLU, 2: sigmoid, 3: hyperbolic tangent, 3: ELU, 4: SELU, 5: GELU, and 6: Swish.

The architectural search space was constrained to improve stability and reduce computational cost. The number of neurons in the first hidden layer was selected from a discrete set of powers of two from 32 to 256. The second parameter determining the number of neurons in subsequent layers was the reduction factor α. Instead of directly optimizing the reduction factor, an unconstrained auxiliary variable z was used in the PSO and then mapped to the admissible range via the sigmoid transformation (Equation (2)).

$$\alpha = 0.4 + 0.45 * \text{sigmoid}(z) \qquad (2)$$

Applying such a transformation results in a reduction factor ranging from 0.40 to 0.85 and ensures smooth exploration of the entire solution space. Additionally, layers with a small number of neurons destabilize the gradient propagation and increase the variance of the results, therefore a soft architectural regularization was used. For each particle in which a given hidden layer had fewer than 16 neurons, the Root Mean Square Error (RMSE) value was increased by a relative penalty l proportional to both the current prediction error and the deviation from the minimum layer width (Equation (3)).

$$l = 0.2 \cdot \text{RMSE} \cdot \frac{16 - n}{16} \qquad (3)$$

where n is the number of neurons in the hidden layer.

The learning rate was optimized in the logarithmic domain, with the search space defined between $\log_{10}(0.0005)$ and $\log_{10}(0.1)$ which reflects the multiplicative nature of the learning rate and allows the algorithm to explore different orders of magnitude in a balanced manner. The final NN architectures and their RMSE obtained on the FE-sourced test set are presented in Table 1.

Table 1. NN architecture after PSO algorithm

Gate	**Number of layers**	Reducing factor	1st layer	2nd layer	3rd layer	4th layer	5th layer	Learning rate	Activation function	RMSE (kg)
1	4	0.8483	256	217	184	156	–	0.0008	GELU	97.0
2	3	0.5720	256	146	84	–	–	0.0119	GELU	115.3
3	4	0.6896	128	88	61	42	–	0.0061	Swish	110.8

4 Results

The accuracy of the system has been verified using vehicles of known weights and different configurations of axles, passing the bridge in various scenarios. The basic scenario, representing the target traffic conditions expected during the operational phase and detailed in Section 3.1, consists of a single truck passing the bridge in the left or right lane. Exemplary passages of multiple trucks and involving varying speed are presented in Sections 3.2 and 3.3, respectively.

4.1 Single-truck runs

The single-truck tests involved nine types of vehicles with gross weights in the range between 27.8 t and 41.5 t and a wheel arrangement including 3 to 6 axles (Table 2). Figure 5 shows the strain change in consecutive gates during a run of a 4-axle truck of 32.7 t total weight. The vehicle moves in the direction of the target traffic, first passing through Gate 3, then Gate 2, and finally Gate 1. The most significant strain increase is observed in the middle sensors, CB1-2, CB2-2, and CB3-2, in Gates 1, 2, and 3, respectively. The magnitude of strain increase in the outer sensors is consistent in all three gates and indicates the pass of the truck on the lane by side of the sensors labeled CB1-3, CB2-3, and CB3-3. The gross vehicle weight is independently estimated by each gate, resulting with values 34.4 t in Gate 1, 33.8 t in Gate 2, 33.4 t in Gate 3, and the average of 33.9 t (error: 3.5%).

The results of the rest of the single-truck runs, 18 in total, and the mean performance metrics of the system are given in Table 2. The mean absolute percentage error of 4.6% and respective mean absolute error of 1.5 t is achieved in the given scenarios, while maintaining the mean percentage error of –2.6% and the mean error of 0.7 t when considering the sign of predictions against the true values. Two tests out of the performed ones, namely the 6-axle truck of 41.4 t in the right lane and the 3-axle truck of 28.7 t in the left lane, are clearly outstanding. This kind of effect can be accounted for additional uncertainties related to transversal positioning of vehicles, axle configuration, and the overall impact of the axles spacing compared to the range of the influence area.

Table 2. Weight estimation and performance metrics in single-truck tests: ACC – Accuracy, MPE – Mean Percentage Error, MAPE – Mean Absolute Percentage Error, ME – Mean Error, MAE – Mean Absolute Error

		Weight estimation, w				**Metrics**

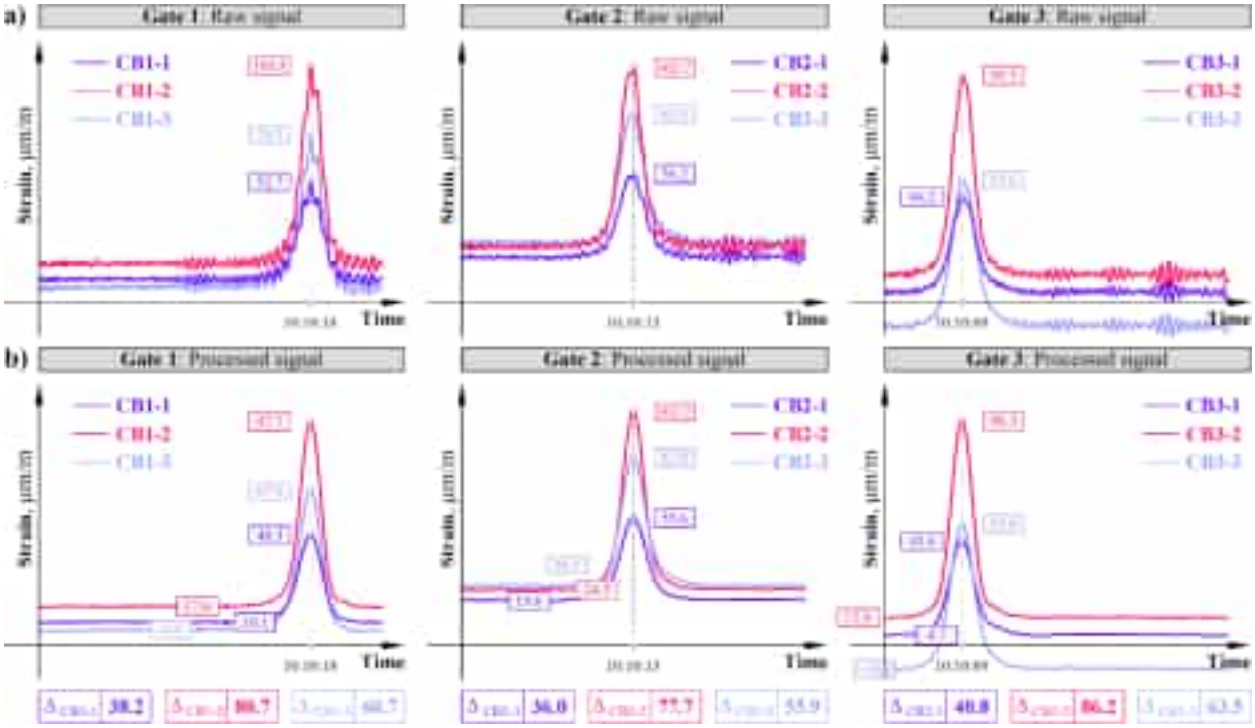

Figure 5. Exemplary strain change in a single-vehicle test in three consecutive measurement gates: a) raw signal, b) filtered signal, moving average, and the respective strain change

4.2 Multiple-truck runs

Although still relatively rare, the system should be resistant to vehicles arranged in groups and crossing the bridge in a convoy. To measure accuracy in this kind of scenarios, several tests were performed, among which the passage of 4-axle trucks of gross weights 33.0 t, 32.2 t and 32.7 t in the right lane was reported in the paper. The overview of the raw and filtered signals is shown in Figure 6. The performance of the system maintains the desired accuracy given by the MPE of –2.2%, MAPE of 2.2%, and both ME and MAE of 0.7 t, despite the clear overlapping of the second and third impacts. Thanks to the reduced range of the influence surface for crossbeam strains, relatively close vehicles can be separated and estimated with no additional measures, just due to the structural specificity of network arch bridges. The weight estimations reported for the three trucks in the test convoy are given in Table 3.

4.3 Runs of varying speed

Considering that specific applications are prone to the varying speed of vehicles, including the influence line-based ones, the given approach is evaluated against different velocities of trucks passing the bridge. An integral part of field tests is the vehicle moving at a speed of 30 km/h through an artificial obstacle, in this case a transversal step on the carriageway. In the given context, the step allows inducing additional dynamic excitations

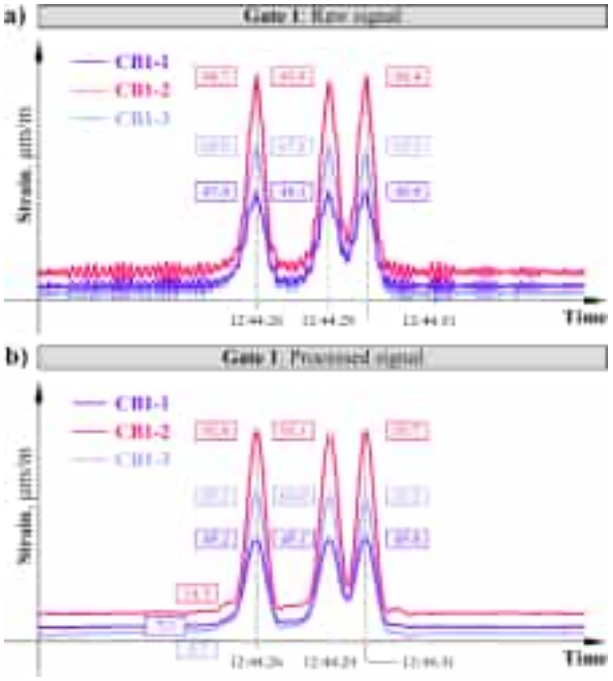

Figure 6. Exemplary strain change in a multiple-vehicle test in the Gate 1: a) raw signal, b) filtered signal

and signal disturbance and evaluate the system against unpredictable side-effects. The tests performed, among which the passage of the 4-axle truck in the left lane is

reported in the paper, indicate the consistent performance in varying speed conditions. In Figure 7, compared to Figure 5, the strain increase in the sensors CB1-1 and CB1-2 in Gate 1, CB-2-1 and CB2-2 in Gate 2, and CB3-1 and CB3-2 in Gate 3 are alike, indicating the placement of the vehicle being away from the CB1-3, CB2-3, and CB3-3 sensors in the consecutive gates. One should note the distinctive signal artifacts in the 30 km/h passage with the artificial step mounted right above the gate. Despite the perturbations, the filter is able to reduce additional effects, and produce clear enough signal for further processing by the neural network.

Table 4 and Figure 7 report gross vehicle weights for varying passage velocities, indicating consistent results given by MPE of –0.8%, MAPE of 2.9%, ME of 0.3 t, and MAE of 0.9 t. Based on the results, the presented approach allows for achieving good estimation accuracy regardless of the accompanying dynamic effects and variations in vehicle type.

5 Limitations

The proposed WIM approach constitutes a promising solution for long-term bridge monitoring under realistic traffic conditions, however several aspects may benefit from further investigation. The current validation was conducted on a single bridge structure, and future work will focus on extending the methodology to other bridge types. In addition, the neural networks were trained using data from a calibrated finite element model, which proved effective but could be further enhanced with larger datasets obtained directly from field measurements.

Moreover, although a range of vehicle configurations was considered, expanding the dataset may further improve the robustness of the model. These aspects do not affect the overall applicability of the method but rather indicate its potential for further development.

6 Conclusions

This research integrates the bridge SHM system using FBG sensors and ML to estimate the gross vehicle weight in real-word traffic. Unlike many existing WIM studies, the proposed approach was experimentally validated under realistic traffic conditions, without requiring prior knowledge of vehicle path or speed as input to the estimation algorithm.

The system achieved an average MAPE of 4.6% for single-vehicle run and 2.2% for multiple-vehicle runs, confirming its robustness to varying traffic scenarios. Moreover, the influence of vehicle speed and dynamic effects was shown to be limited and did not significantly degrade the prediction accuracy.

A key feature of the proposed methodology is the use of three independent measurement gates distributed along the span. The structural features of the network arch bridge, primarily the short-range influence area of the crossbeam strain, proved to beneficial in separating closely spaced vehicles, constituting an important component of the framework.

Abstract –

Heat-related illnesses (HRIs) pose a persistent threat to construction workers' safety. Effective risk assessment enables early detection of hazardous conditions and timely prevention of illness, yet incident logs and narrative reports are seldom leveraged for computational risk analysis. This research develops a data-driven framework to (i) identify HRIs from routine safety records and (ii) predict heat-related risk based on historical incident and environmental conditions to support planning and site controls. The approach combines text mining and supervised classification to detect heat-related cases from narratives, supported by structured incident details, including task, project context, and HRI indicators. Incident time and location are combined with environmental heat-stress indices to analyze environment–task–risk relationships. A predictive model is developed to estimate near-term risk levels for various construction activities. Results reveal clear seasonal and regional patterns, with higher risks in outdoor and heavy-civil operations during prolonged heat waves. The classification model performed well, with an F1 score of about 0.72–0.81 across trade groups, and probabilistic heat-related risk prediction offers actionable lead time for planning adjustments. The risk scores provide a foundation for potential integration into construction scheduling systems to support work–rest planning, hydration strategies, shade provisioning, and task resequencing during high-heat periods. This work provides a scalable computational framework that transforms routine safety records into predictive insights, enabling proactive, climate-aware risk mitigation in construction.

Construction; Heat-related Illnesses; Heat Stress; Prediction; Risk Assessment

1 Introduction

The construction industry remains one of the most labor-intensive and risk-prone sectors worldwide, where workers are frequently exposed to physically demanding tasks, hazardous environments, and adverse climatic conditions [1-3]. Among environmental stressors, occupational heat exposure has emerged as a critical and escalating threat due to rising global temperatures, intensifying heat waves, and prolonged outdoor work durations [1-6]. Elevated heat exposure has been associated with reduced physical performance, impaired cognitive function, increased fatigue, and heightened risk of occupational injuries, particularly in labor-intensive construction activities such as heavy civil, infrastructure, and building operations [7-9]. As climate change continues to amplify thermal stress across geographic regions, heat-related health risks in construction are expected to intensify, reinforcing the need for improved prevention and mitigation strategies [10-12].

Effective identification and prediction of heat-related illnesses (HRIs) are central to protecting worker health and supporting proactive safety management in construction environments [13, 14]. Timely detection of hazardous heat conditions enables the implementation of preventive interventions, such as optimizing the work–rest cycle, planning hydration, rescheduling tasks, and deploying cooling or shading resources [15-17]. Predictive heat-risk modeling further strengthens operational decision-making by providing early warnings that help reduce injury rates, minimize productivity losses, and lower medical and compensation costs [8, 18, 19]. As regulatory agencies and industry stakeholders increasingly recognize heat exposure as a critical occupational hazard, data-driven identification and forecasting mechanisms are becoming integral to modern construction safety frameworks [20, 21].

Previous studies have proposed a variety of approaches for assessing heat exposure and managing

thermal risk in occupational settings, including physiological monitoring, wearable sensing technologies, heat-stress indices, and real-time environmental advisory systems ([4, 22]. Research has examined the influence of meteorological variables, workload intensity, acclimatization, and organizational controls on worker heat strain and injury outcomes [7, 8, 23]. More recently, machine learning and artificial intelligence techniques have been applied to predict heat strain, occupational accidents, and safety risks, demonstrating promise for automated hazard detection and decision-support applications [12, 18]. In parallel, organizational and policy-based interventions have been explored to enhance heat awareness, regulatory compliance, and protective behaviors among construction workers [24].

Many existing models rely on physiological sensors, wearable devices, or experimental data collected under controlled conditions, which constrains scalability and limits practical deployment across large construction workforces [11, 16, 22]. Despite these advances, several critical knowledge gaps remain. First, existing research largely relies on structured datasets or sensor-based measurements, while unstructured narrative safety records remain underutilized for identifying heat-related risks. Second, few studies integrate historical construction injury data with environmental heat-stress indicators to establish explicit environment–task–risk relationships. Third, prior work has focused primarily on general heat exposure or physiological responses, with limited attention to task-specific risk stratification and severity-oriented modeling using real-world incident data [25, 26]. Incident narratives frequently contain rich contextual information about environmental exposure, work tasks, symptoms, and contributing risk factors, yet these unstructured data sources remain underutilized in computational safety analytics. In addition, few studies have integrated historical construction injury records with environmental heat-stress metrics to develop probabilistic heat-related risk predictive frameworks tailored specifically to construction operations [14, 17]. These gaps indicate a need for scalable, data-driven methodologies that transform existing safety documentation into actionable heat-risk intelligence.

This study develops a computational framework to identify HRIs to predict probabilistic heat-related risk by integrating historical injury records with environmental heat-stress indicators. The study seeks to answer three research questions: How effectively can HRIs events be detected using text-based analysis of occupational incident narratives? Which environmental and task-related factors are most strongly associated with heat-related risk in construction activities? Can historical safety records be leveraged to forecast near-term heat risk to support proactive planning and site-level intervention?

2 Literature Review

Table 1 summarizes key prior studies on occupational heat stress, predictive safety modeling, and data-driven construction risk assessment, highlighting their data sources, methodological approaches, and limitations.

Table 1. Prior Studies on Heat Stress in Construction

Study	Focus / Data Source	Key Findings & Limitations
[7]	Experimental heat exposure data	Identified physiological heat stress thresholds; limited real-world field scalability
[4]	Climate and occupational health data	Linked heat indicators to worker health outcomes; not construction-specific
[8]	Construction field injury data	Associated heat exposure with injury risk; limited predictive capability
[22]	Wearable physiological sensor data	Enabled real-time heat strain monitoring; costly and difficult to scale
[27]	Environmental heat index datasets	Proposed heat-stress assessment metrics; no injury outcome integration
[19, 28]	Construction injury records	Applied machine learning to predict safety risk; relied on structured data only
[14]	Historical construction safety data	Modeled task-based injury risk; did not incorporate heat exposure
[18]	Multi-source safety datasets	Improved automated hazard detection using AI; limited climate integration
[25]	Incident narrative text data	Extracted safety risk factors using natural language processing (NLP); not heat-specific
[26]	Construction safety narratives	Demonstrated text-based risk prediction; HRIs not addressed

2.1 Occupational Heat Stress in Construction

Heat stress has been widely recognized as a major occupational health hazard, particularly in labor-intensive industries such as construction, where prolonged outdoor exposure and physically demanding tasks elevate physiological strain [4, 7]. Prior research has linked high ambient temperatures and humidity to increased fatigue, dehydration, reduced cognitive performance, and heightened risk of injury among construction workers [8, 9]. These effects are often exacerbated by inadequate rest schedules, insufficient hydration, and limited access to cooling resources [23].

Several studies have examined the broader implications of climate change on occupational heat exposure, highlighting the growing frequency and intensity of heat events and their disproportionate impact on outdoor workers [6, 11].

2.2 Heat Risk Monitoring and Measurement Approaches

A range of methods has been proposed to quantify and monitor heat exposure in occupational environments. Traditional approaches rely on environmental heat-stress indices, such as temperature–humidity metrics, Wet Bulb Globe Temperature proxies, and meteorological forecasting models [16]. Other studies have focused on physiological monitoring, employing wearable sensors to track heart rate, body temperature, sweat rate, and metabolic workload in real time [22].

While sensing technologies offer high-resolution physiological data, their deployment at scale is often constrained by cost, maintenance requirements, privacy concerns, and worker compliance challenges [11, 22].

2.3 Predictive Modeling and Machine Learning for Safety Risk

Machine learning and artificial intelligence techniques have increasingly been applied to occupational safety research, enabling predictive modeling of accident risk, hazard exposure, and injury likelihood [12, 18]. In construction contexts, predictive models have been developed to estimate injury risk based on task attributes, environmental factors, worker demographics, and historical incident data [14].

Several studies have demonstrated the potential of supervised learning algorithms, including decision trees, support vector machines, and ensemble models, for forecasting safety outcomes and supporting proactive intervention [19]. However, many existing models rely on structured datasets and do not fully leverage unstructured narrative data or historical safety documentation, limiting their ability to capture nuanced causal and contextual risk factors [25, 29].

2.4 Use of Safety Records and Data for Risk Analysis

Occupational safety incident reports contain rich qualitative information describing task conditions, environmental context, worker behavior, and contributing factors. Recent research has explored the use of NLP to extract risk indicators, classify injury mechanisms, and automate hazard identification from narrative safety records [25, 26]. Despite growing interest in narrative-based safety analytics, few studies have applied text-mining techniques to identify HRIs or to link narrative injury data to environmental heat metrics [12, 29].

Despite these advances, existing studies have not fully integrated narrative-based safety data with environmental heat metrics to develop scalable, task-specific, and probabilistic heat-risk assessment frameworks in construction.

3 Materials and Methods

This study employed a retrospective, data-driven analytical framework to identify HRIs cases in construction and to predict probabilistic heat-related risk using historical occupational safety records and environmental heat indicators. The methodology integrates natural language processing, supervised machine learning, and predictive modeling to extract heat-related risk signals from narrative-based incident reports and structured injury attributes. Figure 1 illustrates the overall methodological workflow from data acquisition to predictive modeling.

Figure 1. Methodological Workflow for HRIs Identification and Risk Prediction

3.1 Data Sources and Study Sample

This study adopted a retrospective, data-driven research design to identify HRI cases in construction and

to develop a predictive framework for probabilistic heat-related risk. Occupational injury and incident records were obtained from the OSHA Severe Injury Reports database, covering construction-related incidents across multiple industry subsectors, including commercial, industrial, residential, highway, utility, and pipeline construction. Each record contains structured attributes such as event date, geographic location, industry classification, injury type, and severity indicators, along with an unstructured narrative field describing the circumstances, contributing factors, and outcomes of each incident. Only construction-related cases with complete narrative descriptions were retained for analysis. Table 2 summarizes the primary data sources and analytical variables used in the study.

Table 2. Data Sources and Key Variables Used in the Study

Data Source	Variable Category	Key Variables
OSHA Severe Injury Reports	Incident & injury data	Event date, location, NAICS, injury type
OSHA Final Narrative	Unstructured text	Heat exposure cues, symptoms, task context, risk factors
NOAA / Meteostat weather	Environmental heat	Temperature, humidity, heat index, WBGT proxy
Derived temporal features	Time & seasonality	Month, season, heat-wave indicator
Machine learning features	Modeling inputs	TF–IDF text features, structured injury fields, heat metrics

3.2 Narrative Processing and Heat-Related Case Identification

Incident narratives in the Final Narrative field served as the primary source for identifying heat-exposure conditions, symptoms, and contributing risk factors. Text data were pre-processed using standard natural language processing procedures, including normalization, tokenization, lemmatization, and removal of non-informative terms. Heat-related linguistic cues and symptom descriptors were compiled to support the semantic interpretation of narratives.

A supervised classification approach was used to distinguish heat-related from non-heat-related incidents. A subset of records was manually labelled based on narrative evidence of heat exposure, thermal stress symptoms, or heat-induced medical outcomes. The labeling process was conducted by two independent reviewers with domain knowledge in construction safety. Incidents were classified as heat-related if the narrative contained explicit references to elevated ambient temperature or heat exposure, or described symptoms consistent with heat-related illness, such as dizziness, heat exhaustion, or loss of consciousness. Inter-annotator agreement was evaluated using Cohen's kappa, and any discrepancies were resolved through discussion to achieve consensus labeling. Textual features were extracted using term-frequency–inverse-document-frequency representations and combined with relevant structured injury attributes.

Model hyperparameters were selected via a 5-fold cross-validation grid search. Key parameters, including regularization strength, class weighting, and TF–IDF feature settings (e.g., n-gram range and minimum term frequency), were systematically varied to identify the configuration that maximized F1-score. This approach ensured model performance while mitigating overfitting.

3.3 Environmental Heat Exposure Integration

Incident records were linked to historical meteorological conditions using reported event dates and geographic coordinates. Weather data were retrieved from gridded historical climate datasets to obtain hourly and daily measurements of ambient temperature, relative humidity, and related atmospheric variables at the time and location of each OSHA incident. When precise hourly timestamps were unavailable, daily averages and maximum heat values were used to approximate environmental exposure conditions.

Composite heat-stress indicators, including the heat index and a Wet Bulb Globe Temperature (WBGT) proxy, were computed to characterize the thermal load at the time of each event. These indices were derived from established thermophysiological formulas that combine temperature and humidity to estimate perceived heat stress. Additional temporal variables, such as season, month, and heat-wave occurrence, were generated to capture climatic patterns and prolonged heat exposure.

3.4 Predictive Modeling of Heat Risk

To estimate probabilistic heat-related risk in construction operations, predictive models were developed to assess the likelihood of heat-related incidents based on environmental exposures, industry subsector, temporal factors, and narrative-derived risk indicators. Supervised learning algorithms, including logistic regression and ensemble tree-based models, were trained to generate probabilistic heat-risk scores. Feature-importance analysis identified key predictors of heat risk, thereby enabling interpretation of the environmental and operational drivers of heat-related incidents.

4 Results

4.1 Dataset Summary and Incident Characteristics

The final OSHA construction dataset included 216 reportable incidents recorded between 2015 and 2023, spanning eight construction subsectors. Highway construction accounted for the largest share of records (30.6%), followed by commercial building construction (23.1%) and water and sewer line construction (13.4%). Incident narratives averaged 52.3 ± 18.6 words, providing textual detail for narrative-based analysis. Temporal distribution indicated that 61.8% of incidents occurred between May and September, consistent with peak seasonal heat exposure. Table 3 summarizes the distribution of incidents across construction subsectors.

Table 3. Distribution of OSHA Construction Incidents by Subsector

Construction Subsector	NAICS Code	Incident Count	Percentage (%)
Highway / Street / Bridge	237310	66	30.6
Commercial Building	236220	50	23.1
Water / Sewer Line	237110	29	13.4
Power / Communication Line	237130	25	11.6
Industrial Building	236210	20	9.3
Oil & Gas Pipeline	237120	12	5.6
Other Heavy / Civil	237990	9	4.2
Single-Family Residential	236115	5	2.3
Total	—	*216*	*100.0*

4.2 Narrative-Based Analysis of Incident Causes

Analysis of the Final Narrative field revealed distinct causal patterns between heat-related and non-heat-related incidents. Among heat-related cases (n = 47), the most frequently reported contributing factors were heat exposure or high ambient temperature (78.7%), physical overexertion (63.8%), dehydration or inadequate fluid intake (46.8%), and prolonged sun exposure (42.6%). Commonly documented physiological symptoms included dizziness or fainting (51.1%), heat exhaustion (38.3%), and loss of consciousness (23.4%), indicating acute heat strain as a primary mechanism of injury.

Task-level narrative evidence showed that outdoor, labor-intensive operations, including asphalt paving, concrete placement, trenching, roofing, and utility line installation, occurred in 69.1% of heat-related incidents. Furthermore, limited access to shade or cooling resources was noted in 34.0% of heat-related narratives, and insufficient rest breaks were cited in 28.9%, suggesting gaps in heat-mitigation practices.

In contrast, non-heat-related incidents (n = 169) were predominantly associated with falls (31.4%), struck-by events (26.0%), equipment-related injuries (22.5%), and material-handling incidents (18.9%), indicating fundamentally different causal mechanisms. These findings show that heat-related incidents have distinct exposure conditions, symptom profiles, and operational risk factors, underscoring the value of narrative-based analytics for differentiating injury etiology in construction safety data.

4.3 Heat-Related Illness Identification Performance

The supervised NLP classifier identified 47 incidents (21.8%) as HRIs within the OSHA construction dataset. Model performance, evaluated using five-fold cross-validation, demonstrated stable classification capability, yielding a mean accuracy of 0.84 (95% CI: 0.81–0.87), precision of 0.79 (95% CI: 0.75–0.83), recall of 0.76 (95% CI: 0.72–0.80), and an F1-score of 0.81 (95% CI: 0.78–0.84). The classifier achieved an ROC–AUC of 0.87, indicating high discriminative power between heat-related and non-heat-related narratives.

Subsector-specific performance analysis revealed modest variation across trade groups, with F1-scores ranging from 0.72 in residential construction to 0.81 in heavy civil construction, suggesting consistent generalizability across operational contexts. Collectively, these results demonstrate that narrative-based machine learning can reliably distinguish heat-related occupational incidents from other injury events. Table 4 summarizes the classification performance metrics.

Table 4. Performance of the HRIs Classification Model

Metric	Value
Accuracy	0.84
Precision	0.79
Recall	0.76
F1-score	0.81
ROC–AUC	0.87
Heat-related cases identified	47
Share of dataset (%)	21.8

4.4 Environmental Heat Exposure at Time of Incidents

Meteorological observations obtained from NOAA/Meteostat were successfully linked to 94.9% of OSHA construction incidents recorded between 2015 and 2023, enabling a quantitative assessment of ambient

thermal exposure at the time of injury. Comparative analysis revealed that heat-related incidents occurred under significantly greater heat stress than non-heat incidents. Wet Bulb Globe Temperature (WBGT) proxy was 28.9°C for heat-related incidents versus 24.7°C for non-heat incidents (mean difference = 4.2°C; Cohen's d = 1.21), reflecting substantially elevated physiological heat strain. As shown in Figure 2, 44.7% of heat-related cases occurred in July and August, corresponding to periods of peak regional thermal load.

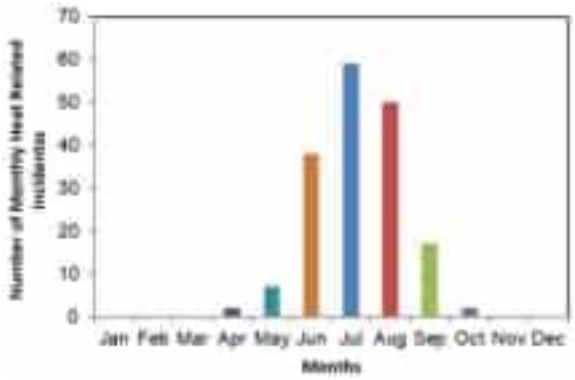

Figure 2. Monthly Distribution of Heat-Related OSHA Incidents

4.5 Predictive Heat-Risk Model Performance

The risks of HRIs were modelled as a binary outcome at the incident level, as presented in Equation 1, where indicates whether the OSHA incident $i$was classified as heat related. The probability of HRIs occurrence was estimated using a regression model in which explicitly defined risk factors ,derived from OSHA Narrative text and structured incident attributes ,served as predictors:

$$P(HRI_i = 1) = 1 / (1 + exp(-(\beta_0 + \beta_1\, DEHYD_i + \beta_2\, OVEREX_i + \beta_3\, OUTDOOR_TASK_i + \beta_4\, MONTH_i + \beta_5\, SECTOR_i))) \quad (1)$$

Where $P(HRI_i = 1)$denotes the predicted probability that the incident $i$is heat-related, and $\beta_0$through β_8, are the estimated model coefficients. The binary predictors $HEATEXP_i$, $DEHYD_i$, $OVEREX_i$, SUN_i, $SHADE_i$, and $REST_i$ indicate the presence (coded as 1) or absence (coded as 0) of narrative-identified risk factors extracted from the OSHA Narrative field. These indicators represent explicit mentions of heat exposure or elevated ambient temperature, dehydration or insufficient fluid intake, physical overexertion, direct sun exposure, limited access to shade or cooling resources, and inadequate rest breaks, respectively. Temporal variation is captured by $MONTH_i$, encoded as categorical month indicators with January serving as the reference category, while industry context is represented by $SECTOR_i$, encoded as construction subsector indicators with a defined reference subsector.

Table 5 reports the fitted coefficients, odds ratios, standard errors, and 95% confidence intervals. Physical overexertion emerged as the strongest predictor of severe heat illness, with an estimated coefficient of $\beta = 2.95$corresponding to an odds ratio of 19.11 (95% CI: 7.66–47.65; $p < 0.001$). This indicates that incidents involving exertion-related language were associated with a nearly 20-fold increase in the odds of severe heat outcomes.

Table 5. Logistic Regression Coefficients for Predicting Severe Heat-Related

Predictor	β	Interpretation
Intercept	−2.104	Baseline odds of severe heat illness when all predictors = 0
Dehydration mentioned (DEHYD)	−3.111	Dehydration mentions are associated with lower odds of severe outcomes, likely reflecting reporting patterns in non-collapse cases
Overexertion mentioned (OVEREX)	2.950	Overexertion increases the odds of severe heat illness by ~19×
Outdoor high-intensity task (OUTDOOR _TASK)	0.543	Outdoor heavy work increases odds by ~72% (not statistically significant)
Month (numeric)	−0.094	Each month later in the year reduces the severity odds by ~9%
Construction subsector (SECTOR)	Category -specific	Risk varies across subsectors relative to the reference sector

The model output is a continuous probability value between 0 and 1, interpreted as an incident-specific heat risk score. To compute $P("HRI"_i = 1)$ for any OSHA record, a reader may substitute observed predictor values into the linear predictor term, sum the corresponding coefficient contributions, and apply the logistic transformation. Figure 3 also shows the relative effect sizes of narrative-derived risk factors on the odds of severe heat-HRIs.

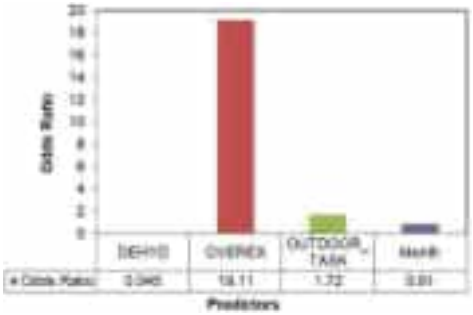

Figure 3. Odds Ratio Effect Sizes of Narrative-derived Risk Factors Predicting Severe HRI

4.6 Risk Stratification by Construction Activity

Risk stratification analysis revealed substantial heterogeneity in predicted HRI probabilities across construction activities, reflecting variation in physiological workload, exposure duration, and task intensity. Predicted risk scores from the fitted logistic model were aggregated by activity type to quantify differential vulnerability across operational contexts. Activities involving high physical exertion and prolonged outdoor exposure had the highest predicted heat-related risk. Asphalt paving, roofing, trenching, concrete placement, and utility-line installation ranked among the highest-risk task categories, with mean predicted severe-heat probabilities exceeding 0.65 and upper-quartile probabilities surpassing 0.80.

In contrast, activities with lower metabolic demand, such as interior finishing, equipment inspection, and light electrical work, showed lower risk, with mean probabilities below 0.35. The mean difference in predicted risk between high-intensity outdoor tasks and lower-intensity activities exceeded 0.30. Subsector-level stratification further indicated elevated risk concentrations in heavy civil construction, followed by utility and pipeline installation, consistent with their greater reliance on continuous outdoor labor under thermally stressful conditions. Conversely, commercial building and interior construction exhibited comparatively lower predicted heat-related risk profiles.

5 Conclusion

This study developed a data-driven model to identify, quantify, and stratify heat-related injury risk in construction, leveraging OSHA incident narratives, structured injury records, and predictive modeling. By extracting mechanistic risk factors from injury narratives and modeling their association with HRIs' severity, the analysis advances beyond descriptive or seasonal assessments toward a task-specific and causally informed understanding of heat-risk dynamics.

The results indicate that physical overexertion is the primary driver of HRI, with elevated odds of acute outcomes among incidents involving high metabolic workload. Risk stratification further demonstrates that outdoor, labor-intensive activities, including paving, roofing, and utility installation, exhibit a high predicted severity. The resulting predictive model provides a probability-based risk score that supports heat-mitigation planning, work–rest scheduling optimization, and the prioritization of high-risk construction tasks.

Several limitations warrant consideration. First, the analysis relies on OSHA narrative records, which may contain reporting inconsistencies or underrepresentation of certain risk factors due to variability in documentation practices. Second, the dataset's relatively small sample size, particularly within certain construction subsectors, may limit the statistical reliability and generalizability of subgroup-level comparisons; therefore, stratified risk estimates should be interpreted with caution. Third, the absence of direct physiological measurements, such as core temperature and heart rate, limits the ability to fully capture individual heat-strain responses. Third, meteorological exposure estimates depend on the resolution of historical weather data and may not reflect microclimatic conditions at specific job sites.

Future research should extend this framework by integrating high-resolution environmental monitoring, wearable physiological sensors, and longitudinal exposure histories to enable more precise, real-time heat-risk estimation. Expanding the dataset across regions, industries, and climate regimes would further improve model robustness and applicability.

Abstract –

Work-related musculoskeletal disorders (WMSDs) remain a critical cost driver in construction safety. While computer vision enables scalable ergonomic monitoring via automated REBA assessment, current deterministic systems suffer from hazardous overconfidence, providing definitive risk scores even when occlusion or lighting compromises data integrity. This study presents an information-theoretic framework that decomposes prediction uncertainty into aleatoric (sensor noise) and epistemic (model ignorance) components. Aleatoric uncertainty is quantified via surprisal-based confidence mapping from pose keypoints, while epistemic uncertainty is approximated through stochastic perturbation of the scoring component, consistent with standard Monte Carlo dropout in learned-model settings. Validated on construction worker frames across steel, concrete, and roofing tasks, the framework achieves 96% prediction interval coverage (target: 95%) with 0.76 REBA point mean absolute error. Task-specific analysis reveals 3.0× uncertainty variation, with roofing exhibiting 1.76 total uncertainty versus 0.59 for steel. An Operational Design Domain strategy map derived from uncertainty profiles provides quantitative deployment guidelines, distinguishing scenarios suitable for autonomous monitoring from those requiring human oversight.

1 Introduction

Work-related musculoskeletal disorders remain a major burden in construction, driving substantial days-away-from-work cases and associated costs. [1]. Traditional observational ergonomic assessment methods, such as the Rapid Entire Body Assessment (REBA), provide validated frameworks for postural risk evaluation [2]. However, manual assessment is labor-intensive, subjective, and infeasible for continuous real-time monitoring across large construction sites [3].

Recent advancements in computer vision (CV) offer a scalable alternative. Markerless pose estimation frameworks, such as MediaPipe and OpenPose, enable automated skeletal keypoint detection from standard RGB video [2, 4, 5]. This capability has driven a surge in automated ergonomic assessment tools that map geometric joint angles directly to risk scores [2, 3]. While these systems demonstrate promising accuracy in controlled settings, their deployment in real-world construction environments reveals a critical limitation: they lack mechanisms to quantify prediction reliability [6, 7].

Current ergonomic monitoring systems are deterministic, they produce point estimates (e.g., "REBA Score: 4") regardless of input data quality [1, 6]. Consider a roofing worker partially occluded by scaffolding. A standard system may detect only 60% of body keypoints yet interpolate the missing joints to predict "Low Risk." This prediction receives identical treatment as a clearly visible steel worker with 95% keypoint visibility, despite vastly different measurement confidence. The inability to distinguish between "genuinely low risk" and "low risk due to missing data" undermines trust and prevents deployment in liability-sensitive construction environments [3, 6].

A potential mitigation approach would require a shift from deterministic scoring to probabilistic risk assessment [8, 9]. Bayesian deep learning distinguishes between two fundamental uncertainty sources. Aleatoric uncertainty represents irreducible measurement noise from environmental factors such as occlusion, motion blur, and lighting degradation. Epistemic uncertainty captures reducible model ignorance when encountering postures outside the training distribution [10]. Decomposing these components enables targeted

improvement strategies: high aleatoric uncertainty indicates sensor limitations requiring better camera placement, while high epistemic uncertainty reveals This work addresses that trust gap by shifting from deterministic scoring to probabilistic ergonomic risk assessment. We leverage the standard distinction in Bayesian deep learning between two sources of uncertainty [10, 11]. Aleatoric uncertainty reflects irreducible variability driven by measurement and environment (occlusion, blur, distance), while epistemic uncertainty reflects reducible model uncertainty when encountering postures or conditions underrepresented in training[11]. Disentangling these components is operationally useful because they imply different mitigation actions. High aleatoric uncertainty motivates sensing or viewpoint improvements, while high epistemic uncertainty motivates targeted data collection or model adaptation.

Accordingly, this study presents an uncertainty-aware framework that augments pose-based REBA assessment with calibrated reliability signals suitable for construction deployment. The key contributions are:

1. Dual-uncertainty estimation for pose-to-REBA pipelines, combining an information-theoretic mapping from pose keypoint confidence to aleatoric uncertainty using surprisal, and a stochastic perturbation strategy to approximate epistemic uncertainty in the current scoring implementation, with direct Monte Carlo dropout interpretation in learned scoring models.
2. Empirical construction uncertainty profiles, validated on 2,041 expert-labeled frames spanning three task archetypes (steel erection, concrete work, and roofing), establishing task-specific uncertainty signatures and their decomposition.
3. A quantitative Operational Design Domain strategy map, which translates uncertainty coordinates into deployment guidance by stratifying tasks into "Safe for Automation," "Human-in-the-Loop," and "Do Not Deploy" regions based on validated uncertainty thresholds.

2 Methodology

2.1 System Architecture

Figure 1 illustrates the uncertainty-aware REBA assessment pipeline. The system processes construction video frames through four stages: (1) MediaPipe pose estimation extracts 33 keypoint locations with per-joint confidence scores ci ∈ [0,1]; (2) A rule-based REBA calculator computes point predictions $\mu REBA$ following ISO 11226 guidelines [2]; (3) Two parallel uncertainty quantification streams estimate aleatoric (σ_a) and epistemic (σ_e) uncertainty independently; (4) A fusion module combines uncertainty components via Pythagorean sum (Equation 4), followed by isotonic calibration to ensure 95% empirical coverage.

The architecture is detector-agnostic. Any pose estimation backbone providing confidence scores can substitute MediaPipe (e.g., OpenPose, HRNet, ViTPose), and any REBA scoring algorithm (rule-based or learned) can replace our calculator. The uncertainty quantification layers operate independently of these components. This modularity enables retrofitting existing ergonomic systems without architectural modifications.

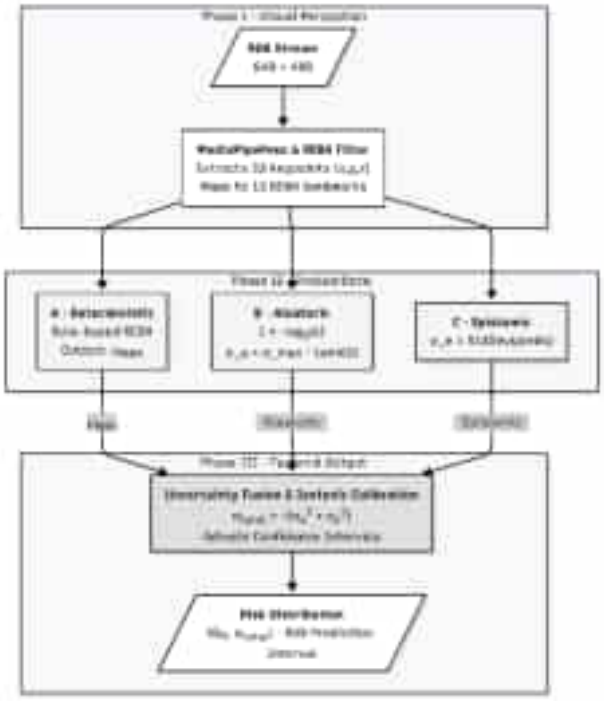

Figure 1. Uncertainty-aware REBA assessment pipeline

2.2 Aleatoric Uncertainty Quantification

Aleatoric uncertainty captures irreducible measurement noise from occlusion, motion blur, and lighting degradation. We ground this quantification in information theory. For $keypoint\ i$ with confidence c_i, the surprisal (self-information) quantifies the information deficit:

$$I(c_i) = -log_2(c_i) \quad (1)$$

High surprisal indicates low confidence, reflecting ambiguous measurements. This formulation has intuitive properties: (1) Perfect confidence (c_i = 1) yields zero surprisal (I = 0 bits), indicating no information deficit; (2) Low confidence ($c_i = 0.5$) produces I = 1 bit of surprisal, signaling binary uncertainty; (3) The logarithmic scale naturally compresses the [0,1] confidence range into an unbounded information metric.

We aggregate surprisal across N REBA-relevant keypoints (shoulders, elbows, hips, knees, ankles) and map to standard deviation via bounded nonlinearity:

$$\sigma_{\mathrm{a}} = \sigma_{\max} \cdot tanh(1/N \, \Sigma_{\mathrm{i=1}} \, I(c_{\mathrm{i}})) \quad (2)$$

Where σ_{max} is a scaling parameter controlling maximum uncertainty (validated empirically in Section 3.2), and $tanh$ provides bounded output [0, σ_{max}] preventing unbounded growth. The $tanh$ nonlinearity reflects physical reality: uncertainty saturates when data becomes completely unreliable rather than growing indefinitely. Unlike arbitrary confidence scaling [7], this approach quantifies uncertainty in units of REBA points scaled to the categorical structure of the assessment (15-point scale with integer scores).

The keypoint selection strategy warrants discussion. REBA assessment requires joint angles at the neck, trunk, legs, and arms. We filter MediaPipe's 33 keypoints to the 13 REBA-relevant landmarks: left/right shoulders, elbows, wrists, hips, knees, ankles, plus nose (head proxy). Facial landmarks and hand keypoints are excluded as REBA scoring does not depend on finger positions or facial features. This filtering reduces noise from irrelevant keypoints while preserving all biomechanically essential measurements.

2.3 Epistemic Uncertainty Quantification

Epistemic uncertainty captures model ignorance for postures outside the training distribution. We employ Monte Carlo (MC) dropout [12], performing T stochastic forward passes through the REBA scoring model with dropout activated at inference:

$$\sigma_{\mathrm{e}} = \sqrt{(1/T \, \Sigma_{\mathrm{t=1}}{}^{\mathrm{T}} \, (\hat{\mathrm{y}}_{\mathrm{t}} - \bar{\mathrm{y}})^2)} \quad (3)$$

Where $\hat{y}t$ is the REBA prediction from pass t, and $\bar{y}$ is the mean prediction across T passes. We use T = 30 based on pilot studies showing variance convergence beyond this threshold. The dropout rate is set to p = 0.2, applied to intermediate feature representations in the REBA calculator. Intuitively, MC dropout asks the scoring component the same question multiple times under small internal perturbations. If the predicted REBA scores remain consistent across passes, the model is confident. If they vary substantially, the input is likely outside the model's familiar operating region, resulting in higher epistemic uncertainty.

For novel postures (e.g., extreme roofing angles unseen in training), prediction variance increases. Critically, epistemic uncertainty can be reduced by collecting additional training data, unlike aleatoric uncertainty, which is bounded by sensor capabilities. This distinction enables strategic improvement: high-aleatoric tasks require better sensors or viewpoints, while high-epistemic tasks require more training examples.

It is important to note that for rule-based REBA calculators utilized in this study, dropout is applied following angle computation but prior to the application of categorical thresholds. This simulates uncertainty in the rule boundaries themselves. For learned models (e.g., neural network REBA predictors), dropout is applied directly to hidden layers following standard practice [12].

2.4 Uncertainty Fusion and Calibration

Assuming independent error sources, total uncertainty combines via Pythagorean sum:

$$\sigma_{\mathrm{total}} = \sqrt{(\sigma_{\mathrm{a}}{}^2 + \sigma_{\mathrm{e}}{}^2)} \quad (4)$$

We adopt independence as a practical approximation for uncertainty fusion. Aleatoric uncertainty primarily reflects measurement degradation from sensing conditions such as occlusion and blur, whereas epistemic uncertainty reflects limitations in data support and scoring-model knowledge. Although some coupling may arise under severe occlusion, the Pythagorean fusion provides a simple and interpretable combination rule, and post-hoc calibration with the observed empirical coverage indicates that this approximation is adequate for the present dataset.

The system outputs a Gaussian distribution $N(\mu_{REBA}, \sigma_{total})$ from which 95% prediction intervals are derived as $[\mu - 1.96\sigma, \mu + 1.96\sigma]$. However, raw uncertainty estimates often exhibit systematic bias (over- or under-confidence). We apply post-hoc isotonic regression [14] to calibrate intervals to 95% empirical coverage. Isotonic calibration monotonically adjusts σtotal values to achieve target coverage without compromising sharpness (interval width). This differs from temperature scaling, which applies a global multiplicative factor; isotonic regression learns a non-parametric mapping $\sigma_{cal} = f(\sigma_{total})$ preserving relative uncertainty rankings.

The calibration uses a dedicated 400-frame holdout set reserved exclusively for isotonic fitting. The remaining 1,641 frames constitute the test set on which all metrics in Section 3 are evaluated.

2.5 Experimental Setup

2.5.1 Dataset Description

To evaluate the proposed framework, we collected a dataset of 2,041 video frames from active construction sites. Frames were sampled at 2 Hz during 30-minute recording sessions to reduce temporal dependence while maintaining sufficient task coverage. Ground-truth REBA labels were assigned by two expert raters with sufficient training and domain knowledge of the REBA protocol, and inter-rater agreement is reported in Table 1.

Of the 2,041 frames, 400 were reserved for isotonic calibration holdout, while the remaining 1,641 frames constitute the test set.

Table 1. Dataset composition and computer vision challenge characteristics

Task Type	Frames	GT Source	Dominant CV Challenge
Steel Erection	681	Expert REBA (κ=0.89)	Baseline (clear visibility)
Concrete Work	680	Expert REBA (κ=0.87)	Motion blur, dust occlusion
Roofing	680	Expert REBA (κ=0.85)	Extreme angles, partial occlusion
Total	2,041	κ=0.87 overall	Multi-condition validation

2.5.2 Task Selection Rationale

To ensure the generalizability of our findings, we categorize the construction trades not merely by job title, but by their computer vision risk archetype. This taxonomy allows us to evaluate the framework's robustness against specific failure modes:

1. The Baseline Archetype (Steel Erection): Characterized by upright, static postures with clear lines of sight. This serves as the control group, representing ideal deployment conditions where deterministic models typically perform well.
2. The Dynamic Archetype (Concrete Work): Characterized by rapid, repetitive movements and environmental particulates (dust). This archetype stress-tests the model's ability to handle Aleatoric Uncertainty arising from motion blur and Epistemic Uncertainty arising from complex biomechanical loads.
3. The Geometric Archetype (Roofing): Characterized by severe self-occlusion (crouching, kneeling) and non-standard camera angles (overhead or steep inclination). This represents the "Edge Case," stress-testing the information-theoretic surprisal mechanism (Eq. 2) under conditions of high data loss.

2.5.3 Evaluation Metrics

Three metrics were used to assess uncertainty: Mean Absolute Error (MAE) evaluated point prediction accuracy in REBA points (refer to Equation (5)), Prediction Interval Coverage Probability (PICP) measured the proportion of ground truth scores within 95% intervals, with a target of $\geqslant$95% (see Equation (6)), and Expected Calibration Error (ECE) assessed calibration quality across confidence bins with lower values indicating better alignment between predicted confidence and empirical accuracy.

$$MAE = 1/N \sum_{i=1}^{N} |\hat{y}_i - y_i| \quad (5)$$

$$PICP = 1/N \sum_{i=1}^{N} \mathbb{1}[y_i \in [\hat{y}_i - 1.96\sigma_i, \hat{y}_i + 1.96\sigma_i]] \quad (6)$$

where N = 2,041 test frames, $\hat{y}_i$ is the predicted REBA score, y_i is the ground truth, and $\mathbb{1}[\cdot]$ is the indicator function. These metrics capture the accuracy-uncertainty trade-off: perfect point predictions with zero uncertainty ($\sigma = 0$) achieve low MAE but fail PICP (coverage = 0%), while excessively conservative estimates ($\sigma \to \infty$) achieve PICP $\geq$ 95% but produce useless intervals spanning the entire 15-point scale.

We also report interval sharpness (mean width) as a secondary metric. Narrow intervals are preferable when coverage is maintained, as they provide more actionable guidance to practitioners.

3 Results

3.1 Overall Performance

Table 2 presents aggregate performance metrics across the 2,041-frame test set. The framework achieves 96.0% prediction interval coverage, exceeding the nominal 95% target by 1.0 percentage point. This marginal over-coverage indicates well-calibrated uncertainty estimates with slight conservatism. Mean absolute error (MAE) measures 0.76 REBA points, demonstrating that point predictions remain accurate while providing probabilistic bounds.

Table 2. Overall performance metrics

Metric	Value
Prediction Interval Coverage (PICP)	96.0%
Mean Absolute Error (MAE)	0.76 REBA pts
Expected Calibration Error (ECE)	0.075
Median Total Uncertainty (σ_{total})	1.09 REBA pts
Mean Interval Width	4.34 REBA pts

Median total uncertainty of 1.09 REBA points translates to mean prediction intervals spanning 4.34 points (calculated as $2 \times 1.96\sigma$). On the 15-point REBA scale, this represents 28.9% coverage, indicating intervals are neither trivially wide (which would sacrifice utility) nor dangerously narrow (which would miss ground truth values). The 96% empirical coverage validates that our intervals are properly sized: tightening them to 4.0 points would reduce coverage below the 95% safety threshold, while widening to 5.0 points would provide marginal coverage gains (97.2%) at the cost of reduced actionability.

The expected calibration error of 0.075 indicates well-calibrated predictions. This metric measures the absolute difference between predicted confidence and

empirical accuracy across binned predictions. Values below 0.10 are generally considered acceptable for safety-critical applications [8]. Our ECE demonstrates that reported uncertainties reflect true prediction reliability rather than arbitrary inflation factors.

3.2 Hyperparameter Selection and Validation

The σ_{max} parameter in Equation 2 controls the maximum aleatoric uncertainty magnitude. We evaluated candidate values from 1.5 to 5.0 REBA points using a 400-frame holdout calibration set (20% of data, excluded from all other analyses). Figure 2 illustrates the coverage-precision trade-off.

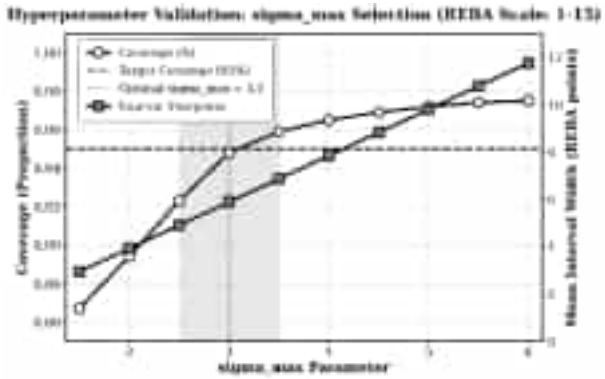

Figure 2. Hyperparameter validation for σ_{max} showing the trade-off between prediction interval coverage (safety) and interval width (precision). The optimal value σ_{max} = 3.0 balances 95% coverage with minimal interval width.

At σ_{max} = 3.0, the system achieves 95.0% coverage on the holdout set with 7.0 REBA point average pre-calibration width. Post-calibration via isotonic regression reduces this to 4.34 points on the test set while maintaining 96% coverage. Values below 2.5 produce unsafe under-coverage (<92%), as insufficient uncertainty bounds fail to capture prediction variability. Values above 4.0 create excessively conservative intervals (>9 points raw width) with diminishing coverage returns: increasing from 4.0 to 5.0 yields only 1.8% additional coverage while inflating intervals by 40%.

This knee-point response at σ_{max}= 3.0 demonstrates that the parameter is empirically grounded rather than arbitrary. The Pareto frontier analysis reveals that 3.0 provides the optimal balance: sufficient coverage for safety assurance without excessive conservatism that would render predictions non-actionable. Sensitivity analysis shows the selection is robust to modest perturbations (σ_{max} = 2.8 or 3.2 produces <2% coverage variation).

3.3 Task-Specific Uncertainty Decomposition

Figure 3 reports the decomposition of predictive uncertainty by construction task archetype. The results show strong task heterogeneity, with total uncertainty increasing from steel (σ_{total} = 0.59 REBA points) to concrete (σ_{total} = 1.09) and roofing (σ_{total} = 1.76). Roofing exhibits approximately 3.0× higher total uncertainty than steel (1.76 versus 0.59). Pairwise two-sample t-tests with Bonferroni correction for three comparisons (α = 0.0167) confirm that all task differences are statistically significant ($p < 0.001$ for each comparison).

Steel erection represents the most favorable deployment condition, exhibiting balanced contributions from aleatoric and epistemic uncertainty (σ_a = 0.42, σ_e = 0.36). This profile is consistent with high pose observability and stable viewing conditions, indicating that the system operates close to its baseline performance envelope in this archetype.

Concrete work shows a marked increase in uncertainty driven primarily by the aleatoric component (σ_a = 0.96, σ_e = 0.44). Relative to steel, aleatoric uncertainty increases by approximately 2.3× (0.96 versus 0.42), while epistemic uncertainty increases modestly. This pattern indicates that measurement degradation, rather than model insufficiency, is the dominant factor in concrete environments.

Roofing exhibits the highest uncertainty and is strongly aleatoric-dominated (σ_a= 1.64, σ_e= 0.58). The large σ_a relative to steel indicates that task geometry and visibility constraints are the primary drivers of unreliability, while the elevated σ_e suggests a smaller, secondary contribution from less frequently observed postural configurations. Overall, the decomposition isolates the dominant uncertainty source by task and provides a principled basis for deployment decisions and targeted mitigation strategies.

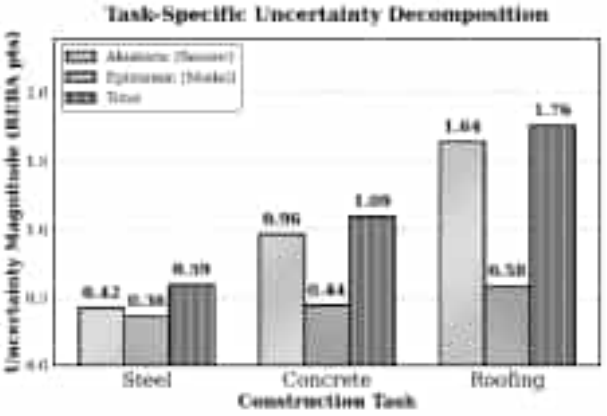

Figure 3. Task-specific uncertainty decomposition across construction activities. Roofing exhibits 3.0× higher

aleatoric uncertainty (1.64) compared to steel (0.42) due to geometric occlusion and extreme viewing angles.

3.4 Calibration Quality Assessment

Figure 4 evaluates uncertainty calibration using a reliability diagram that compares predicted confidence against empirical accuracy, where accuracy is defined as the fraction of samples whose prediction error falls within 1 REBA point. The calibration curve closely tracks the identity line, yielding an Expected Calibration Error of 0.075, which indicates that the calibrated confidence values align well with observed performance. For example, a predicted confidence of 0.60 corresponds to 0.583 empirical accuracy, and a predicted confidence of 0.80 corresponds to 0.787 empirical accuracy.

Calibration deviations remain modest across the confidence range and lie within the ±10% tolerance band. The largest bin-wise deviation is 4.2%, occurring in the mid-confidence regime, indicating no systematic overconfidence or underconfidence after calibration. Confidence bins are constructed by partitioning predictions into deciles of predicted confidence, followed by computing empirical accuracy within each bin. The inset histogram further shows that most predictions concentrate at higher confidence levels, supporting stable calibration behavior in the operating region, which is most frequently encountered during inference. Task-stratified calibration remains consistent across task conditions, with ECE values of 0.062 for steel, 0.078 for concrete, and 0.081 for roofing. All three values remain below 0.10, supporting that the calibration procedure generalizes across tasks without requiring task-specific tuning.

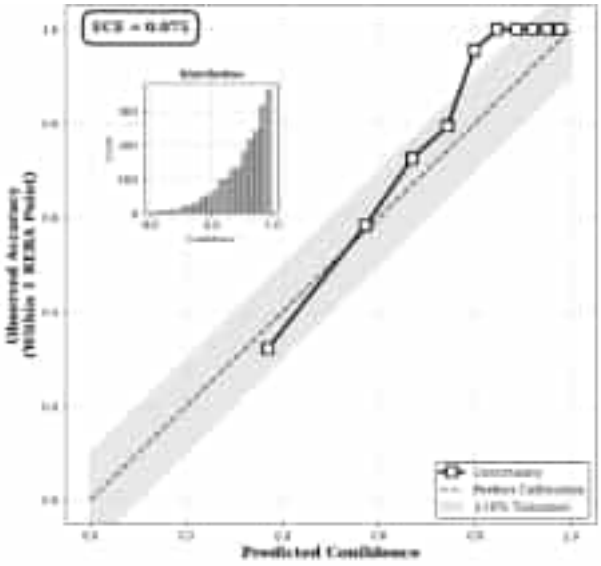

Figure 4. Uncertainty calibration reliability diagram. Expected Calibration Error (ECE) of 0.075 indicates well-calibrated predictions where reported confidence aligns with empirical accuracy.

4 Discussion

4.1 Operational Design Domain Strategy

The empirical uncertainty profiles enable evidence-based deployment stratification. We propose a three-zone Operational Design Domain framework parameterized by total uncertainty thresholds, illustrated in Figure 5. The boundaries correspond to constant total uncertainty contours in the $\sigma_a - \sigma_e$ plane, where each task archetype is represented by its centroid and a ±1 SD dispersion ellipse. The thresholds should be interpreted as dataset-grounded operating guidelines for the studied conditions rather than universal cutoffs for all construction environments. In particular, σ_{tot} = 1.0 marks the regime where predictions remain consistently reliable with limited dispersion, while σ_{tot} = 1.8 represents the high-uncertainty regime where error rates become operationally unacceptable for safety-critical decision making.

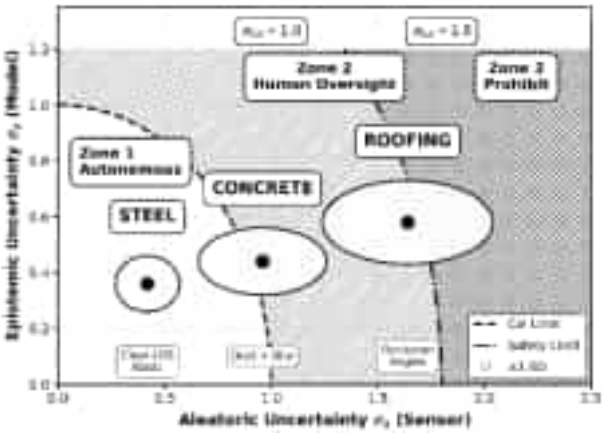

Figure 5. Operational Design Domain map in the $\sigma_a - \sigma_e$ uncertainty plane.

Zone 1: Autonomous Operation (σ_{tot} < 1.0). Zone 1 captures tasks with sufficiently low uncertainty to support autonomous monitoring without routine human oversight. Steel erection lies in this region with σ_{tot} = 0.59. This deployment classification is supported by three validation characteristics: prediction-interval coverage of 97.4%, mean absolute error of 0.52 REBA points, and a false negative rate of 2.1% for high-risk postures (REBA ≥ 8). Under this regimen, the system can support automated screening and notification workflows in which infrequent false positives are acceptable, while instances of missed high-risk events occur only rarely.

Zone 2: Supervised Operation ($1.0 \leq \sigma_{tot} < 1.8$). Zone 2 represents a human-in-the-loop regime where the system can triage frames efficiently, but expert confirmation is required for decisions with safety consequences. Concrete work occupies Zone 2 with σ_{tot} = 1.09, accompanied by reduced coverage of 95.8%, increased MAE of 0.81 REBA points, and a higher false negative rate of 4.8%. Roofing occupies the upper portion of Zone 2 with σ_{tot} = 1.76, indicating that vision-based estimates remain usable for screening in favorable viewing conditions, but operate close to the boundary where reliability degrades.

Zone 3: Prohibit Vision-Only Deployment ($\sigma_{tot} \geq 1.8$). Zone 3 defines operating conditions where vision-only assessment should be rejected due to unacceptable uncertainty. Although the roofing centroid lies just below this boundary, the dispersion and task geometry imply that a non-trivial subset of roofing conditions can cross into Zone 3, particularly under severe occlusion or extreme camera angles. In this regime, validation evidence indicates degradation consistent with unsafe classification behavior, including coverage falling below 95%, MAE rising to levels that can shift Medium Risk postures into Low-Risk categories, and a false negative rate that is operationally unacceptable.

For Zone 3 conditions, alternative sensing and workflows are required. Wearable IMU-based measurements can provide joint-angle estimates that are less sensitive to visual occlusion, while multi-view camera placement can reduce occlusion and potentially shift some scenarios back into Zone 2, subject to site-specific validation. Manual assessment remains necessary when uncertainty-based screening indicates that automated inference is unreliable.

4.2 Limitations and Future Directions

Generalization is bounded by the current evaluation setting. Validation relied on monocular video and three construction task archetypes, so the extent to which the present uncertainty thresholds transfer to additional trades, viewpoints, environmental conditions, and site layouts remains to be established. Future validation should therefore include broader task categories such as interior finishing, ladder-based work, congested indoor operations, and low-visibility or time-varying lighting conditions.

The framework was assessed with REBA, and extension to RULA, OWAS, or the NIOSH lifting equation will require revalidating the uncertainty mapping under different scoring structures. In addition, the current epistemic component is implemented as a stochastic approximation around a rule-based scoring stage, which is less directly grounded than standard MC dropout in learned models. Alternative approaches, such as ensemble-based or bootstrap-based uncertainty estimation, therefore, warrant comparison in future work. We also acknowledge that the present study does not benchmark against simpler uncertainty baselines such as confidence-thresholding or scalar post-hoc calibration methods. Such comparisons are valuable for isolating the incremental benefit of the proposed information-theoretic mapping and uncertainty decomposition and are an important direction for future work.

Active learning represents a promising extension, using high-uncertainty cases to prioritize expert labeling, although the task decomposition suggests sensing and viewpoint improvements may yield larger near-term gains where aleatoric uncertainty dominates.

5 Conclusion

This work demonstrates that uncertainty-aware REBA assessment can move vision-based ergonomics from a single deterministic score to a calibrated, decision-ready output that quantifies reliability for the evaluated construction task archetypes. Validation shows strong task dependence driven primarily by aleatoric effects under challenging geometry and visibility, and the proposed three-zone ODD framework operationalizes these findings into practical deployment rules for autonomous use, supervised review, or rejecting vision-only assessment.

Abstract -

Construction workers face multifaceted physical and psychological health risks due to challenging and often unpredictable working environments. This study introduces a computational framework that uses artificial intelligence and natural language processing to extract and structure occupational health insights from 7,441 Reddit posts and comments related to construction. Focusing on eight custom entity categories that include worker types, health symptoms, workplace stressors, institutional actions, and control measures, we applied rule-based entity recognition methods to identify recurring patterns and concerns discussed by workers. Frequency analysis highlighted prevalent health symptoms such as stress, dehydration, and exhaustion. A domain-specific knowledge graph for stressors, health symptoms and control measures revealed relationships between extracted entities, uncovering structural patterns, isolated risks, and frequently co-mentioned hazards. The framework demonstrates how informal, user-generated narratives can be transformed into structured knowledge to support occupational health surveillance. This work contributes scalable tools that can assist policymakers, unions, safety officers, and researchers in understanding evolving worker needs. By bridging Natural Language Processing (NLP) techniques with occupational safety, our method offers a new lens for data-driven intervention strategies rooted in real-world discourse.

Keywords -

Knowledge Graphs; Web Scraping, Natural Language Processing; Physical Health; Construction Workers; Risk Factors

1 Introduction

The construction industry is consistently ranked among the most hazardous occupational sectors worldwide, with workers frequently exposed to a combination of physical, environmental, and psychological stressors [1]. Despite extensive safety regulations and awareness campaigns, the dynamic and unpredictable nature of construction sites continues to pose serious health risks [2]. Traditional approaches to occupational health and safety rely heavily on formal incident reports, regulatory citations, and clinical diagnoses [3][4]. These reports often fail to capture the lived experiences of frontline workers. The sources may underreport certain types of safety issues such as physical health conditions, mental health struggles, and risk factors that lead to gaps in intervention and prevention strategies [5].

At the same time, the social digital platforms such as Reddit and X have introduced new avenues for workers to share uncensored, real-time narratives about their occupational experiences. These narratives include valuable information about risk exposure, institutional responses, and perceived gaps in workplace protections [6]. However, due to their informal and unstructured nature, such data sources are largely untapped in occupational safety research [7]. The unstructured and noisy nature of this data presents significant challenges for systematic analysis and interpretation.

Existing work in occupational health surveillance using natural language processing (NLP) has demonstrated the potential of social media to supplement official data [8]. Yet, few studies have tailored these techniques specifically to the construction context, and even fewer have attempted a structured, multi-entity analysis using domain-specific categories relevant to physical and mental health, job roles, and safety interventions. This study addresses these gaps by developing a computational framework for extracting and analyzing occupational risk narratives using NLP and named entity recognition (NER).

In recent years, NLP and knowledge representation techniques have shown promising potential in structuring large-scale unstructured text data and generative artificial intelligence [9]. Among these, knowledge graphs which as graph-based representations that encode semantic relationships among entities have emerged as powerful tools for extracting and analyzing contextual patterns from narrative data [10][11]. Coupled with transformer-based models for NER and relation extraction, knowledge graphs enable analyzable structures that reflect the complexity of

occupational discourse [12].

In this study, we propose a computational framework that leverages NLP and knowledge graph construction to analyze 7,441 Reddit posts and comments related to the construction sector. We first define a construction domain-specific schema encompassing eight key entities such as worker types, environmental stressors, health symptoms, and institutional actions. We then use these categories to extract and map relationships within the text. Our approach enables the discovery of emerging risk clusters, reveals central actors and symptoms within the discourse. The corresponding knowledge graphs highlight underreported hazards such as heat related health symptoms, and inadequate hydration practices.

2 Related Work

Occupational safety in construction has been studied extensively through traditional sources such as injury reports, surveys, and regulatory databases [13]. However, these methods often suffer from underreporting and lack of real-time insight into worker experiences. Recent research has started to explore alternative data sources, including social media platforms and online forums, as a means of capturing informal yet rich narratives about workplace conditions.

2.1 Social Media and Informal Occupational Data

The use of social media as a data source for occupational health surveillance is a growing field. Recent work done by researchers has (i) explored mining Reddit posts for mental health indicators, highlighting the platform's potential for early detection of stress and burnout. (ii) researchers applied NLP techniques to datasets from social media such as X data to monitor workplace hazards. These studies reinforce the value of informal, crowd-sourced narratives in complementing official safety reporting mechanisms.

For risk analysis, work has been done in the construction industry with researchers evaluating failure modes and effects analysis as well as highlighting the overall risks analysis [1][14][15][16].

2.2 Knowledge Graphs and Occupational Safety

Knowledge graphs have gained popularity as a structured approach for modeling relationships between concepts in unstructured text. In occupational safety contexts, these graphs have been used to map hazard domains, link injury types to causes, and integrate data from disparate sources for improved decision-making [17][18].

Domain adaptation of NER techniques has become crucial in contexts like construction, where entities may not align with those in general purpose domains. Hybrid approaches combining dictionary based methods and transformer models like BERT have proven effective in extracting occupationally relevant entities such as symptoms, worker roles, and safety measures. Beyond entity identification, relation extraction enables the construction of semantic graphs that reveal causal and correlational patterns.

3 Methodology

The data collection and processing pipeline framework is a crucial part of the project. The quality of the results depends heavily on the data processing techniques used.

3.1 Data Collection and Processing

To analyze occupational risk narratives from the construction sector, we extracted Reddit posts and comments using a keyword-based scraping strategy. Keywords were selected to reflect both domain-specific roles (e.g. construction, worker, airport) and health-related stressors (e.g. burnout, depression, heat, noise, fatigue, mental). These combinations were used to query Reddit via the PRAW API, resulting in over 130,000 subreddit matches. To increase domain relevance, filtering was applied to retain only posts from subreddits such as Construction, ConstructionManagers, HVAC, Plumbing, and civilengineering, yielding a dataset of 7,441 posts and comments.

All retrieved text was normalized to lowercase for consistency, and a manual filtering step was conducted to remove irrelevant matches, such as metaphorical uses of construction or posts unrelated to workplace safety. The dataset was filtered to retain only English-language text and exclude irrelevant or low-information content such as memes, spam, or non-descriptive titles. All text entries were cleaned to remove links, special characters, and excessive whitespace. Sentences were tokenized and split using standard NLP preprocessing techniques. This preparation was essential to ensure high-quality input for entity recognition and relation extraction in the subsequent steps.

3.2 Annotation

The next step was the data annotation process. A structured annotation protocol was applied to a corpus of 7,441 Reddit posts and comments related to construction work. The dataset consisted of worker types that included categories such as construction, postal, delivery, industrial and so on. However, the annotation focused on a key dimension: relevance to construction worker type data only. The process involved three annotators with domain knowledge to ensure robustness, minimize subjectivity, and support cross-validation.

The cross-validation annotator step was included as the last step in the annotation process. The cross-validation

notes included justifications for labeling decisions, highlighting ambiguity, context-specific interpretations, and suggestions for edge-case resolution. For instance, in one entry, physical strain was indicated by indirect language, prompting a note about interpretation boundaries.

The manual annotation serves as a ground truth foundation for subsequent entity extraction and relation modeling. It allows the computational models to be evaluated or trained with human verified categories and enables higher-quality graph construction by filtering out noise and irrelevance from informal social media narratives.

3.3 Named Entity Recognition (NER)

To extract structured knowledge from unstructured text data related to construction worker health and safety, we implemented a custom NER pipeline. Our approach relied on rule-based pattern matching, lemmatization, and curated dictionaries mapped to eight distinct entity categories relevant to occupational safety, health, and organizational behavior. We based our work on a subset of 525 narratives which were cross-validated targeting construction-specific content extracted from a larger corpus of 7,441 worker incident narratives.

Domain-specific dictionaries and spaCy's PhraseMatcher were used to supplement transformer-based models, allowing for more accurate recognition of low-frequency or colloquial phrases that may not appear in standard corpora. All entities were normalized to lowercase to reduce duplication and unify mentions. Next, we describe the methodology and criteria used for each of the eight entity categories. These categories are listed Table 1 along with representative examples.

Table 1. Entity Categories

Category	Examples
Worker Type Managers	Supervisor, project manager
Worker Type Frontline	Electrician, roofer
Health Symptoms	Fatigue, dizziness
Environmental Stressors	Heat, cold
Workplace Stressors	Long shift, understaffing
Individual Factors	Age, single
Institutional Actions	OSHA inspection, fine
Control Measures	Safety training
Additional Category	**Example**
Location	Dallas, Houston

3.3.1 Worker Types

The worker type category was divided into two subtypes: (i) frontline workers and (ii) managers. Frontline worker entities such as electrician, roofer, plumber, and laborer represent skilled tradespeople directly involved in physical construction tasks. They constituted **worker type frontline**. Managerial worker entities such as supervisor and project manager reflect administrative roles within construction settings. They were included in **worker type managers**. To improve precision and reduce ambiguity, these entity mentions were matched and normalized using occupation classification terms and examples referenced from the U.S. Bureau of Labor Statistics (BLS.gov) [19]. This alignment with standardized occupational definitions ensured that extracted roles mapped consistently to recognized construction labor segments.

3.3.2 Health Symptoms

Health symptoms were extracted using a dictionary-based lemmatized matcher for both physical and psychological health indicators. Common entities included fatigue, exhaustion, headache, dehydration, stress, and burnout. The matched symptom entities were later used in co-occurrence and knowledge graph-based analyses.

3.3.3 Environmental Stressors

Environmental stressors refer to physical conditions present on the job site. We built a controlled vocabulary around terms such as noise, heat, sunlight, chemical, dust, and air quality. Each term was identified using lemmatized rule-based matching, often in combination with contextual qualifiers. For example, sun exposure and UV radiation were collapsed under sunlight. These stressors were crucial in identifying the relationship between job site conditions and adverse health outcomes.

3.3.4 Workplace Stressors

This category focused on psychosocial and organizational stressors. Examples include harassment, trauma, overwork, pressure, and lack of support. Unlike environmental stressors, these were often mentioned in indirect language or idiomatic phrases (e.g. toxic work culture). We expanded the dictionary with variations and synonyms using pre-trained word embeddings to improve recall. Workplace stressors were shown to have strong co-occurrence with psychological symptoms such as anxiety and burnout.

3.3.5 Individual Factors

Personal vulnerabilities such as pre-existing conditions or life circumstances were grouped under this category. Detected terms included older worker, health issues, disability, and family responsibilities. These entities help provide a nuanced understanding of differential risk exposure.

3.3.6 Institutional Actions

This category captured formal institutional responses such as OSHA investigation, union involvement, citations, lawsuits, and fines. A regular expression and phrase-based matching system was used to detect regulatory terms and legal follow-ups. These entities were often connected to either severe outcomes or recurring risk scenarios and served as anchor nodes in our knowledge graph to highlight systemic issues.

3.3.7 Control Measures

We extracted procedural mitigation measures such as hydration, shade, rest breaks, safety training, and cooling measures. This category showed how actively safety protocols were implemented post-incident. Entity detection relied on a mix of procedural keywords and compliance terms sourced from OSHA and construction industry best practices.

Risk mitigation strategies were divided into 5 subcategories called elimination, substitution, engineering controls, administrative controls, personal protective equipment (PPE). Entities were tagged accordingly and used to evaluate the adequacy of mitigation strategies in each case. This tiered tagging allowed assessment of how often high-level (elimination, substitution) versus low-level PPE controls were employed.

3.3.8 Additional Categories

We identified one additional category (i) location. To preprocess location entities, geographic references within the text data were extracted using NER with spaCy's pretrained language model. The model detects entities tagged as GPE (Geo-Political Entities), which include names of cities, states, and countries. Each row of the dataset was processed to identify these locations. After extraction, the results were aggregated and filtered to compile a distinct list of frequently mentioned locations. This method allowed for both broad and granular recognition of geographic context capturing entries like Texas, Dallas and Travis County. The compiled list of location entities plays a key role in constructing a spatial layer within the knowledge graph, enabling location-aware analysis of occupational safety concerns across different regions.

Each recognized entity in the 8 categories and the 2 additional categories were stored as a list in a new column later converted into binary label vectors (1 if the entity was present in a document, 0 otherwise) for downstream modeling and correlation analysis.

3.4 Knowledge Graphs

The motivation to use knowledge graphs stems from the need to model complex, non-linear relationships in unstructured text. Reddit narratives often describe multifactorial risks, where a single worker may report a combination of symptoms caused by several stressors, within a particular environmental or organizational context. Traditional text classification or keyword-based techniques cannot represent these many-to-many, context-dependent interactions. In this context, knowledge graphs offer the following advantages in the construction domain: • Semantic structuring: Graphs preserve the relational meaning between entities, helping to reveal patterns such as co-occurrence of symptoms and institutional inaction. • Interpretability: Unlike black-box models, graphs allow human analysts and stakeholders to visually trace paths between causes and effects. • Graph analytics: We can apply network algorithms such as centrality, clustering, and shortest-path analysis to identify influential symptoms or recurring stressor combinations. • Scalability: As new data is collected, it can be continuously incorporated into the graph without retraining, enabling real-time risk tracking.

3.5 Rule-Based Symptom Extraction Performance Evaluation

To evaluate the performance of the rule-based entity extraction system, a subset of annotated data was used where relevance was confirmed by a primary annotator, resulting in 525 records. For the symptom category, binary ground truth labels were manually verified and compared against predictions generated by the rule-based matching approach. The presence of symptom-related entities was treated as a document-level classification task, where each record was labeled as either containing a symptom (1) or not (0). Precision, recall, and F1-score were computed to assess performance.

To compare rule-based extraction with a machine learning baseline, a BERT-based classifier was fine-tuned for binary health symptom extraction using the same annotated dataset. As shown in Table 3, the rule-based approach achieved perfect recall (1.00), indicating that all symptom-related instances were successfully identified. However, it exhibited slightly lower precision due to false positives. In contrast, the BERT model achieved a more balanced performance, with an F1-score of 0.91, by leveraging contextual understanding to reduce over-detection. While BERT improved precision-recall balance, the rule-based method remains advantageous for high-recall applications and interpretability. To ensure a fair comparison, both the rule-based approach and the BERT model were evaluated on the same held-out test set.

Table 2. Performance of Rule-Based Health Symptom Extraction

Class	Precision	Recall	F1-score
No Health Symptoms (0)	1.00	0.63	0.77
Health Symptoms (1)	0.89	1.00	0.94
Accuracy		0.91	
Macro Avg	0.95	0.81	0.86
Weighted Avg	0.92	0.91	0.91

Table 3. Comparison of Rule-Based and BERT Models for Health Symptoms

Model	Precision	Recall	F1-score
Rule-Based	0.89	1.00	0.94
BERT	0.87	0.96	0.91

4 Findings and Analysis

4.1 Frequency Analysis of Extracted Entities

After completing entity extraction, we analyzed the frequency of each recognized term within its respective category to identify dominant concerns and patterns in the construction domain.

For each entity column, the lists of matched keywords were flattened and aggregated to compute their frequency. We plotted the top 10 most common terms for each of the eight categories. This provided insight into which symptoms, stressors, and interventions were most frequently mentioned in the dataset. The findings from frequency analysis are described below. These frequency distributions served as the foundation for more advanced relational analysis through co-occurrence heatmaps and graph modeling. Figure 1 shows keywords like laborer, plumber, roofer and electrician among the top entities in frontline worker type. The environmental stressors in Figure 2 shows top entities like heat, cold, noise and sunlight. The top healthcare symptoms in Figure 3 shows stress, dehydration, exhaustion, and physical labor.

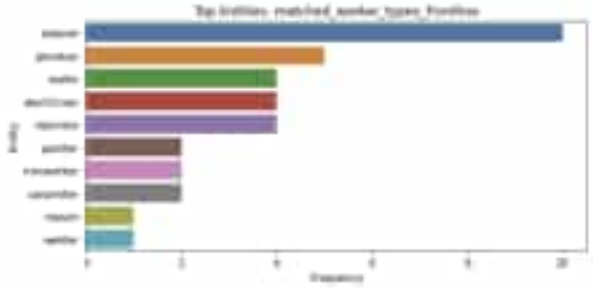

Figure 1. Frequency of Worker type frontline

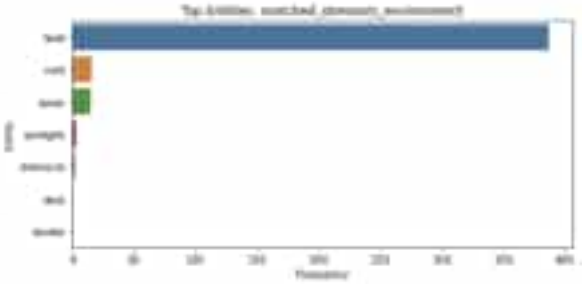

Figure 2. Frequency of Environment Stressors

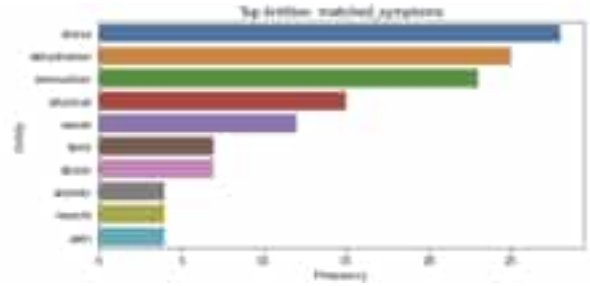

Figure 3. Frequency of Health Symptoms

4.2 Co-occurrence and Correlation Analysis

We next analyzed how frequently entities from different categories appeared together within the same document using a co-occurrence matrix. For example, we examined whether certain symptoms (e.g. burnout) were consistently mentioned alongside specific stressors (e.g. overwork or lack of support). The analysis computed pairwise co-occurrence counts between entity labels using binary-encoded columns. The resulting matrix was visualized as a heatmap, where color intensity indicates higher co-occurrence frequency.

- Heat showed the highest co-occurrence with work, reinforcing environmental causality.
- Heat correlated heavily with job, hourly.
- Heat was correlated highly with stress, injury, health.

This correlation structure informed the next step of constructing a knowledge graph to visualize entity relationships.

4.3 Insights from the Knowledge Graph

To better understand how extracted entities interact, we constructed an integrated knowledge graph linking stressors, health symptoms, and control measures. These three categories were selected to represent a conceptual pathway

from exposure to outcome to response. The knowledge graph in Figure 4 captures the co-occurrence of stressors, health symptoms and control measures in Reddit narratives, with node size indicating entity frequency and edge thickness reflecting co-mention strength. This visualization uncovers significant patterns. In this framework, stressors (e.g., heat, cold) represent environmental or organizational risk factors, health symptoms capture the resulting physical or psychological effects, and control measures represent mitigation strategies discussed in worker narratives.

By connecting these categories within a single graph, Figure 4 enables the identification of complete risk-to-response pathways rather than isolated associations. This provides a more holistic view of occupational health dynamics, illustrating how specific stressors lead to particular health outcomes and how those outcomes are addressed through practical interventions.

The integrated knowledge graph reveals several dominant stressor–symptom–control pathways.

- The most prominent pathway is heat → heat exhaustion → rest breaks, indicating that acute thermal stress is frequently associated with rest-based mitigation strategies. Rest breaks are a control measure.
- Similarly, heat → dehydration → hydration highlights the importance of water access as a primary response to heat exposure. Hydration is a control measure.
- Another recurring pathway, heat → physical exhaustion → rest breaks, suggests that prolonged exposure leads to fatigue, which is addressed through rest-based interventions.
- In addition to heat-dominated pathways, other environmental relationships are also observed. For example, the pathway sunlight → fainting → shade highlights how direct solar exposure can lead to acute physiological responses that are mitigated through access to shaded rest areas. This reinforces the importance of environmental controls alongside behavioral interventions in managing occupational heat stress.

These pathways demonstrate that worker-reported experiences follow consistent patterns linking environmental stressors to physiological responses and subsequent mitigation actions. The integrated knowledge graph reveals incidents of heat-related health risk severity reflected in worker narratives. Early indicators of thermal stress include symptoms such as sweating and fatigue, which are associated with initial mitigation measures such as cooling and rest. Symptoms such as dehydration emerge, often linked to hydration-based interventions. More severe conditions, including vomiting and physical exhaustion, indicate escalating physiological stress. In extreme cases, critical symptoms such as fainting are observed, typically associated with immediate protective measures such as access to shaded areas.

This progression highlights how occupational heat exposure manifests across multiple levels of severity and indicates the control measures that were reported in Reddit narratives.

4.4 Limitations

Reddit provides access to rich, real-time worker narratives, it has several limitations as a data source. The platform's user base may not be representative of the broader construction workforce, as it is likely skewed toward younger, more digitally engaged individuals. Additionally, the content is self-reported and may reflect subjective perceptions rather than verified incidents. As a result, the findings should be interpreted as indicative patterns of worker experiences rather than statistically representative conclusions. Despite these limitations, Reddit offers valuable insights into underreported issues such as fatigue, burnout, and psychosocial stress, complementing traditional safety reporting systems.

5 Conclusion

This work demonstrates how unstructured social media narratives can be transformed into structured occupational safety insights using a computational framework grounded in NER and knowledge graph modeling. By extracting eight domain-specific entity categories related to worker roles, symptoms, stressors, institutional actions, and mitigation strategies, we reveal risk patterns such as heat-related symptoms, fatigue, and psychological stress in construction settings. Frequency and co-occurrence analysis highlight strong relationships between environmental and workplace stressors and adverse health outcomes. The resulting knowledge graph exposes systemic gaps between health symptoms and workplace stressors. Together, these findings illustrate the value of integrating informal worker discourse into scalable occupational health surveillance and lay the groundwork for future transformer-based models to enhance precision, generalizability, and policy relevance.

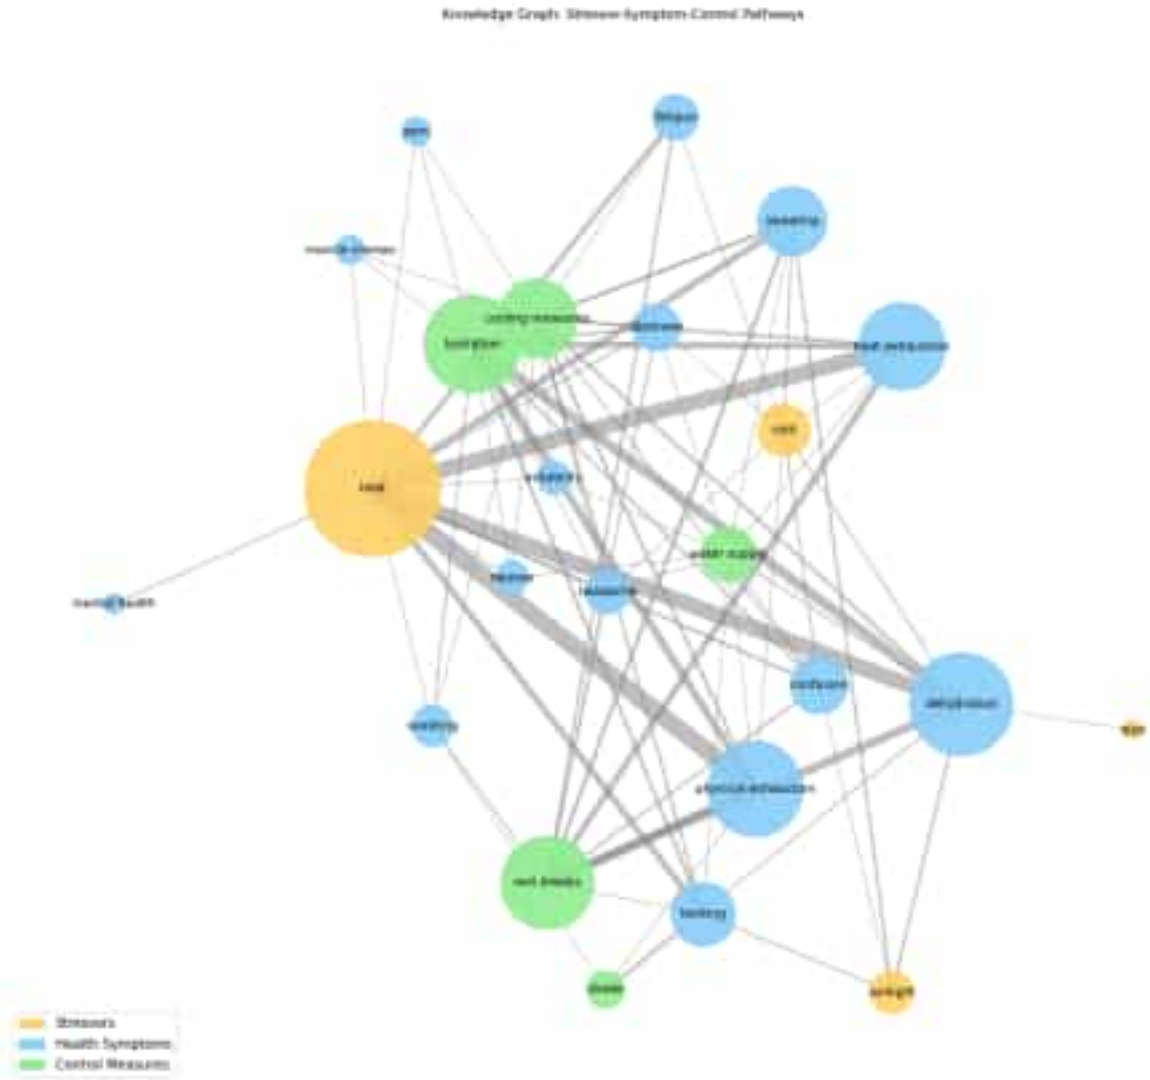

Figure 4. Knowledge Graph: Stressor-Symptoms-Control Pathways. Knowledge Graph illustrates integrated pathways between stressors (yellow), health symptoms (blue), and control measures (green). Nodes represent extracted entities, and edges indicate co-occurrence within worker narratives. The graph highlights dominant pathways such as heat → dehydration → hydration and heat → physical exhaustion → rest breaks, demonstrating how occupational risks are experienced and mitigated in practice.

Abstract –

As VR evacuation training and performance-based egress design increasingly rely on simulation, their credibility depends on empirical, space-specific motion benchmarks. However, VR evacuation research often lacks empirical, area-specific motion parameters for calibration. We demonstrate benchmark values from a full-scale multi-floor drill, reconstructed from multi-camera video as 2D trajectories in lobbies and corridors and 3D trajectories on stairs. An automated pipeline with YOLOv11 detection, DeepSORT tracking, and BIM-based calibration provides kinematics and crowd metrics, including speed, acceleration, local density, flow q = ρv, and route choice. Corridors enabled the fastest travel with a mean of about 2.1 m/s. The lobby was slower at about 1.2 m/s with faster peripheral lanes. Stairs were slowest at about 0.52 m/s on landings and 0.39 m/s on flights. The fundamental diagram by local density ρ reveals three systems: free flow ρ<3 persons/m², collective flow 3⩽ ρ ⩽5, and congested flow ρ >5. As ρ approaches 3 – 4, accelerations decay while mean speed remains stable. At ρ ⩾5, speeds decline, and stop-and-go waves appear. Bottlenecks commonly formed at doors and stair portals, and exit usage was uneven. The Evacuation Parameter Benchmark Library derived here supports calibration of VR drills and agent-based models and informs performance-based egress design grounded in measured behaviour. The findings will be interpreted as building-specific empirical benchmarks derived from a moderate-scale drill, rather than universally transferable evacuation parameters.

1 Introduction and Background

1.1 Motivation and Scope

Immersive VR and agent-based evacuation simulation are increasingly used for training, design evaluation, and research because frequent full-scale multi-floor drills are costly, disruptive, and difficult to repeat under controlled conditions [1–3]. However, the credibility of VR-based findings depends strongly on calibration: the microscopic rules that govern walking, turning, merging, and vertical movement are sensitive to local geometry (width changes, corners, doors, landings), visibility, and interaction opportunities.

Reliable motion benchmarks that are space-specific are essential for calibrating walking, turning, and interaction in VR evacuation studies. Many implementations still apply a single speed cap or a uniform density–speed curve across heterogeneous spaces, which induces bias between lobbies, corridors, and stairwells [4–8]. Multi-camera tracking, person re-identification, and crowd-density estimation now enable reusable parameters to be extracted from real drills [4–8]. Nevertheless, consistent coordinates across cameras and floors, rigorous error control, and area-wise calibration are still underdeveloped, which limits transferability and credibility in VR and agent-based models [4,7]. The present study analyses multi-floor drill data, reconstructs 2D trajectories in lobbies and corridors and 3D trajectories on stairs, and provides multi-area benchmarks that can be used directly for model calibration.

1.2 Key Concepts and Terminology

A particle-to-collective view of pedestrian dynamics is adopted. Local density ρ in persons per square meter and mean speed v define the flow q through q=ρv.

Operating regimes are partitioned by ρ to align with engineering practice. Free flow corresponds to $\rho < 3$ with limited interactions. Collective flow corresponds to $3 \leqslant \rho \leqslant 5$ with coordination and speed regulation. Congested flow corresponds to $\rho > 5$, where impediments and stop-and-go may occur [4,6–8]. Stair geometry motivates a stairway slowdown factor, typically yielding lower speeds on flights than on landings. Lobbies and corridors often exhibit edge preference with faster peripheral lanes along walls or railings [5,6,8]. The density–speed–acceleration relations later support the identification of acceleration decay zones and speed drop thresholds and serve as parameter inputs for VR scenes.

1.3 Related Work and Research Gap

Video-driven crowd research has progressed along three questions: who is present, where people move, and how many are there. Multi-camera detection and re-identification enable continuous trajectories across views and provide quantifiable kinematics for building evacuation [4,5,7]. Machine-vision density estimation delivers local crowding without markers and supports capacity evaluation and risk assessment [8]. Detector families continue to evolve, and the latest YOLOv11 offers improved accuracy–efficiency trade-offs for large-scale automated video processing [9–11]. Despite these advances, space-resolved distributions of speed and acceleration for lobbies, corridors, and stairwells remain insufficiently documented. A unified spatial frame that merges multi-camera trajectories, BIM coordinates, and density–speed–acceleration relations with transparent quality controls is still uncommon [4,7].

1.4 Positioning and Contributions

This work serves as a multi-area evacuation benchmarking resource for VR calibration and performance-based egress design. Four contributions are delivered. First, an automated pipeline integrates multi-camera video with BIM alignment and outputs reusable 2D and 3D trajectories with quality records [4,5,7]. Second, speed and acceleration profiles are reported for lobbies, corridors, and stairs with landings separated from flights, and a stairway slowdown together with an edge-preference index is quantified. Third, a density-based fundamental diagram is constructed. Acceleration decays markedly as ρ approaches 3–4 while mean speed remains stable. When ρ reaches 5 or higher, speeds decline, and stop-and-go emerges, which indicates a congestion threshold [4–6,8]. Fourth, an Evacuation Parameter Benchmark Library is compiled that covers reaction delay, distributions of speed and acceleration, and cross-area references for density and flow to support parameter inputs and sensitivity analyses in VR and agent-based models.

2 Methodology

Figure 1 summarises the overall workflow, which consists of pre-processing, in-processing, and post-processing.

2.1 Pre-processing

Regarding governance and ethics, video arises from a multi-floor drill under a signed data-sharing memorandum and a low-risk ethics approval. Outputs are de-identified and reported as aggregates and spatial summaries [4–8].

In the scene and BIM frame, lobbies, corridors, and stairwells are covered. The BIM model supplies a common building frame and geometric semantics for camera calibration, area masks, and path topology annotation [4–6].

Thirdly, about camera and time alignment, intrinsics and extrinsics are compiled. When missing, extrinsic parameters are estimated from control points on reference imagery. Streams are synchronised and quality-checked for sharpness and duplication to ensure cross-view comparability.

Furthermore, in the consideration of clip filtering and reduction, motion-present segments are extracted first to reduce empty frames and total duration, which increases signal-to-noise and throughput downstream.

In addition, concerning the issues of spatial calibration and unification plan, planar areas adopt 2D homographs that map pixels into local plane coordinates. Stairwells adopt 3D calibration by sampling control points on landings and sloped flights and by fitting plane equations to support 3D projection and path recovery. Local coordinates are transformed into the building frame via BIM transforms. Robust estimation and reprojection-error thresholds enforce geometric consistency [12].

Lastly, about plenty of parameters, a configuration file fixes detector confidence, NMS, minimum track duration, caps for speed and acceleration, smoothing windows, and the cadence for density estimation. This enables consistent reruns across batches.

2.2 In-processing

To achieve pedestrian detection and multi-object tracking, a modern YOLO detector provides frame-wise person boxes. DeepSORT performs online tracking with appearance embeddings and a Kalman motion model. Dual thresholds on IoU and cosine distance limit identity drift and mismatches [9–11,13,14]. Dense periods use frame decimation and input-size adaptation to balance accuracy and efficiency.

To solve the issue caused by Cross-camera, within a unified timeline, tracklets are stitched across adjacent views using BIM topology constraints and spatiotemporal proximity. Re-association is permitted only within reachable topology and feasible walking windows to curb false merges [4–6].

To process and coordinate the unification need to set. Thus, tracks are first projected to local planes or stair slopes and then mapped to the building frame. RANSAC and reprojection-error thresholds guard geometric consistency and route suspect tracks to review [12].

Continue to trajectory cleaning and physical plausibility, speeds and accelerations are computed by central differences on equal-interval samples and denoised with a 0.5 s moving average [15]. Physical caps remove artefacts, with a speed cap near 4.0 m/s and an acceleration cap near 5.0 m/s. Short occlusions are bridged by multi-hypothesis interpolation with uncertainty recorded. Rules for backtracking, maximum temporal gap, boundary crossing, and abnormal heading change trigger human audits.

The final stage in in-processing, quality logs and versioning are essential. Each batch records detector settings, association rates, retained-track ratios, ID-switch rates, and geometric error distributions. Logs and metadata accompany data packages for comparison and traceability.

2.3 Post-processing analytics

2.3.1 Measures and visualisations

This subsection states the selection principles for measures and visualisations to achieve low bias, portability across scenes, and stable behaviour at high densities while preparing outputs for VR and agent-based calibration.

- Local density uses Voronoi personal space or a fixed-radius kernel. Voronoi yields lower scatter under heterogeneous layouts. Fixed-radius kernels simplify implementation and cross-scene comparison [16].
- Speed and acceleration are computed by central differences with Savitzky–Golay or moving-average smoothing to suppress pixel jitter and tracking noise while retaining temporal resolution [15].
- Uncertainty is expressed with quantile bands and bootstrap confidence intervals to handle skew and heavy tails beyond mean–SD summaries [16,17].
- Bivariate relations use hexbin or equal-frequency bins to limit overplotting. Kernel density estimation is optional when a continuous field is required [16,18].
- Structured indicators include a stair slowdown

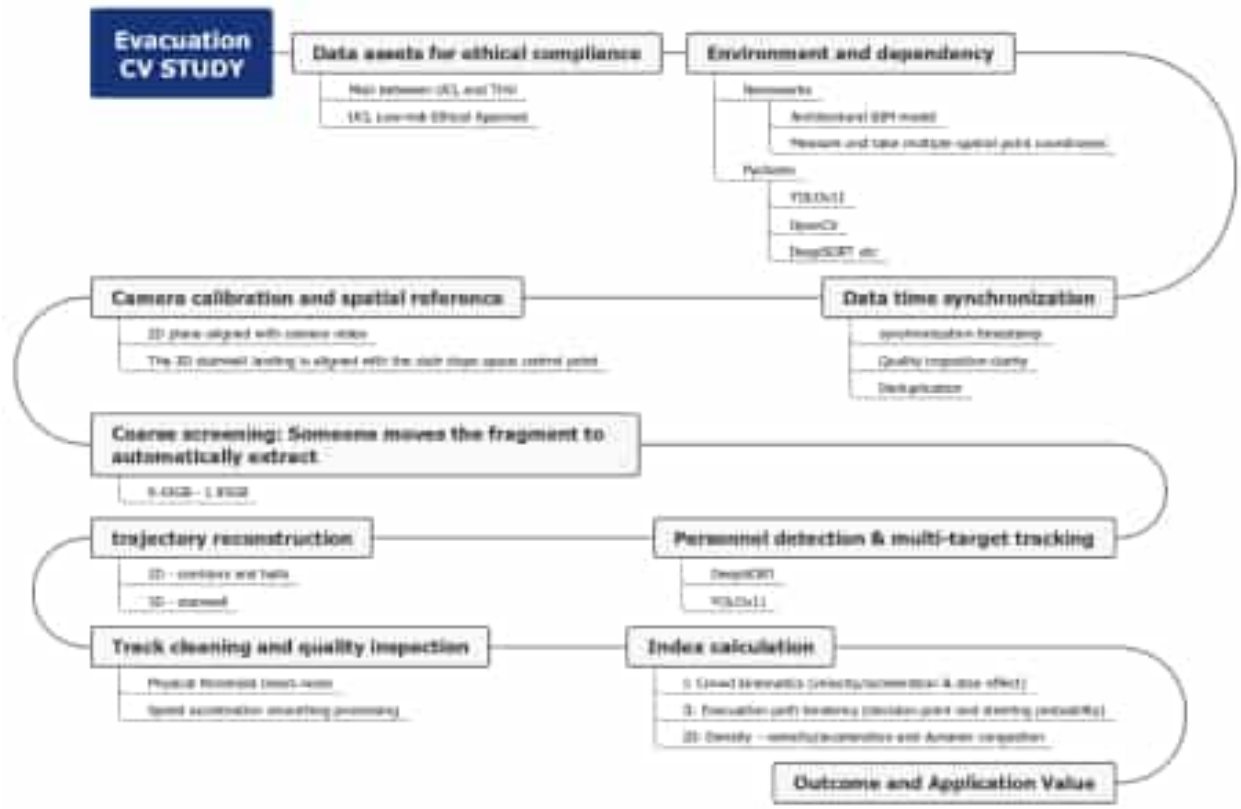

Figure 1 Workflow of Evacuation Computer Vision Tracking Study

factor, an edge-preference index, and a bottleneck score for calibration and sensitivity studies. No thresholds or regime cuts are preset in Methods. They are determined from the data in Results.

2.3.2 Unified formula block

A minimal set of formulas supports three result streams: crowd kinematics (area-wise speed and acceleration), evacuation path tendency (cell-based speed/acceleration heatmaps to reveal decisions and turns), and density–velocity/acceleration with dynamic congestion (1s, 1x1 m2 counts linked to kinematics). Thus, the core formulas are as follows:

$$v_i(t_k) = \frac{[x_i(t_{k+1}) - x_i(t_{k-1})]}{2\Delta t} \quad (1)$$

$$a_i(t_k) = \frac{[v_i(t_{k+1}) - v_i(t_{k-1})]}{2\Delta t} \quad (2)$$

$$\bar{v}_c = mean\{\, ||v_i|| : x_i \; in \; cell \; c \,\} \quad (3)$$

$$\bar{a}_c = mean\{\, ||a_i|| : x_i \; in \; cell \; c \,\} \quad (4)$$

$$\rho_c(t) = \frac{N_c(t;\, \Delta t = 1\; s)}{A_c} \quad (5)$$

$$q_c(t) = \rho_c(t) \cdot \bar{v}_c(t) \quad (6)$$

Use (1)–(4): Direct inputs for crowd kinematics by area and for cell-wise speed/acceleration heatmaps (decision/turning zones).

Use (5)–(6): Density axis at one-second cadence and local flow to build density–speed/acceleration relations and identify regimes in Results.

Symbols and parameters:

- x_i, v_i, a_i: position, speed, acceleration vectors
- A_c: cell area (e.g., 0.2 m × 0.2 m)
- $N_c(t;\, \Delta t = 1\; s)$: unique headcount in cell c within [t, t + 1 s)
- $\bar{v}_c$, $\bar{a}_c$: cell-wise mean speed and acceleration magnitude (quantiles may be used for robustness)
- $\rho_c(t)$: one-second density (persons/m²); $q_c(t)$: local flow

2.3.3 Parameterisation and reproducibility

This subsection summarises parameter settings and reproducibility rules so that outputs remain comparable and traceable across batches in time granularity, smoothing strength, and visualisation strategies.

- One-second density cadence balances frame-level jitter against pedestrian interaction timescales and aligns with common 0.5–1.0 s decision steps in VR or ABM [15,16].
- Smoothing window for kinematics is set near 0.5 s to reduce quantisation noise without lagging peaks materially [15].
- Density-axis cap is fixed at 8 persons per square meter to cover extreme congestion yet avoid unstable extrapolation during fitting [16–18].
- Distributional reporting uses quantile regression and bootstrap to generate trend bands and confidence intervals that remain comparable across floors and areas under skew and heavy tails [16,17].
- Visualisation robustness prefers hexbin or equal-frequency bins to reduce overplotting and sampling bias. KDE is optional for continuous fields, and legends report windows, bandwidths, sample sizes, and exclusion rules for interpretability and reruns [16,17].
- No preset regimes. Thresholds such as free or congested are not specified in Methods. Any segmentation is data-driven and reported in the results after sensitivity checks.

3 Results

This section reports multi-camera trajectory patterns and area-wise kinematics, distils density–movement relations and behavioural tendencies, and delivers reusable benchmarks for calibration.

3.1 Crowd kinematics: area benchmarks

Table 1 compiles representative parameters for calibration and cross-area comparison. Values result from multi-camera trajectory reconstruction with centralised differencing and unified smoothing; density cadence is one second to balance jitter suppression and interaction timescales.

Table 1 Key kinematic parameters by area

Area / Scenario	Mean speed v (m/s)	Mean |a| (m/s²)	Notes
Corridors (2F–4F)	2.072	0.079	Straight corridors permit brief running; 4F start-up means ≈ 1.2; 2F nearer the exit shows higher sustained speeds.
Lobby (ground floor)	1.233	0.071	Merging and route choice broaden the spread; door zones remain slow.
Stair landings	0.524	-0.088	Faster than flights with turning and re-entry at corners.
Stair flights	0.390	0.001	≈25% lower than landings; slowdown factor ≈ 0.75.

3.2 Evacuation path tendency: grid heatmaps

BIM-aligned 0.2 × 0.2 m tiles aggregate speed and

acceleration to expose spatial structure. The lobby exhibits a fast perimeter lane and a slow door basin, indicating boundary following and exit coupling. Corridors display a start-up burst to mid-segment dip to pre-door adjustment pattern. Stairwells show speed peaks at landings and acceleration pulses at corners and door thresholds, confirming the landing–flight rhythm. Lobby, stairs and corridor's path trajectory visualisation are shown in Figure 2 to Figure 6.

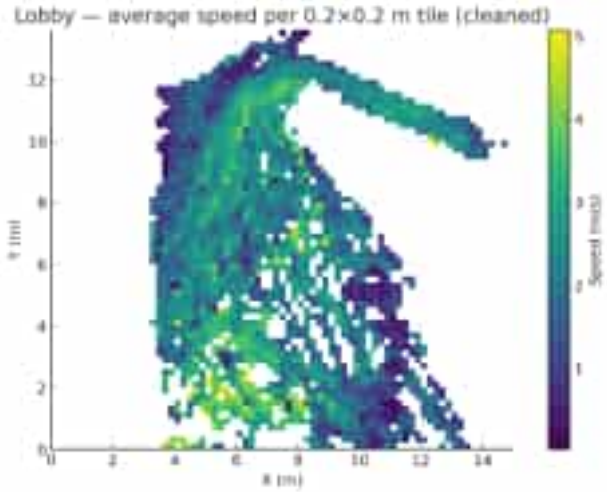

Figure 2 Lobby—average speed per 0.2 × 0.2 m tile (cleaned). Faster edge lane and a slow zone within ~1 m of the exit.

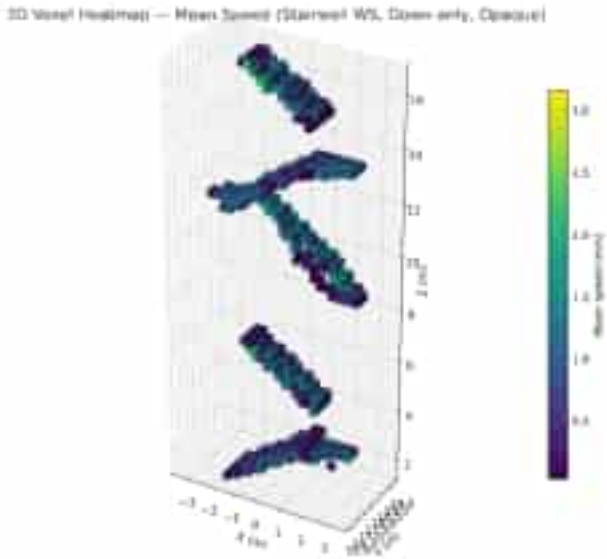

Figure 3 Stairwell WS—3D voxel heatmap of mean speed (down only). Periodic landing–flight texture with faster landings

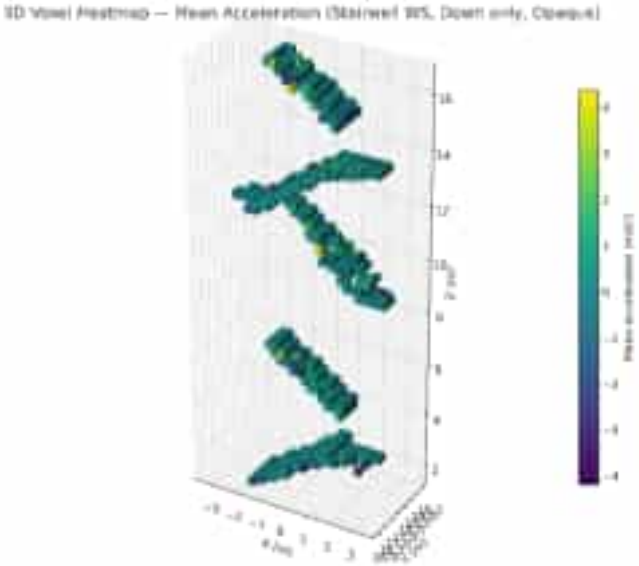

Figure 4 Stairwell WS—3D voxel heatmap of mean acceleration (down only). Pulses at landings and door thresholds indicate braking and restarting.

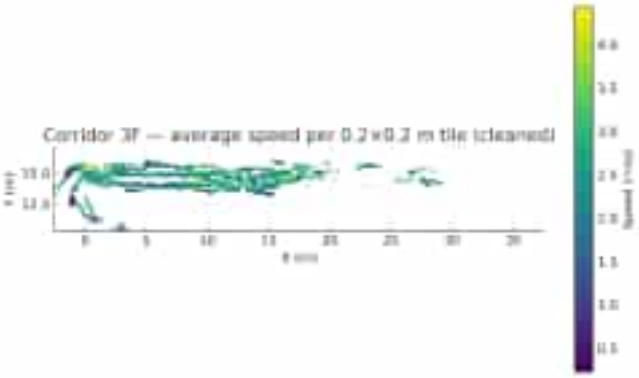

Figure 5 Corridor 3F—average speed per 0.2 × 0.2 m tile. Mid-segment steady; fluctuations near the stair door.

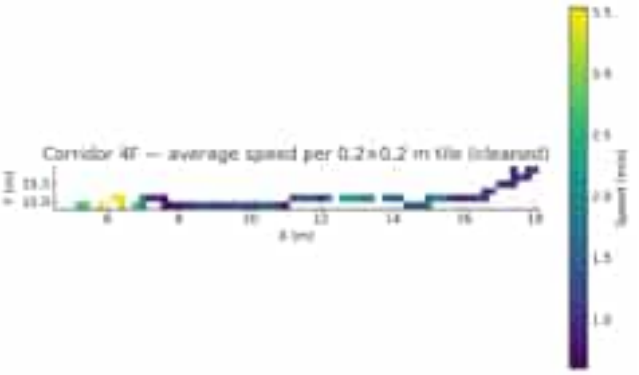

Figure 6 Corridor 4F—average speed per 0.2 × 0.2 m tile. Short start-up acceleration, slowdown near the wall, and accelerate again to the stair area.

3.3 Density–velocity/acceleration and dynamic congestion

Local density ρ is defined as the unique headcount per square meter within one second and is linked to tile-level speed and acceleration. The results are shown in Figure 7 to Figure 8 (Lobby) and Figure 9 to Figure 10 (Stairs).

Lobby. A strong negative density–speed relation is observed: the median speed is ~1–1.5 m/s at ρ≈1–2, falls to ~0.5–0.8 m/s at ρ≈4, and in micro-cells near the exit at ρ≈6–7, speeds are often < 0.5 m/s or momentarily zero. The acceleration–density relation shows maximal variability at moderate density ρ≈2–4, consistent with frequent avoidance and short stop–start movements.

Stairs. The speed–density decline is steeper than on flat areas. Even at ρ≈3–3.5 on landings, speeds converge to ~0.3–0.4 m/s, reflecting tread spacing and safety-distance constraints. Combined with acceleration trends, the evidence indicates that around ρ≈3–4 acceleration dampens markedly while speed changes little, consistent with controlled flow, and that for ρ≥5 speed drops sharply with intermittent movement—consistent with congested flow.

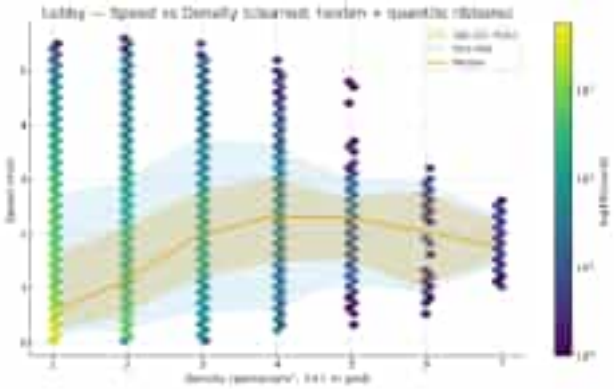

Figure 7 Lobby—Speed vs Density (hexbin with quantile ribbons).

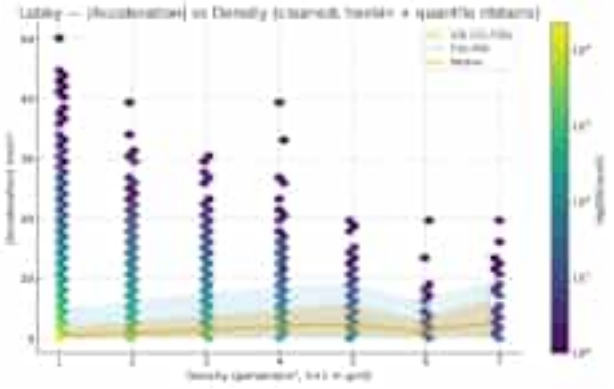

Figure 8 Lobby—|Acceleration| vs Density (hexbin with quantile ribbons).

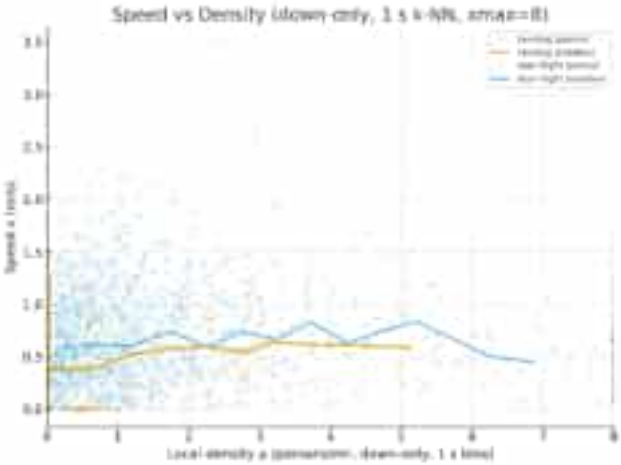

Figure 9 Stairs—Speed vs Density.

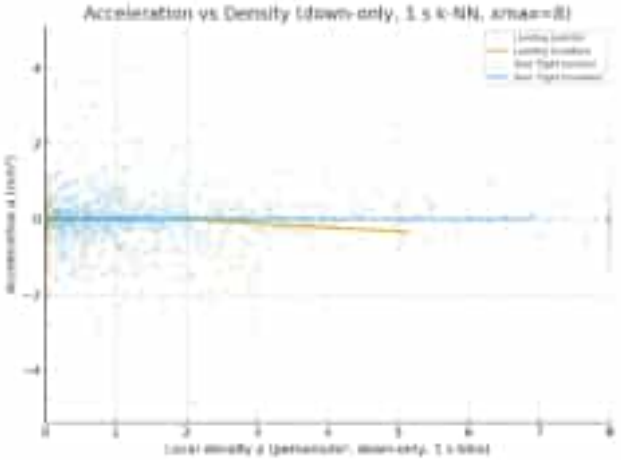

Figure 10 Stairs—Acceleration vs Density.

4 Discussion

The results show pronounced spatial dependence of movement. Corridors support high speeds. The lobby slows under merging and choice. Stairs exhibit a stable landing–flight contrast. Heatmaps (Figures 2–6) reveal fast perimeter lanes, turning nodes, and doorway coupling. Density vs. speed and density vs. acceleration relations (Figures 7 – 10) are consistent with three regimes: free flow ($\rho < 3$ persons/m²), controlled flow ($3 \leqslant \rho \leqslant 5$), and congested flow ($\rho > 5$). Table 1 provides reusable kinematic benchmarks for calibration and design.

4.1 Spatial movement patterns and congestion

Area-specific priors should replace uniform parameters. Table 1 gives representative means for corridors, lobby, and stairs that can anchor prior distributions and validation targets. The stair slowdown

factor (~0.75 from landing to flight) parameterises staircase submodels. Speed – density curves should be calibrated by area, with slope and intercept estimated from Figures 7 – 10. Quantile trends are preferable to mean-only fits to capture heavy tails and heterogeneity. Around $\rho \approx 3 - 4$, acceleration attenuates while speed changes little. This pattern identifies controlled flow and should be represented by lower stochastic acceleration and higher temporal persistence in velocity updates. Above $\rho \geqslant 5$, speed drops sharply and stop – go emerges, which calls for stronger interaction forces and tighter headway rules.

Path tendency maps (Figures 2–6) provide spatial priors for decision nodes and turn costs. Perimeter bands should carry a lower movement cost to reproduce edge preference, while door cells should carry a higher cost to reproduce slow zones. The landing–flight rhythm in the stair voxel maps supports a periodic turn–align–re-enter sequence with short acceleration pulses that can be encoded as state transitions. Local co-occupancy in corridors must be interpreted with care. Two-person tiles on 2F reflect brief overtakes rather than sustained crowding and should be modelled as transient events, not capacity increases. Route imbalance between twin stairs indicates familiarity and accessibility bias. These biases should be explicit in route choice utilities. Reaction delay should follow a right-skewed distribution with short upper-floor delays and a long lower-floor tail.

4.2 Design and operational implications

Throughput is governed by stair–corridor coupling. Speed troughs and acceleration pulses cluster at landings and door thresholds (Figures 3–4 and 5–6 near stair doors). Priority actions include clearing the first step beyond each door, increasing landing turning radius where feasible, and improving sight lines at corners. The lobby shows a fast perimeter lane and a slow door basin (Figure 2). Centre guidance markings and floor cues can draw flow off walls and reduce corner convergence. Doorway slow zones warrant checks of clear width, door swing, and obstacle placement. Twin-stair imbalance highlights that adding exits does not guarantee balanced use. Training and dynamic signage can redistribute demand in real time. High corridor speeds raise fall and collision risk during emergencies. Non-slip finishes, local slowdown cues, and staff positioning at corners and exits can mitigate these risks.

4.3 Limitations and future work

The drill involved about ninety participants and reflects moderate loading. Extreme congestion appears in micro-cells near the exit. Extrapolation to extremely high densities should be cautious. Occlusion and camera geometry can cause occasional track loss. Spatial quantisation and smoothing may damp noticeably short peaks in speed or acceleration. Geometry is site-specific, including stair width, tread rise–run, and doorway layout, so cross-building transfer requires recalibration. The benchmark represents the first step toward a VR evacuation parameter library. Expansion is needed across occupancies and layouts, broader building typologies, and outdoor domains such as forecourts and sidewalks. Higher-density drills should bound performance in congested regimes. Standardised schemas, quality control, and uncertainty reporting will support reuse. With progressive release of parameters and visual assets, calibrated immersive studies can feed validated insights back into performance-based egress design and operations.

5 Conclusion

An automated multi-camera pipeline aligned to BIM reconstructed 2D/3D evacuation trajectories across corridors, lobby, and stairs. Results deliver a reusable, multi-area benchmark for VR and agent-based calibration. Corridors supported higher speeds (overall mean $\approx$ 2.07 m/s). The lobby averaged $\approx$ 1.23 m/s under merging and choice. Stairs showed a stable geometric effect with means $\approx$ 0.52 m/s on landings and $\approx$ 0.39 m/s on flights, implying a slowdown factor $\approx$ 0.75. Density and speed were negatively related beyond $\approx$ 2 persons/m^2. Acceleration variability peaked at moderate density. Edge preference and doorway slowdowns dominated open areas. Twin stairs showed route imbalance. Reaction times were right-skewed with short upper-floor delays and a lower-floor long tail.

These outputs constitute the first step toward a VR evacuation parameter benchmark library. Area-specific speed and acceleration distributions provide priors and validation targets. The stair slowdown factor parameterises staircase submodels. Density–speed and density–acceleration curves set quantitative goals for interaction strength and stochastic noise. Edge preference and door penalties can be encoded in path-cost fields to reproduce observed streamlines. The intended outcome is a practical feedback loop where calibrated immersive studies inform real-world egress planning and operations.

Current limits include moderate loading, site-specific geometry, and potential occlusions. Next steps expand coverage across different occupancies and layouts, additional interior zones such as atria and large assembly spaces, and outdoor domains including forecourts and sidewalks. Higher-density drills will bound congested-regime performance. Standardised schemas, quality control, and uncertainty reporting will support reuse. Progressive public release of parameters and visual assets will grow the library into a shared reference for performance-based design and for immersive

technologies that return validated insights to practice. Accordingly, the contribution lies not in universal parameter claims, but in a reproducible workflow for deriving space-specific benchmarks from real drills.

Abstract

Facade shading systems can reduce cooling energy demand in office buildings located in tropical-humid climates, but the additional materials required may also increase embodied carbon emissions. Although many parametric facade optimization studies focus on operational energy and daylight performance, the temporal relationship between embodied carbon and operational carbon savings remains insufficiently explored. Carbon Payback Period (CPP) is therefore rarely integrated into parametric facade optimization and decision-making workflows. This study proposes an integrated framework combining Life Cycle Assessment (LCA), CPP, multi-objective optimization, and Multi-Criteria Decision-Making (MCDM) to support low-carbon facade design. A parametric facade model was developed for a medium office building in Taipei, Taiwan, with variations in window-to-wall ratio, glazing type, shading depth, and window configuration. Energy and daylight performance were simulated using Honeybee and Ladybug, while Wallacei was used to optimize Energy Use Intensity (EUI), Annual Sunlight Exposure (ASE), Whole-Life Carbon (WLC), Carbon Payback Period (CPP), and Spatial Daylight Autonomy (sDA). The resulting 20 Pareto-optimal alternatives were then evaluated using TOPSIS under multiple weighting scenarios. The results revealed clear trade-offs between operational efficiency and life-cycle carbon performance. Building Type 02 emerged as the most robust and balanced alternative, ranking first across the energy-priority, carbon-priority, and balanced scenarios and achieving a positive CPP of 8.95 years. These findings highlight the value of CPP as a complementary time-based indicator for verifying whether additional embodied carbon can be offset by future operational carbon savings in facade design decision-making.

Keywords –

Parametric facade design; Carbon payback period; Life cycle assessment; Genetic algorithms; Multi-criteria decision-making; Tropical-humid climate

1 Introduction

Global warming remains a major global challenge and has accelerated the use of life cycle assessment (LCA) to quantify emissions and support SDG 13 and long-term net-zero targets[1]. In the building sector, particularly in office buildings located in humid tropical climates, high cooling demand makes facade design a critical strategy for reducing operational energy use. In Taipei's hot-humid context, facade measures such as high-performance glazing and external shading can improve thermal and visual performance, but they may also increase embodied carbon.

Recent advances in parametric modeling, building performance simulation, and genetic algorithms have enabled the systematic exploration of facade alternatives based on indicators such as Energy Use Intensity (EUI), Spatial Daylight Autonomy (sDA), and Annual Sunlight Exposure (ASE)[2]. However, many studies still primarily focus on operational performance and give limited attention to embodied carbon throughout the building life cycle. Although LCA has increasingly been applied in building evaluation, aggregated carbon indicators often fail to reflect the temporal relationship between additional embodied carbon and future operational carbon savings. In this regard, the Carbon Payback Period (CPP), defined as the time required for operational carbon savings to offset additional embodied carbon, provides an important time-based perspective[3]. Yet CPP remains rarely integrated into parametric facade optimization workflows.

At the same time, multi-criteria decision-making (MCDM) methods such as TOPSIS are widely used to rank Pareto-optimal solutions under different decision priorities[4]. However, most facade-related MCDM studies still emphasize energy, cost, and daylight metrics, while time-based carbon indicators, such as CPP, receive limited attention. This gap is particularly relevant in humid tropical and subtropical climates such as Taipei,

where the interactions among shading, glazing, daylight availability, and life-cycle carbon performance remain insufficiently explored.

Therefore, this study proposes an integrated LCA-CPP-MCDM framework that combines parametric facade modeling, Wallacei-based multi-objective optimization, and TOPSIS evaluation for an office building in Taipei. CPP is incorporated in the optimization stage as a time-based carbon objective, but it is excluded from the final TOPSIS ranking because negative CPP values represent no-payback conditions rather than stable and directly comparable ranking criteria. Instead, CPP is used as a post-evaluation indicator to verify whether the highly ranked alternatives also achieve meaningful carbon payback performance. This approach provides a more comprehensive and time-sensitive basis for low-carbon facade design in humid tropical climates.

2 Literature Review

2.1 Parametric Design and Multi-Objective Optimization for Facade Performance

Facade design strongly influences building performance by affecting solar heat gain, daylight availability, visual comfort, and energy use. In tropical office buildings, key variables such as window-to-wall ratio (WWR), glazing type, and shading depth must be carefully balanced because improving one aspect of performance may reduce another. Facade design should therefore be treated as a multi-criteria problem rather than a single-objective task[5].

Parametric design helps manage this complexity by defining geometric and performance-related properties as adjustable variables. When integrated with building performance simulation, it supports the rapid generation and evaluation of design alternatives during the early design stage. Because facade objectives are often conflicting, multi-objective optimization (MOO) is widely used to identify Pareto-optimal solutions rather than a single best design. In this context, Wallacei, which implements NSGA-II in Grasshopper-based workflows, has become a relevant tool for facade optimization[6].

However, most parametric multi-objective optimization studies still focus mainly on operational indicators, particularly energy use and daylight performance, with limited attention to embodied carbon and broader life-cycle carbon trade-offs. This limitation is also evident in tropical office building studies, where optimization frameworks often prioritize operational efficiency and indoor environmental quality over long-term carbon implications. As a result, life-cycle carbon indicators, especially time-based measures such as Carbon Payback Period (CPP), remain insufficiently integrated into facade optimization. To address this gap, the present study incorporates LCA-based metrics, including Whole-Life Carbon (WLC) and CPP, into facade optimization and design decision-making.

2.2 Life Cycle Assessment in Parametric Design Workflows

Life Cycle Assessment (LCA) is increasingly important in building evaluation because it captures environmental impacts beyond operational energy use[7]. In facade design, this is particularly relevant because strategies that improve energy and daylight performance may also increase embodied carbon through additional materials, such as glazing, framing, and shading systems.

To support early-stage design, parametric Life Cycle Assessment (pa-LCA) links parametric models with environmental impact calculations, enabling rapid comparison of design alternatives[8]. However, its application remains limited by data uncertainty, interoperability issues, and the computational burden of repeated quantity take-off and carbon calculations. Accordingly, this study adopts a partial life-cycle scope based on EN 15978, covering A1–A3 for embodied carbon and B6 for operational energy use[9]. This boundary is appropriate for early-stage facade evaluation, where detailed life-cycle data are still unavailable. Within this framework, Whole-Life Carbon (WLC) is used to assess combined embodied and operational emissions, while Carbon Payback Period (CPP) captures the time dimension of carbon performance[10].

2.3 Carbon Payback Period (CPP)

Carbon Payback Period (CPP) is a time-based indicator that measures how long it takes for the additional embodied carbon caused by a design intervention to be offset by annual operational carbon savings[11]. In facade design, CPP is particularly relevant because variables such as window-to-wall ratio (WWR), glazing type, and shading depth affect both embodied and operational carbon, thereby creating a trade-off between upfront and long-term environmental impacts. CPP is therefore useful for evaluating whether a facade strategy can deliver meaningful carbon benefits within a relevant time frame[12].

A key strength of CPP is its ability to introduce a temporal perspective into carbon assessment. A facade alternative may reduce operational energy use and even achieve lower Whole-Life Carbon (WLC), yet still require a long time to offset its initial embodied carbon burden when annual carbon savings are limited[13]. In this way, CPP helps distinguish between solutions that provide near-term carbon benefits and those whose advantages only emerge over longer time horizons. This distinction is important because earlier carbon reductions

are generally more valuable for climate change mitigation than delayed ones[14].

Despite its relevance, CPP remains underused in parametric facade optimization studies, where most research continues to focus on energy use, operational carbon, or Whole-Life Carbon[15]. Therefore, this study adopts CPP as a complementary indicator to strengthen life-cycle carbon evaluation and support early-stage facade design decision-making. Positive CPP values indicate a valid carbon payback duration, meaning that the additional embodied carbon can be offset over time through annual operational carbon savings. Negative CPP values do not represent a valid payback duration; rather, they indicate that carbon payback is not physically meaningful under the given condition. This occurs when annual operational carbon savings are absent or insufficient to offset the initial embodied carbon increment.

2.4 Facade Optimization in Tropical-Humid Climates

Facade optimization in tropical-humid climates requires climate-specific evaluation because high solar radiation, temperatures, humidity, and daylight availability create performance conditions distinct from those in temperate regions[11]. In Taipei, facade design influences cooling demand, glare risk, and daylight distribution, making variables such as window-to-wall ratio (WWR), glazing type, and shading geometry critical to performance. These trade-offs are commonly assessed using metrics such as sDA, ASE, and DGP, which reflect daylight adequacy, excessive sunlight exposure, and visual comfort. Although previous studies in hot-humid climates have emphasized operational energy and comfort performance, life-cycle carbon and carbon payback remain less explored. Therefore, this study extends climate-responsive facade optimization by integrating energy, daylight, glare, and life-cycle carbon metrics for an office building in Taipei.

2.5 Research Gap

The reviewed literature demonstrates substantial progress in parametric facade optimization, life-cycle assessment integration, and multi-criteria decision-making. However, three critical gaps remain:

(1) First, CPP is rarely integrated into parametric optimization workflows and is typically applied only as a post-evaluation metric.

(2) Second, existing LCA-based facade studies rely heavily on aggregated carbon indicators, overlooking the temporal relationship between embodied and operational emissions.

(3) Third, tropical-humid climates remain underrepresented in integrated LCA–optimization studies, particularly those addressing facade shading systems.

To address these gaps, there is a clear need for an integrated framework that embeds CPP within parametric facade optimization and decision-making processes, enabling designers to evaluate not only energy and daylight performance but also the time-dependent carbon effectiveness of facade interventions. This study responds to this need by proposing a combined LCA–CPP–MCDM framework applied to a tropical-humid office building case study.

3 Method

This study adopts an integrated, multi-stage framework (see Figure 1) combining parametric facade modeling, life cycle assessment (LCA), carbon payback period (CPP) analysis, genetic algorithm optimization, and multi-criteria decision-making (MCDM). The overall workflow is structured into four sequential stages: (1) literature review and framework setup, (2) parametric modeling and simulation, (3) multi-criteria decision-making, and (4) validation and final decision support.

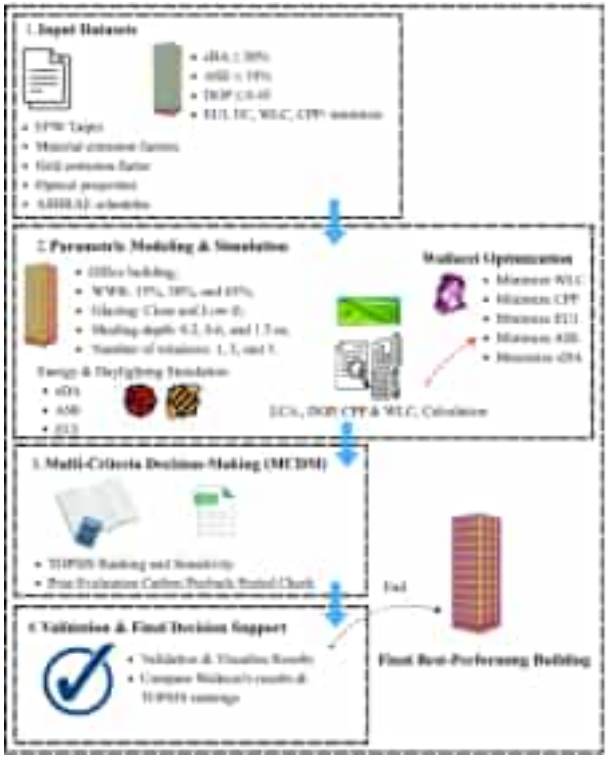

Figure 1. Research Workflow

3.1 Stage 1: Input Datasets

In the first stage, the study defines the input datasets, analytical boundaries, and performance targets for the integrated facade optimization framework. The case study is a medium office building in Taipei, where solar

radiation, cooling demand, and daylight availability strongly influence facade performance. The main inputs include the Taipei EPW weather file, material emission factors, grid emission factors, optical properties, and ASHRAE schedules, which together support energy, daylight, and carbon assessment. The facade is defined by four key variables: window-to-wall ratio (WWR), glazing type, shading depth, and number of windows. At this stage, the performance criteria are established as sDA ≥ 50%, ASE ≤ 10%, and DGP ≤ 0.45, while EUI, embodied carbon (EMB), WLC, and CPP are treated as indicators to be minimized.

3.2 Stage 2: Parametric Modeling and Simulation

In the second stage, a parametric facade model was developed in a visual programming environment by varying the window-to-wall ratio (WWR), shading depth, glazing type, and number of windows within predefined ranges, as summarized in Table 1.

Table 1. Building Geometry & Simulation Setup

No	Category	Value
1.	Building Type	Medium Office Building
2.	Location & Climate	Taipei, Taiwan; Tropical-Humid
3.	Geometry	15 × 15 m plan, 12 floors, floor height 4.0 m
4.	Spatial Model	Single zone per floor
5.	Orientation	North, East, South, and West
6.	Facade Variables	WWR: 15% / 30% / 65%; Glazing: Clear / Low-E; Shading depth: 0.2 / 0.6 / 1.5 m; Number of windows: 1 / 3 / 5
7.	Simulation Platform	Rhino + Grasshopper + Honeybee/Ladybug
8.	Weather Data	EPW (Taipei)
9.	Energy Simulation	Honeybee Energy (Energy Plus)
10.	Daylight Standards	EN 17037, LEED v4.1
11.	Energy Metric	EUI (kWh/m²·yr)
12.	Daylight Metrics	sDA, ASE, DGP
13.	Carbon Metrics	Embodied Carbon, CPP, WLC
14.	LCA Data Source	QTO and EF-based carbon coefficients
15.	Grid Emission Factor	Taiwan electricity grid
16.	Optimization Method	Wallacei Genetic Algorithm (GA)
17.	Optimization Objectives	Maximize sDA; minimize ASE, EUI, WLC, and CPP
18.	Decision-Making Method	TOPSIS (MCDM) with DGP as a supporting visual comfort criterion
19.	Facade Final Output	Optimal facade parameters

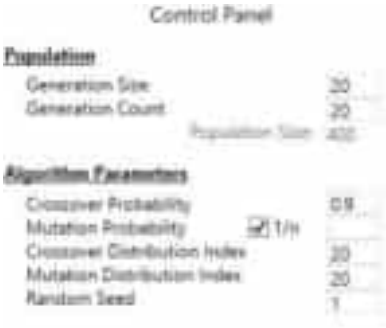

Figure 2. Wallacei optimization settings

Multi-objective optimization was then performed using the Wallacei genetic algorithm to minimize EUI, ASE, WLC, and CPP while maximizing sDA. The optimization settings are shown in Figure 2. During the evolutionary search, a simplified embodied carbon proxy was adopted to represent carbon sensitivity within the optimization loop, while Daylight Glare Probability (DGP) was evaluated separately at the post-optimization stage. For the selected Pareto-optimal alternatives, embodied carbon was recalculated using quantity take-off (QTO)-based geometry and emission-factor-based carbon coefficients. These recalculated embodied carbon values were then combined with annual operational carbon emissions to determine Whole-Life Carbon (WLC) and Carbon Payback Period (CPP), enabling an integrated assessment of energy, daylight, and carbon performance.

Accordingly, this study used two embodied carbon representations with distinct roles. QTO-based embodied carbon was used for the final calculation of WLC and CPP, whereas the simplified embodied carbon proxy in Wallacei served only as a surrogate indicator to test the influence of carbon sensitivity during the evolutionary search. Although the proxy may affect which solutions are explored and retained in the Pareto set, the final carbon assessment of the selected alternatives was based entirely on the more detailed QTO-derived embodied carbon values.

3.3 Stage 3: Multi-Criteria Decision-Making (MCDM)

In the third stage, the 20 Pareto-optimal facade alternatives generated by Wallacei were evaluated using TOPSIS to identify the most balanced final design. Four weighting scenarios were defined: energy-priority, carbon-priority, comfort-priority, and balanced.

TOPSIS ranked the alternatives using six criteria: sDA, ASE, DGP, EUI, WLC, and embodied carbon (EMB). Carbon Payback Period (CPP) was excluded from the final ranking because negative CPP values do not represent a valid payback duration but rather indicate a no-payback condition. This occurs when a design fails

to generate sufficient annual operational carbon savings to offset the additional initial embodied carbon, meaning that the carbon payback mechanism is not achieved in physical terms. Therefore, CPP was not used as a primary ranking criterion, but was instead treated as a post-evaluation indicator to verify whether the highly ranked alternatives also demonstrated meaningful carbon payback performance. A post-evaluation CPP check was also applied to all Pareto-optimal solutions. Together, these analyses provided a stronger basis for selecting the final facade design for validation and interpretation.

3.4 Stage 4: Validation and Final Decision Support

In the fourth stage, the optimization outcomes from Wallacei were compared with the TOPSIS ranking results to assess the consistency between search-based and decision-based evaluation. This stage also included visual validation and post-evaluation CPP verification to support the final selection of the best-performing facade alternative. Through this process, the final design was assessed not only on ranking performance but also on its practical balance among daylight, visual comfort, operational energy, and life-cycle carbon performance.

4 Optimization Results: Pareto Front Analysis

4.1 Multi-Objective Optimization Outcomes

The Wallacei optimization generated a range of facade design alternatives that balance energy, daylight, and life-cycle carbon objectives. Building Type 00 served as the baseline reference case, and 20 Pareto-optimal solutions were identified as non-dominated alternatives.

Figure 3 shows the distribution of these solutions in the objective space, and Figure 4 summarizes the facade parameters and performance values of the baseline and optimized cases. Together, these results define the feasible trade-off space among the main optimization objectives.

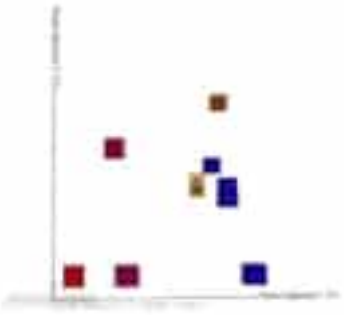

Figure 3. Wallacei Objective Space Results

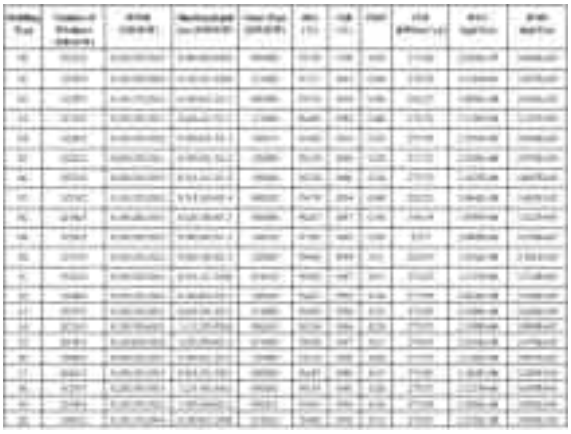

Figure 4. Pareto Dataset of Optimized Designs

4.2 Characteristics of Pareto-Optimal Facade Solutions

The 20 Pareto-optimal facade solutions show variations in WWR, shading depth, glazing type, and window configuration that affect energy, daylight, and carbon performance. However, daylight performance remains consistently high across the Pareto set, with all solutions satisfying the applied sDA, ASE, and DGP criteria. This indicates that daylight primarily serves as a compliance condition rather than as the main source of variation among the final alternatives.

The main differences among the Pareto solutions are observed in EUI, WLC, and embodied carbon. Lower EUI does not always correspond to lower WLC, showing that operational energy savings may be accompanied by higher facade-related carbon impacts. These results reflect the trade-off between operational efficiency and life-cycle carbon performance in the optimized facade set.

4.3 Pareto Trade-Offs between Energy, Daylighting, and Carbon Performance

The Pareto set shows that the main trade-off lies between EUI and WLC rather than between acceptable and unacceptable daylight performance. Because all solutions meet the applied daylight and glare criteria, the final comparison is mainly driven by differences in energy use and carbon impact.

CPP provides an additional layer of interpretation in this trade-off. Although it is included in the optimization stage, it is used only as a post-evaluation indicator in the final analysis, as negative CPP values indicate no-payback conditions and are not suitable for direct MCDM comparison. CPP, therefore, helps verify whether alternatives with favorable energy and carbon performance also achieve meaningful carbon payback.

4.4 Selection of Pareto Dataset for Decision Analysis

The 20 Pareto-optimal facade alternatives were retained as the input dataset for the subsequent TOPSIS analysis, while Building Type 00 was treated as a separate baseline reference case. For each alternative, facade parameters and performance indicators were compiled into a unified evaluation table. At this stage, final embodied carbon values were calculated using detailed QTO-based results from the optimized facade geometries. These values were then used to derive WLC and support the post-evaluation assessment of CPP. This data set provides the basis for transparent multi-criteria comparison of the optimized facade alternatives.

5 Multi-Criteria Decision-Making Results

5.1 TOPSIS Evaluation under Different Priority Scenarios

Following the Pareto front analysis, the 20 Pareto-optimal facade alternatives were evaluated using TOPSIS to support final decision-making. The decision matrix included six criteria: sDA, ASE, DGP, EUI, WLC, and embodied carbon (EMB). All criteria were normalized using vector normalization, and benefit and cost criteria were treated accordingly, as shown in Table 2. Four weighting scenarios were defined: energy-priority (EUI, ASE), carbon-priority (WLC, EMB), comfort-priority (sDA, DGP), and balanced. TOPSIS then produced a closeness coefficient for each alternative under each scenario.

Table 2. TOPSIS Normalization

Building Type	sDA	ASE	DGP	EUI	WLC	EMB
1	0.223	0.219	0.258	0.231	0.227	0.205
2	0.223	0.219	0.258	0.201	0.203	0.212
3	0.223	0.219	0.258	0.231	0.227	0.210
4	0.223	0.228	0.232	0.227	0.226	0.222
5	0.224	0.223	0.181	0.227	0.231	0.250
6	0.224	0.223	0.181	0.227	0.232	0.257
7	0.223	0.219	0.258	0.209	0.211	0.219
8	0.223	0.226	0.232	0.208	0.207	0.203
9	0.223	0.228	0.232	0.227	0.224	0.212
10	0.223	0.219	0.258	0.209	0.208	0.198
11	0.224	0.226	0.200	0.227	0.229	0.235
12	0.223	0.228	0.232	0.227	0.226	0.221
13	0.223	0.223	0.226	0.228	0.226	0.216
14	0.224	0.223	0.181	0.227	0.231	0.250
15	0.224	0.226	0.200	0.227	0.226	0.218
16	0.223	0.223	0.181	0.227	0.229	0.242
17	0.223	0.223	0.226	0.228	0.226	0.213
18	0.224	0.223	0.181	0.227	0.228	0.232
19	0.223	0.228	0.232	0.227	0.225	0.219
20	0.223	0.223	0.226	0.228	0.228	0.229

Table 3 presents the weighting scenarios used in the TOPSIS evaluation, including the energy-, carbon-, and comfort-priority settings.

Table 3. TOPSIS Weighting Scenarios

Scenario	sDA	ASE	DGP	EUI	WLC	EMB
Energy	0.05	0.15	0.05	0.55	0.10	0.10
Carbon	0.03	0.02	0.02	0.08	0.75	0.10
Comfort	0.20	0.10	0.40	0.10	0.10	0.10
Balanced	0.050	0.100	0.050	0.400	0.300	0.100

5.2 Ranking Results and Identification of the Optimal Facade Design

The TOPSIS results in Figures 5–8 indicate that the preferred facade alternative changes with the weighting scenario, confirming that the final ranking is highly dependent on decision priorities. Building Type 02 ranked first in the energy-priority, carbon-priority, and balanced scenarios, demonstrating robust performance across multiple evaluation contexts. In contrast, Building Type 18 ranked first only in the comfort-priority scenario, indicating stronger performance when daylight and visual comfort are emphasized. These findings suggest that no single facade alternative is universally optimal under all weighting scenarios. Overall, Building Type 02 can be regarded as the most robust option, whereas Building Type 18 is preferable when comfort is prioritized.

Figure 5. TOPSIS Results: Energy-Priority

Figure 6. TOPSIS Results: Carbon-Priority

Figure 7. TOPSIS Results: Comfort-Priority

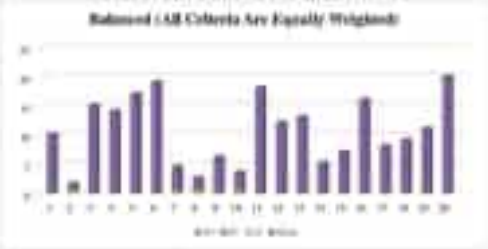

Figure 8. TOPSIS Results: Balanced

Table 4. Post-Evaluation Carbon Payback Period Check

BUILDING TYPE	CPP (YEARS)	CPP STATUS
1	-30.24	No payback
2	8.95	Achieved
3	-43.80	No payback
4	-953.39	No payback
5	-1670.47	No payback
6	-1893.55	No payback
7	17.92	Achieved
8	6.39	Achieved
9	-606.39	No payback
10	3.31	Achieved
11	-514.18	No payback
12	-914.38	No payback
13	-129.70	No payback
14	-1681.97	No payback
15	-299.12	No payback
16	-1444.11	No payback
17	-108.48	No payback
18	-1135.95	No payback
19	-847.28	No payback
20	-217.64	No payback

As shown in Table 4, positive CPP values indicate a valid carbon payback duration, meaning that the additional embodied carbon can be offset over time through annual operational carbon savings. By contrast, negative CPP values do not represent a valid payback duration; instead, they indicate a no-payback condition in which annual operational carbon savings are absent or insufficient to offset the initial embodied carbon increment.

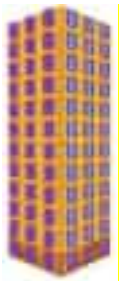

Figure 9. Final Selected Facade Design

Figure 9 presents the final selected facade design for Building Type 02. The figure visualizes the overall facade composition of the selected alternative, highlighting the arrangement of windows and shading features across the building form. This design was chosen as the final recommendation because it showed the most stable overall performance across the TOPSIS scenarios and also achieved a positive CPP value, indicating acceptable carbon payback performance over the building life cycle.

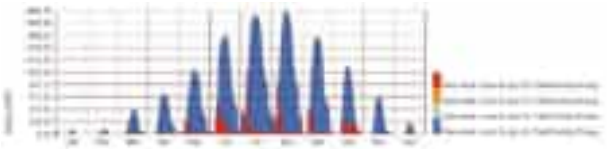

Figure 10. Monthly Cooling Energy Profile (HB-Energy)

Figure 10 presents the monthly cooling energy profile of the selected facade design. A pronounced seasonal variation can be observed, with cooling demand remaining minimal during the winter months, increasing steadily through spring, and peaking in July and August before declining again toward the end of the year. This distribution is consistent with Taipei's hot-humid climatic context, in which cooling loads are primarily driven by elevated summer air temperatures and increased solar exposure. The figure therefore highlights the strong seasonal dependence of cooling energy use in the evaluated office building.

6 Conclusion

This study developed an integrated LCA–CPP–MCDM framework combined with parametric modeling and Wallacei-based multi-objective optimization for office facade design in Taipei's hot-humid climate. The results revealed clear trade-offs among energy use, daylight availability, glare performance, and life-cycle carbon outcomes. Shading strategies were found to reduce cooling demand, but they could also increase embodied carbon, making the Carbon Payback Period (CPP) an important indicator for evaluating long-term carbon effectiveness. The optimization process generated 20 Pareto-optimal solutions, and the TOPSIS analysis identified Building Type 02 as the most robust and balanced alternative across the evaluated weighting scenarios. Building Type 02 also achieved a positive CPP of 8.95 years, indicating that its additional embodied carbon can be offset by annual operational carbon savings within a measurable period. This result was therefore classified as Achieved. However, CPP was not included as a direct TOPSIS criterion because negative CPP values are not physically interpretable as valid payback durations in a conventional ranking process. Therefore, CPP was treated as a post-evaluation indicator to verify whether the selected alternatives also achieved meaningful carbon payback performance.

This study was tested on a single office-building case in Taipei, which limits the direct generalizability of the findings. Nevertheless, the proposed workflow remains adaptable to other tropical and subtropical contexts through adjustment of weather data, grid emission factors, and building geometry inputs. Future work should extend the framework to multiple building types and climatic conditions to further examine the robustness of facade design trade-offs under different environmental and carbon scenarios.

Acknowledgment

The authors would like to thank the National Science and Technology Council (NSTC) for their support of this research and for providing the funding necessary for conference participation.

Abstract –

Building Information Modelling (BIM) is widely recognised as a key driver of digital transformation in the architecture, engineering and construction industry. However, its full potential remains underutilised, partly due to the vast and complex nature of BIM-related data. At the same time, Natural Language Processing (NLP), a rapidly evolving field of artificial intelligence, offers advanced methods for interpreting and leveraging text-based information. The convergence of these two technologies holds considerable potential to facilitate human interaction with BIM data by making it more accessible. Despite this potential, research directly linking NLP and BIM remains limited. This paper attempts to bridge this gap by mapping and evaluating the current state of research on NLP applications within BIM workflows. To this end, a Systematic Literature Review is conducted in accordance with the methodological framework proposed by Fink, identifying 92 relevant publications. The metadata of these publications was analysed using VOSviewer, followed by a detailed content analysis. For each source, the BIM-related tasks optimised by NLP and NLP functionality applied to BIM data are identified, and a novel approach is proposed to classify the BIM-NLP integration into five categories: Extract, Query, Enrich, Modify, and Match. The analysis reveals that most existing literature explores NLP application in a peripheral or exploratory manner, with few instances of deep integration into BIM workflows. Nevertheless, the reviewed literature highlights the potential of NLP to improve data accessibility, automate information processing, and enhance human-machine interaction.

Keywords –

BIM–NLP integration, Large Language Models, Human–Machine Interaction, Data Accessibility

1 Introduction

The architecture, engineering, and construction (AEC) industry is a highly data-intensive domain. Throughout the entire building lifecycle, large volumes of heterogeneous information are generated and exchanged. Despite ongoing digitisation and the increasing adoption of Building Information Modelling (BIM), a substantial share of information exchange in the AEC sector continues to rely on textual information, from both unstructured documents and semi-structured but fragmented information systems. [1–3]

Natural Language Processing (NLP) provides methods for the automated analysis of such textual information [4, 5]. Recent advances in NLP, particularly the emergence of Large Language Models (LLMs), have significantly expanded the ability to capture semantic meaning, contextual relationships, and domain-specific knowledge from vast and unstructured text sources [6, 7]. In the context of the transition toward a data-driven and model-based construction industry, the combination of BIM and NLP has been identified as a technology with considerable potential [8–10]. BIM relies on structured information models that are commonly exchanged using the Industry Foundation Classes (IFC) standard, which is based on formal, machine-readable text [11]. Integrating NLP techniques with BIM, therefore, enables the linkage of textual information from other sources within one central information model of a built asset. This provides the potential for more data-driven processes, which can result in enhanced decision-making and greater automation across the entire lifecycle of a building.

To understand the potential of BIM–NLP integration current applications and limitations need to be analysed. But only a limited number of studies have explicitly reviewed the combined application of BIM and NLP. Di Giuda et al. [12] presented a literature review, identifying several potential application areas of NLP in AEC, but

with a strong focus on using NLP for requirements engineering at an early project phase to initialize BIM. Two subsequent studies by Locatelli et al. [2, 13] applied scientometric methods to analyse BIM–NLP integration. These analyses identified a rapidly increasing scientific interest in NLP and Semantic BIM as independent research domains and clustered the identified articles thematically. However, the clusters lack a unified clustering strategy, consisting of a mix of BIM-related tasks, NLP tasks, and review articles.

Overall, the existing review studies indicate growing academic interest in the integration of BIM and NLP but also reveal unresolved research gaps. In particular, there is a lack of a systematic, content-oriented literature review that critically examines NLP integration into BIM-centred workflows. In addition, due to rapid developments in Artificial Intelligence (AI) methods, NLP is a dynamically evolving field [5]. Consequently, the findings of existing studies are no longer up to date. Hence, the objective of this article is to conduct a Systematic Literature Review on the combined use of BIM and NLP in the AEC sector. The study aims to approach existing research from a content perspective, identify dominant application areas, and assess current limitations to outline directions for future research.

2 Theoretical Background

2.1 Natural Language Processing

NLP is a technique to analyse, understand, and work with human language with the help of computers [14]. NLP involves converting unstructured language data into a structured data format. This enables machines to identify and understand language and text to generate relevant responses [15]. Contrary to some definitions, NLP does not constitute a subfield of AI per se; however, it does utilise AI methods [4, 5], as shown in a schematic classification of different forms of NLP in Figure 1.

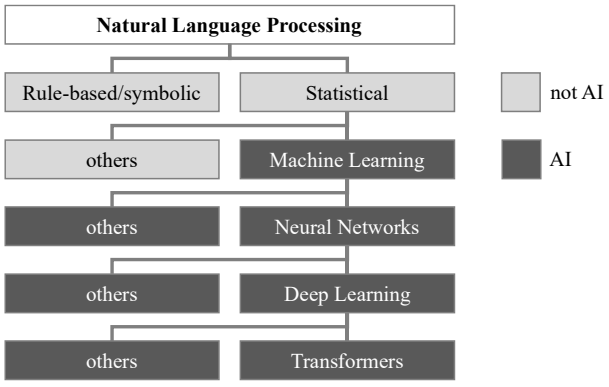

Figure 1. Schematic classification of NLP methods and models based on Canchila et al. [5]

According to Locatelli et al. [2] the first scientific article about NLP application in the field of AEC was published in 1989 by Logcher et al., in the form of an article bearing the title "Knowledge Processing for Construction Management Data Base"[16]. Since then, methods have evolved from rule-based/symbolic procedures, such as ontologies, to statistical procedures. In the field of statistical methods, it is possible to distinguish between classical statistical methods and machine learning methods, which are part of the field of AI. Within machine learning, one can differentiate between Neural Networks (NN) and other methods. Continuing along the chain, among NN methods, Deep Learning is the subfield leading to Transformer architectures, which have attracted considerable attention for several years [15]. Transformer models refer to a NN architecture introduced by Vaswani et al. [17]. It is a general-purpose architecture that can be applied to many tasks beyond language. Most contemporary LLMs (e.g. GPT-5, LLaMa, and BERT) are implemented using Transformer architectures [5]. LLMs, in turn, are models defined by their large scale in terms of parameters, training data, and computational resources, as well as their ability to perform a wide range of language-related tasks [18].

2.2 Building Information Modelling

BIM is a model-based methodology for the digital representation and management of physical and functional characteristics of built assets [19]. BIM enables the integration of geometric, semantic, and relational information into a coherent information model that can be used across different phases of the building lifecycle [19]. In this context, the 3D geometric model is commonly extended by additional information, so-called dimensions. Typically, temporal information to support construction sequencing and scheduling is referred to as 4D-BIM, and adding cost-related data to enable quantity-based cost estimation and financial control is referred to as 5D-BIM [20]. Beyond these dimensions, BIM models can be further enriched with information related to aspects such as sustainability, safety, or facility management [20]. The extension of BIM into multiple dimensions enables a more comprehensive and integrated management of construction projects by combining heterogeneous information within the digital model of the built asset. A central aspect of storing the relevant information is the underlying data structure of the BIM model. BIM models are typically exchanged using the IFC standard, which provides a formal, object-oriented schema for representing building components, their properties, and their relationships [11, 21]. IFC is based on machine-readable and hierarchical data structures that support interoperability between software systems [22]. These structured representations allow information to be

queried, validated, and processed algorithmically, forming the basis for NLP applications [11].

3 Methodology

To identify relevant publications, a Systematic Literature Review according to the methodology of Fink [23] is conducted. The first step in this methodology is defining research questions (RQs). In this article, three RQs are posed. The first RQ pertains to the identification of relevant literature and the initial characterisation of the same. The specific inquiry is as follows:

- RQ1: What scientific articles exist on the integration of BIM and NLP?

Following the next steps according to Fink [23], subsequently the databases for the search are defined. The databases Engineering Village (Compendex), IEEE Xplore, Scopus, Taylor & Francis, Wiley Online Library, and Web of Science are used, since they cover a large part of common databases for both general and engineering-specific topics. Additionally, the DBs allow suitable options for keyword entry, as well as filter and export functions. The search string for the Systematic Literature Review consists of one component on the topic of "BIM" and a second component on the topic of "NLP". Synonyms for the two main search words are additionally collected. In the NLP component, "LLMs" are included as the only specific method, as they have gained particular prominence in recent years. The synonyms are linked by the Boolean operator "OR" and the two components are linked by an "AND" operator.

This procedure identifies 430 articles, from which duplicates are first removed. According to Fink [23], the remaining articles are then subjected to a first and second filtering procedure (screening). Formal quality criteria are applied in the first filtering process. These quality criteria include:

- Article not accessible
- Article no longer available
- Article not in German or English

Material quality criteria are applied in the second filtering process. These include, above all, thematic relevance to the research question. For instance, reasons for exclusion include:

- Article does not relate to the construction industry
- Article does not relate to the use of NLP
- Article only mentions BIM in the outlook/introduction

The review process is shown in Figure 2, based on a PRISMA diagram [24]. It shows the number of articles included or excluded in each step, along with the reason for exclusion.

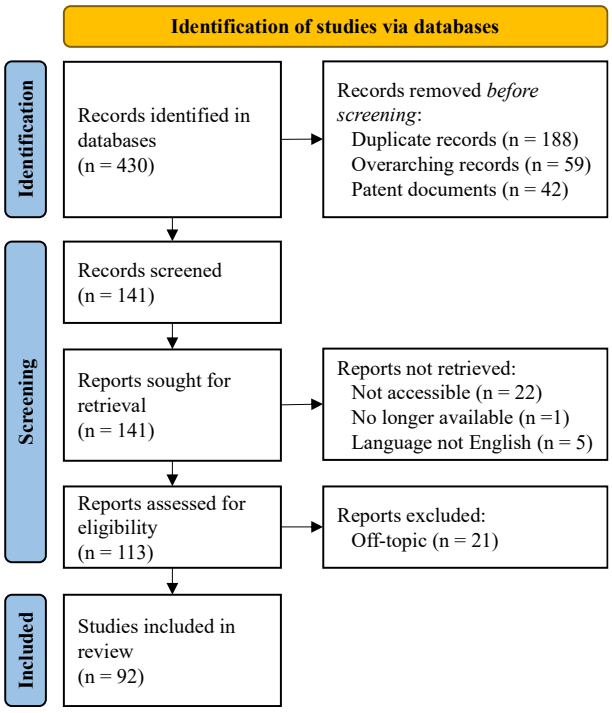

Figure 2. Conducted Systematic Literature Review process based on a PRISMA-diagram

As a result of the Systematic Literature Review, 92 articles remain for further analysis. To answer the first RQ, scientometric data is evaluated by VOSviewer [25]. This paper highlights two aspects: the year of publication and a classification of the publication type. The development of publication frequency indicates the interest in a research field and can show trends. Analysing the publication type, differentiating between "Original Research", "Reviews", and "Case Studies", can give a first impression of the content.

The bibliometric data is followed by an in-depth content analysis of the BIM–NLP applications described in the articles. Therefore, two more RQs are defined:

- RQ2: Which BIM workflow-related tasks are tackled by NLP integration in the identified articles?
- RQ3: Which NLP functionalities are used regarding BIM data in the identified articles?

To answer both RQs, clustering techniques are applied. For RQ2, the clusters are formed based on the BIM-related tasks within a building's lifecycle. At this point, the primary focus is on the identification of tasks within the BIM workflow that are impacted, while the specific functionality of NLP is not a primary concern. The task clusters are developed based on existing review research articles, and are then adapted to or supplemented by novel categories. For RQ3, the clusters are formed based on the NLP functionality applied to BIM data. These clusters are not related to specific NLP methods or

models, but rather characterise the actions performed by the NLP application on the BIM data. Therefore, new categories are developed.

4 Analysis

4.1 Year of Publication

Figure 3 shows how the identified publications are distributed over time. The diagram starts in 2014, as no articles published before this date were identified.

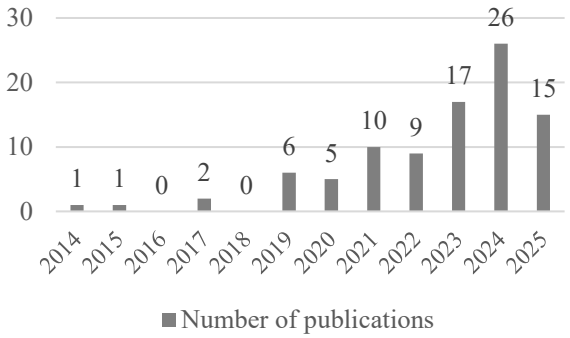

Figure 3. Development of the number of publications about BIM–NLP integration

It should be noted that the number of articles for 2025 only covers part of the year, as the research was conducted in May 2025. Based on the results from May, a higher number of publications can be expected for 2025 than for 2024. The development of publication numbers shows a rising research interest in the integration of BIM and NLP, confirming the findings of the reviews mentioned in Chapter 1. At the same time, the number of existing studies is still rather limited.

4.2 Type of Publication

The following section provides a concise overview of the categorisation of each publication into one or more types of publication. The results of the publication type analysis are shown in Table 1.

Table 1. Number and percentage of articles per publication type

Publication type	Number	% (N=92)
Original Research	78	84
Review	11	12
Case Study	3	3

The majority of the identified publications are classified as Original Research. These contributions investigate a wide range of applications related to the integration of BIM and NLP, typically focusing on specific methods, tools, or workflows. Given the diversity of application contexts and technical approaches, a detailed content-oriented analysis of these studies is provided in Chapters 4.3 and 4.4.

The second largest group consists of Reviews. Three of these publications [2, 12, 13], briefly introduced in Chapter 1, focuses explicitly on the combined application of BIM and NLP. One additional review addresses the use of NLP in the context of construction schedule management [9]. The remaining Reviews cover related but more specialized topics, including reviews of computational techniques supporting specific BIM-related tasks, such as quantity take-off, knowledge management, and compliance checking, as well as broader technological perspectives on digital twins, big data analytics, and AI in the AEC industry. Two reviews focus on specific NLP-related models or techniques, namely GPT models (short for: Generative Pre-trained Transformer models; a special kind of Transformer model) and Deep Learning approaches, while one addresses digital twin applications in tunnel construction.

Only a small number of publications are classified as pure Case Study. This limited representation indicates that, to date, relatively few BIM–NLP applications have been empirically evaluated in real-world settings. The field, therefore, currently remains largely exploratory, and there is an evident need for further validation of proposed approaches through practical implementations.

4.3 BIM Task Classification

This section provides a concise overview of the BIM workflow-related task clusters identified in the relevant publications. The results of the clustering are demonstrated in Table 2. The total number of clusters is nine. Seven publications, all Reviews, were excluded from this analysis as they deal with various BIM task clusters.

Table 2. Number and percentage of articles per BIM task cluster

BIM task cluster	Number	% (N=85)
Knowledge Management	23	27
Compliance Checking	16	19
BIM Authoring	12	14
Design and Planning	10	12
Facility Management	6	7
Risk and Safety Management	6	7
Cost Management	3	4
Robot Control	3	4
Schedule Management	3	4
Sustainability Assessment	3	4
various	7	-

Knowledge Management: This category comprises the capture, structuring, and reuse of project-related

knowledge, such as information from previous projects, guidelines, and experiential knowledge. Its purpose is to systematically provide knowledge to support and enhance other BIM-related tasks. The cluster is only assigned if the activities are not related to any of the following specific BIM task clusters. In previous review articles, the cluster was named differently, e.g. Information management.

Compliance Checking: This category refers to the verification of BIM models against regulatory requirements, standards, codes, and project-specific rules. It encompasses both formal rule-based checks and content-related compliance assessments. The cluster has the second highest number of assigned publications and was already mentioned in all previous reviews on BIM–NLP integration. This indicates that Compliance checking is one of the most well-established BIM workflow-related tasks, where NLP application is studied.

BIM Authoring: This category covers the creation, modification, and continuous maintenance of BIM models throughout the project lifecycle. It includes model structuring, attribute management, and information enrichment. In previous studies, only information enrichment of BIM models was mentioned. This shows that BIM modelling from scratch is new, but, as the high number of publications indicates, it is a topic of rising interest.

Design and Planning: This category focuses on supporting decisions during early project phases. It includes design alternative exploration, scenario analysis, and generative approaches that support decision-making. A similar task cluster, namely Design management, was identified in one previous study. The name of the cluster was adapted to focus on the design process and illustrate the difference from the cluster Compliance Checking.

Facility Management: This category describes the use of BIM information to support building operation after project completion. It includes activities related to maintenance, operation, and asset management, mostly related to decision support during those stages. The task cluster was only mentioned by the more recent of the previous studies and seems to be a rather slowly developing application of NLP.

Risk and Safety Management: This category addresses the identification, assessment, and prevention of risks and safety issues in a BIM context. Most publications in this cluster focus on the construction phase. Previous studies also mentioned risk and safety-related applications. Partly, publications related to this BIM task cluster were excluded during the Systematic Literature Review, due to the NLP application often focusing on safety reports as separate documents, as opposed to being incorporated into BIM workflows.

Cost Management: This category addresses activities related to cost estimation, cost planning, and cost control based on 5D BIM. As the number of publications shows, it is currently a rather small research field.

Robot Control: This category covers the application of robotic and automated systems in construction and building operation contexts. It includes automated execution activities and interactions between humans and robots in a BIM context.

Schedule Management: This category involves the planning, monitoring, and optimization of 4D BIM. It includes construction sequencing, progress tracking, and coordination of resources. Even though the number of assigned publications is relatively small, one of the Reviews is related to the BIM task cluster Schedule Management.

Sustainability Assessment: This category focuses on the evaluation of buildings across their lifecycle, especially in the context of Life Cycle Assessment (LCA). It intentionally does not include design recommendations to improve the sustainability of the building, nor does it consider energy optimization decision-making, as both activities are included in other BIM task clusters.

4.4 NLP Functionality Classification

In order to explore the functions performed by NLP in more detail, this section examines the functionality of NLP methods with BIM data, independent of the concrete BIM task supported. The NLP functionality clusters intentionally avoid using a hierarchical structure. To characterize the functionality, five distinct clusters were developed. The resulting clusters and the number and percentage of assigned publications are demonstrated in Table 3 and discussed following the table. All eleven publications classified as Review were excluded from the analysis, as they deal with various NLP functionality clusters. The remaining publications can be assigned to more than one NLP cluster, as some of the presented approaches incorporate more than one NLP application.

Table 3. Number and percentage of articles per NLP functionality cluster

NLP functionality cluster	Number	% (N=81)
Extract	32	40
Query	31	38
Match	20	25
Enrich	17	21
Modify	12	15
various	11	-

Extract: This category refers to approaches in which NLP is applied to derive structured or semi-structured information from BIM-related sources, such as regulatory texts, technical specifications, or reports. The extracted information is typically transformed into formats suitable for further processing and use in BIM-

based workflows. The BIM database itself is not analysed or changed by NLP methods in this cluster. Extract has the highest number of allocated publications. This may well be the case, given that NLP was originally developed to work with human language rather than machine-readable texts, such as IFC models.

Query: This category includes methods that allow users to access BIM-related information through natural language queries. NLP is employed to interpret user inputs and retrieve relevant data from BIM models, databases, or linked information systems, often via conversational or assistant-based interfaces, without altering the underlying model. Chatbots are identified to be a trending research topic in this cluster, leading to the second highest number of allocated publications.

Match: This category comprises methods that establish correspondences between BIM data and external information sources, such as regulations, schedules, databases, or real-world entities. NLP supports the alignment and comparison of heterogeneous representations, enabling activities such as data integration and cross-system mapping. Thus, the IFC file of the BIM model is unaffected.

Enrich: This category encompasses techniques that use NLP to augment BIM data with additional semantic information. Such approaches add or infer attributes, classifications, relationships, or ontological links, thereby improving the semantic completeness and interpretability of BIM models and associated datasets. BIM data is enhanced by adding information, but no previously existing data is changed or deleted.

Modify: This category covers approaches in which NLP is used to directly influence or perform changes to BIM data. It includes text- or speech-driven creation and modification of model elements, execution of modelling commands, and automated or semi-automated generation of BIM content. The limited number of publications assigned to this cluster could indicate the novelty of these NLP functionalities or the complexity, resulting from the profound impact on the BIM data structure in this cluster.

5 Discussion

The analysis reveals distinct patterns regarding both the BIM-related tasks addressed and the functionalities for which NLP is integrated into BIM-based workflows.

Among the BIM task clusters, Knowledge Management represents the largest share of publications. This finding reflects the strong reliance of BIM processes on textual information, such as requirements, reports, guidelines, and project documentation, which can be processed effectively using NLP techniques. The predominance of this category is consistent with earlier observations [12, 13]. Compliance Checking constitutes the second most frequent task cluster. The review shows that compliance-related studies often combine information extraction from regulatory texts with alignment or comparison against BIM data, indicating a close relationship between the Compliance Checking task cluster and the NLP functionality clusters Extract and Match. Tasks related to the clusters BIM Authoring and Design and Planning are also well represented. A shift toward more interactive and model-centred applications can be observed. Similar tendencies are discussed in one of the identified review articles [7]. In contrast, task clusters that typically depend on numerical/geometric data or require tight integration with domain-specific tools remain limited. This suggests that current methods are less applicable to such data-intensive tasks and are less applicable in complex BIM ecosystems.

Regarding NLP functionality clusters, the categories Extract and Query are most prevalent, followed by Match. The strong presence of Extract and Query is consistent with the dominance of the BIM task clusters Knowledge Management and Compliance Checking, both of which primarily involve handling textual information. The comparatively lower frequency of Enrich and Modify shows that semantic augmentation and model-altering applications remain limited. Extract and Query functionalities may dominate, due to requiring only limited interaction with BIM schemas, whereas the more advanced functionalities Modify and Enrich remain comparatively rare due to their need for strict compliance with structured data models and semantic consistency. This discrepancy can be interpreted as a representation mismatch problem: NLP systems operate on probabilistic, context-dependent representations, while BIM relies on deterministic, schema-constrained data structures. Bridging this mismatch is therefore a broader integration problem between statistical and symbolic systems.

To enable a transition from passive NLP interaction, such as querying, to active model modification, this study proposes several technical prerequisites. First, the development of schema-aware language models is essential, as current LLMs lack an explicit understanding of BIM (especially IFC) schemas. Future research should therefore focus on fine-tuning models on IFC-based datasets. Second, formal validation layers are required to ensure the correctness of model modifications. This includes the integration of rule-based validation systems for IFC compliance, as well as hybrid pipelines that combine NLP outputs with symbolic reasoning. Without such mechanisms, NLP-generated modifications risk producing invalid or inconsistent BIM models. [26]

The analysis also indicates significant barriers to real-world adoption, as reflected in the low number of case studies identified in the literature. One possible reason is data privacy and security concerns, as construction projects often involve sensitive contractual and design information [27]. Additionally, issues of trust play a

crucial role, as practitioners require transparent and verifiable outputs due to the high impact of modifications on BIM data, which the black-box nature of many AI-based NLP techniques precludes. Inaccuracies can propagate into design decisions, cost estimation, or construction execution, leading to considerable financial risks [28]. Instead of fully automated pipelines, human-machine-interaction, like Explainable AI and human-in-the-loop approaches are therefore seen as promising [29]. This trend can also be observed in the review, namely in the rising number of co-pilot systems.

Overall, the results indicate that current research mainly applies NLP at the interface or preprocessing level, while deeper integration into BIM workflows remains uncommon. Although recent publications demonstrate technically advanced prototypes, particularly in connection with Transformer architectures, their scope is often limited to controlled scenarios and lacks validation in complex, real-world projects.

6 Conclusion

This study presents a Systematic Literature Review on the integration of BIM and NLP, identifying 92 relevant publications and analysing them with respect to BIM-related tasks and NLP functionalities. The results confirm that BIM–NLP integration is an emerging but still fragmented research field. To characterise the nature of BIM–NLP integration, this study introduces a novel classification of NLP functionalities in connection with BIM data, consisting of the five clusters Extract, Query, Enrich, Modify, and Match. The analysis shows that most existing work focuses on information extraction and querying, whereas deeper integration forms, such as semantic enrichment and model modification, are less common. The discussion identifies barriers that hinder deeper integration of NLP into BIM workflows. A key finding is the mismatch between probabilistic NLP models and schema-based BIM representations, which limits the ability of current approaches to directly modify or enrich BIM data. Furthermore, data privacy concerns in handling sensitive project information, and a lack of trust due to limited reliability of NLP outputs obstruct real-world adoption.

Some limitations of this review should be acknowledged. The literature search was conducted up to May 2025, which restricts the coverage of very recent developments in a rapidly evolving field. In addition, the clustering of BIM-related tasks and NLP functionality involves interpretative decisions, particularly for studies addressing multiple objectives.

To bridge the gap between NLP and BIM, future research should focus on the development of schema-aware language models and NLP–rule-based validation frameworks including technical and human quality assurance. In addition, the evaluation of approaches in real-world scenarios is a high-priority step toward practical adoption. Ultimately, the integration of NLP into BIM has the potential to improve automation of complex information processes and enhance decision-making in a BIM context. However, realising this potential requires solutions that can operate reliably within existing BIM workflows.

Abstract

In space-constrained modular construction, stochastic work content renders deterministic scheduling ineffective, often leading to production deadlocks. While Simulation-Based Optimization (SBO) addresses these dynamics, it typically lacks the operational utility for routine daily planning due to its high computational intensity. To bridge this gap, this study adopts a Design-Science Research (DSR) approach to design and evaluate a Surrogate-Based Scheduling Framework. The methodology follows a structured cycle where a Hierarchical Stochastic Demand Model generates a wide spectrum of synthetic production scenarios, which are evaluated via high-fidelity simulation to determine optimal Inter-Project Time Buffers. These complex optimization results are subsequently instantiated into a lightweight planning rule via surrogate-based heuristic derivation. To validate the utility of this artifact, a case study was conducted on a wood-frame wall panel assembly line. The resulting "Peak Workload" heuristic (instantiated via Linear Regression) achieved an R2 of 0.657, demonstrating that a simple linear approximation sufficiently captures dominant variability trends despite the system's inherent non-linearity. Operationally, the heuristic reduced average Cycle Time by 37.7% compared to the baseline while maintaining equivalent throughput. These results confirm the feasibility of transforming complex buffer optimizations into transparent, data-driven policies that stabilize production flow without requiring real-time computation.

Keywords – Modular Construction; Simulation-Based Optimization; Production Scheduling; Surrogate Modelling; Data-Driven Heuristics; Work-in-Process (WIP)

1 Introduction

Modular construction offers a promising, factory-based alternative to the inefficiencies of traditional building practices; however, its full potential is often constrained by unique scheduling complexities [1]. The Engineer-to-Order (ETO) nature of modular projects means that each component has a distinct work content, introducing significant process time variability [2]. In space-constrained production facilities, this unpredictability creates a precarious planning environment. Schedules that fail to account for this stochasticity often cause production lines to become either deadlocked with excess inventory or idle from a lack of available work, undermining the very efficiency the factory setting is meant to provide [3].

To navigate this uncertainty, production planners rely on look-ahead scheduling to sequence upcoming projects. However, the foundational tools for this task, such as the Critical Path Method (CPM), are inherently deterministic and ill-suited for dynamic environments [4,5]. Planners often compensate for this rigidity by inserting intuitive temporal buffers between projects [6]. This manual approach to creating "safety time" is unreliable; an insufficient gap between projects risks system-wide congestion, while an overly generous one leads to poor resource utilization and reduced capital efficiency [7,8]. The central challenge, therefore, is to develop a data-driven, simulation-informed optimization procedure that determines project-specific inter-project buffer times and is explicitly evaluated under stochastic variability [9,10].

Academic research has explored advanced computational methods to address this. Discrete Event Simulation (DES) has been used to model factory dynamics, while metaheuristic algorithms have been

applied to optimize production sequences [11]. A disconnect persists, however, between these sophisticated optimization techniques and the practical cadence of production planning. While Simulation-Based Optimization (SBO) offers high rigorous validity, it often lacks the operational utility necessary for the routine generation of weekly schedules [12–14]. The operational reality of construction management rarely accommodates the computational expense or specialized expertise required to maintain complex optimization engines. Consequently, there is a critical need for a new class of decision-support artifacts that bridge this gap—providing the rigor of simulation without the computational burden [15].

To address this challenge, this study adopts a Design-Science Research (DSR) approach to design and evaluate a novel scheduling artifact: the Surrogate-Based Scheduling Framework. The objective is to equip planners with a scientific basis for determining project start times. The core logic of this artifact is that robust schedules must be derived from a realistic understanding of operational uncertainty. To achieve this, the framework utilizes a multi-level probabilistic demand model to generate a wide spectrum of potential production scenarios. Through extensive simulation, an optimization process identifies the ideal inter-project lag time needed to absorb variability. This complex relationship is then instantiated into a computationally simple planning rule via a Surrogate-Based Heuristic Derivation strategy. The final output is a practical decision-making tool that translates project-specific data into scientifically sized buffers, enabling the creation of resilient look-ahead plans without the need for real-time computational analysis.

Figure 1: Structure of the proposed framework.

2 Research Methodology

2.1 Research Approach

This study adopts the Design-Science Research (DSR) methodology [16]. DSR is a problem-solving paradigm focused on the creation and rigorous evaluation of innovative "artifacts" to address practical organizational challenges.

Consistent with the DSR process, this research follows a three-stage cycle:

1. Problem Identification (Relevance): Defining the need for a dynamic buffer allocation method that overcomes the limitations of static scheduling practices.
2. Artifact Design: Developing the "Offline Learning Framework." This framework operates through a structured learning cycle (Figure 1): (1) synthetic demand scenarios are generated to capture operational variability; (2) these scenarios are evaluated within a high-fidelity simulation model; (3) an optimization algorithm solves for the optimal Inter-Project Time Buffer (τ^*); and (4) the results are instantiated into a lightweight planning rule via surrogate-based heuristic derivation.
3. Evaluation (Rigor): Validating the utility of the artifact through a case study application (Section 3).

Unlike deterministic planning that assumes fixed task durations, this DSR artifact recognizes that robust schedules must be informed by the probabilistic reality of ETO production. The methodology shifts the decision point to the planning phase, allowing buffers to be sized scientifically before production begins.

2.2 Hierarchical Stochastic Demand Modelling

To ensure the scheduling artifact addresses the 'Relevance' requirement of DSR, the design process begins by modelling the environment's true variability. Therefore, a Hierarchical Stochastic Model synthesizes look-ahead windows that reflect the variability inherent in actual ETO demand. This scenario-based modelling logic is consistent with prior work that uses Monte Carlo / scenario sampling to generate diverse

realizations of uncertain future conditions before evaluating candidate strategies [17,18]. The model integrates four interdependent sub-components:

Project Occurrence Process: The arrival of incoming orders varies with market conditions. The number of projects N_{proj} within a planning horizon is modeled as a Poisson process:

$$P(N_{proj} = k) = \frac{\lambda^k e^{-\lambda}}{k!} \quad (1)$$

where λ is the mean arrival rate, calibrated to reflect Low, Medium, or High workload intensities.

Project Scope: Each project has a defined work volume. The total quantity of units Q_i for Project *i* follows a discrete uniform distribution bounded by facility constraints:

$$Q_i \sim \mathcal{U}\{Q_{min}, Q_{max}\} \quad (2)$$

Product Mix (Complexity): Engineer-to-Order environments involve heterogeneous products with different complexity profiles. Let ρ denote the complexity ratio—the fraction of "complex" (high-variability) units within a project. The number of complex units is:

$$n_{c,i} = \text{Round}(\rho \cdot Q_i) \quad (3)$$

This parameter directly influences downstream processing time variability and resource contention, making it a critical input for buffer determination.

Delivery Constraints: External logistics (e.g., trailer availability, site readiness) constrain when projects can start. The allowable lead time δ_i is modeled stochastically to reflect real-world scheduling pressures:

$$D_i = T_{entry,i} + \text{Duration}_{est,i} + \delta_i \quad (4)$$

This temporal coupling ensures that the optimization considers both internal production variability and external logistical constraints.

2.3 Production System Simulation Environment

The simulation environment serves as the design testbed, allowing the artifact to be iteratively tested against non-linear dynamics before deployment. The stochastic production scenarios generated in Section 2.2 are evaluated within a computational simulation environment acting as a virtual testbed. While the specific modelling paradigm (e.g., Discrete Event Simulation, System Dynamics, or Agent-Based Modelling) may vary based on the facility's characteristics, the environment must faithfully replicate the non-linear dynamics of constrained production. The simulation framework generally operates on two critical layers to ensure validity:

Constraint-Based Physical Layer: The flow of work units is governed by rigorous physical and logical constraints rather than deterministic lead times. This includes finite buffer capacities (B_{Cap}) between workstations and specific resource availability windows (R_{avail}). By enforcing these limits, the simulation allows complex system behaviours—such as blocking (upstream work halting due to downstream congestion) and starvation (downstream idleness due to upstream delays)—to emerge endogenously from the system state rather than being pre-programmed.

Stochastic Process Execution: Task durations are modelled as stochastic variables drawn from probability distributions calibrated to historical performance data. To capture the heterogeneity of Engineer-to-Order (ETO) production, processing time P_t for a unit u is defined as a function of its specific complexity attributes:

$$P_t(u) = \begin{cases} f_{std}(\cdot) & \text{if } u \text{ is Standard Class} \\ f_{cplx}(\cdot) & \text{if } u \text{ is Complex Class} \end{cases} \quad (5)$$

where $f(.)$ represents a probability density function (e.g., Triangular, Log-Normal) appropriate for the specific task. This structure ensures that the optimization process specifically accounts for the volatility introduced by product mix variability, a primary driver of schedule unreliability in modular construction.

2.4 Optimization Formulation

This component represents the search process of the design cycle, identifying optimal configurations τ^* that maximize the utility function $J(\tau)$. The central problem is to determine the optimal Inter-Project Time Buffer vector $\tau^* = \{\tau_{1,2}, \tau_{2,3}, \dots, \tau_{N-1,N}\}$ that balances competing objectives. Here, $\tau_{i,i+1}$ denotes the scheduled lag between the planned completion of Project J_i and the start of Project J_{i+1}.

To avoid a highly fragmented ("scattered") schedule, the optimization procedure minimizes a weighted multi-objective cost function $J(\tau)$, which trades off process efficiency, production throughput, and overall schedule compactness:

$$J(\tau) = w_1 \cdot \widehat{CT} - w_2 \cdot \widehat{TH} + w_3 \cdot \widehat{MS} \quad (6)$$

where $\widehat{CT}$, $\widehat{TH}$, and $\widehat{MS}$ are the min-max normalized values of Cycle Time (CT), System Throughput (TH), and Makespan (MS), respectively. For a generic metric M, the normalized quantity is defined as:

$$\widehat{M} = \frac{M(\tau) - M_{min}}{M_{max} - M_{min}} \quad (7)$$

Within this framework, minimizing CT promotes efficient flow at the individual project level, while maximizing TH (achieved via the negative term) incentivizes higher production volume. The Makespan term (MS) serves as a penalty against schedule scattering, compelling the optimizer to select the tightest feasible buffers that avoid overlap without creating unnecessary idle time. The weights w_1, w_2, w_3 are user-specified and satisfy $w_1 + w_2 + w_3 = 1.0$.

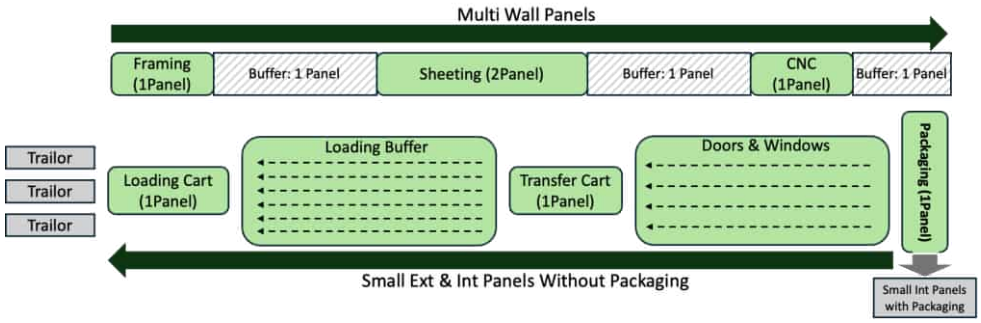

Figure 2: Schematic layout of the wall-assembly line.

The optimization is carried out under the domain constraint $0 \leq \tau_{i,i+1} \leq \tau_{max}$, where τ_{max} is the maximum commercially acceptable idle period (for example, one shift), ensuring that the solution is operationally realistic. The start-time relationship is given by:

$$Start_{i+1} = Finish_i^{planned} + \tau_{i,i+1} \quad (8)$$

By solving this optimization across all synthetic scenarios, the algorithm produces a rich dataset of optimal buffer configurations, each linked to the project characteristics that generated it.

2.5 Surrogate Heuristic Derivation

The final step in the design cycle is to instantiate the complex optimization results into a usable tool. As running the full simulation-optimization loop for every scheduling update is computationally prohibitive for routine operations. To bridge the gap between high-fidelity analysis and practical daily planning, the framework synthesizes the complex relationships found by the optimization engine into a lightweight Planning Heuristic via surrogate modelling. This step effectively "crystallizes" the intelligence of the simulation into a static format.

We posit a functional relationship between the project state vector *X* and the optimal inter-project buffer τ^*. Crucially, *X* comprises not only independent attributes of the incoming project (e.g., work content Q_i) but also transition metrics that capture the shift in operational intensity between sequential projects (e.g., Δ Complexity or Δ Volume between J_i and J_{i+1}). This ensures the heuristic accounts for sequence-dependent setup risks.

During the design phase, the optimization algorithm generates a training dataset $D = \{(X_n, \tau_n^*)\}_{n=1}^{M}$ spanning *M* diverse scenarios. A regression analysis is performed on *D* to approximate the function *f*. While the specific architecture of the surrogate model can range from non-linear approximators to decision trees depending on data complexity, a linear approximation is often preferred for its interpretability in industrial contexts. The general form of the heuristic is defined as:

$$\tau^* \approx \beta_0 + \sum_{j=1}^{k} \beta_j \cdot x_j \quad (9)$$

where, β_0, β_j are the learned coefficients representing the weight of each factor. x_j represents the Significant Predictors extracted from the project state vector *X*. These features are selected based on their correlation with production variability (e.g., total work content, resource intensity variability, or sequence-dependent complexity shifts).

The resulting output is a transparent, closed-form equation that eliminates the need for repeated simulation. This allows planners to implement the scientifically derived policy using standard spreadsheet tools or elementary calculation tables. By simply inputting the scheduled project attributesx_j, the heuristic instantaneously provides the optimal "safety time" τ^* required to maintain flow, transforming a computationally expensive optimization problem into a practical arithmetic task.

3 Artifact Evaluation: Case Study Implementation

To validate the proposed scheduling framework, a comprehensive case study was conducted within a real-world manufacturing environment. This section details the experimental setup, bridging the theoretical methodology with the specific physical constraints of an operating facility.

3.1 Evaluation Domain: Edmonton Assembly Line

The validation domain is a wood-frame wall panel assembly line in Edmonton, Alberta, organized as a flexible flow shop. As schematically illustrated in **Error! Reference source not found.**, the process flows sequentially from Framing through Sheeting and Nailing to Packaging. At the Packaging station, the flow splits: completed interior panels route directly to storage, while exterior panels proceed to four parallel

Door & Window (DW) installation lanes before reaching the Loading buffer. The layout is characterized by severe spatial constraints, featuring minimal buffer capacities (often limiting WIP to a single panel) between stations—a typical challenge in "volumetric" construction where large product dimensions restrict storage.

This specific facility was selected because it presents a convergence of internal variability and external logistical constraints that render static scheduling ineffective. The production environment is highly stochastic, with heterogeneous project specifications driving variable processing times. Crucially, the system is constrained by outbound logistics: panels must be loaded onto project-dedicated trailers, which have limited daily availability (avg. 3/day). In this tight spatial environment, traditional scheduling strategies that fail to account for variability frequently lead to immediate blocking when trailers are unavailable, causing cascading flow stagnation. This susceptibility to gridlock makes the line an ideal testbed for validating the proposed buffer optimization approach.

3.2 Configuration of the Simulation Testbed

To represent the stochastic production dynamics of the Edmonton facility, a hybrid simulation model was developed in Python using SimPy. The model combines a Discrete Event Simulation (DES) layer for material flow and capacity constraints with an Agent-Based Simulation (ABS) layer for workforce behavior. Physical constraints such as finite buffer capacities and the single-table Packaging limit are explicitly modeled, allowing blocking and starvation to emerge naturally from congestion. The ABS layer captures crew collaboration, non-linear productivity effects, and task-priority rules, with complex exterior panels prioritized over standard interior units.

The model was parameterized using empirical field data from the partner facility, including 100–150 processing-time records per station, supported by expert input to confirm logic and variability ranges. Processing times were differentiated by panel characteristics, such as interior versus exterior units. Triangular distributions were used as a practical representation of uncertainty in this data-constrained setting because they preserve minimum, most-likely, and maximum values and are easy to calibrate. The model was validated against a historical dataset of 84 Multi-Wall projects, achieving R^2 values of 0.95 for Framing and 0.89 for Doors & Windows, with MAPE between 16% and 18%.

Key assumptions include fixed observed routing, finite buffer capacities, rule-based crew collaboration and prioritization, station-specific triangular processing-time distributions, and schedule control through inter-project buffers rather than dynamic resequencing.

3.3 Evaluation Protocol

The framework was implemented through the 'Surrogate-Based Derivation' phase specified in the methodology. Leveraging the Hierarchical Stochastic Model, thirty distinct production scenarios were generated to encompass a broad range of workload intensities, spanning from low-demand periods (Poisson $\lambda = 8$) to high-intensity surges ($\lambda = 25$). The choice of 30 scenarios reflects a balance between coverage and computational tractability for this conceptual design stage. Rather than serving as an exhaustive sample, these scenarios were constructed to span low-, medium-, and high-intensity workload regimes and to expose the framework to diverse operating conditions. Moreover, because each scenario yields multiple adjacent project-pair decisions, the resulting surrogate was calibrated on approximately 800 optimized decision points rather than on only 30 scenario-level observations. While this was sufficient to derive and interpret a stable first-order heuristic, future work should examine convergence of the surrogate coefficients and scheduling performance as the number of generated scenarios increases.

For each scenario, the Simulation-Based Optimization engine determined the optimal Inter-Project Time Buffer (τ^*). The decision variable was the elapsed time (in minutes) between the planned finish of Project J_i and the release of Project J_{i+1}. The Genetic Algorithm minimized a weighted cost function that integrated Cycle Time, System Throughput, and Makespan. For this study, the weighting configuration was set to w_1=0.35 (Cycle Time), w_2=0.35 (Throughput), and w_3=0.30 (Makespan). Equal priority was assigned to the efficiency metrics (CT and TH), while the Makespan term served primarily as a 'control variable' to prevent the optimizer from suggesting an overly scattered schedule. It is important to note that this cost function is modular; in practice, facility managers can adjust these weights or introduce new metrics to reflect shifting operational priorities (e.g., prioritizing maximum volume during peak seasons).

3.4 Artifact Instantiation: Heuristic Calibration

To translate the simulation-based optimization results into a practical planning tool, a surrogate model was calibrated using the ~800 optimal decision points generated by the simulation. Linear Regression was selected for its interpretability and stability, with the aim of relating high-level project attributes to the optimal inter-project buffer (τ^*).

To identify the most informative predictors, a Theory-Guided Sparse Model Discovery approach was applied. The candidate library included raw production

metrics (e.g., Multi-Wall count, Small Panel count) and derived workload-intensity terms. Using LASSO with bootstrap-based stability selection, the process filtered out weak predictors and showed that raw unit counts alone were insufficient. Instead, the model consistently retained variables linked to bottleneck workload intensity, particularly the peak boundary intensity between adjacent projects and the directional change in workload.

Based on these results, the final regression was defined as:

$$\tau^* = \alpha + \beta\, M_i + \gamma\, \Delta M_i^+ + \epsilon \qquad 10$$

Where:

$M_i = \max(\text{mode}_{i-1}, \text{mode}_i)$ signifies the Peak Workload Intensity across the two adjacent projects. $\Delta M_i^+ = \max(\text{mode}_i - \text{mode}_{i-1}, 0)$ signifies the Anticipatory Workload Increase, triggered only when the incoming project is more demanding than the outgoing one.

The model was calibrated against the simulation-generated dataset, producing the following coefficients: $\alpha = -46.57$, $\beta = 0.186$, and $\gamma \approx -0.084$.

The coefficients illuminate distinct operational mechanisms. The positive weight on M_i ($\beta = 0.186$) reinforces that the primary constraint is the magnitude of the bottleneck; heavier project pairs require larger buffers. However, the negative coefficient for the anticipatory term ($\gamma \approx -0.084$) introduces a crucial insight: the "Clean-Slate Effect."

Mathematically, this term diminishes the required buffer when progressing from a lighter to a heavier project. Operationally, this suggests that a lighter outgoing project clears the system efficiently, establishing a stable, low-congestion environment for the subsequent demanding project. Conversely, a heavy outgoing project leaves residual variability in its wake, necessitating a larger safety margin for the next task regardless of its intensity.

The calibrated heuristic achieved an In-Sample Mean Absolute Error (MAE) of 32.46 minutes and a Root Mean Square Error (RMSE) of 37.40 minutes, with an R^2 of 0.657. Although an MAE of approximately 32 minutes indicates a noticeable gap from the theoretical optimum, its practical acceptability in this study is supported by the downstream validation results rather than by the error magnitude alone. When applied to the validation-week schedule, the calibrated heuristic still produced substantial system-level improvements, including a 37.7% reduction in average cycle time while maintaining statistically equivalent throughput. This suggests that the surrogate captured the dominant scheduling signal required for look-ahead decision support, even if individual buffer predictions were not exact. The R^2 value confirms that nearly two-thirds of the variability in optimal buffer sizing is captured by this transparent "Peak Workload" heuristic, establishing its validity as a dependable planning rule. However, the present study did not explicitly quantify how surrogate prediction error propagates into secondary operational risk metrics such as blocking frequency, due-date deviation, or extreme-case instability under peak conditions; this should be examined in future work.

It is acknowledged that the underlying production system exhibits inherent non-linear dynamics due to finite buffering and complex resource interactions. However, at this preliminary stage, high-fidelity feature data (e.g., granular task-level specifications) is often unavailable during the look-ahead planning phase. Consequently, a Linear Regression model was selected to demonstrate the potential of the methodology using only high-level metrics available to planners (e.g., panel counts, expected execution times). While an R^2 of 0.657 indicates that roughly one-third of the variance remains unexplained—suggesting the need for future non-linear modelling (e.g., Random Forests) as data granularity improves—the current model successfully captures the dominant 'Peak Workload' trend required to stabilize the schedule.

4 Results and Discussion

To assess the operational utility of the designed artifact, the methodology was evaluated using a calibrated simulation testbed initialized with a real 14-project production schedule from the partner facility. While a comprehensive live field implementation remains a subject for future research, this validation horizon was selected to align with the standard 1–2 week look-ahead planning window used by facility management. This experiment specifically tests the preliminary robustness of the heuristic in handling a realistic batch of heterogeneous projects compared to the facility's current static planning approach. The reported execution timelines, cycle times, and throughput values are simulation-derived performance measures obtained by applying the baseline and heuristic-controlled schedules to the calibrated testbed.

The comparative assessment demonstrates a marked enhancement in flow efficiency. The application of heuristic-derived buffers decreased the average Cycle Time (Lead Time) by 37.7%, declining from a baseline of 328.65 minutes to 204.70 minutes. This substantial reduction signifies a considerable drop in Work-in-Process (WIP) accumulation throughout the production floor. Notably, this improvement in flow speed was realized while maintaining the system's production rate; the heuristic-controlled throughput (3.617 panels/hour) was statistically equivalent to the baseline (3.668 panels/hour). Following the fundamental principles of Factory Physics [19], a reduction in Cycle Time (*CT*)

coupled with constant Throughput (*TH*) mathematically necessitates a reduction in Work-in-Process (*WIP*) (Little's Law: $WIP = TH \times CT$). In the context of volumetric construction, where floor space is the primary constraint, this reduction in on-line inventory is critical. It implies that the facility achieves the same output with significantly less physical clutter, reducing material handling risks and freeing up capital, thereby validating the heuristic's value beyond simple output metrics. The key simulation outputs considered in this evaluation are project execution timelines, average cycle time, and throughput; these are reported quantitatively in the text and visually compared in Figure 3. The Baseline schedule (Blue) displays extended project durations accompanied by significant temporal overlaps. These overlaps characterize periods of intense congestion where multiple projects contend for constrained buffer capacity, producing the "deadlocks" endemic to the facility's existing operations.

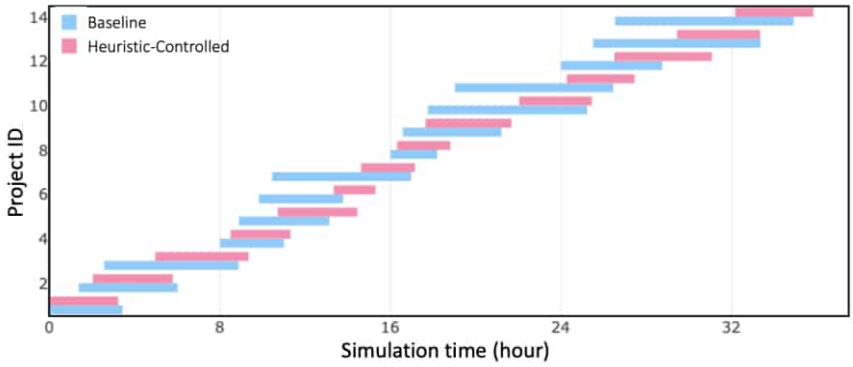

Figure 3: Comparative project execution timeline for the 14-project validation week: Baseline schedule vs. Heuristic-Controlled schedule.

By contrast, the Optimized schedule (Pink) exhibits more compressed execution windows with regular, orderly spacing. By introducing scientifically calibrated lags informed by the bottleneck intensity (M_i), the heuristic efficiently "harmonizes" the flow. Remarkably, the total Makespan of the production week remained essentially unchanged. This counterintuitive finding demonstrates that the "safety buffers" introduced by the heuristic do not postpone overall batch completion. Rather, they redirect unproductive "congestion time" (waiting within the line due to blockage) into productive "waiting time" (waiting outside the line prior to commencement). In volumetric construction, where floor space represents the limiting factor, the 38% improvement in Cycle Time bears strategic significance. By synchronizing production velocity with the stochastic properties of the bottleneck, the framework eliminates the cascading delays that characterize static schedules. The findings establish that disciplined planning can stabilize operations and reduce WIP liability while maintaining the facility's total weekly output capacity.

5 Conclusion

This study addresses the scheduling challenge in High-Mix Low-Volume (HMLV) modular construction, where product variability frequently disrupts static plans. Using a Design-Science Research (DSR) approach, it develops and evaluates a Surrogate-Based Scheduling Framework that translates complex simulation-optimization results into a practical daily planning rule. The framework follows a structured design cycle. A Hierarchical Stochastic Demand Model generates diverse synthetic production scenarios reflecting the variability of Engineer-to-Order projects. These scenarios are evaluated in a calibrated simulation testbed to identify the optimal inter-project buffers required to absorb system variability. The resulting decisions are then converted into a simplified surrogate-based heuristic, enabling planners to size safety margins based on project workload intensity without real-time optimization. Evaluation on a real wood-frame wall panel assembly line showed that the derived “Peak Workload” heuristic reduced average Cycle Time by 37.7% while maintaining statistically equivalent throughput. Under Little’s Law, this implies a substantial reduction in Work-in-Process (WIP), which is especially valuable in space-constrained prefabrication environments where congestion limits operational efficiency. The study also highlights several limitations. The current surrogate uses a linear regression model ($R^2 \approx 0.657$) to preserve interpretability under limited planning-stage information, but future work should explore richer features and non-linear models to better capture buffer-sizing behavior. In

addition, validation was limited to a one-week look-ahead horizon, so longer-term testing is needed to confirm robustness and generalizability. Finally, the optimization used fixed objective weights; future research should support dynamic weight adjustment so managers can adapt scheduling priorities to changing operational conditions.

Abstract –

Industrialized construction relies on the tight integration of production, logistics, and on-site assembly, making the process highly sensitive to dynamic disturbances. To achieve rescheduling with minimum human intervention, this study proposes an intelligent rescheduling framework based on AI agents. First, we establish a unified Mixed-Integer Linear Programming (MILP) model to provide a standardized mathematical foundation for the rescheduling process. Second, a collaborative architecture comprising five functional AI agents is developed. By utilizing Large Language Models (LLMs) as their cognitive cores, these agents automatically transform natural-language disturbance reports into structured model patches and executable code. To ensure technical precision, a Retrieval-Augmented Generation (RAG) mechanism is integrated to ground the agents in domain-specific knowledge. Experimental results demonstrate that the framework can effectively bridge the gap between unstructured field reporting and mathematical optimization, enabling automated responses to disruptions.

Industrialized Construction; Dynamic Rescheduling; AI Agents; Framework

1 Introduction

Industrialized construction shifts traditional cast-in-situ construction methods toward a highly coordinated process of component production, transportation, and assembly. This transformation imposes spatiotemporal synchronization constraints across factories, logistics, and on-site resources[1]. Guided by just-in-time principles, buffer resources throughout the supply chain should be minimized, rendering the supply chain highly sensitive to various disturbances[2]. Consequently, local delays can propagate through the chain[3], triggering cascading effects such as vehicle idling[4] and on-site work stoppages[5]. Without mechanisms to generate actionable instructions, these chain reactions lead to overall performance degradation[6]. Therefore, prefabricated component scheduling requires not only robust static optimization but also agile operational rescheduling to mitigate disruptions.

Existing research in this domain spans from centralized optimization to distributed collaboration. While centralized approaches pursue global optimality, they often suffer from computational latency and lack the flexibility required to handle frequent disturbances[7-8]. To overcome these limitations, research has increasingly adopted Multi-Agent Systems (MAS) [9]. By modeling resources or tasks as autonomous entities with independent decision-making capabilities, MAS offer an adaptive alternative rooted in collaboration[10]. However, real-world disturbances are typically communicated via unstructured natural language such as site logs and verbal change orders. Traditional MAS, restricted by hard-coded decision logic[11], lack the ability to interpret ambiguous information and autonomously construct mathematical models. As a result, the pipeline from disturbance perception to decision generation remains heavily reliant on human intervention.

The emergence of Large Language Models (LLMs) provides a transformative pathway to overcome these hurdles. The primary advantage of LLMs lies not in replacing specialized optimization solvers, but in their capacity to serve as semantic translators[12]. This capability has catalyzed the rise of AI agents—autonomous entities that utilize LLMs as a cognitive core to perceive, reason, and act. An AI agent does not merely follow rigid rules; it interprets the intent behind a disturbance and manipulates computational tools to synthesize solutions.

Accordingly, this study proposes an intelligent rescheduling framework driven by AI agents. We first establish a unified Mixed-Integer Linear Programming (MILP) model to provide a standardized, solvable mathematical foundation for rescheduling[13]. Building on this, the framework employs AI agents as semantic-to-code bridges. By incorporating domain-specific

constraints through Retrieval-Augmented Generation (RAG), these agents automatically map unstructured disturbances into structured model modifications and executable solver code[14]. A collaborative workflow among specialized agents helps to achieve a fully automated loop from semantic disruption reporting to executable rescheduling commands.

2 Problem Description and Model Construction

This study specifically addresses the dynamic rescheduling of precast concrete components under disturbances. Grounded in the concept of interrupt management, the rescheduling strategy aims to minimize deviations between the revised schedule and the original baseline plan[15]. The optimization objective functions as a multi-criteria priority, balancing factors including (1) reducing costs associated with early or delayed component arrivals and (2) minimizing temporal shifts and resource reallocation overhead caused by schedule adjustments.

Coordination between the production facility and the construction site is maintained through the dynamic balancing of on-site inventory levels I_t. This framework adopts an event-driven rescheduling mechanism: upon the detection of a disturbance, a specialized Patch Agent translates the unstructured information into localized updates to automatically generate a reschedule solution.

Based on the problem description, the collaborative scheduling model is constructed as follows.

$$min\ Z = c_{late} * \sum_i l_i + c_{early} * \sum_t e_i + k_{time} * \sum_i shift_i^{time} + k_{line} * \sum_i \varphi_i^{line} \quad (1)$$

Equation (1) formulates the minimization objective, where c_{late} and c_{early} represent the unit penalty costs for the late arrival period l_i and early arrival period e_i of component i, respectively. To ensure schedule stability, the objective also penalizes deviations: k_{time} and k_{line} denote the penalty coefficients for temporal shifts and production line reallocations. Here, $shift_i^{time}$ represents the absolute deviation of the casting start time relative to the baseline, and φ_i^{line} is a binary variable indicating whether the production line assignment for component i has changed.

$$C_{i,o} = S_{i,o} + p_{i,o}, \forall\, i \in I \quad (2)$$

$$S_{i,od} \geq C_{i,oc} + \theta_i, \forall\, i \in I \quad (3)$$

$$S_{j,oc} \geq C_{i,od} - M_{big} * (1 - u_{i,j,l}^{line}) - M_{big} * (2 - x_{i,l} - x_{j,l}), \forall i, j \in I, i \neq j, \forall\, l \in L \quad (4)$$

$$S_{i,oc} \geq C_{j,od} - M_{big} * u_{i,j,l}^{line} - M_{big} * (2 - x_{i,l} - x_{j,l}), \forall i, j \in I, i \neq j, \forall\, l \in L \quad (5)$$

Equations (2-5) define the physical production logic. In Equation (2), $S_{i,o}$ and $C_{i,o}$ denote the start and completion times of process o (containing casting o_c and demolding o_d), and $p_{i,o}$ represents the processing duration. Equation (3) strictly enforces the curing constraint, requiring that the demolding start time $S_{i,od}$ must occur after the casting completion $C_{i,oc}$ plus the minimum curing time θ_i. Resource conflicts are resolved in Equations (4-5): $x_{i,l}$ is a binary variable indicating if component i is assigned to production line l, and $u_{i,j,l}^{line}$ manages the processing sequence between components i and j to prevent temporal overlap. M_{big} is a sufficiently large positive constant.

$$a_i = C_{i,od} + \tau_i, \forall\, i \in I \quad (6)$$

$$l_i \geq a_i - L_i, \forall\, i \in I \quad (7)$$

$$e_i \geq E_i - a_i, \forall\, i \in I \quad (8)$$

$$\sum_t z_{i,t} = 1, \forall\, i \in I \quad (9)$$

$$\sum_t (t\Delta) * z_{i,t} < a_i \leq \sum_t \big((t+1)\Delta\big) * z_{i,t}, \forall\, i \in I \quad (10)$$

$$I_t = I_{t-1} + \sum_i z_{i,t} - D_t, \forall\, t \in T \quad (11)$$

$$0 \leq I_t \leq W_{site}, \forall\, t \in T \quad (12)$$

Equations (6-12) bridge production and on-site assembly. Equation (6) calculates the site arrival time a_i based on the fixed transportation duration τ_i. Equations (7-8) quantify the deviation from the ideal arrival time window $[E_i, L_i]$. To map continuous arrival times to discrete time slots, Equations (9-10) introduce the binary variable $z_{i,t}$, which equals 1 if component i arrives within the time interval t of length Δ. The dynamic equilibrium of on-site inventory is governed by Equations (11-12), where I_t denotes the inventory level at time t, D_t represents the number of consumables used for assembly, and W_{site} is the maximum capacity of the on-site storage yard.

$$shift_i^{time} \geq S_{i,oc} - S_{i,oc}^0, \forall\, i \in I \quad (13)$$

$$shift_i^{time} \geq S_{i,oc}^0 - S_{i,oc}, \forall\, i \in I \quad (14)$$

Finally, Equations (13-14) define the absolute temporal deviation $shift_i^{time}$ by comparing the rescheduled casting start time $S_{i,oc}$ against the original baseline schedule $S_{i,oc}^0$. In summary, the collaborative scheduling model maintains physical and process

feasibility while minimizing deviations from the baseline plan. This provides a solvable MILP formulation for subsequent local rescheduling under event-driven mechanisms.

3 Methods

3.1 Overall Architecture of the Framework

Figure 1 shows the overall architecture of the proposed framework. Within this framework, LLMs are enabling advanced semantic comprehension and causal reasoning upon agent invocation. These agents map dynamic events to specific model patches and executable scripts, synthesizing structured scheduling instructions. To ensure domain alignment, RAG performs semantic similarity searches across specialized databases to retrieve contextually relevant knowledge fragments. This process guides LLMs in generating outputs that strictly adhere to established industry norms and technical constraints[16]. The MAS comprises sense agent (A_{sense}), patch agent (A_{patch}), code agent (A_{code}), scheduling agent ($A_{schedule}$), and dispatch-feedback agent ($A_{dispatch}$). These agents collaborate to form a standardized pipeline, spanning disturbance perception, model updating, code generation, optimization, and instruction dispatching.

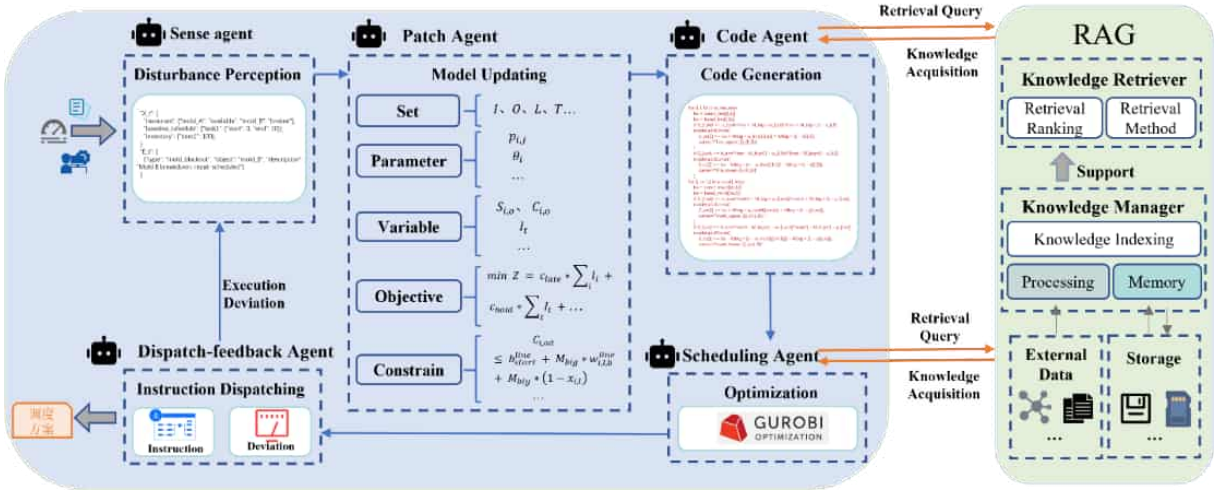

Figure 1. Framework Architecture

Information is transmitted between agents in standardized message formats, collectively completing the management from disturbance perception to instruction dispatching. For any message sent from agent i to agent j, the format is uniformly defined as follows:

$$m_t^{i\to j} = \langle type, payload, t\rangle \tag{15}$$

Here, $type$ specifies the message classification, while $payload$ contains the substantive data encoded as a JSON object. The variable t represents the timestamp, evolving over discrete time horizons $t = 0, 1, 2, \ldots$. Adopting this standardized protocol facilitates modular decoupling and ensures efficient inter-module communication.

3.2 Roles and Functions of AI Agents

The framework comprises five agents, each assigned specific functions and input/output parameters. The rescheduling process is initiated by A_{sense}, which aggregates multi-source data (e.g., operator logs, documents) into production states X_t and disturbance events E_t via function f_{sense}.These structured inputs are transmitted to A_{patch}, as shown in Equations (16-17). A_{patch} maps the disturbances into a mathematical model patch Π_t (Equation 18), which defines parameter variations and constraints, thereby updating the MILP model to M_t (Equation 19).

$$(X_t, E_t) = f_{sense}(NL_t^{req}, docs_t) \tag{16}$$

$$m_t^{sense\to patch} = \langle event_report, \{X_t, E_t\}, t\rangle \tag{17}$$

$$\Pi_t = \langle \Delta\text{Param}, \text{Blackouts}, \text{NewTasks}, \text{Cancels}, \text{WindowShifts}, \text{Freezes}\rangle = f_{patch}(X_t, E_t) \tag{18}$$

$$M_t = P(M_{t-1}, \Pi_t) \tag{19}$$

$$m_t^{patch\to code} = \langle model_update, \{M_t\}, t\rangle \tag{20}$$

Following the model update, A_{code} translates the intermediate model M_t into solver-specific executable code $code_t$, accompanied by a static analysis report R_{mod} to ensure syntax validity (Equation 21). This code

drives $A_{schedule}$, which invokes the optimization solver to generate the optimal plan sol_t and diagnostic metrics $Diag_t$ (Equation 23). Finally, $A_{dispatch}$ operationalizes the plan into production instructions and monitors execution feedback $feedback_{t+1}$ (Equation 25), which serves as the input for the subsequent rescheduling iteration (Equation 26).

$$(code_t, R_{mod}) = f_{code}(M_t) \quad (21)$$

$$m_t^{code \to schedule} = \langle MILP_code, \{code_t, R_{mod}\}, t \rangle \quad (22)$$

$$(sol_t, Diag_t) = f_{schedule}(code_t) \quad (23)$$

$$m_t^{schedule \to dispatch} = \langle plan, \{sol_t, Diag_t\}, t \rangle \quad (24)$$

$$(orders_t, feedback_{t+1}) = f_{dispatch}(sol_t) \quad (25)$$

$$m_{t+1}^{dispatch \to sense} = \langle \text{exec_feedback}, \{feedback_{t+1}\}, t+1 \rangle \quad (26)$$

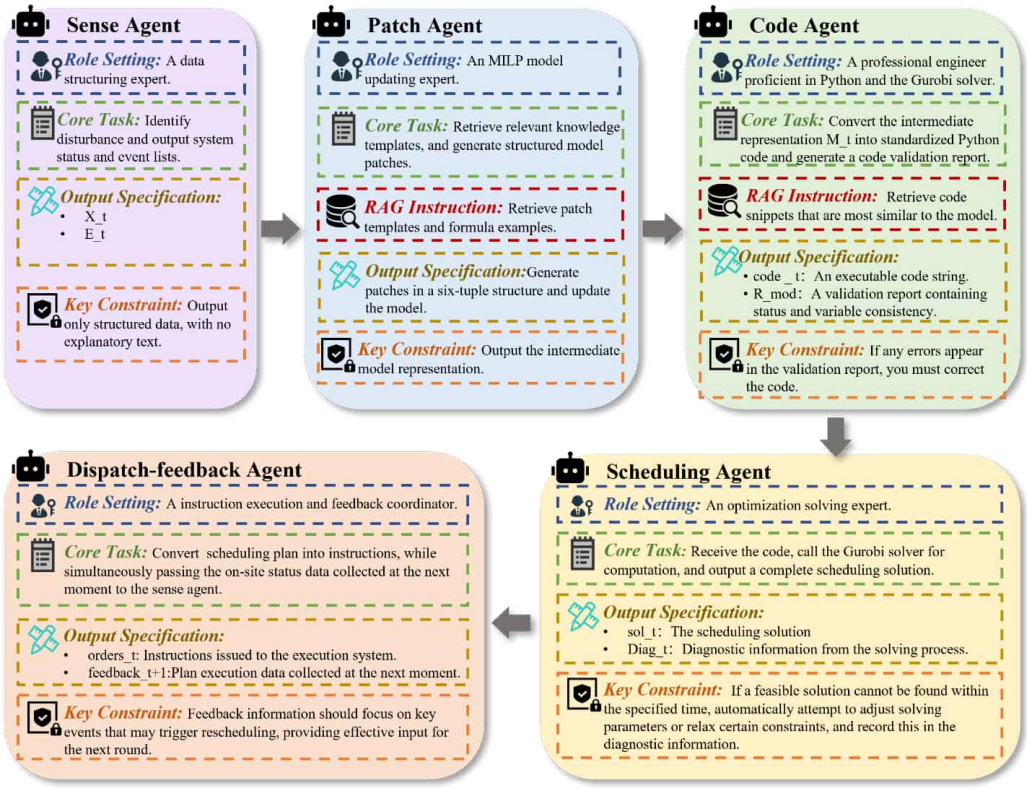

Figure 2. Prompt Structure for Each AI Agent

Prompt engineering enables LLMs to adapt to specific domains through techniques such as task decomposition and example-based guidance[17]. This study designed structured prompts that explicitly specify each agent's role, primary task, output format, and key constraints (see Figure 2). Notably, the prompts for A_{patch} and A_{code} incorporate specific retrieval instructions to leverage external domain knowledge.

3.3 RAG-Based Domain Knowledge Enhancement Mechanism

To ensure factual accuracy and executability, the framework incorporates RAG for A_{patch} and A_{code}. By retrieving relevant domain knowledge via vectorized indexing and injecting it into prompts, RAG mitigates LLM hallucinations and enforces contextual consistency.

3.3.1 Construction of External Knowledge Bases for A_{patch}

The A_{patch} knowledge base maps disturbances to corresponding MILP updates via scenario-patch-MILP pairs. Each entry defines transformation rules for constraints, parameters, and objective functions.

(1) Production Line Unavailability

For disturbances involving production line unavailability, the knowledge base instructs A_{patch} to generate $Blackouts$ patches. A binary auxiliary variable $w_{i,l,b}^{line}$ is introduced to depict the non-overlap logic

between the production line unavailable time $B_l^{line} = [b_{start}^{line}, b_{end}^{line}]$ and production tasks. Constraints (Equations 27-28), active only when $x_{i,l} = 1$, ensure that any tasks assigned to line l do not overlap with the blackout period.

$$C_{i,od} \leq b_{start}^{line} + M_{big} * w_{i,l,b}^{line} + M_{big} * (1 - x_{i,l}), \quad \forall i \in I, \forall l \in L, \forall b \in B_l^{line} \tag{27}$$

$$S_{i,oc} \geq b_{end}^{line} - M_{big} * (1 - w_{i,l,b}^{line}) - M_{big} * (1 - x_{i,l}), \quad \forall i \in I, \forall l \in L, \forall b \in B_l^{line} \tag{28}$$

(2) Emergency Insertion

When an emergency order arrives, it is translated into a $NewTasks$ patch via three update rules: (1) defining the new task set U to expand the total collection to $I^+ = I \cup U$ with initialized decision variables; (2) enforcing the required process and resource constraints for the inserted tasks; and (3) assigning a significantly higher delay penalty w_{i^*} to prioritize urgent insertions. The updated objective function is shown in Equation (29), and the inventory balance constraint is simultaneously extended to I^+, with the updated expression shown in Equation (30).

$$min\ Z = w_{i^*} * \sum_{i^* \in U} l_{i^*} + c_{late} * \sum_{i \in I} l_i + c_{early} * \sum_t e_i + k_{time} * \sum_{i \in I^+} shift_i^{time} + k_{line} * \sum_{i \in I^+} \varphi_i^{line} \tag{29}$$

$$I_t = I_{t-1} + \sum_{i \in I^+} z_{i,t} - D_t, \forall\, t \in T \tag{30}$$

While the preceding discussion primarily addresses disturbances at the production stage, the framework maintains the flexibility to map on-site construction disruptions to specific parameter updates in Equations (1-14). For instance, when encountering exogenous factors such as extreme weather or labor fluctuations, the knowledge base directs A_{patch} to generate a parameter patch ΔParam, reducing the assembly consumption rate D_t for the affected duration and triggers WindowShifts patches to recalibrate the ideal arrival time windows for various components. By continuously indexing disturbances into model parameter updates, the framework ensures its scalability in on-site construction.

3.3.2 Construction of External Knowledge Bases for A_{code}

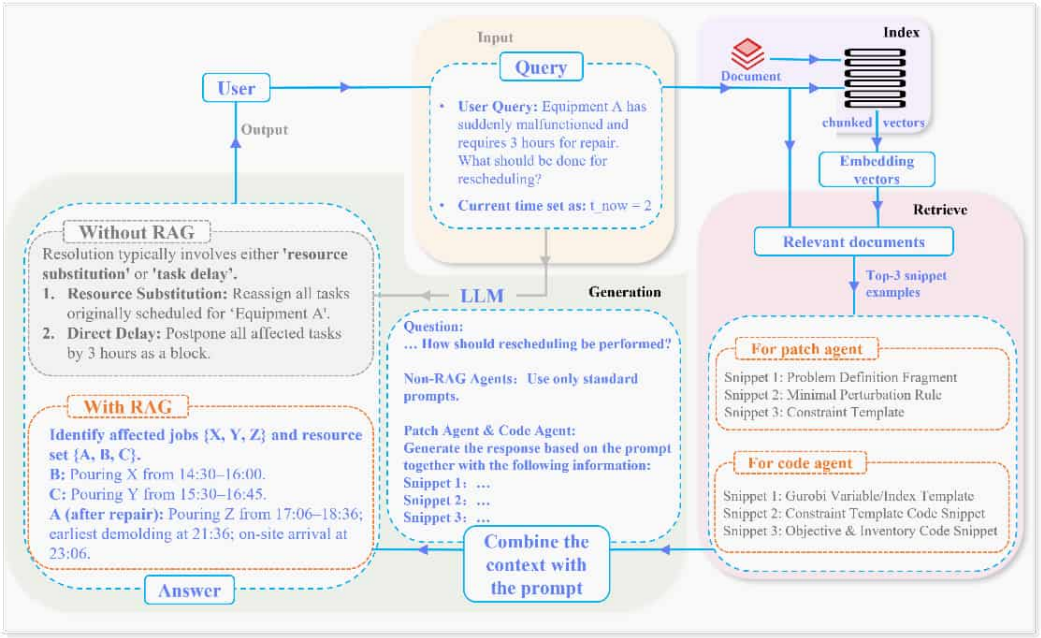

Figure 3. A representative example of the RAG process

The external knowledge base of A_{code} supports the conversion of MILP formulations into executable code by covering common MILP model structures, templates for variable and index definitions, and exemplars for constraint construction and solver interfaces. Given Gurobi's speed and stability for large-scale MILP[18], this study selects Gurobi as the solver for MILP models. To enhance the LLMs' ability to convert formulas into code, the process involves: (1) obtaining normalized MILP expressions from the A_{patch} external knowledge base; (2) driving the LLMs to generate model code using standard prompts without RAG technology; (3) validating executability via the Gurobi solver. This approach avoids semantically correct but non-executable issues that may

arise from relying solely on textual similarity[19-20]. Samples passing this verification are incorporated into the A_{code} knowledge base.

During the reasoning phase, RAG is introduced to reduce the hallucinations in LLM-generated responses and strengthen adherence to domain constraints. When A_{patch} or A_{code} is triggered, the framework retrieves the most contextually relevant template from its corresponding knowledge base. This retrieved knowledge is not memorized by the collaborative scheduling model but dynamically injected as critical contextual information into the original prompt, enhancing generation quality without fine-tuning[17]. The RAG application workflow is illustrated in Figure 3.

Despite the generative capabilities of LLM, the resulting code may encounter execution failures during the solving phase, such as syntax errors, undefined variables, or solver-induced infeasibility. To enhance execution robustness, this framework integrates automated fault diagnosis and repair mechanisms in A_{code} and $A_{schedule}$. In instances of code execution failure, the error message is fed back to A_{code} for context-aware rewriting. Furthermore, when the solver fails to identify a feasible solution, $A_{schedule}$ identifies conflicting constraints and passes the semantic feedback to A_{patch}, which facilitates the dynamic adjustment of non-hard constraints to restore feasibility.

In scenarios where a disturbance is not represented in the existing knowledge base, the framework extracts the original event E_t, the intermediate model M_t, and the diagnostic log $Diag_t$ to generate an anomaly report for expert review. Following manual intervention and verification, the unrecorded disturbance is vectorized and added to the knowledge base. In this way, the knowledge base is continuously expanded through both operational failure records and expert-in-the-loop corrections.

4 Case Study

4.1 Experimental Setup

The experimental environment is implemented in Python 3.9, integrating LangChain for agent orchestration. We employ GPT-4 as the inference model for the AI agents and Gurobi 10.0 as the MILP solver. The case scenario is set in a prefabrication factory containing two parallel production lines (l_1, l_2). The production plan encompasses tasks for facade i_1, composite slab i_2, balcony i_3, air conditioning panel i_4, and staircase i_5. Among these, facades, composite slabs, and staircases are critical path elements, with their late arrival penalty set at a higher rate of 10 units/hour[21]. The early arrival penalty coefficient is set at 50% of the late penalty to reflect that while early arrivals occupy inventory, their consequences are less severe than work stoppages due to material shortages.

The production includes casting, curing, and demolding, with casting and demolding occupying production-line capacity. After completing the casting process, components are transferred via an automated conveyor to the curing chamber. During this period, components are subject only to the minimum curing time constraint and do not occupy production line resources. That is, within the interval $(C_{i,oc}, S_{i,od})$, production line resources can be released for casting or demolding other components. Transportation time is set as $\tau_i = 1.5$ h. Time deviation penalties k_{time} and production line change penalties k_{line} are set at 5 units per hour and 10 units per occurrence, respectively. Other key process parameters are shown in Table 1. For case simplification, only one piece is produced for each component.

Table 1. Component Production Parameters and Logistics Constraints Setting

Component	$p_{i,oc}$ (h)	θ_i (h)	$p_{i,od}$ (h)	c_{late} (units/h)	c_{early} (units/h)
i_1	0.5	10	1.0	10	5
i_2	0.4	10	1.0	10	5
i_3	0.4	10	0.5	8	4
i_4	0.3	10	0.3	8	4
i_5	1.0	10	1.5	10	5

Before production begins, the framework invokes $A_{schedule}$ to construct the MILP model using the aforementioned parameters. All component castings must be intensively completed within the first few hours after t=0 to reserve sufficient curing time. Detailed data for the initial production schedule is shown in Table 2.

Table 2. Initial production schedule

Component	Line	$S_{i,oc} - C_{i,oc}$	$S_{i,od} - C_{i,od}$	a_i	$[E_i, L_i]$
i_1	l_1	0.0-0.5	10.5-11.5	13.0	[12, 15]
i_5	l_1	0.5-1.5	11.5-13.0	14.5	[12, 15]
i_2	l_2	0.0-0.4	10.4-11.4	12.9	[12, 15]
i_3	l_2	0.4-0.8	11.4-11.9	13.4	[12, 15]
i_4	l_2	0.8-1.1	11.9-12.2	13.7	[12, 15]

4.2 Disturbance Scenario Simulation

Production begins at t=0. At t=0.5, the framework receives the natural language log: “Hydraulic system failure on Production Line l_1. Full line shutdown required for 4 hours. Urgent action needed; prioritize staircase delivery.”.

The framework then initiates a collaborative response according to the workflow described in Section 3. A_{sense} parses the log, identifies the affected resource (l_1), the

outage duration, and the impacted task (i_5 casting), and outputs a structured report. A_{patch} generates a mathematical patch Π_t using retrieved knowledge about production line unavailability. The patch freezes completed tasks i_1, imposes fault period constraints on l_1, and reactivates stability penalty terms $k_{time} * \sum_i shift_i^{time} + k_{line} * \sum_i \varphi_i^{line}$ in the objective function. A_{code} converts the patched model into executable code, which is subsequently solved by $A_{schedule}$. Given the high lateness penalty for i_5, $A_{schedule}$ reallocates its casting operation by switching production lines and scheduling it after i_3 and before i_4. Finally, $A_{dispatch}$ is triggered to issue maintenance instructions to l_1 and revised production instructions to l_2.

4.3 Discussion

Table 3 compares a baseline response strategy (Strategy A) with the proposed cross-line rescheduling approach (Strategy B). The results demonstrate that, upon a production-line failure, the proposed framework can parse the disturbance semantics, patch the MILP formulation, and generate an updated production plan.

Strategy B represents an optimized trade-off. By accepting a fixed changeover penalty and small delays for low-priority component i_4, the framework prevents severe delays for critical component i_5. This decision stems from mathematical optimization of the updated model, highlighting the framework's advantage over simple rule-based responses. The end-to-end process completes automatically in under one minute, validating the framework's ability to bridge the semantic-to-model gap and support fully automated rescheduling in practical settings.

Table 3. Full Cost Comparison of Rescheduling Strategies

Cost Item	Strategy A (Wait)	Strategy B (Switch)
$k_{line} * \sum_i \varphi_i^{line}$	0	10.0
$k_{time} * \sum_i shift_i^{time}$	20	6.5
Late arrival penalty of i_5	35.0	0.0
Late arrival penalty of i_4	0.0	1.6
Z	55.0	18.1

5 Conclusion and Future Work

This study proposes an intelligent rescheduling framework that integrates the semantic reasoning of AI agents with the optimization capabilities of MILP. By positioning LLMs as the core cognitive processors, the framework delivers two primary contributions. First, it introduces an automated semantic-to-constraint translation mechanism that autonomously converts unstructured disturbance reports into formal mathematical constraints, thereby accelerating the transition from perception to solution. Second, the framework facilitates localized model refinement, which preserves computational efficiency by bypassing the need for a full model reconstruction.

However, current validation is limited to small-scale disturbance scenarios involving five components. This initial stage serves primarily as a proof-of-concept to demonstrate the feasibility of employing LLM-centric cognitive cores in scheduling workflows. As project scales expand, exact solvers often encounter exponential computational complexity. Therefore, future work should evaluate the framework against large-scale datasets featuring multi-node concurrent disturbances.

Abstract –

Indoor air quality management remains largely reactive due to limited multi-horizon forecasting capabilities and deployment challenges under real-world constraints. This paper presents a Digital Twin (DT)-enabled framework for multi-horizon indoor $PM_{2.5}$ forecasting from 1 to 6 hours ahead using machine learning and multi-source environmental data from a university campus in Abu Dhabi, UAE. Indoor sensor measurements are combined with outdoor monitoring data and ERA5 wind variables used with a realistic five-day availability delay. CatBoost and Transformer models are evaluated using seasonal cross-validation, with CatBoost demonstrating advantages at short-term horizons while Transformer marginally performs better at the long-term horizon. SHAP analysis reveals that current indoor $PM_{2.5}$ is the dominant predictor for short-term forecasts. An ablation study demonstrates that incorporating lagged wind data yields statistically significant improvements in non-winter seasons.

Keywords –

Indoor air quality; CatBoost; Transformer; Reanalysis data

1 Introduction

Indoor air quality (IAQ) has gained increasing attention globally, particularly as people spend approximately 90% of their time in indoor environments and ambient $PM_{2.5}$ concentrations remain a persistent public health concern in many urban environments [1]. Among various indoor pollutants, particulate matter with a diameter of less than 2.5 micrometers ($PM_{2.5}$) poses significant health risks, including diabetes and prenatal disorders [2]. Indoor $PM_{2.5}$ primarily enters indoor environments through ventilation and infiltration processes, or is generated internally by human activities such as printing and photocopying, cleaning and maintenance activities (e.g., use of disinfectant sprays), frequent door opening that resuspends settled dust, and movement of occupants [2]. Many studies have proposed models to predict indoor PM2.5, but far fewer have dealt with what happens when those models must run continuously with delayed external data, mixed sensor streams, and decision-support needs in a live DT.

Digital Twin (DT) technology offers a transformative paradigm for data-driven IAQ management by creating virtual replicas of physical indoor spaces that enable real-time monitoring, prediction, and optimization. Current $PM_{2.5}$ monitoring systems in DT applications are primarily reactive, alerting occupants after pollutant concentrations exceed threshold levels. With advanced predictive analytics, DTs enable proactive measures for indoor $PM_{2.5}$ risk prevention and support preventive health management [3]. However, the application of predictive models to indoor environments faces unique challenges, particularly the need for real-time predictions with integration of available near real-time data sources such as indoor sensors, outdoor atmospheric monitoring stations, and satellite reanalysis data. What is still limited is the deployment of multi-horizon forecasting that can give operators useful lead time while relying only on data that are available at prediction time. Besides, wind-related variables from ERA5, the global meteorological reanalysis produced by the European Centre for Medium-Range Weather Forecasts (ECMWF) [4], which are widely used in indoor and outdoor $PM_{2.5}$ studies for reliable wind data [5], [6], are subject to an inherent latency of approximately five days before becoming available. To the best of the authors' knowledge, the influence of this latency on indoor PM2.5 prediction has not been fully investigated, representing an operational constraint in real-time prediction deployment in DT applications.

This paper presents a framework that integrates near real-time multi-source data to forecast indoor $PM_{2.5}$ within a DT managed environment. Environmental data from indoor sensors ($PM_{2.5}$, humidity, and pressure), outdoor atmospheric monitoring stations (PM_1, $PM_{2.5}$, PM_{10}, temperature, humidity, pressure, and dew point), and lagged ERA5 meteorological reanalysis data (U and

V wind components, wind gust) are integrated to train CatBoost, Transformer, and persistence models for predictions up to six hours ahead. The contribution is not a new forecasting algorithm; it is a deployment-oriented forecasting workflow that accounts for data latency, tests whether delayed wind information is still useful, and shows how multi-horizon predictions can be pushed into a live DT interface.

2 Previous Studies

2.1 Hourly Indoor $PM_{2.5}$ Prediction

Recent studies have employed diverse machine learning architectures for indoor $PM_{2.5}$ forecasting. Recurrent architectures including LSTM, BiLSTM, and GRU have been widely adopted for capturing temporal dependencies in time-series air quality data [7]. Gradient boosting methods such as XGBoost and LightGBM demonstrate strong performance through ensemble learning approaches [6], [8]. Sparse attention–based Transformer models efficiently capture long-term dependencies in $PM_{2.5}$ time series and demonstrate improved performance for both short-term and long-term air quality forecasting [9]. Feature selection for indoor $PM_{2.5}$ prediction typically incorporates indoor environmental parameters ($PM_{2.5}$, temperature, humidity), outdoor atmospheric conditions (meteorological variables, ambient pollutants), and contextual factors (occupancy, season, time), resulting in a total of 10 to 21 features used for prediction [10], [11]. Even so, most published studies emphasize model accuracy, whereas deployment-oriented questions such as data latency, inference timing, and how much lead time is practically useful receive much less attention.

Current studies on indoor $PM_{2.5}$ forecasting primarily focus on model development and performance validation, with limited attention to real-world deployment challenges and operational constraints.

2.2 Predictive Digital Twin Application

DT technology has emerged as a promising platform for IAQ management, integrating IoT sensors, Building Information Modeling (BIM), and machine learning for real-time monitoring and visualization. Hu et al. [12] proposed a CNN-BiLSTM-MHA model for IAQ failure prediction integrated with a DT platform, demonstrating real-time alert capabilities but emphasizing anomaly detection over continuous predictive forecasting. Khosh-Amadi et al. [13] proposed an AIR-DT framework integrating IoT sensors, BIM, spatial analytics, and short-term IAQ prediction to enable real-time, asthma-oriented indoor air quality monitoring and intervention. Qian et al. [14] presented an intelligent IAQ management system based on DT platforms that integrates multi-source data from IoT and BIM, achieving rapid prediction and control responses within 30 minutes of threshold exceedance.

Despite these developments, critical gaps remain in integrating heterogeneous near real-time data sources from multiple domains (indoor, outdoor, meteorological) and implementing multi-horizon forecasting models that provide actionable lead times for building management interventions.

3 Framework of Digital Twin Enabled Predictive Analysis

The proposed framework comprises three layers encompassing seven processes, shown in Figure 1.

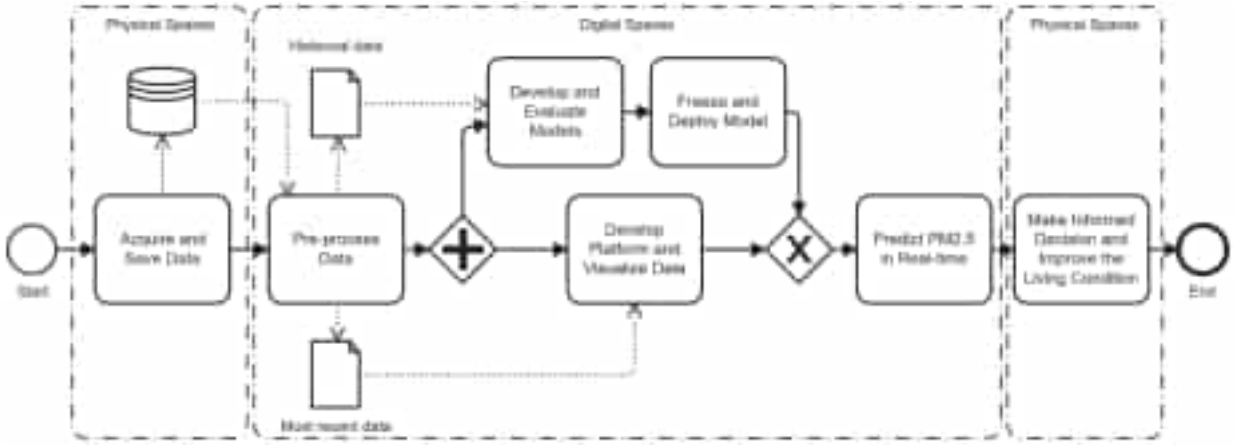

Figure 1: BPMN diagram for Digital Twin-enabled IAQ improvement with indoor $PM_{2.5}$ prediction

Data Acquisition Layer: acquire and save data from indoor sensors, outdoor stations, and ERA5 reanalysis; pre-process data through outlier removal following Tukey 1.5 × IQR rule, data imputation using KNN

method [15], and hourly aggregation and temporal alignment.

Model Development Layer: develop and evaluate models using CatBoost and Transformer through seasonal cross-validation and Diebold-Mariano (DM) tests [16], then freeze and deploy models in the backend DT system.

Broadcasting of Real-time Prediction Layer: develop platform and visualize data, predict $PM_{2.5}$ in real-time, make informed decisions and improve living conditions, enabling bilateral information flow in DT.

4 Implementation

4.1 Data Acquisition

Three categories of environmental data were collected to capture the multi-scale influences on indoor $PM_{2.5}$ concentrations. Indoor environmental parameters were measured using sensors deployed at NYU Abu Dhabi, recording $PM_{2.5}$, humidity, and pressure at 1-minute intervals [17]. Outdoor atmospheric conditions were monitored using two complementary systems. Outdoor air quality stations provided measurements of particulate matter (PM_1, $PM_{2.5}$, PM_{10}), temperature, relative humidity, and atmospheric pressure at 1-minute intervals, and meteorological stations supplied dew point observations at 15-minute intervals.

The realistic 5-day lag constraint of the ERA5 data source was considered in this study. Hourly measurements of 10-m wind gust, as well as zonal (U) and meridional (V) wind components, were extracted from ERA5 for the New York University Abu Dhabi campus location. The complete dataset spans from April 6, 2024, to November 16, 2025, covering approximately 19 months of observations. All variables used in this study are summarized in Table 1.

As part of data preprocessing, 3.2% of indoor sensor readings, 4.0% of outdoor measurements, and 0.7% of meteorological station data were classified as outliers and excluded from further analysis. All variables were subsequently resampled and temporally aligned to an hourly resolution using mean aggregation. Missing values were handled using k-nearest neighbors (KNN) imputation, which filled 3.6% of indoor sensor data, 2.9% of outdoor data, and 22.9% of meteorological station data. Although the meteorological station dataset (dew point) exhibited a higher proportion of missing values, this feature was retained due to its moderately positive Pearson correlation of 0.28 with indoor $PM_{2.5}$. The final dataset comprises 14,129 hourly observations with 13 input features.

An overview of the indoor $PM_{2.5}$ after the data pre-processing is shown in Figure 2. The monthly statistics reveal substantial temporal variability, with mean $PM_{2.5}$ concentrations ranging from 4.1 μg/m³ in May 2024 to 10.2 μg/m³ in October 2025. Lower concentrations were generally observed during winter and spring months (December-May), while elevated levels occurred during summer and fall months (June-November), a pattern consistent with the influence of intense heat, enhanced secondary aerosol formation, frequent dust events, and reduced atmospheric dispersion during warmer periods in Abu Dhabi. Accordingly, a seasonally stratified cross-validation strategy was implemented to evaluate model performance under varying climatic conditions.

Table 1: Parameters collected from different sources

Abbreviation	Parameter	Data source
Ind. PM2.5	Indoor $PM_{2.5}$	Indoor*
Ind. Humi.	Indoor Humidity	Indoor
Ind. Press.	Indoor Pressure	Indoor
Outd. PM1	Outdoor PM_1	Outdoor**
Outd. PM2.5	Outdoor $PM_{2.5}$	Outdoor
Outd. PM10	Outdoor PM_{10}	Outdoor
Outd. Temp.	Outdoor Temperature	Outdoor
Outd. Humi.	Outdoor Humidity	Outdoor
Outd. Press.	Outdoor Pressure	Outdoor
Dew Point	Dew Point	Meteo. station***
Wind Gust	Instantaneous 10-meter wind gust	ERA5
U Wind	10-meter U wind component	ERA5
V Wind	10-meter V wind component	ERA5

4.2 Model Development

4.2.1 Model Selection and Configuration

CatBoost gradient boosting and Transformer neural network architectures were selected for systematic comparison based on their respective strengths in ensemble learning with feature interaction capabilities [8] and attention-based temporal modeling [9]. CatBoost is a strong choice for heterogeneous tabular inputs with nonlinear interactions and relatively limited feature engineering, while the Transformer is well suited to learning longer temporal dependencies from lagged sequences. Preliminary experiments with other models, such as Random Forest and BiLSTM, showed almost 50% higher RMSE and were therefore excluded from this study. Additionally, a persistence baseline model, which assumes future $PM_{2.5}$ concentrations remain equal to the current observed value, was included for statistical comparison as a benchmark baseline [10].

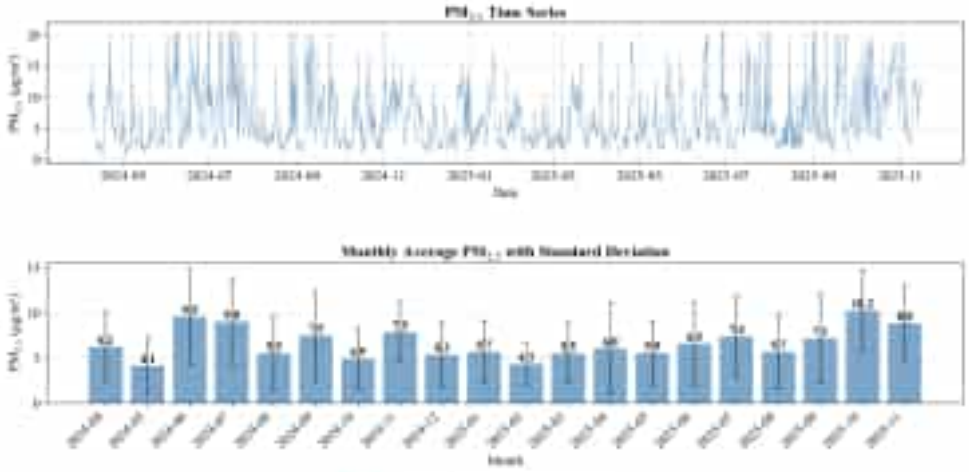

Figure 2: The overview and monthly average of the indoor $PM_{2.5}$

As previously indicated, the ERA5 API exhibits a five-day latency in data acquisition, which poses a limitation for real-time prediction in DT applications. Correlation analysis reveals that Wind Gust, U Wind, and V Wind exhibit moderate Pearson correlations of -0.27, -0.12, and 0.06, respectively, with indoor $PM_{2.5}$ when using contemporaneous data, but this operational lag constraint reduces these correlations to -0.04, -0.03, and -0.01. Nevertheless, the lagged wind features were retained as machine learning models may capture long-term and non-linear relationships that traditional linear regression cannot easily detect, potentially revealing residual atmospheric circulation patterns relevant to $PM_{2.5}$ dynamics. NaN wind data at the beginning of the dataset due to the five-day latency were filled using the earliest available wind observations.

Lag features are applied to all components to capture their temporal dependencies and periodicities [8]. Specifically, for each prediction horizon h, the input feature set includes observations from the current hour and the preceding six hours (at times t through $t-6$), as well as the corresponding hourly observation from 24 hours prior to the target prediction time (at $t+h-24$). All features were normalized using min-max scaling to ensure comparability across features and to support stable model training.

To evaluate model performance under different climatic conditions, a rolling-window cross-validation strategy was employed. Four folds (i.e., temporal splits) were constructed, as summarized in Table 2. For each fold, data from the eight months preceding the target season were used for model training. The data within the target season were then chronologically divided into two equal parts, with the first half used for validation and the second half reserved for testing. Across all folds, the approximate train/validation/test ratio is 72%/14%/14%.

The Transformer model was implemented using PyTorch, while the CatBoost model was implemented using the CatBoost Python library. Configurations of both models are listed in Table 3.

Table 2: Dataset splitting for cross validation

Split	Targeting Season	Time Frame
1	Spring	March, 2025 - May, 2025
2	Summer	June, 2025 - Aug., 2025
3	Fall	Sep., 2025 - Nov., 2025
4	Winter	Dec., 2024 - Feb., 2025

Table 3: Model configurations

CatBoost	Transformer
Max iterations: 2000	Max epochs: 200
Early stopping: yes	Early stopping: yes

0.8	Embedding dimension: 64
Random strength: 0	Number of attention heads: 8
	Transformer layers: 3
	Dropout rate: 0.1

4.2.2 Results of Model Training

Performance metrics were computed for each cross-validation fold and for each prediction horizon (H1-H6). Model performance was evaluated across RMSE, MAE, MAPE, and R^2 at six prediction horizons, as shown in Figure 3-Figure 6.

1. Performance comparison of horizons

The results indicate a consistent decline in prediction accuracy as the forecast horizon extends from H1 to H6, a trend observed across all models and validation splits.

For CatBoost, mean performance metrics averaged over all splits indicate RMSE values of 0.9412, 1.3176, 1.6461, 1.9479, 2.2253, and 2.4647 μg/m³ (Figure 3), and MAE values of 0.4854, 0.8147, 1.0878, 1.3006, 1.5342, and 1.6996 μg/m³ across the six horizons (Figure 4). Corresponding mean MAPE increased from 8.3% to 28.6% (Figure 5), while mean R^2 decreased from 0.9420 to 0.6332 (Figure 6).

Despite this degradation, CatBoost and Transformer models at the H6 demonstrate predictive ability with average R^2 values of 0.6332 and 0.6278, surpassing the persistence model of 0.5797 by 9.2% and 8.3% respectively.

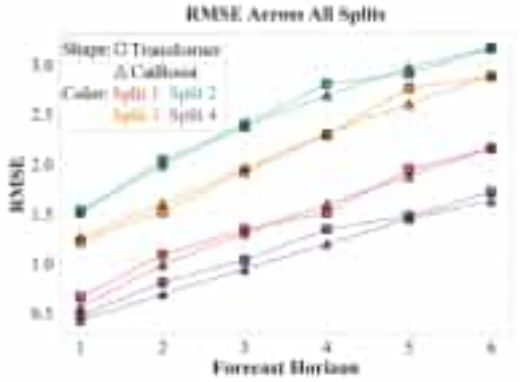

Figure 3: RMSE across all splits and 6 horizons

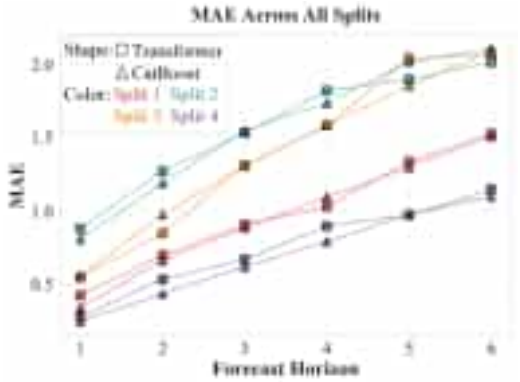

Figure 4: MAE across all splits and 6 horizons

2. Performance comparison of models

CatBoost demonstrated lower predictive error (RMSE, MAE, and MAPE) at short-term horizons compared to both Transformer and persistence models. At H1, CatBoost achieved an average MAE of 0.4854 μg/m³ across the four splits, compared to 0.5297 μg/m³ for Transformer and 0.5062 μg/m³ for persistence, representing improvements of 9.1% and 4.3% respectively. At H6, this reverses, with Transformer achieving 1.6870 μg/m³ while CatBoost achieving 1.6996 μg/m³. Both machine learning models outperformed the 1.7516 μg/m³ of persistence baseline by 3.1% and 3.8% respectively. CatBoost's gradient boosting architecture effectively captures the temporal dynamics and feature interactions governing indoor $PM_{2.5}$ evolution, particularly at shorter prediction horizons while Transformer marginally surpasses CatBoost at long-term prediction at H6.

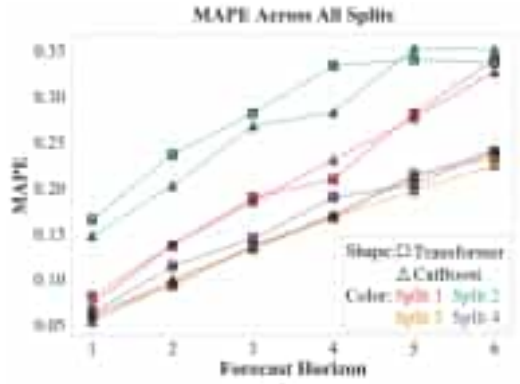

Figure 5: MAPE across all splits and 6 horizons

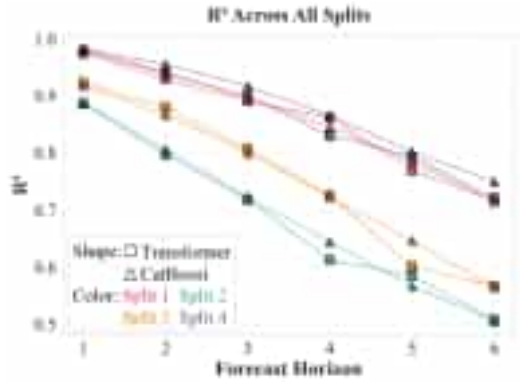

Figure 6: R^2 across all splits and 6 horizons

3. Performance comparison of seasonal split

Seasonal variations significantly influenced model performance across the four cross-validation splits, with Splits 1 (spring, in red) and 4 (winter, in purple) demonstrating notably better performance than Splits 2 (summer, in green) and 3 (fall, in orange). For Split 4, CatBoost achieved the lowest errors with MAE of 0.2448 μg/m³ at H1 and 1.0967 μg/m³ at H6, while for Split 1 CatBoost showed similarly favorable results with MAE of 0.3405 μg/m³ at H1 and 1.5067 μg/m³ at H6. In contrast, Splits 2 and 3 exhibited higher errors, with CatBoost's MAE at H6 reaching 2.1083 μg/m³ and 2.0868 μg/m³, representing increases of 92.2% and 90.3%, respectively, compared with Split 4.

This seasonal performance pattern is consistent with

the $PM_{2.5}$ concentration trends shown in Figure 2. Spring and winter are characterized by lower and more stable pollutant levels, resulting in smoother temporal dynamics that are easier for data-driven models to learn. In contrast, summer and fall exhibit higher mean concentrations and greater short-term variability, driven by dust events, heat-induced atmospheric stagnation, and changing wind patterns in the UAE. These factors increase the volatility of indoor $PM_{2.5}$, thereby amplifying forecast uncertainty and contributing to the observed degradation in model performance for Splits 2 and 3.

4.2.3 Statistical Validation

One-sided DM test was employed to evaluate the statistical significance of performance differences between models using absolute error. Table 4 presents the DM statistics and p-values for all pairwise comparisons across prediction horizons. For example, at the two-hour forecast horizon (H2), the DM statistic for CatBoost vs. Transformer is -1.91 with a p-value of 0.0281. Because the statistic is negative and the p-value is below 0.05, this indicates that CatBoost performs significantly better than the Transformer at this horizon across all splits, and the observed improvement is unlikely to be due to random variation.

Table 4: DM test results on different horizons

Horizon	CatBoost vs Persistence	Transformer vs Persistence	CatBoost vs Transformer
1	-3.47 (0.0003)	-1.53 (0.0635)	-0.81 (0.2096)
2	-3.86 (0.0001)	-1.28 (0.0997)	-1.91 (0.0281)
3	-4.07 (0.0000)	-3.08 (0.0010)	-0.61 (0.2714)
4	-4.02 (0.0000)	-2.75 (0.0029)	-1.00 (0.1577)
5	-3.61 (0.0002)	-2.48 (0.0065)	-1.11 (0.1333)
6	-3.20 (0.0007)	-3.02 (0.0013)	-0.19 (0.4242)

Note: Data pair format - DM statistic (p value). Negative DM statistic indicates superior performance of the first model. $p < 0.01$ indicates strong significance; $p < 0.05$ indicates significance; $p < 0.10$ indicates marginal significance.

The CatBoost model significantly outperformed the persistence baseline across all horizons ($p < 0.01$) while the Transformer model significantly outperformed the persistence baseline from H3-H6 ($p < 0.01$) and marginally outperformed persistence baseline at H1 and H2 ($p < 0.1$). Both models showed their ability to capture temporal dynamics beyond simple autocorrelation. CatBoost exhibited the stronger superiority over persistence, with DM statistics ranging from -3.20 to -4.07 ($p < 0.01$). Comparing the two machine learning models, CatBoost demonstrated marginal significance over Transformer at horizon H2 ($p < 0.05$). On the other horizons, the performance differences were not statistically significant ($p > 0.10$), indicating comparable predictive capabilities at these horizons.

4.2.4 Importance Analysis

The model interpretability and the importance of the features are supported by the SHAP (Shapley Additive exPlans). Figure 7 shows an example of feature importance and directional impact for indoor $PM_{2.5}$ at H1 of split 4 of CatBoost model. It shows that indoor $PM_{2.5}$ at the current emerges as the dominant predictor, with high feature values strongly driving higher predictions, while outdoor PM_1 ranks second, reflecting the close coupling between indoor and outdoor particulate matter. Contribution of wind gust feature emerges after indoor $PM_{2.5}$ and other outdoor features.

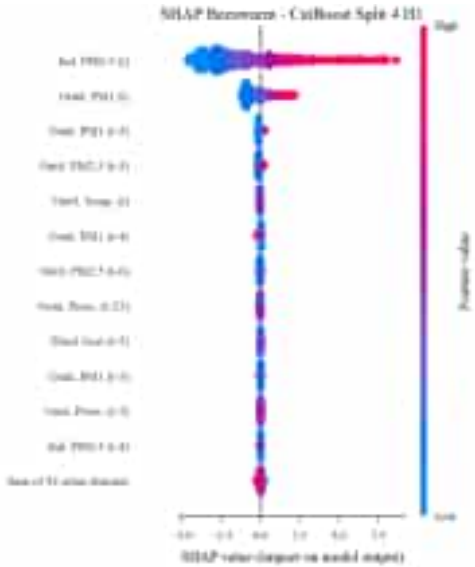

Figure 7: SHAP Beeswarm of CatBoost (H1)

4.3 Broadcasting of Real-time Prediction

A implementation of the real-time forecasting module is shown in Figure 8 and is accessible on the prototype online platform [18]. The data ingestion layer continuously acquires the most recent environmental measurements. Wind inputs are retrieved from the ERA5 reanalysis through the ECMWF API and incorporated into the forecasting workflow under a five-day availability delay, thereby ensuring consistency with operational data-access constraints. The forecasting service executes multi-horizon inference using the trained CatBoost models and publishes prediction outputs to the DT interface for visualization.

Although the models are developed using the data

collected at NYUAD campus, the workflow and three-layer framework can be transferred to other buildings that have comparable indoor sensing, outdoor measurements, and meteorological inputs.

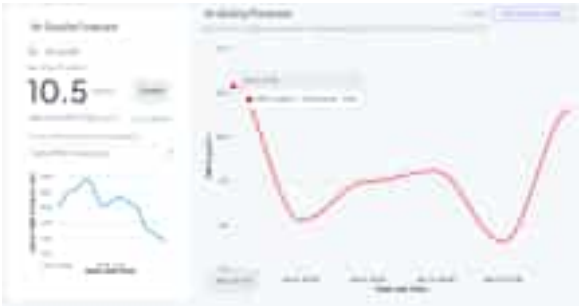

Figure 8: Screenshot of real-time forecasting platform

5 Ablation Study: Lagged Wind Feature

To validate whether using the lagged wind features provides meaningful predictive value, an ablation study was conducted using the CatBoost model aggregating all horizons. Table 5 shows the DM test results comparing the "Lagged ERA5" and "No ERA5" configurations over the four splits. It indicates that predictions with "Lagged ERA5" wind features are strongly significant in Split 1 (spring, $p < 0.01$) and 2 (summer, $p < 0.01$), marginally significant in Split 3 (fall, $p < 0.1$), while not significant in Split 4 (winter).

Table 5: DM test results of "Lagged ERA5" vs. "No ERA5" configurations

Split 1	Split 2	Split 3	Split 4
-3.42 (0.0003)	-3.31 (0.0005)	-1.51 (0.0658)	3.66 (0.9999)

Table 6 compares MAE performance across all prediction horizons for the "Lagged ERA5" and "No ERA5" configurations in Split 1. Overall, incorporating lagged ERA5 wind variables yields modest performance gains, with MAE variations remaining within ±2% across forecast horizons H2–H5.

Table 6: MAE (μg/m³) comparison of "Lagged ERA5" and "No ERA5" configurations in Split 1

Horizon	Lagged ERA5	No ERA5	Improvement
1	0.3405	0.3387	-0.5%
2	0.6594	0.6605	0.2%
3	0.8844	0.8863	0.2%
4	1.0954	1.1091	1.3%
5	1.2960	1.3070	0.9%
6	1.5067	1.5149	0.5%

6 Limitations

The five-day latency in ERA5 wind data yields only modest improvements (under 2%), suggesting a need for more recent wind data sources to enhance predictive performance. Reliance on a single reanalysis dataset (ERA5) and a single imputation method (KNN) may introduce dataset- or method-specific biases. In addition, all predictors used here are observational rather than directly manipulatable. Occupancy-related activities and HVAC operational variables were not available, even though such inputs would be valuable in a DT setting because they are closer to actionable control decisions. Finally, the framework was evaluated on a single campus in Abu Dhabi with a specific building configuration, and its generalizability to other climates and building configurations remains untested.

7 Conclusion

This paper presents a DT-enabled framework for multi-horizon indoor $PM_{2.5}$ forecasting using multi-source environmental data. CatBoost and Transformer models were evaluated using seasonal cross-validation, with CatBoost achieving average MAE of 0.4854 μg/m³ ($R^2 = 0.9420$) at one hour and 1.6996 μg/m³ ($R^2 = 0.6332$) at the six-hour horizon. Both models significantly outperformed persistence baselines, with CatBoost demonstrating statistically significant advantages at several intermediate horizons. SHAP analysis shows that current indoor $PM_{2.5}$ dominates short-term predictions, with its importance declining from 0.408 to 0.300 in CatBoost. An ablation analysis comparing "Lagged ERA5" and "No ERA5" configurations confirmed that incorporating lagged wind features yields statistically significant improvements, strengthening the case for deployment-ready forecasting.

Overall, the proposed framework provides a scalable foundation for data-driven indoor air quality management in DT–enabled environments. Future work should examine alternative real-time meteorological data sources, extend validation across diverse indoor settings and climates, and integrate building operational and occupancy information to further enhance predictive performance.

Abstract

Scaffolding accidents account for significant fatalities in the construction industry, with deviations between erected structures and approved design drawings being a leading cause. However, automated verification of scaffold compliance with design specifications remains an open challenge due to the difficulty of extracting geometric information from engineering drawings and matching them to as-built point cloud data. This paper presents a three-stage framework for automated design compliance checking of steel scaffolds that integrates multi-view drawing analysis with 3D point cloud verification. The first step extracts geometry from scaffold drawings using computer vision algorithms. The second step involves extracting geometry from as-built scaffolds based on point cloud analysis method. The third step verifies the existence of components by comparing the extracted as-built information with the design information. Validation experiments were conducted on a point cloud dataset acquired from a scaffold system in a construction site in Hong Kong. The results provided 100% detection accuracy for tubes and safety-critical components (toe-boards, platforms and stairs), with drawing-based geometric reconstruction accuracy achieving sub-centimeter precision (mean error: 1.94 mm for tube length). This work represents the first automated system for verifying scaffold adherence to design specifications, addressing a critical gap between code compliance and design compliance in construction safety automation.

Keywords –

3D point cloud; Design compliance checking; Drawing analysis; Scaffold; Construction automation; Computer vision

1 Introduction

Scaffolding is a critical yet potentially hazardous temporary structure in construction, often associated with severe accidents due to structural failures. While adherence to safety standards and design specifications during scaffold assembly is crucial for mitigating accident risks, deviations between erected scaffolds and approved safety drawings are frequently observed. These deviations include unauthorized changes to the structural configuration and improper installation of key components. Consequently, the verification of erected scaffolds against approved safety drawings is a routine and essential practice. However, manual design compliance check of scaffolds is slow, inaccurate, qualitative and dangerous. Frequent compliance checking of scaffolds is necessary as scaffolds are often taken down and rebuilt as the project moves forward. To address this challenge, there is a growing focus on developing automatic systems for compliance checking for scaffolds. The advancements in technologies such as computer vision, robot dogs, and unmanned aircraft can assist or replace workers in conducting efficient and safe compliance checks. Adopting automatic compliance checking for scaffolding is essential for advancing engineering management [1].

Recent studies on scaffold compliance checking have concentrated on component detection, including toe-boards [2], guard-rails [2,3], and work platforms [3]. Wang [2] analyzed the geometric attributes of platform-related components, though the scope remained limited. Kim et al. [3] relied exclusively on point cloud quantity to identify elements, overlooking critical geometric dimensions. Conversely, Luo et al. [4] fused imagery with point cloud data, utilizing Graph Neural Networks (GNNs) to evaluate structural metrics such as upright verticality and bottom runner clearance. However, reliance on single-image analysis renders such methods susceptible to occlusion, limiting their application to

single-layer scaffolds. Currently, a comprehensive approach that leverages geometric characteristics to verify all scaffold component types is lacking. Furthermore, few studies address compliance checking against architectural drawings, despite the critical importance of ensuring consistency between the as-built scaffolding and the original design.

To address these limitations, this study aims to develop an automated framework for design compliance checking of scaffolds, specifically focusing on component presence verification. Unlike previous approaches, this research bridges the gap between 2D design documentation and 3D site data. The primary contributions are twofold: 1) a novel drawing analysis method is proposed to automatically extract component positions and geometric attributes from rasterized design drawings; and 2) a robust compliance checking algorithm is developed to verify component existence through geometric feature extraction.

2 Literature Review

Some studies proposed automatic metal scaffolding inspection methods through analyzing point cloud data. Wang [2] proposed an automated technique utilizing 3D point cloud data to extract scaffold platforms and verify the regulatory compliance of toe-boards and guard-rails. Most studies employ rule-based approaches which have limited general applicability, while a small portion uses learning-based methods due to the scarcity of data. Kim, et al. [3] developed an automated scaffold inspection methodology integrating terrestrial laser scanner data acquisition and RandLA-Net-based 3D segmentation. However, the practical implementation of these systems faces two significant hurdles: the scarcity of large-scale, labeled scaffold datasets for model training, and the substantial degradation of prediction performance when processing sparse point cloud data [5]. To address the limitations regarding point cloud scarcity and non-uniformity in large-scale scaffold monitoring, Kim, et al. [5] proposed a reconstruction method that utilizes synthetic datasets for semantic segmentation and an upsampling adversarial network to generate 3D CAD models. Some researchers apply advanced robotic technologies to automate data collection. Chung, et al. [6] developed a fully automated point cloud acquisition system using a quadruped robot that autonomously executes a three-stage workflow of initial site exploration, SLAM-based scan plan generation, and scanning execution without requiring prior information. Due to the height restrictions of robot dogs, the collected point cloud data contains missing and omitted parts. Johansen, et al. [7] employed specialized UAVs to autonomously capture point cloud data from the building exterior during inactive hours using optimized flight paths derived from digital safety plans. Furthermore, there have been few studies on the geometric quality assessment of scaffolding. Therefore, this study proposes a method to extract geometric features from point cloud data.

3 Methodology

The proposed framework consists of three integrated modules (Figure 1): (1) Multi-view Drawing Analysis, which extracts 3D geometric information from 2D raster drawings, (2) Component Detection, which extracts 3D geometric information from point cloud data, (3) Design Compliance Checking, which verifies component existence by comparing as-built component information against extracted design information.

3.1 Multi-view Drawing Analysis

This module extracts 2D information from multiple views and then matches and reasons to obtain 3D coordinates and geometry. Table 1 shows the data extracted from the drawings, and the different elements (tube, toe-board, platform, and stair) are described in the following subsections.

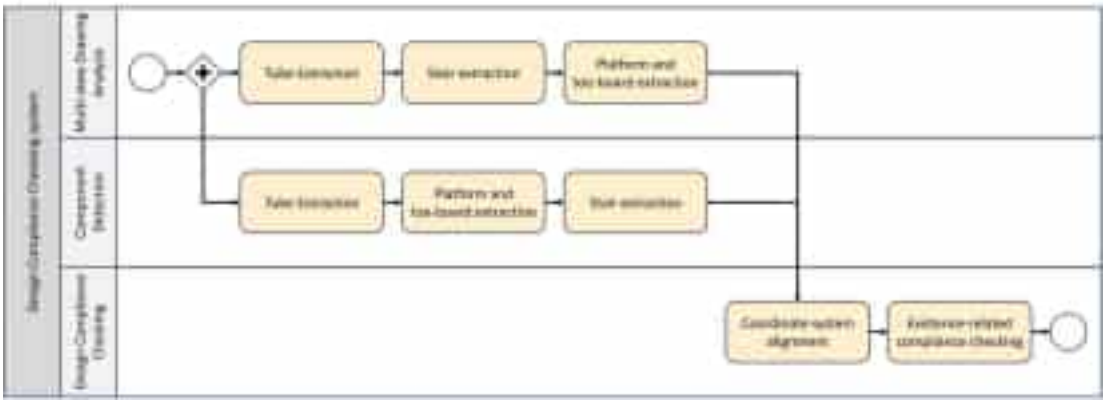

Figure 1. Proposed framework for design compliance checking of scaffolds

3.1.1 Tube Extraction

Scaffolding is defined as a temporary framework structure composed of tubes, with other types of components functioning as attachments to these tubes. Based on chromatic features, various components are extracted from the drawings, encompassing tubes, boards, and stairs. The Canny edge detector and Hough transform are utilized to identify and extract line segments representing the tubes. Given that a single tube in scaffold drawings may be represented by either a rectangle or a line segment, the detected segments are merged. Subsequently, the method of least squares is applied to perform linear fitting and generate definitive line segments. Finally, the starting and ending coordinates of each line segment are extracted to serve as the basis for subsequent analysis. When poor drawing quality compromises line segment extraction accuracy, the lengths and positions of the segments are calibrated by matching numerical annotations to the corresponding segments based on relative positions.

To integrate data extracted from different views, a unified coordinate system must be established. Scaffold drawings typically lack the axis lines and labels previous studies relied on to establish coordinate systems. Optical Character Recognition (OCR) techniques are employed to extract annotations from each view and filter for numerical annotations representing dimensions. These dimensional annotations are then matched with the corresponding tubes based on their coordinates. The scale ratio is calculated by dividing the annotated physical length by the pixel length of the tubes, which subsequently allows for the calculation of the actual tube lengths and 3D coordinates. Since image detection algorithms typically define the top-left corner of the image as the coordinate origin, a coordinate transformation is necessary to map image coordinates to the world coordinate system. When the world coordinate system is projected to form individual views, it is equivalent to retaining only two dimensions from the three-dimensional coordinates. An inverse operation is performed to restore the coordinates from all views to the world coordinate system with one dimension remains indeterminate at this stage. The origin of the world coordinate system is defined by the minimum coordinate values found among the start and end points of all detected tubes.

Existing two-view matching algorithms, utilizing either feature engineering or deep learning, prove ineffective for the three-dimensional reconstruction of scaffolding from engineering drawings. This ineffectiveness stems from the orthogonal projection of such drawings, where a 90-degree angular disparity often causes a structural member in one view to degenerate into a single node in another. To address this geometric ambiguity, the ‘Two-View Matching with Third-View Validation’ technique is employed to recover the missing spatial dimensions of individual tubes. The algorithm matches the endpoints of extracted line segments across two selected views and subsequently validates these candidates against a third view. However, this methodology inherently generates redundant line segments, thereby necessitating manual intervention for their removal.

3.1.2 Stair Extraction

The graphical representation of stair stringers and railings is morphologically similar to that of tubes. The location of the staircase and the quantity of steps are derived based on the position of the stringers. In the frontal view of the staircase, stringers are rendered as paired line segments perpendicular to the ground or as rectangles with their major axes aligned vertically. Conversely, in the lateral view of the staircase, the stringers manifest as inclined line segments or rectangles with tilted major axes due to projection and occlusion effects. The steps are depicted as short straight lines or rectangles that bridge the stringers and are horizontally relative to the ground. The Hough transform was utilized to extract stringers from both front and side views. The orientation of the staircase was determined based on the quantity of these detected stringers, which subsequently determined whether the identified geometric features represented the step length or width. Finally, the precise spatial position and dimensions of the staircase were derived using the coordinate transformation and 3D reconstruction methodologies previously applied to the tubes.

3.1.3 Platform and Toe-board Extraction

Scaffolding platforms are horizontal planar surfaces designed to support loads of personnel, tools and materials, represented in the plan view as shaded, colored or hatched rectangles. By extracting the minimum bounding rectangle from the top view, the actual x and y coordinates of the platforms within the world coordinate system are derived using the same transformation logic as tube detection. These rules stipulate that: 1) platforms must be located at the head and foot of staircases; 2) upper platforms require a minimum of four horizontal tubes for structural support; and (3) these supporting tubes must form a ground-parallel rectangular configuration.

Toe-boards are vertical plates positioned along platform perimeters to prevent slips and falls. Their extraction follows the platform methodology but utilizes front and side views. The final spatial coordinates of the toe-boards are determined by referencing the boundary coordinates of the underlying platforms.

Table 1. Component categories and checking items of the inspected scaffolds

Checking item	Extracted data from drawings				Extracted data from point cloud data			
	Tube	Toe-board	Platform	Stair	Tube	Toe-board	Platform	Stair
Number	√	√	√	√	√	√	√	√
Position	√	√	√	√	√	√	√	√
Orientation	√	√			√	√		
Length	√	√	√		√	√	√	
Width		√	√			√	√	
Thickness						√	√	
Radius					√			
Straightness					√			
Number of steps				√				√

3.2 Component Detection

3.2.1 Tube Extraction

Scaffolding tubes are typically composed of circular steel tubes, which are classified into various types based on their position and function, such as upright tubes, transverse horizontal tubes, and cross bracing. The Hierarchical Density-Based Spatial Clustering of Applications with Noise (HDBSCAN) algorithm considering principal direction and cylindricity is employed to perform the initial clustering of the point cloud. The principal direction is initially estimated using Principal Component Analysis (PCA) and subsequently refined through line fitting via the Maximum Likelihood Estimation Sample Consensus (MLESAC) algorithm within the vicinity of the principal axis [8]. Due to high noise levels, non-uniform density, and the presence of numerous irregularly shaped connectors within the scaffolding point cloud, HDBSCAN tends to segment the data into multiple fragments. To address this, these fragments are merged based on collinearity and spatial distance to generate nearly complete point cloud clusters for individual tubes.

Constrained by scanner positioning and occlusions, the resulting scaffolding point clouds often appear as partial cylinders. Thus, the principal direction calculated directly via PCA exhibits significant deviation and renders direct cylinder fitting methods ineffective. Therefore, an iterative slicing approach to determine the centerline is adopted [9]. First, the point cloud is sliced equidistantly along the initial principal direction calculated by PCA. Circles are fitted to each slice using Least Squares to extract centers and diameters. Slices with highly reliable fitted circles within a preset diameter threshold are selected. Then, Random Sample Consensus (RANSAC) is employed to fit a straight line through their centers. This process is repeated iteratively until the angular difference between two consecutive centerlines falls below a specified threshold, at which point the fitted line is defined as the final centerline. The final diameter is determined by averaging the diameters of the valid slices.

3.2.2 Platform and Toe-board Extraction

The positions and geometric dimensions of the platforms and toe boards are determined by extracting planes from the point cloud. For platform detection, local normal vectors are calculated based on the eight nearest neighbors of each data point to filter for approximately horizontal points within the entire point cloud dataset. A Z-value histogram with a bin width of 0.1 m is computed for all data points. Bins positioned above ground level, containing a point count exceeding three times the average of all bins, are identified as potential working platform locations. Consecutive bins are merged, and the M-estimator Sample Consensus (MSAC) algorithm is employed to fit the planes. The extracted platforms are projected onto the xy-plane, and DBSCAN clustering is utilized to separate distinct planes located at the same elevation but spatially disconnected. However, in practical scaffolding scenarios characterized by high noise levels, erroneous planes may be generated from connected surfaces at identical heights, such as stair treads or the upper surfaces of tubes affected by noise. To mitigate this, a grid coverage-based platform segmentation method is proposed. First, the minimum bounding rectangle (MBR) of the extracted plane is computed and discretized into 5 cm rectangular grids. Coverage rate for each row and column is determined based on the point count within the grid. If two consecutive rows or columns fail to meet the coverage threshold, indicating a potential gap, then a split point is established to segment the point cloud. This segmentation process is iterated until all platform fragments meet the coverage criteria. The principal directions of these fragments are fitted using RANSAC to determine their MBRs. After excluding outliers via histogram statistics, the length and width of each platform fragment are calculated. Fragments meeting the defined minimum size thresholds are retained as

extracted platforms.

Finally, toe boards are searched for within a range of 10 cm inward and outward from the platform boundaries. Planar fragments are extracted using a method similar to that used for the platforms. The proposed grid coverage-based segmentation method is also applied to eliminate the interference of guardrails located above the toe boards.

3.2.3 Stair Extraction

Based on the positions of the uprights and the platform, the potential region of the staircase is identified. The point cloud within this area is subsequently segmented and subjected to planar projection. The Probabilistic Hough Transform is utilized to detect short line segments parallel to the ground, while DBSCAN is employed to cluster similar height values to preliminarily determine the number of steps. Because staircase steps typically share uniform dimensional specifications with identical lengths and widths, these dimensions are applied as constraints for filtering during the extraction process. Finally, the position of the staircase is defined by the geometric centroid of the identified steps.

3.3 Design Compliance Checking

3.3.1 Coordinate System Alignment

To enable subsequent position-based component matching for compliance checking, the drawing coordinate system is aligned with the scanner coordinate system using the coordinates of the uprights. The upright detection pipeline begins by extracting horizontal slices and segmenting points via region growing to fit circles based on radius and root-mean-squared error constraints [2]. The spatial distribution of the resulting centers is converted into a binary density map, facilitating the construction of a convex hull that identifies the precise centroid coordinates of the uprights [2]. To determine the alignment, two upright centroids from the drawing analysis and two from the point cloud are selected. Assuming a correspondence between these pairs, the Singular Value Decomposition (SVD) method is employed to solve for the rigid body transformation matrix. Transformed point cloud upright centroids that fall within a specified distance threshold of the drawing upright centroids are classified as inliers. An Exhaustive Search is performed to iterate through all possible combinations. The transformation matrix maximizing the inlier count is selected as the optimal solution. If several solutions have equal inliers, the one with the matrix with the lowest Root Mean Square Error (RMSE) is selected. Finally, this optimal transformation matrix is applied to the raw 3D point cloud to achieve global alignment.

3.3.2 Existence-related Compliance Checking

Component presence is validated by contrasting the position and geometric attributes derived from the drawings against those from the point cloud. Platforms and toe-boards are matched via centroid distance, with subsequent assessments of their length, width, and orientation. Since the uprights were already filtered by diameter during the extraction process, they are matched based on the orientation and position of their centerlines. The presence of the component is confirmed by a successful match. Finally, stairs are validated by directly comparing their position and the number of steps. The component categories and checking items of the inspected scaffolds are presented in Table 1.

4 Case study

4.1 Data collection

A scaffold system located at a construction site in Hong Kong was selected for this case study. The scaffold system consisted of 42 tubes, 4 toe-boards, 1 platform and 1 staircase with 8 steps. The design drawings for the scaffold system are stored as color raster images, as illustrated in Figure 2. Point cloud data of a scaffold system was acquired using a high-resolution SHARE SLAM S20 handheld 3D LiDAR scanner. During data acquisition, the scanner was maneuvered slowly around the scaffold, continuously emitting laser pulses and recording the reflected signals. The built-in SLAM algorithm within the SHARE PointCloud Studio software was then utilized to generate a high-density point cloud, which was exported in plain text format for subsequent analysis. Finally, manual pre-processing was performed using CloudCompare to remove extraneous environmental data. The resulting pre-processed point cloud is illustrated in Figure 3.

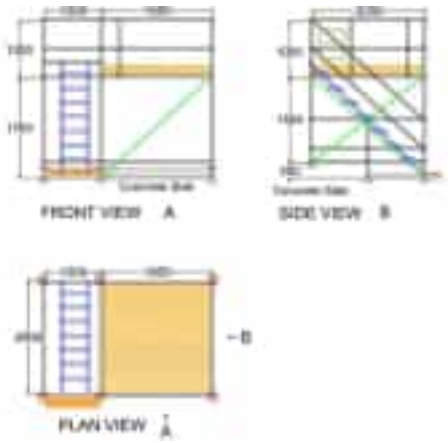

Figure 2. Scaffolding design drawing

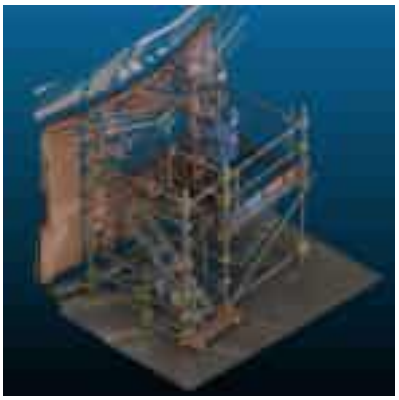

Figure 3. Collected and preprocessed scaffolding point cloud

4.2 Results

4.2.1 Geometry Extraction from Design Drawings

In the drawing analysis, the discrepancies between the measured values and the ground truth values for scaffold tubes were minimal. Figure 4 shows the spatial distribution of errors between the extracted scaffold tube measurements and the ground truth in three dimensions. Each tube is visualized in its 3D location, and its color indicates the magnitude of error according to the corresponding color bar (green = low discrepancy, red = high discrepancy). The position difference heatmap (left) highlights where centerline or endpoint localization deviates from the reference, the length difference heatmap (middle) shows segment-wise deviations in tube length, and the angle difference heatmap (right) summarizes orientation errors. For all three metrics, most tubes appear in green tones, indicating small discrepancies throughout the structure. Using a scale of 4 mm per pixel, the average discrepancies were 8.334 mm for position, 1.935 mm for length, and 0 for angle, confirming minimal deviation from ground truth and high geometric consistency in the drawing-based scaffold analysis. Overall, discrepancies remain low across the scaffold geometry, indicating close agreement between the measured results and the ground truth. However, the extraction errors for platforms and toe-boards were slightly higher (Table 2). Position errors ranged from 8.77 mm (platform) to 49.56 mm (toe-board 3), meaning toe-boards were harder to localize accurately than the platform. Length errors were similar for all components (−72 to −74 mm). Width errors were small and consistent for toe-boards (−8.00 mm), but much larger for the platform (−74.00 mm). The angle error was 0° for every component, showing that orientation was correctly preserved. These differences mainly come from the use of color segmentation, where filled regions start at the tube edges, while the drawing dimensions are referenced to the tube centerlines. Therefore, the deviations are systematic and acceptable for scaffold modeling.

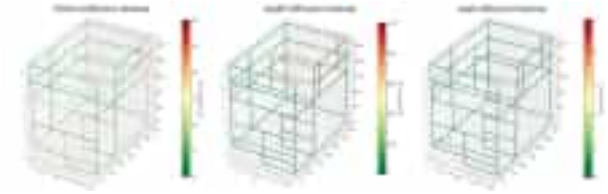

Figure 4. 3D discrepancy heatmaps comparing the measured scaffold tube parameters against ground truth

Table 2. Discrepancies between measured and ground truth values for scaffold toe-board and platform components

Component	Position difference (mm)	Length difference (mm)	Width difference (mm)	Angle difference (deg.)
Toe-board 1	41.42	-72.00	-8.00	0
Toe-board 2	47.97	-74.00	-8.00	0
Toe-board 3	49.56	-72.00	-8.00	0
Toe-board 4	47.97	-74.00	-8.00	0
Platform	8.77	-72.00	-74.00	0

4.2.2 Design Compliance Checking

Table 3 presents the results of the existence-related compliance checking for the case study. A total of 42 tubes, 1 staircase, 1 platform and 4 toe-boards were successfully detected. Compared with the design drawings, an additional stair step was constructed in the as-built scaffold.

Table 3. Results of existence-related design compliance checking of the case study

	Quantity in drawing	Quantity in point cloud data	Detected quantity
Tube	42	42	42
Platform	1	1	1
Toe-board	4	4	4
Stair	1	1	1
Steps of stair	7	8	8

5 Discussion

During tube detection, due to total or partial occlusion and the co-linear superposition of boundaries, segment endpoints or the vertices of overlapping rectangles become indistinguishable, rendering actual geometric attributes indeterminate. This inherent metric ambiguity affects both human and computational systems, necessitating expert knowledge or top-down semantic

constraints for its resolution. As a result, certain short line segments situated within the interior of the scaffold structure may be erroneously extracted as longer segments, leading to the generation of redundant tubes during the 3D reconstruction process. In this study, we manually remove redundant tubes. Future research can incorporate stronger structural and semantic priors into the tube reconstruction pipeline, including scaffold connectivity rules, topological constraints, and the functional roles of the components.

A limitation of this study is that the method was validated on only one small dataset containing 42 tubes. Although the overall framework is not inherently constrained by scaffold size, scaling to larger and more complex scaffolds is expected to introduce additional challenges, including heavier occlusion, denser tube arrangements, repeated structural patterns, and error propagation from local line extraction to global 3D reconstruction. These factors may increase ambiguity in tube interpretation and lead to more redundant tube instances. In future work, we will evaluate the method on larger and more diverse datasets.

In addition, the quality of the Point Cloud Data (PCD) requires further improvement. Primarily, constraints related to scanner elevation and layout, along with the inherent complexity of the scaffolding structure, lead to non-negligible incompleteness in the captured point clouds. Specifically, the numerous support tubes beneath the platforms often generate excessive noise in the undersurface data. Despite deploying handheld mobile scanners carried up the stairs manually, the point clouds of the platform's upper surface remain fragmented due to occlusions caused by other equipment located on the platform. While the proposed grid coverage-based platform segmentation method mitigates the effects of point cloud sparsity and uneven distribution to a certain extent, the accuracy of platform dimension extraction remains compromised. Moreover, regarding scaffolding positioned adjacent to walls, spatial inaccessibility results in blind spots on the back of the structure. Similarly, lower-level components often obstruct the line of sight to higher scaffolding tiers. To address these limitations, future work should employ more flexible devices, such as Unmanned Aerial Vehicles (UAVs), to scan the target range from various angles and heights. Furthermore, developing appropriate point cloud completion methods to increase data density and completeness without altering the geometric characteristics of the components serves as a potential solution.

6 Conclusion

This paper proposed a framework for automated design compliance checking of steel scaffolds, addressing a critical gap in construction safety automation. By integrating multi-view drawing analysis with 3D point cloud verification, the proposed method enables quantitative comparison between as-built conditions and approved design specifications. Specifically, this study has two main contributions: 1) proposes a multi-view drawing analysis method that can effectively extract information and enables 3D reconstruction, and 2) enables effective scaffold design compliance checking. While current results are promising, limitations include occlusion-related false negatives, assumption of approximate positional correctness, and single case study validation. Future work should integrate multi-modal data sources (photogrammetry, BIM) and validate across diverse scaffold configurations.

Abstract -

Urban façade deterioration, especially tile delamination and related surface damage, poses significant safety risks in dense urban environments. Conventional inspections based on manual visual assessment and acoustic sounding are labor-intensive, hazardous, and subjective. This paper presents an autonomous UAV-based façade inspection framework that combines oblique-photogrammetry-driven path planning with decision-level fusion of infrared and visible imagery for defect identification. A 3D model of the target building is reconstructed to extract geometric features for generating safe flight trajectories at a fixed standoff distance of 10 m, supporting near-complete and spatially consistent dual-modal data acquisition under the planned inspection route. Modality-specific defects are then segmented from RGB and thermal data using deep-learning models, and the fused defect map is produced through decision-level fusion of surface appearance cues and subsurface thermal signatures. A field deployment on a building demonstrates the feasibility and efficiency of the framework, completing the inspection of approximately 4,200 m² of façade area using 208 waypoints within 50 minutes of total on-site operation. The results show that the proposed method provides a practical and safer solution for façade condition assessment and maintenance prioritization.

Façade inspection, Drone path planning, Infrared thermography, Decision-level fusion, Subsurface delamination

1 Introduction

Building façades function as the first line of defense for infrastructure, enduring continuous environmental stress throughout their lifecycle. Synergistic effects of material deterioration, construction imperfections, and severe weather can compromise façade integrity, serviceability, and public safety. In China, statistical analysis of façade failures reveals that tile detachment is a predominant hazard, frequently resulting in casualties and economic losses [1]. The risk is amplified in dense urban environments where buildings directly face crowded streets. Consequently, implementing regular and rigorous inspection protocols for aging tiled façades is imperative for public safety maintenance.

Conventionally, façade health monitoring relies on manual visual inspection and acoustic methods. Ground-based visual surveys, often aided by optical telescopes or handheld thermography, attempt to identify external anomalies. However, these methods suffer from low efficiency and are prone to human error due to the inspectors' subjective judgment [2]. Alternatively, hammer sounding—which detects subsurface delaminations via acoustic response—is widely practiced but inherently inefficient. It requires direct physical access via scaffolds or gondolas, exposing personnel to significant safety hazards associated with working at heights.

Recent strides in unmanned aerial vehicle (UAV) technology have significantly improved infrastructure monitoring [3,4]. Equipped with high-resolution sensors, UAVs offer a promising alternative for accessing hard-to-reach vertical surfaces. Despite this potential, a robust methodology for reliably detecting subsurface delaminations through automated means remains underdeveloped. Addressing this gap, this study proposes a novel drone-based inspection framework that integrates infrared thermography and RGB imagery to enhance the precision and efficiency of façade defect detection.

To address these challenges, this paper presents an autonomous inspection framework that integrates

adaptive flight path planning with decision-level fusion of thermal infrared and visible images for façade assessment. The proposed method first leverages oblique photogrammetry to reconstruct a 3D model of the target building, which supports the generation of safe and feasible flight trajectories for data acquisition. Subsequently, synchronized visible light images and thermal infrared data are analyzed using a deep learning-based segmentation pipeline. A decision-level fusion strategy is then applied to combine surface appearance cues with subsurface thermal anomalies, thereby reducing false detections. The feasibility of the framework is validated through a field deployment at a large commercial building, demonstrating efficient on-site operation and reliable defect detection compared with conventional inspection practices.

2 Methodology

2.1 Overview of the Proposed Framework

Figure 1 presents the schematic workflow of the proposed drone-based inspection system, which integrates autonomous path planning with dual-modal defect recognition. The methodology follows a coarse-to-fine strategy. Initially, oblique aerial imagery is acquired to construct a photogrammetric 3D model of the building. This geometric model serves as the environmental baseline for planning a flight path tailored for close-range inspection. During the inspection phase, the drone autonomously captures paired thermal infrared (IR) and visible light (RGB) imagery along the planned route. These images are processed by independent deep learning models to detect surface anomalies (e.g., peeling, cracks) and subsurface delamination. To maximize detection reliability, a decision-level fusion strategy is applied, synthesizing the outputs from both sensors into a unified and more reliable façade health assessment.

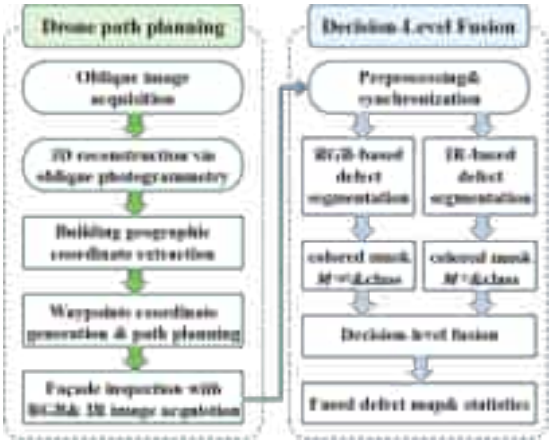

Figure 1. The overall framework of the proposed drone-based façade inspection system

2.2 Drone Path Planning Method

Drones equipped with flight control systems can execute complex, predefined trajectories [5]. However, manual path planning for complex building façades is inefficient and prone to collision risks. This study proposes an automated method for generating optimized inspection routes based on the extraction of architectural envelope key points from a preliminary 3D model.

2.2.1 Oblique 3D Modeling and Geographic Feature Extraction

The prerequisite for precise path planning is an accurate representation of the building geometry. Initially, a UAV imaging system captures the target building from multiple perspectives. This multi-view acquisition strategy reduces visual occlusions and provides sufficient image coverage for high-quality photogrammetric reconstruction.

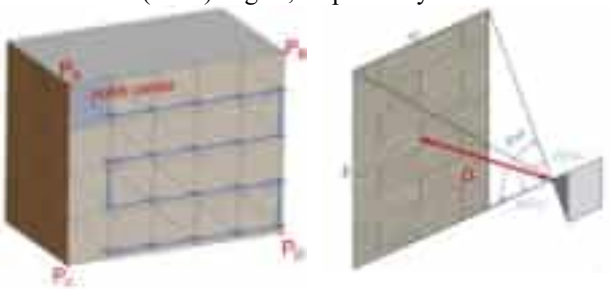
Subsequently, the collected imagery is processed through a photogrammetric workflow, including image distortion correction, feature matching, bundle adjustment, dense point cloud generation, and mesh reconstruction. This process, often implemented using Multi-View Stereo algorithms in software such as Agisoft Metashape or ContextCapture [6,7], produces a high-precision oblique photogrammetric 3D model of the target building, as illustrated in Figure 2.

Based on the georeferenced 3D model, the geographic coordinates, including longitude, latitude, and altitude, of the building’s key corner points are extracted. These coordinates provide the geometric constraints for generating the subsequent inspection waypoints.

Figure 2. Process of oblique photogrammetry 3D reconstruction and key point extraction

2.2.2 Waypoint Generation Mechanism

To ensure complete coverage of the façade, the



continuous wall surface must be discretized into a set of discrete inspection waypoints.

First, the physical dimensions of the single-image footprint are determined. Let the four corner vertices of the target façade be denoted as $\mathrm{P_A}(\lambda_A,\phi_A,h_A),\mathrm{P_B}(\lambda_B,\phi_B,h_B),\mathrm{P_C}(\lambda_C,\phi_C,h_C),\mathrm{P_D}(\lambda_D,\phi_D,h_D)$ (Figure 3(a)). Modeling the camera as a pinhole system, the physical coverage dimensions, namely the width w and height h, at a given inspection distance D can be determined from the camera's horizontal and vertical fields of view, respectively, as illustrated in Figure 3(b):

$$w = 2D \cdot \tan\left(\frac{\theta_h}{2}\right) \tag{1}$$

$$h = 2D \cdot \tan\left(\frac{\theta_v}{2}\right) \tag{2}$$

where θ_h and θ_v represent the horizontal and vertical field of view (FOV) angles, respectively.

(a) Flight trajectory positioning (b) Field of View (FOV) calculation model

Figure 3. Geometric parameters for path planning

Since the extracted building key points utilize the Geographic Coordinate System (GCS, i.e., WGS84), whereas the geometric subdivision necessitates metric computation, a coordinate transformation is required. The geographic coordinates (λ,ϕ,h) are converted to the Earth-Centered, Earth-Fixed (ECEF) Cartesian coordinates (X,Y,Z) using the following standard transformation equations:

$$X = (N+h)\cos(\phi)\cos(\lambda) \tag{3}$$

$$Y = (N+h)\cos(\phi)\sin(\lambda) \tag{4}$$

$$Z = \left[\left(1-e^2\right)N+h\right]\sin(\phi) \tag{5}$$

with the radius of curvature in the prime vertical N defined as:

$$N = \frac{a}{\sqrt{1-e^2\sin^2(\phi)}} \tag{6}$$

where a denotes the Earth's semi-major axis ($\approx 6,378,137\mathrm{m}$) and e represents the Earth's eccentricity (≈ 0.081819).

In the ECEF frame, the Euclidean distances between the corner points (e.g., $\mathrm{P_A}$ to $\mathrm{P_B}$ and $\mathrm{P_C}$) are calculated to determine the total width and height of the façade:

$$d_{AB} = \sqrt{\left(X_B-X_A\right)^2+\left(Y_B-Y_A\right)^2+\left(Z_B-Z_A\right)^2} \tag{7}$$

$$d_{AC} = \sqrt{\left(X_C-X_A\right)^2+\left(Y_C-Y_A\right)^2+\left(Z_C-Z_A\right)^2} \tag{8}$$

Based on the single-image coverage (w, h) and the total façade dimensions, the façade is discretized into an $m \times n$ grid of inspection areas. To ensure sufficient image overlap between adjacent viewpoints, the horizontal and vertical step sizes are defined as $w(1-O_w)$ and $h(1-O_h)$, respectively, where O_w and O_h denote the prescribed horizontal and vertical overlap ratios. Accordingly, the required numbers of inspection columns and rows are calculated as:

$$m = 1+\left\lceil \frac{d_{AB}-w}{w(1-O_w)} \right\rceil \tag{9}$$

$$n = 1+\left\lceil \frac{d_{AC}-h}{h(1-O_h)} \right\rceil \tag{10}$$

The center point $(X_{\text{center}},Y_{\text{center}},Z_{\text{center}})$ of each grid cell is then calculated and translated outward along the normal vector $\vec{N}=(N_x,N_y,N_z)$ of the plane $\mathrm{P_AP_BP_C}$ by the standoff distance D. This operation yields the precise 3D coordinates of each camera waypoint in the Cartesian frame:

$$X_{\text{shifted}} = X_{\text{center}} + D \cdot N_x \tag{11}$$

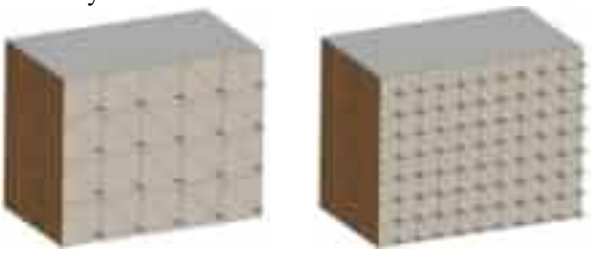
$$Y_{\text{shifted}} = Y_{\text{center}} + D \cdot N_y \tag{12}$$

$$Z_{\text{shifted}} = Z_{\text{center}} + D \cdot N_z \tag{13}$$

Finally, an inverse coordinate transformation is applied to convert these Cartesian waypoints back to the Geographic Coordinate System, allowing them to be uploaded to the drone's flight controller. The longitude λ is calculated directly, while the latitude ϕ and height h are derived using Bowring's closed-form approximation [8]:

$$\lambda = \arctan\left(\frac{Y}{X}\right) \tag{14}$$

$$\phi = \arctan\left(\frac{Z+e'^2\cdot b\cdot\sin^3(\theta)}{p-e^2\cdot a\cdot\cos^3(\theta)}\right) \tag{15}$$



$$h = \frac{p}{\cos(\phi)} - N \tag{16}$$

To facilitate this calculation, the auxiliary parameters are defined as follows:

$$e'^2 = e^2 / (1-e^2),\ p = \sqrt{X^2 + Y^2},\ b = a\sqrt{1-e^2} \quad (17)$$

$$\theta = \arctan(\frac{Z \cdot a}{p \cdot b}) \quad (18)$$

The standoff distance D is a critical trade-off parameter. As illustrated in Figure 4, a smaller D yields smaller (higher spatial resolution) Ground Sampling Distance (GSD) and richer detail but limits the single-image field of view. This necessitates a denser grid of waypoints, resulting in longer flight times. Conversely, a larger D improves efficiency but may compromise the detection of fine cracks. Accordingly, D=10 m was selected for the field deployment as a practical compromise between image resolution and inspection efficiency.

(a) Sparse sampling at a larger distance (b)Dense sampling at a closer distance

Figure 4. Impact of standoff distance on waypoint density

2.2.3 Executable Flight Path Generation

Once the discrete waypoints are generated, the final step is to generate an executable inspection trajectory by determining an appropriate traversal sequence. The objective is to visit all waypoints while minimizing total flight time and energy consumption, subject to practical constraints such as battery endurance and a predefined safety standoff from the façade.

This problem can be addressed using coverage patterns and, when needed, graph-based routing. Geometric coverage strategies such as the Boustrophedon (back-and-forth) or spiral patterns provide simple and consistent coverage with controllable overlap [9]. When obstacle-aware local routing is required, shortest-path solvers (e.g., Dijkstra or A*) can be used to connect adjacent waypoint segments under additional constraints. Figure 5 compares the trajectories produced by different strategies. For façade inspection, the Boustrophedon pattern is adopted in this study due to its implementation simplicity and stable overlap management.

Finally, the optimized trajectory is converted into a DJI Waypoint Mission by exporting the ordered waypoint list together with mission parameters (e.g., altitude, speed, heading/yaw, gimbal angle, and camera triggering). This enables the planned route to be directly uploaded to the DJI flight controller for autonomous execution.

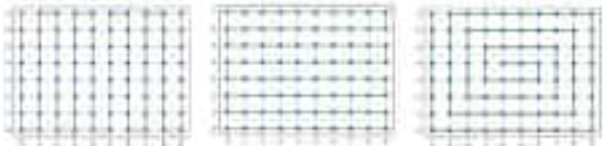


Figure 5. Flight paths generated by different methods

2.3 Façade Defect Detection and Fusion

This section details the proposed dual-modal defect detection framework, which employs deep learning models to process RGB and thermal imagery independently, followed by a decision-level fusion strategy to synthesize the results (as shown in Figure 6).

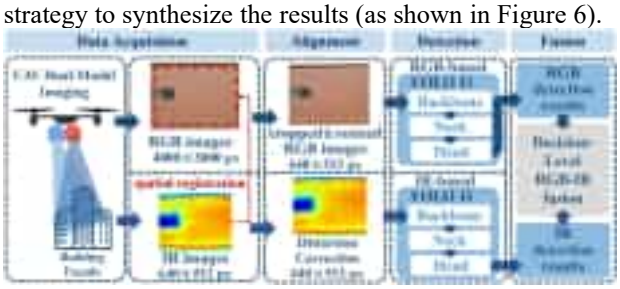

Figure 6. The proposed dual-modal defect detection framework

2.3.1 Surface Anomaly Segmentation via RGB Imagery

RGB imagery is effective in capturing high-frequency texture information and surface chromatic features. However, latent subsurface delaminations typically lack distinct visual characteristics in the early stages. They become observable in the visible spectrum only when the defect evolves into external manifestations, such as peeling or cracking. Consequently, RGB data is primarily utilized in this study to detect surface-level damage (e.g., tile cracking and peeling) associated with advanced deterioration.

To automate defect extraction, YOLO11-seg was adopted from the Ultralytics YOLO family [10,11] because it provides a strong balance between segmentation accuracy and inference efficiency. In this study, it was used as the modality-specific segmentation backbone for both the RGB and thermal branches. As a one-stage segmentation model, YOLO11-seg performs feature extraction, multi-scale feature aggregation, and pixel-level mask prediction in an end-to-end manner, enabling robust defect segmentation across different scales.

2.3.2 Subsurface Delamination Detection via Infrared Thermography

Infrared thermography is employed to reveal non-

visible subsurface defects based on differences in thermal inertia and heat-transfer behavior. In delaminated areas, an air gap between the tile and the substrate increases thermal resistance and disrupts heat conduction. Under solar excitation or during the cooling phase, the detached façade surface exhibits a different heating/cooling rate compared with sound areas, producing a measurable temperature contrast ΔT on the surface that can be captured by the thermal sensor [12].

In this study, the thermal images were converted into pseudo-color representations and used as inputs to a dedicated model. The model was fine-tuned on the infrared dataset to segment thermally anomalous regions associated with subsurface delamination. These thermal anomalies, typically manifested as localized hot or cold regions, are often not visible in RGB imagery.

2.3.3 Decision-Level Fusion of Detection Results

To obtain a holistic and physically interpretable assessment of façade condition, we adopt a decision-level fusion strategy [13] that operates on the independent segmentation outputs of the RGB and IR branches. Unlike pixel-level or feature-level fusion, the proposed strategy integrates detection results after modality-specific inference. This ensures that the distinct physical semantics of each sensor are preserved: visible imagery captures superficial appearance anomalies (M_{surf}), such as cracks and peeling, whereas infrared thermography highlights subsurface structural defects (M_{sub}) through thermal variations.

A key objective of the fusion is to identify compound defects, i.e., surface damage spatially correlated with subsurface delamination, since such regions often indicate elevated structural risk. To account for minor registration errors and boundary uncertainties between the dual-modal images, a morphological dilation is first applied to the subsurface defect mask:

$$\widetilde{M}_{sub} = \text{Dilation}(M_{sub}, r) \tag{19}$$

where r denotes the radius of the structuring element and serves as a small spatial tolerance for overlap matching, rather than a substantial geometric expansion of the defect region. In the present dataset, the residual RGB-IR misalignment after registration was empirically found to remain within approximately 5 infrared pixels. Accordingly, r was selected as a small value within this tolerance range, so that true cross-modal overlap would not be missed due to slight spatial deviation.

Based on the spatial relationship between the surface mask M_{surf} and the dilated subsurface mask $\widetilde{M}_{sub}$, the final fused result map M_{final} is constructed. For any given pixel p on the façade, the defect category is determined according to the following hierarchical logic:

$$M_{final}(p) = \begin{cases} \text{Compound Defect}, & \text{if } p \in (M_{surf} \cap \widetilde{M}_{sub}) \\ \text{Surface Defect}, & \text{if } p \in (M_{surf} \setminus \widetilde{M}_{sub}) \\ \text{Subsurface Defect}, & \text{if } p \in (M_{sub} \setminus M_{surf}) \\ \text{Background}, & \text{otherwise} \end{cases} \tag{20}$$

This hierarchical rule prioritizes compound defects by assigning the label Compound Defect to regions where visible surface anomalies overlap with subsurface delamination, while regions detected by only one modality are retained as Surface Defect or Subsurface Defect. In this way, the fusion result links superficial manifestations to potential internal risks and provides a more interpretable representation of façade condition. From an engineering perspective, cracks or peeling that spatially coincide with thermal anomalies may indicate an elevated likelihood of underlying delamination. In addition, because the RGB and IR models are trained independently, the proposed decision-level fusion decouples optimization across modalities, which simplifies implementation and facilitates the integration of heterogeneous sensing results.

3 Field Experiments and Analysis

3.1 Experimental Setup and Data Acquisition

To validate the feasibility and robustness of the proposed framework, a field experiment was conducted on a commercial building. The DJI Mavic 3T drone was employed as the flight platform. This UAV is equipped with a synchronized wide-angle RGB camera and a thermal infrared camera, enabling the simultaneous acquisition of dual-modal imagery.

The flight mission was executed following the path planning method described in Section 2.2. Figure 7 illustrates the planned trajectory. The captured RGB-IR image pairs are presented in Figure 8. It can be observed that the images collected autonomously along the planned route exhibit high spatial consistency and sufficient overlap, which establishes a high-quality dataset for subsequent algorithmic analysis.

The field deployment was conducted in November under clear-sky conditions, with stable daylight and relatively low outdoor wind speed, which were favorable for both RGB and thermal data acquisition. The thermal campaign was carried out in two rounds corresponding to the façade heating and cooling stages on November 29, 2023, in Chengdu, China, for a façade oriented about 40° south of east. At around 10:30 a.m., the solar azimuth was close to the façade normal direction, providing favorable direct solar excitation. At that time, the incident solar irradiance was

approximately 750 W/m², the ambient temperature was about 14°C, and the convective heat-transfer coefficient was estimated to be 8-10 W/(m²·K). By contrast, at around 5:00 p.m., the façade had entered its self-shadowed condition and direct solar heating was no longer present. The ambient temperature was about 15°C, and the convective heat-transfer coefficient was approximately 10-12 W/(m²·K). As a result, the acquired thermal infrared images covered both the heating and cooling phases of the façade, during which delamination-related thermal signatures were relatively distinct. These conditions provided thermal images with favorable signal-to-noise characteristics for subsequent model training and defect recognition. It should be noted, however, that the quality of defect-related visual and thermal cues may vary under different environmental conditions: RGB imagery is more sensitive to illumination changes, whereas thermal infrared imagery is more strongly influenced by solar loading, wind, and the thermal properties of façade materials.

Figure 7. Visualization of the executed flight path in the 3D model

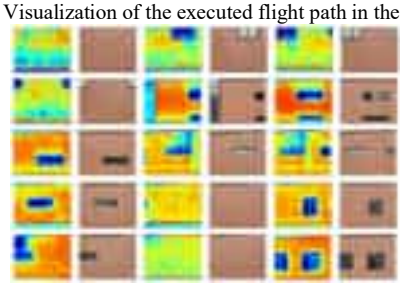

Figure 8. Samples of synchronized RGB and IR image pairs collected during the flight

Since the decision-level fusion in this study depends on the spatial correspondence between visible and thermal defect regions, an explicit cross-modal alignment procedure was applied before defect analysis. The visible and thermal cameras mounted on the UAV gimbal have a fixed relative pose, which provides the geometric basis for stable registration. Both sensors were first calibrated using a calibration board, and all images were corrected for lens distortion prior to alignment. Because the UAV acquired façade images at a fixed standoff distance along the planned route and the imaging parameters were kept unchanged throughout the mission, the relative projection relationship between the two sensors remained approximately constant across the dataset. Therefore, after distortion correction, a single affine transformation matrix was adopted for all RGB-IR image pairs.

The affine transformation parameters were estimated from five representative RGB-IR image pairs with clearly identifiable shared features, and the final matrix was obtained by averaging the estimated parameters. To evaluate the registration quality, 20 additional image pairs were randomly selected for verification. The results showed that the alignment achieved an average registration error of approximately 2 pixels, with all observed errors remaining within 5 pixels. In addition, because the RGB and thermal sensors have different native resolutions, the visible images were resampled to the thermal image size (639×509 pixels) before registration and model inference. This resolution unification improved the consistency of cross-modal spatial matching and also simplified the subsequent defect-detection pipeline.

3.2 Model Implementation and Training Details

The dataset combined the current field campaign with previously accumulated inspection data from the same façade. The waypoint route and two-round acquisition process contributed 416 paired images, yielding a final raw dataset of 766 RGB and 766 original IR images. For the thermal branch, each original infrared image was converted into pseudo-color images using three different palettes. To avoid data leakage, the train/validation/test split was performed at the level of the original RGB-IR pairs before pseudo-color expansion, using a ratio of 7:2:1. The RGB branch focused on visible surface defects, whereas the thermal branch focused on thermally anomalous regions associated with subsurface delamination.

The experimental workflow consisted of data annotation, model training, and performance evaluation. In the data annotation step, the collected images were labeled using LabelMe. Annotation masks were created by experienced civil engineers, who manually annotated tile cracks and peeling in RGB images, and thermally anomalous regions associated with subsurface delamination in infrared images.

For modality-specific defect extraction, two dedicated segmentation models were fine-tuned using the Ultralytics YOLO11 framework, one for the RGB branch and the other for the thermal branch. Training was conducted with an input resolution of 640×640 pixels, a batch size of 16, the AdamW optimizer, and early stopping with a patience of 100 epochs. To improve robustness, data augmentation including color perturbation, rotation, translation, scaling, and flipping was applied to the training set. The best-performing checkpoint was automatically selected based on validation performance. The evolution of the validation

metrics during training is shown in Figure 9.

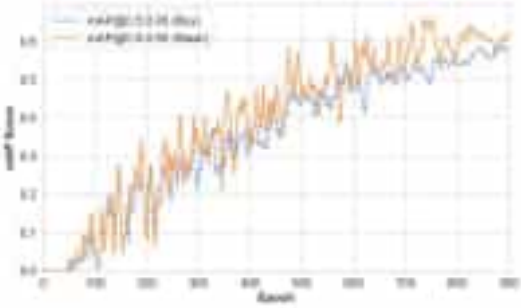

Figure 9. Evolution of validation box and mask mAP@0.5:0.95 over training epochs

3.3 Quantitative and Qualitative Analysis

Quantitative evaluation on the test set demonstrates the robust segmentation capability of the trained YOLO11n-seg model. For the segmentation masks, the overall precision and recall reached 0.795 and 0.869, respectively, with an mAP@0.5 of 0.829 and an mAP@0.5:0.95 of 0.619. Class-wise results indicate that the framework maintained effective performance across subsurface delamination, peeling, and crack categories, although subsurface delamination and crack remained more challenging than peeling. These results confirm that the framework can effectively segment both surface-visible defects and thermally expressed subsurface anomalies. The adopted YOLO11n-seg backbone also showed favorable inference efficiency, with an average per-image processing time of 0.8ms for preprocessing, 0.5ms for inference, and 1.2ms for postprocessing, supporting rapid batch processing and timely on-site review after UAV data acquisition.

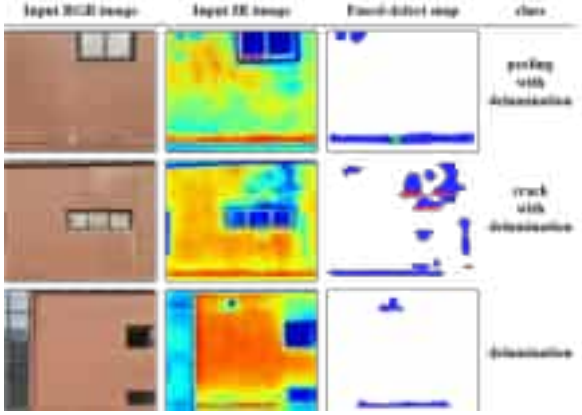

Figure 10. Visualization of defect segmentation results

Qualitative identification results are presented in Figure 10. The proposed framework effectively characterizes damage types in both modalities, identifying tile cracks and peeling in RGB imagery while simultaneously detecting thermally anomalous regions associated with subsurface delamination in infrared imagery. Following the decision-level fusion strategy, the modality-specific masks are combined to generate a comprehensive façade condition map.

In addition to qualitative visualization, the practical value of the decision-level fusion was assessed at the façade level. RGB-only results identified visible surface defects such as cracks and peeling, whereas IR-only results identified thermally anomalous regions associated with subsurface delamination. Based on the spatial-overlap rules, the fusion process further identified 18 compound-defect regions, including crack-with-delamination and peeling-with-delamination cases, which could not be explicitly characterized by either modality alone and therefore provide more actionable information for maintenance prioritization.

A brief sensitivity check, performed by varying the dilation radius from 2 to 8 pixels, showed that the compound-defect results remained largely stable, indicating limited sensitivity to this tolerance parameter under the present registration accuracy.

Field verification was conducted according to defect visibility and accessibility. Visible defects such as cracks and peeling were manually reviewed, accessible low-rise suspected delamination areas were examined by hammer sounding, and higher or less accessible regions were checked indirectly using a telephoto camera, particularly where bulging or outward deformation was visible. The majority of detected defects were practically confirmed, although some inaccessible and visually flat regions could not be fully verified. Therefore, the current validation should be regarded as a practical engineering verification rather than a fully exhaustive ground-truth survey.

4 Discussion

The proposed framework represents a practical improvement over conventional façade inspection and maintenance practices. The field experiments demonstrated that digital 3D façade models can be effectively translated into executable UAV inspection missions, reducing dependence on pilot experience and improving the consistency of image acquisition. In addition, the combination of visible and thermal infrared imagery helps overcome the limitations of single-sensor inspection: visible imagery captures surface defects such as cracks and peeling, whereas thermal infrared imagery provides complementary information related to subsurface delamination. The experimental results show that the proposed dual-modal framework can exploit this complementarity effectively, while the decision-level fusion strategy further improves the interpretability of façade condition by linking visible deterioration with potential internal risks.

The transferability of the framework should be understood at both the detector and fusion levels.

Detector performance may vary with façade material, surface texture, and environmental conditions, whereas the rule-based fusion logic is expected to remain broadly applicable as long as relevant visual and thermal cues are observable. Nevertheless, the current study was validated on a tiled planar façade, and broader validation on other façade types and more complex geometries is still needed. The current path-planning algorithm is mainly suited to planar façades, although irregular envelopes may be approximated as multiple locally planar patches for practical inspection. In addition, thermal-anomaly visibility depends on solar-loading and wind conditions. Future work will focus on broader validation, adaptive planning for complex 3D geometries, and deeper cross-modal fusion.

5 Conclusions

This study presents a façade inspection framework that integrates efficient UAV-based data acquisition with deep-learning-based defect detection for façade safety assessment. The proposed workflow was developed and validated through a field deployment on a commercial building, including oblique photogrammetry-based 3D modeling, route generation, and defect recognition based on modality-specific segmentation and decision-level fusion. The results demonstrate that the proposed approach enables efficient and safe inspections while providing a more informative assessment of both surface-visible defects and subsurface delamination risks.

The main contributions of this research are summarized as follows:

(1) Automated flight route generation: A UAV inspection route generation method was developed based on architectural key points extracted from oblique photogrammetry models, enabling consistent and automated façade data acquisition through waypoint-based missions.

(2) Dual-modal defect detection and interpretable fusion. A defect-identification framework was established using dedicated YOLO11-seg models for visible and thermal infrared imagery, followed by decision-level fusion of the modality-specific outputs. By associating surface appearance anomalies with subsurface thermal signatures, the framework provides a more comprehensive and practically interpretable assessment of façade condition, offering useful support for intelligent infrastructure inspection and maintenance.

Abstract

This paper presents an AI-driven framework designed for automating and optimizing structural systems within a Building Information Modeling (BIM) workflow. The process begins by examining architectural layouts from IFC files to automatically define a valid search space for structural elements, ensuring that the solutions adhere to a set of structural design constraints. Central to this approach is a multi-objective optimization engine driven by a genetic algorithm (GA). It commences with an initial population of structural configurations, which are then validated against criteria for architectural, structural, and seismic design. Versatility and robustness of the framework are demonstrated through three challenging case studies. For reinforced concrete (RC) wall-slab systems and cold-formed steel (CFS) structures, a GA optimally determines the primary load-bearing elements to satisfy structural and seismic requirements. For RC dual systems (RCDS), a novel hybrid optimization strategy was implemented, beginning with a hill-climbing algorithm that performs a targeted search to determine optimal column placements. Following this, a genetic algorithm is employed to refine the positioning and configuration of shear walls within the established column grid, ultimately enhancing the performance of the dual system. The results indicate that the framework consistently produces high-performance, compliant structural designs rapidly. By automating intricate initial design tasks, this approach not only accelerates the design process but also enhances collaboration between architects and engineers, demonstrating significant potential for widespread adoption in the Architecture, Engineering, and Construction (AEC) industry.

Keywords –
Automation Design; Hybrid Optimization; Genetic Algorithm; BIM; Seismic Design; AEC Industry.

1 Introduction

The integration of artificial intelligence (AI) is catalyzing a profound metamorphosis within the Architecture, Engineering, and Construction (AEC) industry. Due to the iterative and multidisciplinary nature of design and construction processes, this sector is particularly well-suited for the application of AI-driven generative and optimization techniques. A comprehensive review of generative AI in structural engineering identifies several pivotal research domains, including data representation, intelligent generation algorithms, design evaluation metrics, and the synthesis of generation and optimization workflows [1, 2].

Architects are increasingly using AI to augment the design process [3, 4, 5]. Machine learning algorithms enable rapid iterations for complex geometries, facilitating the creation of more sophisticated architectural forms [6, 7]. Moreover, AI is optimizing mechanical, electrical, and plumbing (MEP) systems, thereby enhancing energy performance during the early stages of design [8, 9]. Within Building Information Modeling (BIM) environments, these advanced tools contribute to improved project oversight through automated monitoring and analysis [10].

Recent advancements in structural engineering have introduced innovative methods for automation in design and optimization that transcend traditional methodologies. A significant approach is represented by AIBIM, which incorporates Generative AI in conjunction with Building Information Modeling. This methodology employs a Physics-based Conditional Diffusion Model (PCDM) to generate high-quality structural designs, taking into account real-world constraints such as building height and seismic intensity [11]. Furthermore, the utilization of Generative Adversarial Networks (GANs) has been demonstrated in the automation of layout design for steel frame-braced structures, leveraging existing drawings from experienced engineers to enhance design efficiency [12].

Of particular interest, newly developed frameworks, rule-based approaches employing AI algorithms show high potential for BIM integration [13-15]; however, some more case studies for comparison and performance evaluation are required. In continuation of this previous work, the authors present a synthesis of these newly formulated frameworks in a single system-tool outlining the design processes for the three distinct types of structures made from various materials. The first type discussed is wall-slab reinforced concrete (RC) structures [13]. The second type focuses on cold-formed steel (CFS) structures [14]. Lastly, the RC dual systems, as detailed in [15].

The efficiency and robustness of these frameworks have been validated through testing BIM models of 17 architectural buildings, incorporating various configurations and levels of complexity. The unified GA/HCA pipeline automates the process of converting IFC to structural layouts across common systems.

As novelty, our proposed framework advances beyond our prior individual system studies [13-15] through three key innovations: (1) a unified IFC-to-layout pipeline integrating all three structural systems within a single framework; (2) standardized multi-objective fitness functions enabling direct performance comparison across RC, CFS, and dual systems; and (3) comprehensive validation across diverse BIM models demonstrating framework generality and robustness. These advancements transform fragmented single-system tools into a production-ready, multi-material seismic design platform.

2 AI-based structural design framework

The proposed framework addresses three common seismic-resistant structural systems for low to medium-rise buildings: Reinforced Concrete (RC) wall-slab systems, Cold-formed steel (CFS) shear wall panels, and RC dual systems, which combine moment frames and shear walls. These systems represent the load-resisting configurations that are commonly found worldwide.

The approaches reviewed for optimizing structural design start with the implementation of an architectural 3D-BIM model. This model aids in identifying suitable locations for structural elements while taking into account architectural considerations such as openings, slab limits, and partition walls. This ensures a continuous load path from the roof to the foundations. The optimization problem is inherently multi-objective, aiming to select the most effective structural configuration from a range of alternatives. Once common architectural constraints are established, the methodologies diverge based on the type of structure, utilizing specialized algorithms and design focuses. For reinforced concrete (RC) wall-slab systems, a single genetic algorithm is employed to generate an optimized structure from a given set of elements. In contrast, cold-formed steel (CFS) structures use a tailored genetic algorithm to optimize the layout of shear walls, while also evaluating various weights for the objective functions. For dual systems, a hybrid protocol begins with a hill-climbing algorithm to determine an optimal frame, followed by a genetic algorithm to effectively distribute the shear walls. All of these approaches ensure that the optimal solution complies with established structural rules and meets stability criteria in accordance with relevant codes of practice.

3 Structural constraints and design rules

In contemporary architectural practice, it is imperative that structural systems afford architects enhanced flexibility in spatial planning while simultaneously optimizing surface utilization. Engineers are tasked with the challenge of devising efficient structural solutions that align with the architectural design, ensuring that strength and stability are not compromised. Typically, buildings employ self-supporting vertical elements, such as columns and walls, complemented by horizontal components like beams and slabs, to manage lateral forces resulting from seismic and wind loads, effectively transferring these forces to the foundation. This section outlines the structural criteria for the developed Generative Algorithm (GA) and Hill-Climbing Algorithm (HCA) within an automated design framework. Focusing on prevalent structural systems for common multi-storey buildings, the GA optimizes the placement of discrete elements, such as shear walls or CFS panels, while the HCA is utilized to optimize the column positions along the axes in dual systems.

3.1 Reinforced concrete wall-slab system

The design of Reinforced Concrete (RC) Wall-Slab systems adeptly confronts various construction challenges by ensuring a rigid connection between the slabs and RC walls. This integration results in a monolithic structure that significantly enhances stability through inherent redundancy. The walls function as load-bearing elements, effectively resisting both vertical loads and lateral forces. The essential criteria for the genetic algorithm employed in the multi-objective optimization process are summarized as follows [13]:

3.2 Individual shear wall lengths

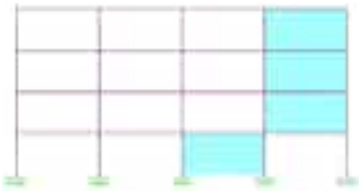
Seismic design codes, such as the Algerian RPA2024 and Eurocode EC8, delineate the parameters for reinforced concrete (RC) shear walls, specifically in terms of their thickness and length. These parameters

critically influence the walls' stiffness, strength, and modes of failure. The minimum thickness of these walls is determined by the free height of the floor, thus ensuring adequate structural integrity. Within the context of the developed framework, the permissible lengths for these shear walls range from 0.8 to 5.5 meters, which aligns with the requirements for low- to medium-height buildings. This framework aims to optimize the performance and reliability of shear walls under seismic loading conditions.

3.3 Total length of RC shear walls

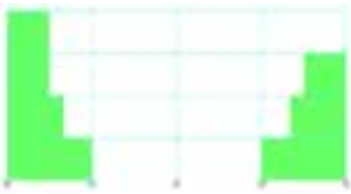
The total length of reinforced concrete (RC) shear walls can be defined as the ratio of their total cross-sectional area to the surface area of the corresponding floor. To ascertain the requisite shear wall length for ensuring structural stability and strength, an iterative parametric analysis, in conjunction with established earthquake engineering recommendations, was employed. The minimum length is calculated based on the floor area (Sf) and the overall height of the building (H) using the following methodology:

$$L_{w,m} = 0.007H.\ S_f \text{ for } H < 30 \text{ m} \quad (1)$$



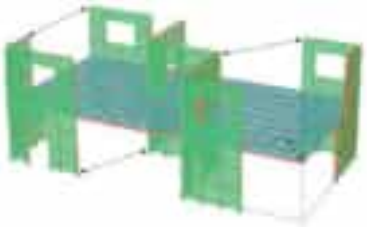
$$L_{w,m} = 0.013H.\ S_f \text{ for } 30 \text{ m} < H < 100 \text{ m} \quad (2)$$

3.4 RC shear wall layouts



The configuration of reinforced concrete (RC) walls is essential for optimizing a structure's torsional response in the face of seismic activity. Two primary criteria are delineated in this context: Firstly, shear walls should be strategically positioned in proximity to the center of stiffness and aligned with the center of mass across both horizontal axes. Secondly, these walls should be situated as distantly as possible from the center of the floor to increase torsional stiffness. This specific arrangement plays a crucial role in preserving plan uniformity and facilitating non-torsional flexibility, thereby enhancing the overall seismic performance of the structure.

3.4.1 Other criteria



- Load path continuity: It is imperative to maintain load path continuity to ensure the effective vertical transfer of lateral forces to the foundation system, as illustrated in Figure 1-a.
- Variation in shear-wall length with height: An optimal structural design necessitates a progressive reduction in the stiffness of shear walls, which is achieved by decreasing their length from the base to the top of the structure, as depicted in Figure 1-b.
- Geometric slab conditions: Established guidelines regarding geometric slab conditions highlight critical parameters, such as the span distance between two reinforced concrete walls and the maximum allowable free length of a cantilever, which is typically restricted to a maximum of 2.5 meters, as shown in Figure 1-c.

a) Vertical continuity

b) Length variation with height

c) Geometric condition for slab

Figures 1. RC Wall-Slab design criteria

3.5 Cold-formed steel structures

A cold-formed steel (CFS) structure represents a sophisticated form of light-frame construction characterized by the assembly of vertical and horizontal components comprised of repetitive framing members (Figure 2). The integration of rigid connections between the slabs and walls significantly contributes to the overall stability and redundancy of the system. Vertical loads are efficiently transferred from the floor joists to lipped channel "stud" members, which are anchored to the foundation utilizing unlipped channel "track" sections. Furthermore, lateral forces resultant from seismic or wind loads are effectively transmitted to the foundation through the incorporation of shear

wall panels or bracing systems, presuming the presence of rigid diaphragms and strict adherence to capacity design criteria. This structural configuration underscores the importance of careful design considerations in ensuring the resilience and performance of cold-formed steel construction in various loading scenarios.

Figure 2. Examples of CFS structure

The shear wall system (SWP) serves as the principal lateral load-resisting framework, employing cold-formed steel (CFS) C-shaped framing affixed to either steel or wood sheathing through mechanical fastening. This system is engineered to exhibit inelastic behavior at the connection points until failure occurs.

The nominal strength of the system will guide the preliminary design process concerning the requisite lengths for each floor, subsequently followed by comprehensive cross-section evaluations.

Fundamental criteria necessary for the effective implementation of this system in the framework of GA multi-objective optimization are delineated below [14]:

3.5.1 Joist directions

The orientation of joists within a structural slab is predominantly influenced by the spans involved as well as the configuration of wall openings. It is recommended that joists be aligned with the longer span; in instances where the dimensions are comparable, they should be oriented parallel to the walls that exhibit fewer openings.

3.5.2 Length of individual wall

The minimum length of a single wall panel is dictated by the spacing between two consecutive studs, with a specified minimum distance of L_{wmin} = 60 cm. Furthermore, the height-to-width (h/w) ratio of an SWP is constrained by a maximum allowable ratio of 4:1. It is posited that the optimal length of an SWP is represented by L_{wopt} = h, where "h" denotes the height of the storey.

3.5.3 Total Length of SWPs

Shear wall panels (SWPs) must exhibit the capacity to withstand lateral loads induced by wind or seismic events from both directions. The minimum total length of shear walls required "L_{wtmin}" at each level and for each directional influence is determined by calculating the level shear lateral load (Vi) and dividing it by the nominal strength of the shear wall per unit length ($R_{nom.}$). This calculation is essential for ensuring structural integrity and stability in the face of lateral forces.

3.5.4 Other criteria

In alignment with the principles established for the RC-SW system, it is imperative to incorporate two critical structural criteria into the objective function on this structural configuration: the continuity of the vertical load path and the spatial distribution of the shear wall panels (SWP) in plan view. The integration of these criteria facilitates a reduction in overall stiffness while mitigating the risk of vertical discontinuities, thereby minimizing the torsional response of the building. This approach not only enhances structural performance but also contributes to the overall stability and resilience of the system.

3.6 Reinforced concrete dual systems

The automated design process for the structural system initiates with the identification of optimal layouts for moment-resisting frames (MRFs), a task that presents significant challenges due to the various configurations available for column placements. The subsequent phase encompasses the strategic arrangement of shear walls within the established MRF framework [15].

The process starts by overlaying architectural floor plans to facilitate the alignment of wall partitions and non-structural components, such as doors and windows, thereby aiding in the identification of potential column locations. To optimize this arrangement, a Hill-Climbing Algorithm (HCA) is selected to define the axis positions of the columns. This is particularly suitable for a given set of predefined potential axes. It iteratively moves from one solution to its neighbors by applying slight changes to the positions of the axes. At each iteration, neighbors of the current solution are generated and evaluated. The best one, based on the

given criteria, is then selected to replace the current one for the next iteration. This allows for rapid convergence to optimal axis positions.

This automated methodology, founded upon the geometric data provided by the Industry Foundation Classes (IFC), yields feasible column positions, as presented in Figures 3 and 4.

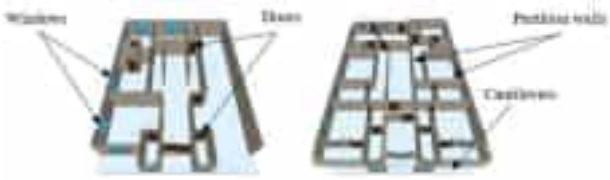


Figure 3. 3D-BIM model (IFC)

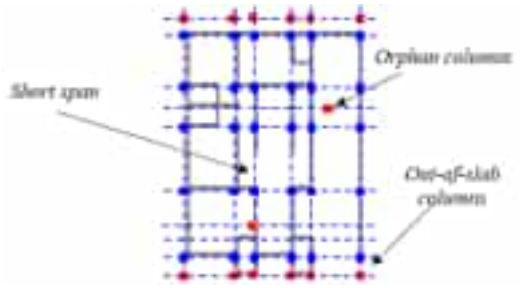

Figure 4. Potential column positions

Once optimal MRF grids have been established, the positioning of shear walls to facilitate the creation of reinforced concrete dual systems (RCDS) must be meticulously aligned with this predetermined grid framework.

It is imperative to enforce a minimum distance constraint to avert the formation of short links between load-bearing elements. Furthermore, in compliance with prevailing seismic codes, the moment-resisting frame (MRF) is required to endure a minimum of 25% of the base shear. The lateral loads acting on the structure are simultaneously resisted by the shear walls (SWs) and the MRF, with their capacity to resist loads being determined by their respective stiffness characteristics.

The seismic design classification of the RCDS as per Eurocode 8 (EC8) is contingent upon the proportion of shear resistance contributed by both the MRF and the shear walls. In scenarios where either the MRF or the shear walls account for more than 50% of the total shear resistance of the structure, stringent control measures must be implemented. This is achieved through the imposition of minimum and maximum length constraints for the shear walls in both principal directions. Optimization of the RCDS layout is facilitated through a scoring approach predicated on a defined fitness function.

In addition to shear wall dimensions, other critical parameters, such as the total slab area and the effective covered area, which accounts for the surface area directly supported by the shear walls while considering overlaps with adjacent structural elements and overhangs from the slab edges, are systematically calculated for each configuration. Scoring formulas are developed and systematically integrated into a multi-objective optimization function, thereby regulating the ratio of shear walls' contributions to the gravity load-bearing capacity within the RCDS framework.

4 GA-based process for generating structural design

In an architectural BIM platform, the IFC protocol facilitates the export of the model's geometry and elements. The algorithm defines slab boundaries and wall partition layouts for each floor, including openings. Structural elements are generated iteratively based on genetic actions. The Genetic Algorithm (GA) optimizes the structural layout after a set number of iterations, effectively meeting constraints and maximizing the objective function.

1. Random generation of the initial population: The algorithm commences by generating an initial population that comprises a diverse set of structural elements. These elements are randomly allocated within the architectural partitions to establish a foundational layout for subsequent iterations.
2. Selection: The selection phase operates on the principle of fitness ranking, wherein the layouts of the subsequent population are chosen based on the performance metrics of all individuals within the current population. This evaluation encompasses layouts produced through crossover and mutation processes, ensuring that the most promising designs are carried forward.
3. Crossover: This function facilitates the unification of structural characteristics from two or more existing configurations to produce a novel layout. This process ensures that the resultant solution retains desirable attributes from the parent layouts while adhering to established structural constraints, thereby enhancing the viability of the new configuration.

Figure 5. Crossover function

4. Mutation: The mutation function serves to enhance the variability within the population by implementing alterations to the structural layout. This may involve the insertion of the new elements, the removal of an existing one, or the modification of the dimensions of the current elements, such as shortening or extending the length of the SW. These changes expand the range of possible designs, enhancing innovative structural solutions.

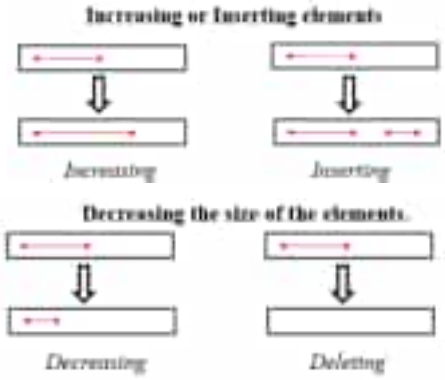

Figure 6. Mutation function

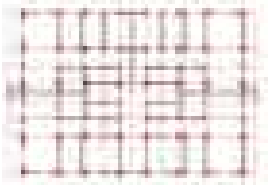
A multi-objective optimization function has been established to direct the population towards an optimal solution, grounded in the established criteria pertinent to each structural type. This optimization function encompasses a diverse set of criteria, each designated with a score ranging from 0 to 1.0, reflecting the validity of the criterion's condition.

The fitness value of a given layout solution is computed through a weighted linear combination of scores across the various criteria. Initially, uniform weights of 1.0 were applied, yielding acceptable outcomes. Subsequently, a sensitivity analysis was conducted to fine-tune these weights in accordance with the significance of each criterion.

The termination process occurs following the completion of the primary evolutionary loop, typically when the objective function reaches a predetermined threshold. However, in the context of multi-objective functions, defining a specific value poses significant challenges. Consequently, a limited number of iterations, generally ranging from 50 to 100, has been implemented, resulting in satisfactory outcomes.

5 Performance criteria of the multi-objective function

The performance parameters associated with the multi-objective function were rigorously evaluated through the analysis of seventeen (17) architectural BIM models, specifically to assess the efficacy of GA in structural design. The selection of samples was methodical, reflecting a diversity in dimensions, forms, placement of openings, and configurations of partitions. The input extracted from the IFC models was instrumental for the GA, which subsequently generated optimized structural solutions through a series of iterative processes. Generated structural designs conformed to established architectural standards, catering to the specified requirements for interior partitions, positioning of openings, and the delineation of wall load paths.



For RC-SW and Dual designs, three-dimensional numerical models were developed utilizing BIM-compatible finite element (FE) software to rigorously evaluate the structural performance of layouts generated through the GA. The assessment was conducted to ascertain compliance with established structural design constraints. The findings reveal that all design criteria were satisfactorily fulfilled, particularly regarding stability conditions and structural strength [13-15]. For the SWP design, the structural performance was evaluated by juxtaposing the GA-generated layout with a conventional structural layout [14]. Figures 7a, 7b, and 7c present examples of generated designs for each type of structure.

a) RC-SW design

b) SWP design

c) Dual system design

Figure 7. Various generated structural designs

Table 5.1 summarizes key metrics that quantify performance, robustness, and efficiency claims across these 17 BIM models:

Table 1: Performance metrics across 17 BIM models

Criterion	RC W-S	CFS SWP	RC Dual
Const. Satisfaction	100%	100%	100%
Avg. Conv. Iterations	50 - 100		
Tors. Irreg. Reduction	~35%	~35%	~30%
Overstrength Factor	> 2.0		

These results confirm the framework's robustness: 100% of seismic code compliance across all systems, consistent convergence within design limits, significant torsional improvements, and ductile overstrength meeting seismic performance objectives, where more than 90% of the structural members of tested models remain in the elastic branch [13-18].

The genetic algorithm demonstrated notable robustness and efficacy in the generation of layouts, particularly for the RC-SW system. This was substantiated by varying key design constraints and adjusting the weight scales within the objective function, which indicated a significant efficiency in managing the design criteria [16-17].

Additionally, a recent analysis reviewed the models based on the hill-climbing algorithm (HCA) for the development of moment-resisting frames (MRFs) structural designs. The structures were subjected to pushover analysis, which facilitated the identification of capacity curves and performance points tailored to specific seismic demands. Notably, despite the utilization of general objective functions, the evaluated layouts exhibited strong performance and adhered to seismic standards. The analysis demonstrated that over 90% of structural members did not exhibit the formation of plastic hinges, with the MRFs sustaining performance within the Immediate Occupancy (IO) to Life Safety (LS) range, indicative of substantial overstrength. These insights suggest promising avenues for future research aimed at enhancing the algorithm through the integration of a Performance-Based Design (PBD) approach, thereby improving the control of structural performance [18].

6 Conclusion

The integration of automation and optimization within the Architecture, Engineering, and Construction (AEC) industry signifies a pivotal transformation in the paradigms of building design and construction methodologies. The deployment of advanced computational tools, artificial intelligence, and data analytics serves to enhance the efficiency, precision, and innovative capacity inherent in structural design processes.

This paper presents a comprehensive review of a newly developed framework proposed by the authors, which employs Genetic Algorithms (GA) and Hill-Climbing Algorithm (HCA) to facilitate the automatic generation of optimal structural systems predicated on specified architectural configurations in a three-dimensional Building Information Modeling (3D-BIM) format. The core premise of this methodology is the establishment of a multi-objective optimization process. This process entails the stochastic generation of a vast array of potential structural configurations that adhere to architectural constraints, alongside a defined set of general structural and seismic design principles. Through successive iterations, the optimization process converges towards solutions that increasingly align with the predetermined criteria.

The proposed method has been systematically applied to three prevalent structural designs:

Reinforced Concrete Shear Wall and Slab (RC SW-Slb), cold-formed steel Panels (SWP), and dual systems. The outcomes relative to the performance, efficiency, and robustness of the generated structures indicate substantial advancements in the formulation of optimized structural configurations for the examined design samples, all of which conform to the specified design criteria for a given architectural layout.

Abstract

Due to construction work's complexity and uncertainty, single simulation methods such as system dynamics (SD), discrete-event simulation (DES), and agent-based modelling (ABM) face significant limitations when applied independently. Hybrid simulation offers a promising solution, yet lacks both a comprehensive review and a structured framework for construction applications. This paper addresses these gaps by providing a thorough review identifying trends and improvement areas, and presenting a detailed framework integrating SD, DES, and ABM tailored to the construction industry. The study also identifies future research directions, including case studies to validate the framework's effectiveness and demonstrate its practical application in real-world construction projects.

Keywords

Hybrid simulation; Construction; System dynamics; Discrete-event simulation; Agent-based modelling; Framework

1 Introduction

In the construction industry, simulation has become an essential tool for planning, analyzing, and optimizing complex projects [1]. The dynamic nature of construction sites, with its multiple variables such as time, cost, labor, materials, and site-specific constraints, makes it challenging to manage efficiently using traditional analytical methods. Simulations provide a means to model construction processes, forecast outcomes, and assess the impact of various strategies across different scenarios. They aid in improving safety, productivity, and quality by providing a virtual platform to test and optimize construction operations prior to real-world implementation [2].

Three fundamental simulation approaches, namely system dynamics (SD), discrete-event simulation (DES), and agent-based modelling (ABM), are widely employed in construction [3]. SD focuses on capturing the behavior of complex systems over time by modelling the interrelationships among components, often through causal loop diagrams and stock-flow models. DES, in contrast, models systems as sequences of discrete events that alter the system state, such as the initiation or completion of tasks, the allocation or release of resources, or the arrival of materials and equipment on site. ABM models systems through autonomous agents whose state-dependent actions and interactions determine both individual behavior and the emergent evolution of the system. In this context, it is important to recognize that SD, DES, and ABM are simulation paradigms, conceptual approaches that define how a system is abstracted and represented at a logical level, and are fundamentally distinct from physics-based simulation platforms that replicate physical-world behaviors within three-dimensional virtual environments. For instance, NVIDIA Isaac Sim provides a GPU-accelerated environment for simulating robotic kinematics, rigid-body dynamics, and sensor responses such as LiDAR and camera feeds, primarily for the purpose of testing and training AI-driven robotic systems [4]. Similarly, Unity, originally developed as a game engine, has been increasingly adopted for robotics and industrial simulation due to its real-time physics engine and photorealistic rendering capabilities, enabling applications such as digital twin development and robot navigation testing [5]. While these platforms offer valuable capabilities for replicating physical interactions at the individual object or equipment level, they do not address how to conceptualize and structure the broader system-level processes and interdependencies that characterize construction projects. This study focuses on the paradigm level, as the integration of these conceptual approaches remains a more pressing methodological challenge in construction simulation compared to the selection of specific implementation platforms. While these methods contribute valuable insights, no single approach can fully capture the multifaceted complexity of real-world construction projects. Reliance on a single method either narrows the scope of analysis or produces oversimplified representations, thereby limiting both validity and practical applicability [3].

To overcome these limitations, an integration

framework is essential to coordinate simulation paradigms, prevent incompatible sub-models, and enable cross-project replication [3]. However, current frameworks for hybrid simulation remain fragmented, hindered by inconsistent terminology and a tendency to operate at high levels of abstraction [6], [7], treating each method as a unified whole. This oversimplification fails to reflect the reality of hybrid modelling, where numerous combinations of interaction are possible, creating significant challenges for model development. Consequently, these frameworks offer limited practical guidance for researchers attempting to construct models, as they lack the details needed to handle the complexity of hybrid modelling.

Although numerous studies have reviewed single simulation methods in construction, research on hybrid simulation in construction remains limited. The few existing studies [2], [8], [9] primarily summarize frameworks developed in other industries rather than proposing approaches tailored to the construction-specific characteristics: temporary nature, site-specific constraints, high uncertainty, and diverse activities requiring different simulation approaches. Moreover, no comprehensive review systematically maps hybrid simulation applications, development trends, and thematic focus in construction, limiting researchers' ability to track field evolution and identify future directions. Therefore, this study aims to address these gaps by providing a comprehensive review and a holistic framework for implementing hybrid simulation approaches in the construction domain.

The remainder of this paper is organized as follows: Section 2 describes the literature collection; Section 3 conducts a bibliometric analysis; Section 4 proposes a framework for hybrid simulation in construction; conclusion and future work are provided in Section 5.

2 Literature collection

This study adopts a comprehensive approach to search and collect literature, guided by Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) [10] (Figure 1). To collect papers on hybrid simulation in construction, databases including “Scopus”, “Web of Science”, and “Google Scholar” were used to search for the papers from 2000-2024. Three search term sets (hybrid simulation-related, method-related, and construction-related) are shown in Table 1. Four method combinations were used: “SD AND DES”, “SD AND (ABM OR ABS)”, “DES AND (ABM OR ABS)”, and “SD AND DES AND (ABM OR ABS)”, where agent-based simulation (ABS) is an ABM variation. Terms from the first and third sets were paired with each method combination, covering all possible combinations (such as “Hybrid simulation” AND “SD AND DES” AND “Construction"). Papers underwent two-stage screening: initial review of titles, abstracts, and metadata, followed by full-text examination. This method maximizes inclusion of relevant papers, with automation tools removing duplicates and ineligible studies.

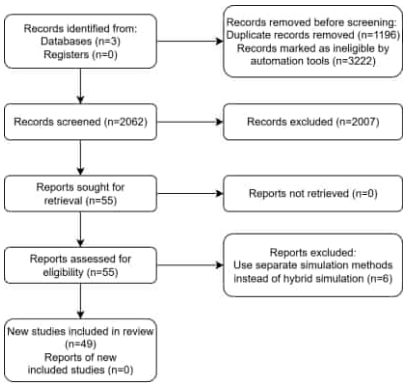

Figure 1. PRISMA flow diagram

The next step involved a manual screening process to exclude irrelevant papers, followed by retrieval of the remaining studies for a more detailed eligibility assessment. Finally, a total of 49 papers were selected (listed in Table 2) for the analysis.

Table 1 Search terms used to collect papers

Hybrid simulation-related search terms	Specific method-related search terms	Construction-related search terms
Hybrid simulation	System dynamics/SD	Construction
Mixed simulation	Discrete event simulation/DES	Civil engineering
Multi-method simulation	Agent-based modelling/ABM	Building
Integrated simulation	Agent-based simulation/ABS	Infrastructure
		Project management

Table 2 Database of papers included

Review & framework	[11] [12] [1] [3] [2]		
Stage	**SD-DES**	**SD-ABM**	**DES-ABM**
Pre-constr.	[13] [14]	[15]	-
Constr.	[8] [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26] [27] [28] [29] [30] [31]	[32] [33] [34] [35] [36] [37]	[32] [38] [39] [40] [41] [42] [43]

Cross-stage	[48] [49]	[50] [51] [52]	[53] [54]

3 Bibliometric analysis

As identified in Section 1, no comprehensive review has systematically mapped hybrid simulation applications, development trends, and thematic focus in construction. To address this gap, this section presents a bibliometric analysis of the collected literature.

3.1 Bibliometric analysis on publications

This bibliometric analysis examines the publication trends from 2007 to 2024. Figure 2 illustrates the yearly distribution of publications, highlighting a peak in 2018 with a total of 9 publications. A polynomial-fitted dashed trend line represents the overall trajectory, indicating a gradual increase in publications leading up to 2018, followed by fluctuations in subsequent years. Notably, during the five-year period from 2015 to 2019, nearly half of the total publications (24 out of 49) were produced, underscoring a concentrated period of research activity.

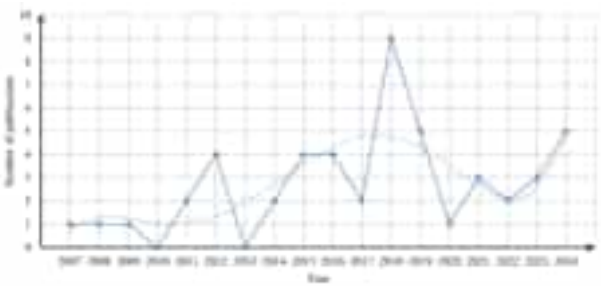

Figure 2. Yearly number of publications

A comprehensive analysis of keywords is conducted. Of 210 unique keywords, 40 appear more than once, signifying recurring research topics. The ten most frequent keywords are: SD, DES, hybrid simulation, simulation, ABM, ABS, construction management, productivity, construction industry, and construction.

3.2 Bibliometric analysis on journals

Bibliometric analysis of journals identifies key publication venues, tracks influential studies, and reveals field impact and productivity. An analysis of 49 selected papers shows that they are distributed across 30 journals or conferences, with only 9 journals featuring more than one publication. "Automation in Construction" leads in publication count, followed by "Construction Innovation" and "Journal of Construction Engineering and Management". 9 journals collectively account for 57.1% (28 out of 49) of total publications.

3.3 Bibliometric analysis on authors

Bibliometric analysis on authors documents contributions. Among the 49 selected papers, 131 authors were identified, of whom 24 published more than one paper. There are 6 distinct research clusters and 5 overall research groups, as some clusters exhibit strong interconnections. The largest group comprises 8 authors with 9 papers, where SangHyun Lee and Simaan AbouRizk occupy key positions. The second largest group consists of 5 authors with 4 papers, centered on Farnad Nasirzadeh. The third largest includes 4 authors with 6 publications, centered on Tarek Zayed.

4 Framework for hybrid simulation

As identified in Section 1, existing hybrid simulation frameworks lack consideration of construction-specific characteristics. To address this gap, this section presents an integrated framework (Figure 3) that serves as a practical decision-support tool for hybrid simulation in construction. The hybrid simulation design framework consists of four phases that guide researchers and industry practitioners systematically from problem definition to implementation.

4.1 Problem definition

The framework's initial phase develops comprehensive understanding of the construction problem, like other hybrid simulation frameworks [55], helping researchers articulate problems with modelling precision and determine whether complexity warrants a hybrid approach. Precise problem definition requires four elements: a problem statement identifying concrete issues and consequences; primary performance focus (productivity, quality, or safety); construction context (temporal and spatial); and scope boundaries balancing comprehensiveness with feasibility. Researchers then analyze characteristics along three dimensions: continuous (feedback loops, flows, accumulations), discrete (events, queuing, sequential operations), and behavioral (autonomous decision-making), each suggesting different modelling requirements. This characterization determines whether hybrid simulation is necessary: single methods suffice when problems align with one dimension, while hybrid approaches are essential when problems span multiple dimensions. If hybrid simulation is needed, proceed to Phase 2 for method selection; otherwise, exit for single methods.

4.2 Model selection

To guide method selection, we systematically analyzed 49 reviewed papers to identify patterns in hybrid simulation applications. Papers were classified by construction phase (pre-construction, construction, post-construction, cross-stage) and hybrid approach. While some papers incorporated all three methods (SD, DES, ABM), they typically applied them in paired

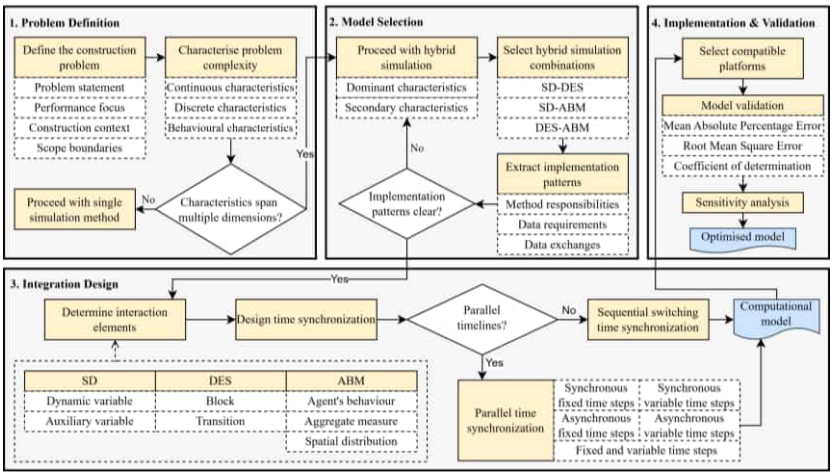

Figure 3. Framework for hybrid simulation design

combinations rather than fully integrated systems. Consequently, we focused on three hybrid subcategories: SD-DES, SD-ABM, and DES-ABM. This systematic classification, calculated from Table 2, revealed clear patterns in how researchers have matched hybrid approaches to specific construction challenges. Construction phase dominates with 30 studies (61%), while pre-construction (3 studies) and post-construction (4 studies) remain underexplored. Cross-stage applications represent 7 studies (14%), addressing strategic planning spanning multiple phases. SD-DES combinations lead with 22 studies, reflecting alignment between system-level dynamics and operational processes. DES-ABM follows with 12 studies addressing process modelling and agent behavior, while SD-ABM accounts for 10 studies focusing on system-wide factors interacting with individual behaviors.

Researchers evaluate hybrid simulation methods based on Phase 1 problem analysis. The dominant characteristic determines the primary method, whilst secondary characteristics guide complementary method selection. Once methods are selected, researchers verify that method responsibilities are clearly defined, required data exists for both methods, and sufficient implementation guidance is available. Meeting these criteria produces a conceptual model for Phase 3 integration design. Gaps require refinement or reconsideration of earlier framework steps.

4.3 Integration design

Phase 3 addresses how the selected methods will exchange information and coordinate their execution. This paper references the hybrid SD-ABM model presented by Nguyen et al. [55]. For each method (SD, DES, and ABM), key elements are identified and summarized, acting as interaction points between different methods. For SD, the key elements are dynamic variables (stocks and flows that accumulate or change over time through feedback) and auxiliary variables (intermediaries that establish relationships without accumulating). In DES, the primary elements are blocks, whose characteristics can influence and be influenced by other methods, and transitions, which are either deterministic (leading to a single block) or stochastic (providing probabilistic pathways to multiple blocks). For ABM, the essential elements include individual agent behavior (rules and decisions guiding actions), aggregate measures (collective outcomes from agent interactions), and spatial distribution (agent positioning and movement within space).

After designing the information exchange elements, the next step is synchronization of time advancement. The summarized categories are presented. The first category is sequential switching, where dynamic switching occurs along a single timeline. In this case, only one method is active at a time, and a new method can only begin once the previous one has ended. For other hybrid simulation models, the timelines are always parallel. In synchronous fixed time steps category, the interchanges of information happen at the same time with equal time intervals. While in synchronous variable time steps category, the data exchanges occur simultaneously but at varying intervals. Asynchronous fixed time steps and asynchronous variable time steps follow a similar pattern to synchronous ones, but in an asynchronous way. Finally, the data exchange can combine both fixed and variable time steps, meaning that whenever a model is updated, it immediately sends information to the other model. Phase 3 results in a computational model ready for implementation.

4.4 Implementation & validation

Phase 4 transforms this design into an executable simulation through systematic implementation and

validation. Implementation begins with choosing between single platforms supporting all methods (simplified integration) or multiple specialized platforms (greater flexibility but complex bridging) [3]. Development follows an incremental approach: build method components independently, verify individual functionality, then implement integration mechanisms. Hybrid model validation addresses three levels. Component validation tests each method against benchmarks [36]. Interface validation ensures data exchanges maintain integrity through transformations and synchronization [44]. Integrated validation examines overall model behavior against historical construction data, revealing emergent properties from method interactions [40].

Accuracy metrics include mean absolute percentage error (MAPE) and root mean square deviation (RMSE), and R-squared for overall fit [17]. Acceptable thresholds depend on application. Sensitivity analysis systematically varies key parameters to identify critical inputs and assess model stability [51]. Well-constructed models demonstrate logical sensitivity to critical parameters while maintaining robustness against reasonable variations in less certain inputs. A final optimized model is obtained once it passes both the accuracy and sensitivity tests.

4.5 Case study of construction equipment repair yard inventory management

To demonstrate the practical applicability of the proposed framework, a hybrid simulation case study involving repair yard inventory management for vibroflotation equipment (hereafter referred to as vibros) in foundation construction is mapped onto the four phases, as illustrated in Figure 4.

In Phase 1, the problem concerns managing spare parts inventory for a fleet of vibros, each comprising interdependent components. Component failures cause equipment downtime and costly emergency procurement, with productivity and cost efficiency as the primary performance focus. The problem spans all three dimensions: continuous dynamics in inventory stock and flows; discrete events in the vibro operational process; and behavioral characteristics from individual vibros and their components, each with unique degradation patterns and interdependencies. A hybrid simulation approach is therefore warranted.

In Phase 2, the DES component serves as the main operational workflow, modelling vibro assignment, spare parts demand prediction, normal ordering, and monitoring. During monitoring, preventive maintenance leads the vibro directly to the repair yard, while corrective maintenance first evaluates whether emergency ordering is necessary. ABM represents individual vibros (Vibro 1 to Vibro n) as agents with status parameters (working, under maintenance, or idle), and each component within a vibro is also modelled as an agent. A component correlation matrix captures part interdependencies and feeds into the DES demand prediction module. SD models the ordering strategy through a stock-flow structure (orders into inventory, demands as outflow), governed by parameters including supplier reliability, safety stock, order quantity, lead time, emergency order quantity, and consumption quantity. Optimization objectives include fill rate, turnover ratio, service level, and cost metrics (normal ordering, emergency ordering, holding, and penalty costs).

Figure 4. Hybrid simulation implementation of construction equipment repair yard inventory management

In Phase 3, the interaction points are defined as follows: ABM transmits component correlation matrices and vibro status to the DES demand prediction module; DES updates the SD model through ordering events (order inflow) and repair completion (consumption outflow); and SD inventory levels and safety stock status influence whether normal or emergency ordering is activated in DES. Historical maintenance and repair records initialize the ABM agents, and a feedback mechanism from the DES "Send to repair yard" block updates these records, enabling dynamic calibration as the simulation progresses. The DES component operates on an event-driven basis while SD advances continuously, with information exchanged at each relevant state change.

In Phase 4, the model will be built in Python as a single-platform approach to simplify integration across the three methods. Development follows an incremental strategy, building and verifying each component

independently before implementing integration mechanisms. Validation will address three levels: component, interface, and integrated, with accuracy assessed using metrics such as MAPE, RMSE, and R-squared against historical construction data. Sensitivity analysis will vary key parameters to identify critical inputs and assess model stability. The validation of this case study is currently ongoing, as data collection from the repair yard is still in progress.

5 Conclusion and future work

This study addresses critical gaps in construction hybrid simulation research: the absence of comprehensive reviews and lack of frameworks guiding SD, DES, and ABM integration. Following PRISMA guidelines, bibliometric analysis of 49 papers revealed declining research from 2019-2021, reversing upward from 2022, with publications spanning interdisciplinary venues and forming 6 distinct authorship clusters.

The developed four-phase framework revealed that SD-DES combinations dominate current research, with focus concentrated on active construction phases. The framework's modular structure enables continuous adaptation as technologies emerge. An illustrative case study on repair yard inventory management for vibroflotation equipment has been presented to demonstrate the framework's applicability, and future work will focus on completing its validation as field data collection progresses, further demonstrating practical value in real-world construction applications.

Abstract –

While Virtual Reality (VR) provides a promising platform for construction safety training, generating virtual environments (VEs) that are tailored to specific project and task contexts remains a bottleneck. Current workflows, ranging from manual modeling to semi-automated BIM-to-VR pipelines, are often labor-intensive and result in static, idealized VEs that fail to capture the dynamic reality of active construction sites. This paper addresses these limitations by proposing a cyclical framework driven by Vision-Language Models (VLMs), designed to both generate procedural fire hazard scenarios and systematically capture expert knowledge for continuous model improvement. By focusing on fire safety, a domain requiring a deep understanding of spatial relationships between objects and activities, the workflow integrates VLMs to extract tacit risk context that traditional object detection misses. Human-in-the-loop corrections then serve as ground-truth data for future model fine-tuning. As an initial proof of concept, we developed a semi-automated Unity prototype that connects unstructured site imagery with 3D asset generation through a hybrid generative pipeline. The prototype illustrates the potential of the proposed workflow to transform raw construction imagery into privacy-preserving, context-specific digital twin training environments. By reducing the manual effort required for VR content creation, this approach lays the foundation for scalable, self-evolving AI-driven safety training systems.

Keywords –

Construction safety, Fire hazards, Virtual Reality, Vision-Language Models

1 Introduction

Construction fire safety remains a persistent challenge, driven by the complex, dynamic nature of job sites and the interactions among workers, equipment, and changing site conditions [1]. VR is a promising solution by providing controlled environments for behavioural research and immersive platforms for safety training [2]. However, the creation and maintenance of VEs for training remains a major bottleneck, limiting both research validity and the scalability of VR-based training systems in practice [3].

This bottleneck is driven by two intersecting challenges. First, high-quality VR training scenarios still rely heavily on the tacit knowledge from senior safety personnel [4]. Existing literature, standards, and reported incidents provide important general principles, but they rarely describe hazards at the level of detail needed to build convincing, site- and task-specific VR scenarios. Additionally, each construction project is unique, requiring flexible, context-specific judgement and decision-making. As a result, expert input remains essential at two crucial stages: (1) to accurately identify complex, context-dependent hazards from raw site data [5]; and (2) to validate the realism of the resulting virtual simulation [4]. Despite this importance, this tacit knowledge of experts is rarely formalized or reused in a structured way [6]. At the same time, the construction industry faces a worldwide aging workforce and accelerating labor shortages [7-9]. As experienced personnel retire, this specialized domain expertise is at risk of disappearing. Without a mechanism to capture and digitize this visual reasoning, the industry risks losing the capacity to generate and verify realistic safety scenarios.

Second, even with expert knowledge available, the technical workflows for turning this hazard-relevant knowledge into VR content remain inefficient. Current

digital twins incrementally update elements or zones based on scans, sensor data, or manual inputs, which is effective for progress monitoring and quality control [10]. However, for safety training, it is still time-consuming and labour-intensive to propagate these updates into VR environments [11]. Most importantly, within the large volume of new data, only a subset of the updated information is needed for safety training. What matters are fire hazard–relevant changes, such as new ignition sources or flammable materials introduced by new construction activities, rather than a perfect geometric copy of every site detail. This suggests an alternative strategy in which, instead of fully twinning the whole site, we focus on twinning hazard-relevant information while still reflecting the local context where workers operate.

Building on these challenges, this paper presents a semi-automated, VLM-driven workflow that twins hazard-specific information into VR while capturing and storing expert knowledge. As a proof-of-concept, we developed an initial prototype implementation within the popular game engine Unity to illustrate the practical feasibility of the proposed framework.

2 Related Work

2.1 Construction VR Scene Generation

VR is increasingly used in the architecture, engineering, and construction (AEC) sector for design reviews, project planning, and safety training, providing more transparent communication and improved learning outcomes [12]. However, achieving high ecological validity in VR scenes, meaning they accurately reflect task-relevant conditions in specific construction environments, remains challenging due to their complexity [3]. These environments contain many objects, changing site conditions, and heterogeneous data sources such as BIM, point clouds, and GIS, all of which require significant cleaning and optimization before becoming VR-ready [13].

Currently, there are two primary workflows to generate virtual environments. Semi-automated BIM-to-VR pipelines are the most common but frequently suffer from loss of BIM semantics during export and require aggressive geometric optimisation to meet the rendering constraints of standalone VR headsets [14]. Manual scene authoring supports highly customized simulations but is slow and requires advanced modelling and game-engine expertise [15]. Crucially, neither workflow includes context-specific hazards, such as oily rags left near heaters or other flammable materials. Standard BIM models focus on permanent, “as-designed” elements [1] and rarely capture short-lived site conditions like waste, temporary storage, or poor housekeeping. In scan- or sensor-based workflows, these transient objects are often filtered out as noise [10]. However, such temporary combustibles and unsafe arrangements are a common source of fire risk on active sites and are therefore essential components of realistic safety training scenarios.

Recent advances in generative AI offer a promising alternative. Text-to-3D and image-to-3D models, such as Hunyuan3D 2.0, Microsoft TRELLIS [16], and Meta SAM 3D [17], can synthesize high-quality 3D objects directly from natural-language descriptions or site imagery, reducing reliance on fragmented asset libraries and bypassing many manual modelling steps. However, despite these advances, the AEC domain still lacks a practical workflow that applies generative models to VR scene generation, especially for safety-critical contexts such as hazard recognition research and training.

2.2 Potential of VLMs for Construction Hazard Recognition Training

The integration of advanced computational models into construction safety management is an active and expanding area of research. Traditional computer vision (CV) techniques, often relying on convolutional neural networks (CNNs), have demonstrated success in object detection tasks, such as identifying personnel, machinery, and personal protective equipment [18]. However, these methods often struggle to interpret context and relationships among objects, which is paramount for safety analysis. A ladder, for example, is not inherently a hazard; it becomes one when it is unsecured, placed on an unstable surface, or used near an open electrical panel.

This is the gap that VLMs are beginning to fill. VLMs such as LLaVA (Large Language and Vision Assistant) [19] and GEMMA 3 [20], and those based on the GPT-4 architecture [21], combine the perceptual capabilities of CV with the sophisticated reasoning of large language models [22]. This multimodal approach allows VLMs to move beyond mere object identification to complex scene contextual processing and complex pattern recognition. Recent studies have explored using VLMs to analyze static site images for safety-rule violations by processing both the visual data and textual prompts containing regulatory guidelines [18,23]. This allows them to identify not only the presence of a potential hazard, but the reason it violates a safety protocol.

Despite these advances, current studies have largely focused on demonstrating the hazard detection capabilities of VLMs [22], while the translation of VLM outputs into reusable, context-rich VR training assets remains underexplored. In particular, limited work has examined how contextual information embedded in construction hazard scenes can be structured into a format that can be directly interpreted and rendered in a virtual environment. Additionally, the use of VLMs in safety-critical settings requires caution. VLMs may generate plausible but incorrect hazard descriptions or

safety explanations, commonly referred to as "hallucinations." They may also struggle with fine-grained spatial reasoning, such as estimating 3D proximity or depth from 2D imagery [27]. Therefore, VLM-generated outputs may require further structuring and validation by human experts before being integrated into VR-based safety training environments.

3 Research Method

We propose a five-stage, human-in-the-loop workflow designed to transform unstructured construction site imagery into structured, context-aware fire hazard libraries for VR. As illustrated in Figure 1, the framework operates iteratively. It not only generates hazard scenarios but also uses expert validation to continuously fine-tune the underlying VLM. This helps the system adapt to specific project constraints and reduces the rate of hallucinations that can contribute to unnecessary information or misleading hazard detections over time. The following sections detail each stage.

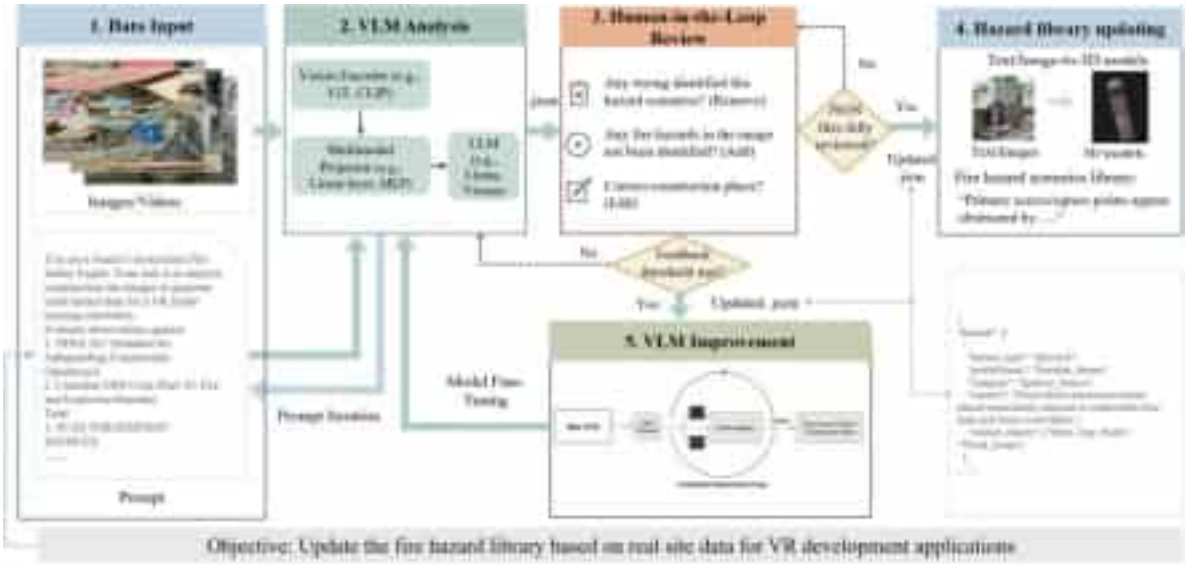

Figure 1. The proposed VLM-driven workflow for virtual fire hazard library update

3.1 Data Input

The workflow begins with the ingestion of raw visual data (images or video frames) captured from active construction sites. To ensure practical scalability and minimize additional hardware costs, the workflow can integrate with existing site CCTV surveillance systems.

To accurately translate these 2D images into valid 3D VR components, we employed a goal-oriented prompt engineering strategy [24]. The prompt design was reverse engineered from the specific data requirements of the VR Scene Library. Specifically, the system requires not only the identification of physical objects (e.g., oil drums or welding equipment) and their spatial context, but also the recognition of abstract violations. Abstract hazards, such as blocked emergency exits or missing fire extinguishers, are critical for safety training but lack a single physical object to detect. Therefore, the prompt is structured to extract both explicit physical assets and implicit procedural non-compliance.

After defining the expected output, we implemented a multi-stage prompting architecture to achieve reliable extraction. First, we applied Role-Prompting by instructing the model to adopt the persona of a "Senior Construction Fire Safety Expert"[25]. This constrains the model's focus to regulatory compliance rather than generic image description. Second, we used Chain-of-Thought (CoT) [26] to ensure the model follows a logical checklist and to mitigate hallucinations. This step-by-step reasoning is critical for visual analysis [22], as it prevents the model from guessing and ensures that every identified hazard is based on clear visual evidence. Finally, we required the output in a strict data format (JSON). This structured format ensures the data is machine-readable, allowing for direct parsing into the user interface and facilitating the automated construction of fine-tuning datasets.

3.2 VLM-based Hazard Analysis

In this stage, the VLM processes the visual input alongside the prompt to generate a structured description of potential hazards. The model identifies specific hazard instances and extracts critical metadata required for VR instantiation. This includes:

- Hazard classification, distinguishing between

physical hazards that must be represented as 3D entities in the virtual environment (e.g., heaters and wood debris) and abstract hazards that represent procedural or regulatory violations (e.g., blocked egress routes, improper material storage).

- Prefab associations, where each physical hazard is mapped to a corresponding VR asset ("prefab") to enable automatic placement within the simulation.
- Contextual metadata, which captures the hazard's relevance, associated risks, and the environmental cues driving the classification (e.g., proximity of a heater to combustible traps, presence of fuel containers near ignition sources).
- Relational linkages, documenting interactions between hazards, such as ignition sources located within NFPA 241's minimum clearance distance from Class A or B fuels, to support scenario logic and rule-based triggers in the simulation.
- Compliance attributes, representing inferred violations of NFPA 241 or the Canadian OHS Code (Part 10), enabling automated generation of safety feedback and assessment scoring.

3.3 Human-in-the-Loop Review

Given the safety-critical nature of this domain, relying on VLM output alone is insufficient due to the potential for semantic errors. We therefore introduce a Human-in-the-Loop review process [27]. A domain expert reviews the JSON output against the original image to verify the presence and classification of the hazard. The expert can correct the output by removing false positives or amending inaccurate context descriptions and can augment it by adding hazards that the VLM has missed. The review is iterative, and the JSON file is edited until the expert confirms that all images in the batch have their hazards fully marked and correctly represented. Only cases where the expert modifies the VLM output are counted as feedback and stored in a feedback repository. The final, validated JSON is stored in an updated JSON file and used both to refine prompts, hazard templates, and configuration rules for the VLM and to populate a feedback repository. VLM updates are triggered once the number of such corrections exceeds a predefined feedback threshold [27]. The specific threshold is configurable depending on project requirements and update cadence; for example, it could correspond to the completion of a scheduled image batch, such as a weekly data collection cycle. In this way, this process acts as a form of "human coaching", helping future hazard descriptions and scene suggestions better align with expert judgement.

3.4 Hazard Library Update

The validated data from Section 3.3 is used to support two parallel processes: generating 3D models (corresponding to the physical field in the VLM output) and populating the Abstract Scene Library (corresponding to the abstract field). This library serves as the semantic back-end for the VR environment. This eliminates the need to repeatedly search for site photographs, locate appropriate 3D objects, or request additional expert validation, thereby streamlining the construction of accurate, context-aware VR fire-safety training scenes.

3.5 Continuous VLM Improvement

A critical component of the proposed workflow is the establishment of a "data flywheel" (Stage 5), which ensures the VLM's accuracy and domain specificity improve over time. This stage operationalizes the feedback gathered during the Human-in-the-Loop Review (Stage 3). The "Updated.json" file generated by the human expert is not only the finalized data for the VR library but also serves as a high-quality, expert-validated ground truth dataset. This curated dataset becomes the training data for iteratively refining the VLM. By comparing the VLM's initial JSON output with the expert-corrected JSON, we can identify systematic errors in the model's reasoning, such as misclassifying construction phases, overlooking "abstract" hazards, or providing incomplete contextual descriptions.

As depicted in the workflow (Figure 1), this refinement process can be efficiently implemented using parameter-efficient fine-tuning (PEFT) techniques, such as Low-Rank Adaptation (LoRA). LoRA allows fine-tuning the VLM on this new, domain-specific dataset by updating only a small subset of the model's parameters. This approach is computationally much more efficient than fully retraining the entire model, making it feasible to run periodic improvements as more curated data is collected. The ultimate goal of this continuous improvement loop is to enhance VLM's performance in construction-specific hazard analysis, thereby reducing the manual correction burden on human experts in future iterations and increasing overall pipeline automation.

4 Implementation

This section presents a proof-of-concept prototype developed as the primary artifact to illustrate the proposed workflow concept. Accordingly, systematic parameterization, full module integration, and empirical evaluation across a larger image corpus will be addressed in future work. Unity (2022.3.46f1) was selected for its mature VR development capabilities and its ability to integrate external AI modules through standard APIs. Although the workflow can be implemented in other engines, Unity provides a stable and practical environment for rapid prototyping. Within Unity, we

implemented a custom user interface (UI) that facilitates user interaction, displays intermediate results, and coordinates communication with external system components. As shown in Figure 2, Unity serves as the central layer, linking data processing, model inference, and VR scene assembly into a cohesive pipeline.

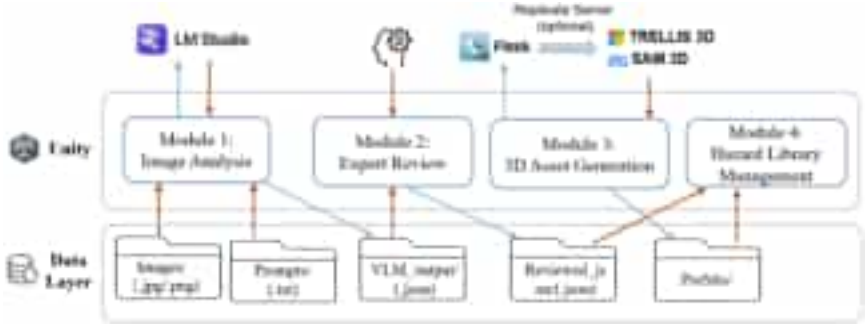

Figure 2. Schematic overview of the Unity plug-in implementing the proposed workflow

4.1 Image Analysis Module

The Image Analysis Module serves as the primary entry point for the fire hazard analysis and hazard library generation workflow. The implementation is compatible with widely used local LLM servers, LM Studio (www.lmstudio.ai/). We selected LM Studio to facilitate the efficient local deployment of quantized models via a standardized REST API, minimizing integration complexity. This enables the use of various open-source VLMs, such as LLaVA or GEMMA 3, which are well-suited for this type of detailed visual analysis (as shown in Figure 3). It is designed with local VLM backends, ensuring data privacy and control.

Figure 3. Locally hosted VLM models in LM Studio

For a proof-of-concept demonstration, the prototype was tested using a small set of publicly available construction-site images. These images were used for feasibility illustration rather than as a formal evaluation dataset. As shown in Figure 4, in the configuration tab, the user selects the VLM model, target image, and domain-specific prompt (from Section 3.1) from the local file system. In our prototype, it is put under the Unity project asset file for easy management. Upon clicking "Analyze", the plug-in converts the image to a base64 string and serializes it into a single API request. This request is sent via an HTTP POST request to the local VLM's API endpoint (e.g., LM Studio's default server at http://127.0.0.1:1234). The plug-in receives the raw JSON text response from the VLM and displays it in the "Results Preview" field. This JSON data is then passed to the "Expert Review" module (Section 4.2), which deserializes the JSON and uses its contents to populate the interactive fields for human-in-the-loop curation. This setup provides a self-contained, integrated toolset for a VR developer to manage the entire data-to-asset pipeline without leaving the Unity editor.

Figure 4. Image Analysis Module UI

4.2 Expert Review Module

This module streamlines the Human-in-the-Loop review stage described in Section 3.3 by providing an interface for experts to inspect and modify all identified fire-hazard scenarios. As shown in Figure 5, it starts with loading the JSON file generated by the Image Analysis module. It presents the extracted fields, such as prefab name, category, and related contextual objects, in a structured and readable format. Experts can edit any field by selecting "Edit," which switches the interface into an editable state, allowing them to correct or update the information. If a scenario has been misidentified, the expert can remove it using the "Remove" option. Conversely, if the VLM-based detection missed a relevant fire hazard, the expert can add a new one using the "Add New Hazard" function. After completing their review, experts can confirm the revisions by "Confirm All Changes." The system then generates an updated JSON file as described in Section 3.3, ensuring that all corrections and additions are incorporated into the downstream modules.

Figure 5. Expert Review Module UI

4.3 3D Asset Generation Module

Module 3 employs a hybrid asset generation pipeline. The system first queries the internal Hazard Library (Module 4) for pre-validated prefabs matching the detected hazard scenarios. If no match is found, the system triggers an on-demand generative workflow, as shown in Figure 6.

The generative process supports both text-to-3D and image-to-3D pathways by choosing different models. In this prototype, we tested the image-to-3D route using TRELLIS [16] and SAM-3D [17]. We explored two deployment strategies to integrate these generative models into the Unity environment. In the local deployment configuration, the models are hosted on the workstation (Intel Core i9-13900KF, 64 GB RAM, NVIDIA GeForce RTX 4090 24GB), and Unity communicates with them through a lightweight Python microservice built with Flask (https://flask.palletsprojects.com), which passes Unity's generation requests to the locally running 3D model. This option avoids per-generation costs but requires a high-performance GPU and sufficient memory.

Alternatively, the cloud-based configuration uses Replicate's model-hosting service (https://replicate.com), where Unity sends requests directly to the cloud and receives generated assets without dedicated hardware. This approach is significantly more accessible and can run on a standard laptop, although each generation incurs a small cost (typically $0.02–$0.07 depending on the model and version). Depending on the available computing resources and budget constraints, either configuration can be used to support text-based or image-based 3D asset generation within the pipeline.

This module is not yet fully developed due to the complexity of integrating Image-to-3D models into the plug-in, but this will be completed in future work. To validate the workflow concept, Figure 7 shows the 3D models generated by SAM 3D through raw construction site images.

Figure 6. 3D Asset Generation Module UI

Figure 7. Example of a 3D construction object generation from raw site images

4.4 Library Management Module

This module aims to display all existing prefabs within the Unity project alongside the fire-hazard scenarios generated or revised in the updated JSON file. As shown in Figure 8, it functions as a central repository, allowing users to review previously identified hazards and track how scenarios have evolved over time. By maintaining a structured record of hazards and their associated assets, the module supports efficient development of VR environments that better reflect real site conditions. Due to current limitations in the 3D asset-generation model, this component is not yet fully implemented. Its underlying functions will be further developed and validated in future work.

Figure 8. Library Management Module UI

5 Conclusion and Future Work

This study makes three main contributions. First, it introduces a hazard-focused twinning concept that updates only fire hazard–relevant elements in VR, rather than mirroring the entire construction environment. This provides an alternative to full digital twins for training use cases where task-relevant ecological validity is more important than exhaustive geometric fidelity. Second, it proposes a novel, semi-automated pipeline connecting real construction data, VLM reasoning, and procedural 3D objects generation. By integrating VLM analysis with a human-in-the-loop verification step, the framework not only automates the creation of context-aware fire hazard scenarios but also systematically digitizes the tacit knowledge of senior safety experts. Third, it presents an initial Unity-based prototype that illustrates how the workflow can be implemented in practice and used to generate fire hazard-relevant models from real construction imagery.

Despite these contributions, several limitations remain. The system's performance is sensitive to the quality and perspective of input imagery. Occluded objects or poor lighting can hinder VLM semantic extraction. Additionally, while the framework extracts spatial context from 2D images, it currently lacks precise depth estimation. In some cases, objects may appear closer or farther away than they actually are in the original scene. Furthermore, while the feedback loop for model fine-tuning is theoretically defined, the long-term impact of expert corrections on model performance has not yet been empirically validated in this study. Finally, the seamless integration of different models within Unity still requires additional development efforts, and systematic quantitative evaluation of hazard identification performance (e.g., precision and recall metrics) is beyond the scope of this proof-of-concept study and is identified as a priority for future empirical validation.

Future research includes strengthening the core components of the proposed workflow. First, improving depth reasoning from 2D inputs, whether through lightweight monocular depth models [28] or multi-view image capture, will help reduce spatial ambiguities during VLM interpretation. Additional effort is also needed to formally evaluate the feedback loop by measuring how expert corrections affect model accuracy across successive fine-tuning cycles. Such an assessment would clarify whether the system can reliably accumulate and operationalize tacit safety knowledge over time. Finally, the framework's scope could be broadened beyond fire safety to address other critical challenges, such as fall protection and visual clutter analysis, thereby validating the generalizability of VLM-driven simulation across the construction safety domain.

Abstract –

Building Information Modeling (BIM) is widely used in construction management, particularly for mechanical, electrical, and plumbing (MEP) systems, where accurate pipeline information is critical for efficient operation and maintenance. In practice, however, as-built pipelines often deviate from the as-designed BIM models, and manually updating these models is time-consuming. This study proposes an automatic pipeline for BIM updating, which leverages laser-scanned point clouds together with as-designed BIM priors. The framework integrates point cloud semantic segmentation, parameter extraction, and spatial topology analysis to establish component correspondences and generate an updated BIM model. A case study in a complex MEP environment demonstrates that this framework can robustly update pipeline BIMs, reducing modeling time from 3-5 days to approximately 3 hours, thereby improving the efficiency of BIM-based MEP management.

Keywords –

Point cloud; Building Information Modeling; As-designed model; Automatic modeling

1 Introduction

BIM has become a key enabler for efficient lifecycle management in the architecture, engineering and construction industry, especially when integrated with Internet of Things (IoT) for real-time data acquisition and facility operation optimization. In smart construction, enriched BIM models are increasingly required to support performance monitoring and maintenance of MEP systems [1]. However, as-designed BIM models often deviate from as-built conditions due to construction tolerances and on-site modifications, which significantly degrades the reliability of BIM-based MEP management.

In practice, BIM models are often generated manually from component specifications and installation records, causing low efficiency in complex MEP environments. Laser scanning can capture dense point clouds that accurately represent as-built environment [2]. However, raw point clouds lack semantic and topological information and cannot be directly used for engineering applications [3]. Although automated scan-to-BIM approaches have been developed [4-5], many rely primarily on local geometric features, which limits their robustness in reconstructing complex MEP systems.

To address these limitations, this paper proposes an automatic framework for updating as-designed pipeline BIM models using laser-scanned point clouds. The main contributions are summarized below. First, a semantic segmentation strategy is developed by integrating DBSCAN with deep learning to improve recognition of multi-scale pipeline components in cluttered MEP environments. Second, a logic-based geometric refinement method is proposed by utilizing as-designed BIM priors to correct coordinate deviations caused by noise and occlusion. Finally, the research bridges the semantic gap between unstructured as-built data and structured as-designed components by applying graph isomorphism, thereby enabling a fully closed-loop parametric update. Overall, the integrated workflow minimizes manual intervention and maximizes MEP modeling fidelity at the same time.

2 Related Work

2.1 Point Cloud Segmentation

Point cloud segmentation is critical for automated scan-to-BIM workflows but remains challenging in complex MEP environments [6-7]. Deep learning approaches such as PointNet++ and transformer-based networks [8] have improved segmentation performance. Synthetic or annotated datasets have also been explored to address data scarcity [9-10]. However, robustness is still limited by scale variation and occlusion, motivating hybrid methods that combine spatial preprocessing with learning-based segmentation.

2.2 Geometry Parameter Identification

Following segmentation, parameter identification extracts geometric information from point clouds for

parametric BIM reconstruction. Early methods mainly relied on manual feature extraction and geometric fitting techniques such as RANSAC [11]. Although effective for regular shapes, these approaches depend on prior knowledge and manual tuning, limiting their applicability to complex MEP components with irregular geometry. Recent studies have therefore shifted toward deep learning-based parameter extraction, which learns structural representations directly from data and can handle both regular and irregular components without explicit feature engineering [12]. This data-driven paradigm improves the automation and robustness of parametric BIM reconstruction in complex MEP systems.

2.3 Automatic Modeling

Automatic modeling aims to convert geometric and semantic data into parametric BIMs. However, accurately reconstructing as-built pipelines remains challenging. Early Scan-to-BIM frameworks focused on detecting spatial discrepancies [13]. Subsequent studies [14-15] leveraged 3D point clouds for automated geometric modeling of cylindrical MEP elements. Recently, combining semantic segmentation with geometric extraction has enabled transformation from point cloud to BIM via visual programming (e.g., Dynamo) [4]. Furthermore, hybrid methods fusing image semantics with LiDAR precision enhance robustness in complex environments [16]. These studies collectively provide a solid foundation for automated pipeline reconstruction.

Despite recent progress in Scan-to-BIM research, several limitations still restrict its practical application in complex MEP environments. First, many existing approaches rely heavily on local geometric features, which reduces robustness in scenes with severe occlusion and dense pipeline layouts. Second, prior information from as-designed BIM models is not sufficiently utilized. Third, current methods still face challenges in achieving automated synchronization between as-designed and as-built pipeline models.

3 Methodology

This study proposes a framework to automatically update as-designed pipeline BIM model with laser-scanned as-built point clouds. As shown in Figure 1, the framework takes data acquired from a laser scanner as inputs. After point cloud preprocessing, DBSCAN and PointNet++ perform semantic segmentation. On this basis, parameter extraction with logical reasoning derives the geometric parameters of the as-built pipelines, while spatial topology analysis is used to establish the mapping between point-cloud instances and BIM components. Finally, as-built parameters are used to automatically update the as-designed BIM model, thereby generating an updated as-built pipeline BIM. The details of each step are presented in the following sections.

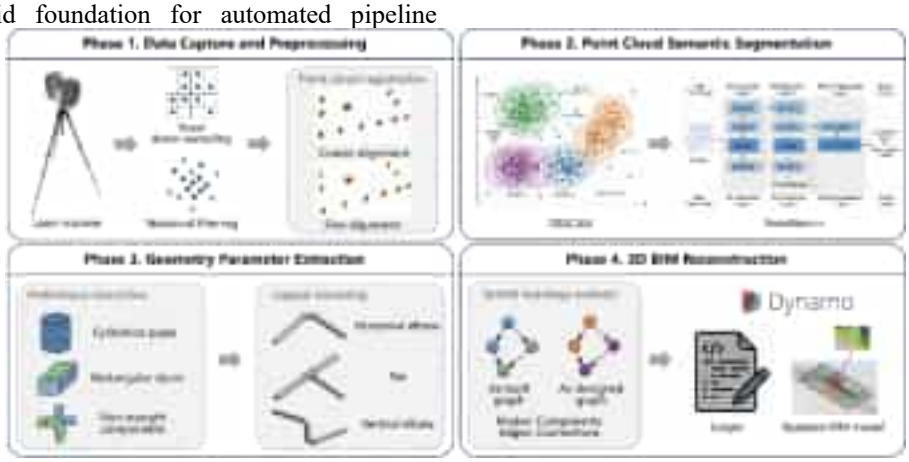

Figure 1. Proposed methodology framework

3.1 Data Capture and Preprocessing

High-quality point clouds are essential for accurate BIM updating, as they directly influence all subsequent steps. In MEP scenarios, dense and accurate laser scans enable reliable identification of pipeline geometry and connections, improving the robustness of BIM updating [17]. Point cloud quality primarily depends on the data acquisition strategy and preprocessing procedures, which together determine point density and noise level.

This study uses a terrestrial laser scanner (Trimble TX5) to obtain the as-built data of the MEP system, its detailed technical specifications are summarized in Table 1. Multi-station laser scanning is employed to ensure adequate coverage and to mitigate the impact of occlusions in indoor MEP environments. The raw point clouds are first preprocessed using voxel down-sampling with a grid size of 0.01 to reduce data redundancy while

preserving key geometric features, and then refined through statistical outlier removal to eliminate noise and irrelevant points. This process yields sparse and low-noise point clouds suitable for subsequent segmentation and parameter extraction.

Table 1. Characteristics of the Trimble TX5 Scanner

Laser Type	Parameters
Distance range	0.6-120 m
Accuracy	±2 mm@25 m
Angle range	Horizontal: 360°; vertical: 300°
Acquisition speed	Up to 976,000 pts/s

The coordinate system of the as-designed model is used as the reference for the workflow. Walls and columns, assumed to be consistent with the design, are selected as registration primitives to align the as-built point clouds. A combined registration strategy using Fast Global Registration (FGR) for coarse alignment and Iterative Closest Point (ICP) for fine alignment transforms the as-built pipeline point clouds into the design coordinate system, providing a reliable basis for further analysis [18].

3.2 Point Cloud Semantic Segmentation

After obtaining the as-built pipeline point cloud in unified coordinate system, it is necessary to segment and identify different pipeline components for parametric modeling. PointNet++ [19] is a widely used semantic segmentation network that samples centroids uniformly and aggregates local features through set abstraction layers. However, in complex MEP environments with large scale variation, large-diameter pipes dominate the sampled points, while small components are under-sampled. This causes the loss of critical local geometry for small parts and reduces segmentation accuracy. To address this limitation, this study proposes a two-stage semantic segmentation method that integrates DBSCAN with deep learning to better capture pipeline components across scales.

3.2.1 Density-Based Pipeline Clustering

To reduce scene complexity and improve sampling balance, this study first applies the DBSCAN algorithm [20] to segment the global point cloud into independent pipeline instances. DBSCAN identifies clusters by locating points that satisfy a minimum density criterion, controlled by the neighborhood radius (ϵ) and the minimum number of points. In MEP systems, pipelines are densely arranged but usually separated by small spatial gaps. By setting ϵ according to the minimum design clearance, DBSCAN clusters points from the same physical run into a single instance while discarding isolated noise. This separation allows each pipeline segment to be processed independently in the subsequent stage, avoiding feature interference from adjacent and unrelated structures.

3.2.2 PointNet++-Based Component Semantic Segmentation

Once individual pipeline instances are extracted via DBSCAN, the resulting segments are fed into PointNet++ model for fine-grained component recognition. This step classifies them into eight key categories: exhaust pipes, exhaust pipe elbows, exhaust pipe tees, air pipes, air pipe elbows, air pipe tees, water pipes and water pipe tees, covering the main elements in MEP layouts.

We construct a dedicated training set by collecting pipeline point clouds from multiple construction sites and manually composing them into diverse spatial layouts. Random translations, rotations and gaussian noise are applied to enhance robustness to sensor errors and scan-angle variations. The final dataset, summarized in Table 2, balances large pipes and small fittings.

Table 2. Dataset description

Label	Category	Train Set	Test Set
1	Exhaust pipe	158	40
2	Exhaust pipe elbow	120	32
3	Exhaust pipe tee	96	24
4	Air pipe	160	46
5	Air pipe elbow	138	40
6	Air pipe tee	96	24
7	Water pipe	180	48
8	Water pipe tee	122	32

In the segmentation stage, each isolated and normalized component is uniformly resampled to 8192 points, ensuring that even small parts retain sufficient point density. The network employs Multi-Scale Grouping (MSG) in its set abstraction layers to capture features across multiple radii, enabling it to learn both the geometry of straight pipes and the complex shapes of elbows and tees. Through feature propagation, local geometric cues are integrated with global context to assign a semantic label to every point. This instance-level strategy significantly improves overall performance and produces accurate component boundaries in dense MEP scenes.

3.3 Geometry Parameter Extraction

3.3.1 Preliminary extraction

For cylindrical pipe segments, RANSAC cylinder fitting algorithm is employed to robustly estimate the centerline and radius by minimizing the orthogonal distance between points and the cylinder surface. Once the axis direction is obtained, the pipe length is computed

by projecting all points onto the axis and measuring the distance between the two extreme projections.

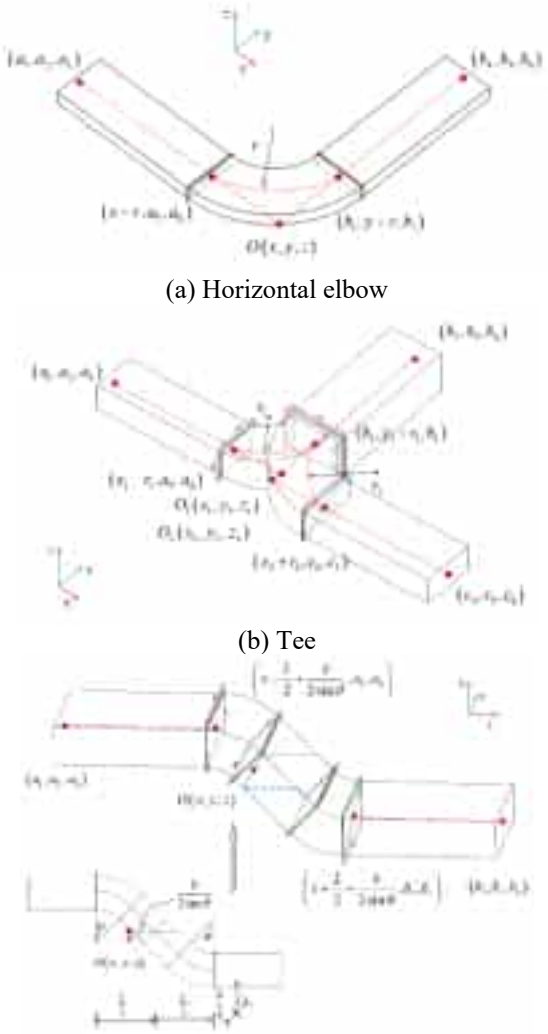
For rectangular pipes, RANSAC-based plane fitting algorithm is applied to extract the four main faces. The width and height are derived from the distances between opposing parallel planes, while the pipe orientation is inferred from the plane normal vectors.

For non-straight components such as elbows and tees, an indirect strategy is adopted. Insertion points and orientations are inferred from the intersections of centerlines of adjacent straight segments, ensuring topological consistency between fittings and pipes during reconstruction.

3.3.2 Correction Based on Logical Reasoning

However, geometric parameters extracted directly from point clouds are often affected by noise, occlusions and fitting errors, resulting in joint gaps. To address this, a logical reasoning scheme adjusts the as-built parameters based on engineering constraints and as-designed data. As shown in Figure 2, the reasoning rules are defined for three types of connections.

If two pipes are connected by a horizontal elbow, we first extend the central axis of the two pipes. Then we calculate the intersection of the two center axes, which can be thought of as the center coordinates of the elbow. Next, we correct the endpoint coordinates of the two pipes by analyzing the known radii in Figure 2(a). The final coordinate formulas are shown below, where r represents the standard elbow radius from as-designed model, x and y represent the calculated horizontal elbow center coordinates, a_5, a_6, b_1 and b_3 represent the original endpoint coordinates.



$$(x - r, a_5, a_6) \quad (1)$$
$$(b_1, y + r, b_3) \quad (2)$$

If two pipes are connected by a tee, we first find the three pipe endpoints around the tee, and distinguish the three pipes into two main pipes on a straight line, and a separate branch pipe. Then, we find the two intersection points of the central axis of the branch pipe and the central axis of each main pipe respectively. Next, we match the two radii with intersection and pipe, so the pipe endpoint coordinates are corrected by analyzing the known radii as shown in Figure 2(b). The inference formulas are as follows, r_1 and r_2 are two known radii of the tee in the as-designed model, x_1, x_2 and y_1 are the calculated center coordinates of the tee, a_5, a_6, b_1, b_2, c_2 and c_3 represent the endpoint coordinates.

$$(x_1 - r_1, a_5, a_6) \quad (3)$$
$$(b_1, y_1 + r_1, b_3) \quad (4)$$
$$(x_2 + r_2, c_2, c_3) \quad (5)$$

If two pipes are connected by upper and lower elbows, we first calculate the horizontal plane between the upper and lower pipes by deriving the central axis of the two pipes. Then we exploit the RANSAC algorithm to extract the cuboidal extent of the elbow horizontal section based on the horizontal plane. Next, we extract the line perpendicular to the tube axis at the edges of the horizontal plane and take their midpoints as standard points as Figure 2(c) shows. Afterwards, we correct the endpoint coordinates by the formulas. L, h and θ represent the horizontal distance, height and curve angle of the upper and lower elbows respectively in the as-designed model, x represents the calculated standard coordinate of elbow and a_5, a_6, b_2, b_3 represent the original coordinates.

$$\left(x - \frac{L}{2} + \frac{h}{2sin\theta}, a_5, a_6\right) \quad (6)$$
$$\left(x + \frac{L}{2} + \frac{h}{2sin\theta}, b_2, b_3\right) \quad (7)$$

(a) Horizontal elbow

(b) Tee

(c) Vertical elbow

Figure 2. Logical reasoning mathematical analysis

The logical reasoning module processes all detected connections in the pipeline network. For each connection node, the module first retrieves the corresponding connector type and its standard size from the as-designed BIM model, then applies the corresponding reasoning rules, and updates the endpoint coordinates of the pipeline accordingly. When the same pipeline involves multiple corrections, the corrections will be carried out sequentially, and the final coordinates are calculated according to the weighted average of the confidence of each connecting node. This iterative optimization process transmits geometric constraints to the entire network, effectively eliminating the cumulative error.

3.4 Graph Isomorphism and Modeling

3.4.1 Spatial Topology Analysis

To establish correspondence between as-built point cloud components and as-designed BIM elements, both datasets are represented as directed graphs. In each graph, vertices denote pipeline components, while directed edges encode physical connection from pipes to connectors based on spatial adjacency. The construction of the as-built graph is based on the segmented point cloud instances. The as-designed graph is generated from the BIM model by extracting component attributes and predefined connection relationships.

Graph matching is performed through a topology guided search strategy. First, candidate node pairs are initialized based on component type consistency and similarity of geometric attributes such as diameter, length and orientation. To reduce ambiguity in repetitive pipeline layouts, node degree and local connection patterns are further used as pruning constraints.

Starting from distinctive seed components, the matching process incrementally propagates along connected branches of the pipeline network. During traversal, each potential correspondence is verified by jointly evaluating geometric compatibility and topological consistency. Backtracking is applied when conflicts occur, ensuring a one-to-one mapping between the as-built graph and the design graph. The resulting correspondence enables automatic transfer of geometric parameters to the as-designed BIM model.

3.4.2 3D BIM Reconstruction

In the final stage, we use parametric programming in Dynamo to update the pipeline BIM model so it matches the as-built data. Dynamo scripts import the updated start and end coordinates, as well as the size and type of each pipe, elbow, and tee. Using the mapping between point cloud instances and as-designed BIM components, the system then automatically updates the corresponding parameters in the prefabricated family library.

4 Results and Discussion

To evaluate the feasibility of the proposed framework, we conducted a case study on standard floor A1# of a shopping center. The environment features a complex MEP layout with narrow spaces and densely distributed pipelines. The scene includes eight types of pipeline components, such as air pipes, exhaust pipes, water pipes and their corresponding elbows and tees. Its complexity is further increased by severe occlusion: 16 pipes are blocked by others, 5 pipes overlap, and 8 connectors are heavily covered. This challenging scenario provides a rigorous test platform for assessing the framework's capability to update the pipeline BIM model based on the as-built point cloud and the as-designed model.

4.1 Point Cloud Collection and Processing

As shown in Figure 3, the acquired point cloud provides comprehensive coverage of the pipeline system despite severe occlusion. After registration, the point cloud achieved accurate alignment with the designed model. The RMSE decreased from 0.16m to 9.97×10^{-3}m, demonstrating effective spatial consistency. This precise alignment establishes a reliable basis for subsequent processes. The registration results are illustrated in Figure 4.

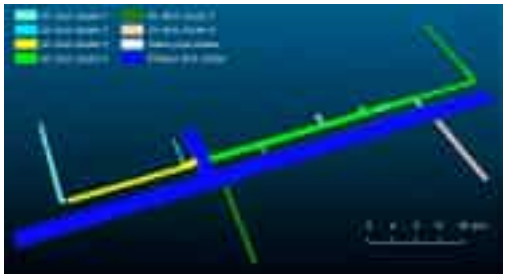
4.2 Point Cloud Segmentation



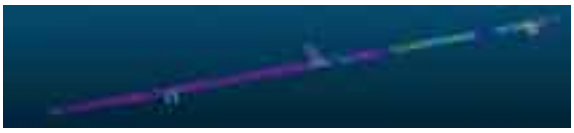


Figure 5. DBSCAN initial segmentation result

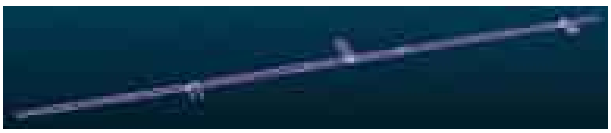

We integrated DBSCAN clustering with PointNet++ for semantic segmentation. With a radius of 0.025m and a minimum of 20 points, DBSCAN partitioned the point cloud into 8 clusters and removed 1,185 noise points (Figure 5). These clusters were subsequently processed by PointNet++, achieving an overall accuracy of 95.85%.

Figure 6. Water pipeline point cloud segmentation results

Figure 6 compares the water pipeline segmentation results in three cases: the actual scene (Figure 6(a)), PointNet++ alone (Figure 6(b)), and the combined DBSCAN-PointNet++ method (Figure 6c). Figure 7 further demonstrates successful instance segmentation of exhaust pipes, elbows and tees.

(a) Pipes

(b) Elbows

(c) Tees

Figure 7.Exhaust pipeline point cloud segmentation results

Table 3. PointNet++ segmentation results with DBSCAN and without DBSCAN

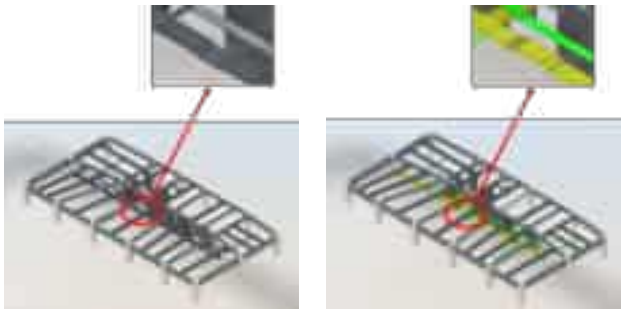
Type	Without DBSCAN			With DBSCAN		
	Precision (%)	Recall (%)	IoU (%)	Precision (%)	Recall (%)	IoU (%)
Exhaust pipe	94.35	93.62	88.65	97.48	94.13	91.89
Exhaust pipe elbow	48.94	94.67	47.63	89.72	91.83	83.09
Exhaust pipe tee	71.58	82.89	62.36	70.80	73.93	56.66
Air pipe	94.69	95.20	90.37	98.90	98.92	97.84
Air pipe elbow	62.19	46.70	36.37	80.28	74.85	63.22
Air pipe tee	40.82	90.59	39.16	59.72	94.11	57.57
Water pipe	96.55	90.92	9.89	99.31	97.18	96.53
Water tee	52.31	82.90	11.54	53.85	83.85	48.79
Average	70.18	65.81	48.25	81.26	88.60	74.45

Using DBSCAN as a preprocessing step proves particularly effective in complex MEP scenes with significant scale variations, where PointNet++ alone often fails to capture data from small pipes. As shown in Table 3, the configuration with DBSCAN improves performance across all categories. For example, precision for air pipe elbows increases from 62.19% to 80.28% and recall for water tees rises from 82.90% to 83.85%. These results demonstrate the robustness of the proposed two-stage semantic segmentation strategy.

4.3 Geometry Parameter Extraction

Geometric parameters were first extracted via the RANSAC algorithm. However, initial extraction exhibited noticeable spatial errors. These were substantially reduced by applying the proposed logical reasoning module, which corrects pipe endpoints using known connector parameters from the as-designed model. Table 4 shows the resulting average coordinate errors.

Table 4. Average Coordinate Error of Different Pipes



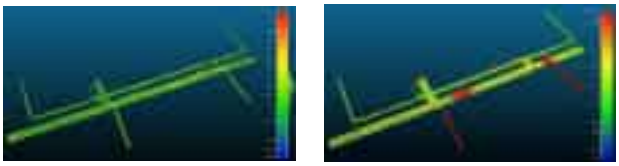
Types		Average spatial coordinate error		
		x (m)	y (m)	z (m)
Cuboidal exhaust pipes	Initial	0.114	0.022	0.002
	Corrected	0.009	0.002	0.002
Cuboidal air pipes	Initial	0.027	0.026	0.003
	Corrected	0.010	0.011	0.003
Cylindrical water pipes	Initial	0.023	0.025	0.003
	Corrected	0.003	0.003	0.003

The results indicate that using RANSAC alone is

often insufficient due to point cloud noise and occlusion, leading to misalignment between pipes and connectors. By mathematically inferring correct endpoints from connection relationships, the logical reasoning module effectively mitigates this issue. The result of errors generally below 0.01 m demonstrates the advantage of incorporating prior knowledge from the as-designed model over purely geometric methods, ensuring both complete and accurate connections.

4.4 Graph Isomorphism and Modeling

To automate the modeling process, spatial topology analysis was performed. Two directed graphs were constructed: one representing the logical structure of the as-built point cloud and the other corresponding to the as-designed BIM model. Graph isomorphism analysis established a one-to-one mapping between point cloud instances and BIM components. Based on this mapping, parametric programming was used to automatically update the geometric parameters. Figure 8 visually compares the as-designed BIM model (Figure 8(a)) with the updated BIM model (Figure 8(b)), demonstrating the success of reconstruction.



(a) As-designed (b) Updated

Figure 8. Pipeline BIM model

This step bridges the gap between geometric data and semantic BIM objects. By representing the pipeline network as a directed graph, the framework resolves the correspondence problem, enabling precise association between each BIM element and its corresponding extracted parameters. This automated mapping streamlines the transition from raw data to an information-rich BIM model, which is essential for the framework's practical application.

4.5 Precision and Efficiency Analysis

Our framework was evaluated in terms of both modeling accuracy and time efficiency. Deviation analysis between the updated BIM model and the laser-scan point cloud is presented in Figure 9(a). Errors followed a normal distribution, with over 90% of points exhibiting deviations under 0.03 m and an average deviation of only 0.0046 m. Figure 9(b) further compares the output with the original as-designed model, clearly indicating areas where on-site modifications were made. A significant gain in efficiency was achieved. Whereas traditional manual modeling for a scene of this complexity typically takes 3-5 days, our framework completed the update in only 3 hours, corresponding to a time reduction of nearly 90%. This demonstrates that the proposed framework offers an accurate and efficient solution for updating as-designed pipeline BIM models.

(a) Deviation distribution (b) Designed vs updated

Figure 9. Model comparison

5 Conclusion and Future Work

This study proposes and validates an automated framework for bridging as-designed BIM models with as-built point cloud data. By integrating two-stage semantic segmentation, parameter extraction with logical reasoning and graph isomorphism analysis, the framework addresses key challenges in complex MEP environments, including severe occlusion, multi-scale components and automated semantic association. Validation using a real-world shopping center case demonstrates that the proposed method can robustly update high-fidelity BIM models that accurately capture on-site conditions.

The results indicate that the hybrid segmentation strategy substantially enhances the detection of small-scale pipelines in cluttered scenes, effectively mitigating the loss of detail associated with conventional approaches. Moreover, by incorporating prior design knowledge through logical reasoning instead of relying solely on geometric fitting, the updated models preserve logical connectivity and topological correctness even when the raw data are imperfect. In addition, graph isomorphism analysis enables automated mapping between point-cloud instances and BIM elements, streamlining the workflow and reducing the time and labor required for manual modeling, while still meeting the accuracy requirements of facility management.

It is important to emphasize that in this study, the term automatic mainly refers to the automated updating of pipeline BIM components after data input and parameter initialization. Although several preprocessing parameters are defined according to engineering experience, the framework eliminates manual modeling operations and enables efficient generation of an updated BIM model.

Despite these contributions, several limitations warrant further research. First, the framework targets

standard pipeline geometries, future work should expand the component library to cover more complex MEP elements, such as valves and pumps. Second, while terrestrial laser scanning is highly accurate, adding complementary data sources such as photogrammetry or handheld SLAM could improve completeness in narrow or occluded areas. Finally, extending the algorithms toward processing in near real time would support quality control during construction by enabling immediate detection and correction of deviations.

Abstract

Modern residential occupants require their affective intents to be reflected in spatial design to achieve satisfaction. However, current generative architectural design studies focus on morphological and functional requirements, overlooking affective intent. This study proposes an affective user requirements realignment framework for automated, minimally disruptive spatial design revision based on Optimal Transport. The proposed BIM-integrated framework (i) represents spatial experience as a multidimensional affective distribution derived from 1,638 annotated responses across 54 parametric configurations, (ii) predicts the distribution from discrete design parameters using a lightweight Transformer regressor, and (iii) selects a minimally disruptive revision via entropic-regularized Wasserstein distance to a user-specified target affect across 6,480 candidate configurations. The selected parameter set is automatically applied through a Revit C# add-in to support closed-loop design review. Results demonstrated consistent convergence toward target affects (reduction: 0.036–0.290) with positive directional alignment across all ten affective dimensions (mean cosine similarity = 0.502), demonstrating the feasibility of affect-preserving revision in BIM workflows as a proof-of-concept.

Design Review, User-Centered Design, Automation, Affective Design, User Requirements.

1 Introduction

Residential architecture has moved beyond meeting morphological and functional needs to accommodate the psychological and emotional expectations [1]. Homes are now considered as personal environments that shape routines, well-being, and identity [2], which increases the pressure to improve the collection and integration of emotional requirements into design workflows. However, most residents lack architectural vocabulary and spatial literacy; therefore, they express their needs through narratives and subjective impressions rather than parametric terms [3]. Feedback such as “the room feels too small” conveys a strong experiential meaning, but is difficult to translate into quantifiable interventions, creating a persistent interpretive gap and risking the loss of user intent [4,5]. Although environmental psychology and neuroarchitecture link built features to emotional responses, real spaces involve tightly interdependent relationships between geometry, materiality, lighting, and atmosphere, making single-variable interpretations unreliable [6,7].

Recent advances in generative Artificial Intelligence (AI) have improved early stage option generation and communication [8]. However, most studies emphasize generation, rather than the more practically critical problem of revision. Revisions require interpreting feedback, preserving design intent, respecting constraints, and maintaining coupled spatial relationships [9]. This is economically important because early design phases account for a large share of the total design/documentation effort; thus, emotional misalignments discovered later can trigger costly rework or discourage necessary changes.

Accordingly, this study focused on affective design revisions in Building Information Modeling (BIM) environments by formulating emotional requirements as explicit affective targets. Rework has been shown to contribute to over 50% of total cost growth in construction project [10], and economic analysis of BIM-based high-rise project have directly quantified design errors as causing 5–20% rework overhead [11]. Those phenomena underscore the economic importance of addressing design intent misalignments early in the review process. To ensure clarity and reproducibility in design review contexts, user input is operationalized as the selection of a predefined affective dimension, allowing the revision process to concentrate on distribution-aware optimization and minimal design modification, rather than linguistic interpretation.

2 Related Studies

2.1 AI Application in Architectural Design Alternatives

The integration of generative AI into architectural workflows transforms traditional decision-making processes. Notably, generative design introduces an AI-powered approach that combines engineering design principles with cloud computing to automatically generate and optimize options based on parameters such as materials, dimensions, and cost constraints. In architectural designs, this approach has been extended to generate reference imagery [8], photorealistic interior visuals [12], and exterior façade designs guided by layout sketches and prompts [13].

The deep learning models employed in these efforts include generative adversarial networks (GANs), diffusion models, and transformers. GANs and diffusion models are particularly effective in image-to-image generation tasks such as diagram alterations and style transfer [14], with diffusion models suited to high-resolution rendering via platforms such as Dream Studio [15]. Transformer-based models, such as generative pre-trained Transformer, specialize in text processing for code generation, design documentation, and javascript object notation BIM object creation [16].

Generative modeling techniques are frequently used in BIM-based research. Studies including computer aided design-to-BIM automation [17] and conversational BIM agents coupled-GAN [18] have demonstrated the efficiency of generating certain objects or resources in BIM-based workflows. These studies highlight the need for multimodal inputs and a semantic pipeline to derive architectural variables for integration into structured BIM. However, generative models focus on generating outputs from zero-based scenarios; therefore, examining the efficiency of revising BIM-based workflows is required.

2.2 User Requirements Realignment

Architectural design is a tightly coupled system. Changing one element (e.g., window size, and ceiling height) can trigger cascading and unintended effects elsewhere; therefore, revision cannot be treated as a wholesale replacement without risking damage to the already successful aspects of the design [4]. Preserving design intent, including both explicit architectural decisions and implicit experiential coherence, is therefore essential because even small edits can disturb spatial harmony, function, and emotional responses [19]. Neuroarchitecture and environmental psychology further demonstrate that affective experiences emerge from multifeatured interactions (e.g., geometry, materiality, lighting, and enclosure), implying that selective change while maintaining stability in other dimensions is generally necessary [20].

This motivates distribution-aware revision. Instead of optimizing a single scalar target, the goal is to move the predicted affective distribution toward the user's intended distribution with minimal collateral displacement [21]. Information-theoretic divergences such as Kullback-Leibler and Jenson-Shannon [22] and overlap-based metrics such as Hellinger and Bhattacharyya [23,24] can quantify mismatch; however, they consider probability shifts as pointwise differences and do not encode how "far" mass moves between affect categories. This is a key limitation of minimal-change design control, in which only a subset of attributes should shift.

Optimal transport (OT) addresses this problem by endowing distributions with geometry. The Wasserstein (Earth Mover's) distance measures the minimum "work" required to transport probability mass between distributions given a ground-cost matrix capturing inter-label distances, making it well suited to small, selective, and cost-aware revisions [25]. Entropic regularization and Sinkhorn-based approximations enable fast and differentiable computation inside iterative optimization loops [26], with theoretical support for stability and sample behavior [27]. Overall, although classical divergences are lightweight, OT-based metrics model label-space transitions more directly, providing a stronger foundation for revision systems that adjust target affects while preserving the other components.

3 Proposed Methods

3.1 Research Framework

The framework began by allowing the user to select a target affective dimension encoded as a target affective distribution. A transformer regressor predicted the affective distributions for candidate spatial configurations, and an OT) module evaluated all 6,480 parametric design vectors (Ceiling Height:8 × WWR:10 × CCT:9 × Floor:3 × Color:3), by computing the Wasserstein distance (WD) from the target. A design with the minimum transport cost was selected, providing a distance-based ordering of alternatives and quantifying the minimal parameter change required to align the predicted affect with the user's intent.

3.2 Design of Experiment

3.2.1 Design Variable Selection

Emotional responses to architectural space originate from the combined effects of multiple spatial features, rather than isolated parameters. Previous studies in environmental psychology, interior architecture, and neuroarchitecture have consistently identified lighting

conditions, materiality, openness, and enclosure-related variables as dominant contributors to affective experiences in residential interiors. In particular, lighting attributes such as correlated color temperature (CCT) and luminance balance regulate arousal and comfort, whereas window-to-wall ratio (WWR) and ceiling height influence perceived openness and spaciousness. The material and surface color further modulate warmth, calmness, and overall valence.

Based on accumulated evidence, five interior design variables were selected for this study: ceiling height, WWR, CCT, room color, and floor material. These variables are strongly associated with emotional evaluations in residential spaces, making them suitable for controlled affective design experiments [28–30].

3.2.2 Affective Annotation

A systematic affective annotation procedure was conducted to construct a dataset linking spatial design parameters to human affective responses. The process began with the development of domain-grounded affective vocabulary. Drawing on environmental psychology, interior architecture, and neuroarchitecture, 22 affective adjectives were initially extracted from previous empirical studies [29–31].

Using four thesaurus expansion steps, synonyms and near-synonyms (e.g., happy-pleasant) were grouped, and semantically redundant terms were merged. Subsequently, the KJ clustering method was applied to identify conceptual clusters and remove ambiguous or overly broad terms. This process resulted in a final set of ten affective vocabularies closely aligned with the spatial experience: pleasant, exciting, cozy, spacious, attractive, simple, bright, open, calm, and comfortable.

3.2.3 Experimental Design

A parametric BIM environment was constructed using Autodesk Revit 2023 to generate the controlled interior design stimuli. The model represented a typical urban apartment living unit common in high-density residential developments with base dimensions of 4380 × 7440 × 2300 mm. The geometry was intentionally simplified to isolate the perceptually salient variables and minimize confounding architectural factors.

Full factorial combinations of the variables yielded 243 possible configurations. An L27 fractional factorial design was adopted to reduce redundancy, while preserving orthogonality. An additional 27 configurations were selected using the cyclic shift method to ensure uniform coverage of the multidimensional design space. In total, 54 interior design stimuli were labeled with their corresponding design vectors.

3.3 Inference Module: Affect-Spatial Elements Mapping

Each design configuration x_i was defined using five parameters: ceiling height, WWR, CCT, floor material, and room color. To ensure compatibility with the learning model $f_\theta(x)$, the data were encoded and normalized as follows. The continuous variables (ceiling height, WWR, CCT) were standardized using a StandardScaler, and the categorical variables (floor material, room color) were one-hot encoded with the first category dropped, yielding a 7-dimensional input vector.

For each configuration, the affective response vector α_i consisted of 10 ratings normalized to [0, 1]. To support OT-based computation, the ratings were further normalized into a probability distribution.

$$\alpha_i' = \frac{\alpha_i}{\sum_{k=1}^{K} \alpha_{i,k}}, K = 10, \sum_{k=1}^{K} \alpha_{i,k}' = 1 \quad (1)$$

A lightweight Transformer regressor was trained on all 54 design configurations to predict multidimensional affective responses from spatial design variables. Model selection and performance estimation were conducted using Leave-One-Out Cross-Validation (LOOCV), the statistically appropriate method for the design-level dataset size. The one-hot encoded design vector was projected onto a 64-dimensional embedding space. Learnable positional encoding was added and treated as a single-token sequence for the transformer processing. The embedding was then passed through a three-layer transformer encoder, where each layer included four-head self-attention, a 128-dimensional feed-forward network, and residual connections with layer normalization, enabling the model to learn nonlinear interactions among the design attributes.

Finally, a two-layer regression head (64→128→10) output continuous scores for the ten affective dimensions. Overall, the model mapped discrete design parameters onto a compact latent space, captured their interdependencies via stacked self-attention, and predicted the affective distribution of each configuration.

3.4 Optimizer Module: Entropic-Regularized Wasserstein Distance

The affective intent selected by the user determines the affective distribution of the target (P^*). When a user expresses a desire to increase or decrease a specific affective dimension, the corresponding component of the distribution is adjusted proportionally, followed by normalization.

$$P^* = \text{Normalize}(P + \Delta) \quad (2)$$

where Δ denotes the user-intended directional change. This normalized vector is the optimization objective of

an OT-based search.

For each spatial design vector x in the Space-Affect database, the transformer regression model $f_\theta(x)$ predicts its affective distribution.

$$Q_x = f_\theta \tag{3}$$

Thus, each candidate design produced a probability distribution over the same 10 affective dimensions as the target.

To quantify the discrepancy between the target affect distribution P^* and each predicted distribution Q_x, the WD was computed using the entropy-regularized Sinkhorn divergence [25].

$$W_\varepsilon(P^*, Q_x) = \min_{\Gamma \in U(P^*, Q_x)} \langle \Gamma, M \rangle + \varepsilon \mathrm{KL}(\Gamma \parallel P^{*} \otimes Q_x) \tag{4}$$

where $U(P^*, Q_x)$ denotes the set of admissible transport plans, M is the ground cost matrix and ε controls the entropy regularization strength. A uniform ground metric ($M_{ij} = 0$ and $M_{ij} = 1$ for $i \neq j$) was adopted as no validated psychometric distance exists for the architectural affective space and inter-affect correlations are uniformly high (mean r = 0.799), making the uniform metric the most conservative prior. The Frobenius inner product formulation enables linear-time Sinkhorn iterations and stable gradient propagation through $f_\theta(x)$.

Because the design space contained all 6,480 possible combinations, the optimizer evaluated the Sinkhorn distance for every candidate x.

$$\mathrm{x}^* = \arg\min_{x \in X} W_\varepsilon\,(P^8, Q_x) \tag{5}$$

where X denotes the full Cartesian product of all design variable attributes. This guarantees that the returned configuration is a globally optimal design vector with respect to the target affect.

3.5 Evaluation Metrics

3.5.1 Affect-Spatial Elements Mapping Evaluation

The proposed regression model was evaluated using metrics that captured the overall error magnitude, proportionality, and explanatory power. As a single metric can be misleading, particularly when targets differ in scale or when large errors are costly, we used five standard regression measures: mean absolute error (MAE) and R^2. MAE measures the average absolute error.

$$\mathrm{MAE} = \frac{1}{n}\sum_{i=1}^{n} |y_i - \hat{y}| \tag{6}$$

It expresses errors as percentages, enabling comparisons across affective dimensions within different ranges. Finally, R^2 measures the proportion of variance explained by the model.

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(y_i - \hat{y})^2}{\sum_{i=1}^{n}(y_i - \bar{y})^2} \tag{7}$$

Higher values indicate a stronger overall fit. Together, these metrics provide a balanced assessment of multidimensional affective regression performance.

3.5.2 Optimization Evaluation

Two complementary success criteria were defined: (i) positive WD reduction, the optimized design achieves a lower WD to the target distribution than the initial design; and (ii) positive directional alignment, cosine similarity > 0 between the intended and actual affective shift direction. WD reduction measures how effectively optimization decreases the discrepancy between the target affective distribution P^* and the predicted distribution Q_x.

$$\mathrm{Reduction} = \frac{W_\varepsilon(P^*, Q_{init}) - W_\varepsilon(P^*, Q_{final})}{W_\varepsilon(P^*, Q_{init})} \tag{8}$$

where Q_{init} and Q_{final} denote the initial and optimized affective states, respectively. Values closer to 1 indicate stronger affective convergence toward the target [25,26].

To assess the directional consistency with user intention, a perceptual alignment score was defined using the cosine similarity between the intended affective shift and the predicted shift.

$$\mathrm{Alignment} = \cos\big((P^* - P), (Q_x - P)\big) \tag{9}$$

A value close to 1 indicates strong alignment with the target affect, whereas negative values indicate a deviation from the intended direction [32].These metrics ensure that optimized revisions are both affectively closer to the target state and directionally consistent with user intent.

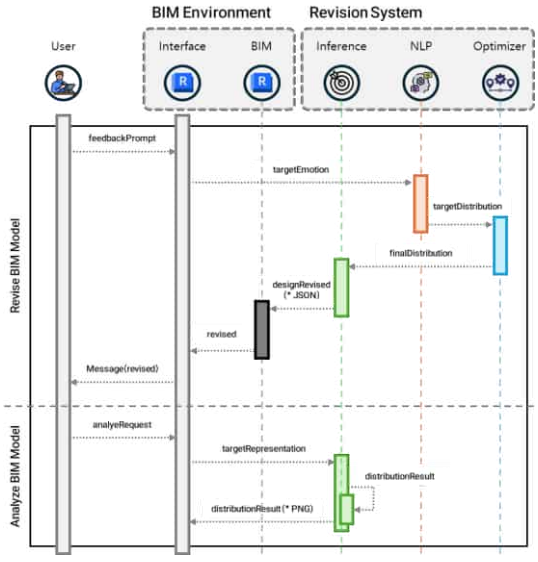

Figure 1. Proposed UML sequence diagram

3.6 BIM Add-in Application

The proposed system for affective design automation was fundamentally instantiated as a cohesive Revit add-in and entirely implemented using C# application programming interface (API) within the Visual Studio Environment. This integral implementation ensures seamless interaction with the BIM, minimizes data latency, and maximizes efficiency within the design workflow [18]. The comprehensive data flow and interlayer communication of this closed-loop system are precisely depicted using a Unified Modeling Language (UML) sequence diagram (Figure 1**Error! Reference source not found.**), which illustrates the sequential interactions among its modular components. This architectural approach directly integrates advanced computational modules into a commercial BIM platform.

4 Results

4.1 Inference Module Results

A total of 182 participants (male: 106, 58.2%, female: 76, 41.8%, age: 35.2±11.7, range 17–63) were recruited across architecture-related (n=70, 38.5%) and non-architecture (n=112, 61.5%) backgrounds, yielding 1,638 affective responses. The internal consistency of the ten affective scales was confirmed with Cronbach's α = 0.938. One-way analysis of variance confirmed statistically significant design condition effects across all ten affective dimensions (F=3.70–11.76, $p < .001$).

To justify the architectural choice of the Transformer regressor, 29 models across seven categories were systematically compared using LOOCV in Table 1. The Transformer (d = 32, nhead = 4, L = 1) achieved the highest overall LOOCV R^2 = 0.588 (MAE = 0.367), outperforming XGBoost (R^2 = 0.576), Gaussian Process-Matern (R^2 = 0.540), and MLP networks (R^2 = 0.352). Beyond predictive accuracy, tree-based XGBoost produced step-function prediction, collapsing to identical values for unseen parameter combinations. Since the OT optimizer searches intermediate values, smooth interpolation is structurally required, making the Transformer the appropriate model.

As shown in Table 1, the Transformer achieved LOOCV R^2 ranging from 0.483 (cozy) to 0.705 (open), with a mean of 0.588. Strong performance was observed for open (0.705), pleasant (0.685), spacious (0.640), attractive (0.636), and bright (0.593), indicating that these dimensions are well captured by the five spatial variables. Excitement (0.531), cozy (0.492), and calm (0.489) showed relatively lower explanatory power, attributable to high within-condition individual variance in these affective dimensions rather than model limitations.

Table 1. Top 10 model comparison using LOOCV.

Model	LOOCV R^2	MAE	Style
TF (d=32, h=4, L=1)	**0.588**	**0.367**	**Smooth**
XGBoost (d=3, n=100)	0.576	0.368	Step
GP (Matérn 1.5)	0.560	0.384	Smooth
RF (n=50, d=5)	0.546	0.381	Step
GBR (n=50, d=3)	0.544	0.385	Step
Ridge (α=1)	0.540	0.392	Linear
Lasso (α=0.01)	0.536	0.392	Linear
GP (Matérn 2.5)	0.534	0.389	Smooth
BayesianRidge	0.534	0.395	Linear
SVR (rbf, C=10)	0.503	0.415	Kernel

4.2 Optimizer Module Results

Across the ten affective categories, the optimization framework consistently reduced the WD to the target distribution, indicating that it can adjust the design variables to decrease the overall affective mismatch. As reported in Table 2, the reduction values ranged from 0.036 to 0.290, indicating meaningful convergence, even within a discrete and limited design space.

Table 2. Performance of the optimizer module

No.	Initial	Target	Final	Red.	Align.
1	0.106	0.255	0.118	0.078	0.388
2	0.092	0.243	0.129	0.247	0.941
3	0.085	0.237	0.108	0.143	0.437
4	0.099	0.249	0.132	0.215	0.699
5	0.126	0.272	0.168	0.290	0.732
6	0.095	0.246	0.111	0.100	0.346
7	0.109	0.258	0.132	0.148	0.373
8	0.082	0.235	0.118	0.232	0.734
9	0.106	0.255	0.115	0.064	0.221
10	0.100	0.250	0.107	0.036	0.150

Note: 1=Cozy, 2=Bright, 3=Excitement, 4=Open, 5=Simple, 6=Pleasant, 7=Spacious, 8=Attractive, 9=Calm, 10=Comfortable

The largest reductions (Red.) were achieved for simple (0.290), bright (0.247), and attractive (0.232), suggesting that these affects were highly responsive to the available physical variables. Spacious (0.148), excitement (0.143), and pleasant (0.100) exhibited moderate improvements, whereas cozy (0.078), calm (0.064), and comfortable (0.036) showed smaller but still positive reductions. The variation in reduction magnitude reflects differences in how sensitively each affective dimension responds to the five design variables.

The directional change was further examined using the alignment metric (Align.), which measures the cosine similarity between the intended affective shift direction and the actual distributional change. Positive alignment was achieved across all ten affective dimensions (mean = 0.502), with particularly strong alignment for bright

(0.941), attractive (0.734), simple (0.732), and open (0.699), confirming that the optimizer reliably moved the affective distribution in the intended direction. Moderate alignment was observed for cozy (0.388), spacious (0.373), and pleasant (0.346), while calm (0.221) and comfortable (0.150) exhibited weaker directional consistency, reflecting the limited sensitivity of these dimensions to the five parametric variables considered. Notably, all alignment scores were positive, indicating that the optimization consistently produced directionally appropriate adjustments without counterproductive shifts.

4.3 Revit API-based Design Revision

This section describes the sequence of steps, target emotion selection, inference, optimization, and the final application of design changes. The efficacy of the add-in was demonstrated by comparing pre- and post-revision affective distributions. The initial spatial parameters of the design case study are listed in Table 3.

Table 3 Initial and revised design parameters

Variables	Initial Design	Revised Design
Ceiling Height	2.7m	2.8m
WWR	30%	90%
CCT	2700K	3500K
Room Color	Gray	White
Floor Material	Tile	Tile

4.3.1 Initial Design Analysis

The add-in performed an objective analysis of the current design state. This involved utilizing a pretrained affective prediction model to estimate the distribution of the 10 affective dimensions induced by the initial spatial configuration. This initial analysis served as the baseline for the design and was used to benchmark the improvement in the target affective dimension after revision. At this stage, the system primarily generated the current affective profile without setting a specific optimization goal. An example of the initial design analysis is shown in Figure 2.

4.3.2 Design Revision Optimization

This module employed a retrieval-based optimization algorithm using the affective prediction model as its objective function to explore new combinations of the five spatial variables. The evaluation of the optimization used an OT-based method to calculate the distance between the affective distributions. In this case, the search successfully identified a revised combination of parameters that achieved the required increase in 'bright' while maintaining the overall coherence of the affective distribution. Based on these, revised design parameters were retrieved from the inference layer and are presented in **Error! Reference source not found.**.

4.3.3 Apply and Reset

Finally, the optimized spatial parameters were automatically applied to the BIM parameters. Following this automatic modification, the system captures the viewpoint image of the revised design. The user is then presented with this rendering, along with the predicted affective distributions, to make a final decision.

The primary validation of the system was a comparison of the initial and revised affective distributions. As shown in Figure 3, the 'bright' score significantly increased in the revised design compared to the initial states. This improvement validated the proposed methodology. Based on the visualization of the rendering and affective data, the user can choose to apply or reset the revised design.

Figure 2. Revit API UI for initial BIM Analysis

Figure 3. Revit API UI for Revised Design

5 Discussion

This study demonstrated the proof-of-concept that affective design revision can be formulated as a distribution-alignment problem rather than a single-variable optimization task. The use of OT provides a principled mechanism for reducing unintended affective shifts, with the degree of collateral affective displacement varying across dimensions. The revised results demonstrate consistent positive WD reduction and directional alignment across all ten affective dimensions, empirically supporting the framework's validity as a proof-of-concept.

The uniform ground metric was adopted because no

validated psychometric distance exists for the architectural affective space, inter-affect correlations are uniformly high (mean r = 0.799), and the uniform metric constitutes the most conservative prior. A sensitivity analysis comparing three cost matrix formulations yielded 70% agreement in optimal design selection, with the uniform metric performing consistently in all discordant cases. Future work may explore empirically grounded cost matrices derived from affective space or psychometric scaling.

This work differentiates itself from three prior streams. BIM optimization studies have targeted structural or cost-based objectives, whereas this work introduces multidimensional affective distributions as the optimization criterion within an automated revision loop. Affective design studies characterize space–emotion relationships without closing the loop into parametric revision, which this work achieves end-to-end. OT applications in affective computing have used Wasserstein distance as a training loss, whereas here OT serves as a design search criterion over a smooth, interpolable 6,480 candidate landscape, made possible by the Transformer's continuous interpolation for unseen parameter combinations. The current exhaustive search guarantees global optimality at negligible computational cost (< 1 ms); scaling to continuous spaces will require Bayesian optimization, differentiable Sinkhorn layers, or reinforcement learning-based exploration.

Perceptual validation through user studies and open-ended natural language feedback interpretation remains critical directions for future work, alongside assessments of design coherence and system usability.

6 Conclusion

This paper presents a BIM-integrated framework for automating affective design revision using optimal transport theory. By linking parametric spatial variables with predicted affective distributions, the proposed method enables designers to enhance selected emotional qualities while reducing unintended distributional displacement in most affective dimensions. The framework was implemented as a Revit add-in, demonstrating its technical feasibility within existing BIM-based design workflows.

The results suggest that optimal transport provides a promising, mathematically grounded foundation for affective design revision, as demonstrated in this proof-of-concept implementation. Although the current framework operates on a discrete set of five spatial variables and ten affective dimensions, it establishes a proof-of-concept foundation for future user-centered design automation. The proposed approach bridges the gap between user affective requirements and parametric design operations, thereby real-world practice validation is required.

Abstract

As the safety of civil infrastructure gains more attention nowadays, inspection plays an important role in evaluating structural conditions. Ranking the level of defect is one of the most direct ways to understand the status of the building. Traditional inspections are based on handwritten records from human inspectors, which tend to be subjective and lack consistency. Therefore, digitalizing the data is a promising solution for recording. Based on the captured data, surface defects can be visualized and parameterized. This research aims to provide an innovative framework to analyze the effect of the defects based on Defect Specification Modeling (DSM) and rank the severity of different sections. A comprehensive diagnosis is conducted by considering the type, dimension, and location of the defects. It can identify structurally dangerous areas and provide solid evidence for decision-making. A case study carried out on a cooling tower is presented to validate the proposed approach. The comparison between severity rankings based solely on defect area and a comprehensive defect index reveals the practicability of the proposed methodology.

Keywords –

Defect Specification Modeling; Defect Ranking; Decision Making

1 Introduction

Traditionally, inspections have been conducted by human inspectors. Although these inspectors possess extensive experience, the reliability of inspection records is difficult to maintain, as report quality varies between individuals, potentially causing inconsistencies within a project. Moreover, manual inspection processes are prone to introduce errors, making them inefficient and time-consuming. In recent years, advancements in Computer Vision (CV) and Light Detection and Ranging (LiDAR) technologies have facilitated the digitization of inspection records in formats such as photographs, mesh models, and point clouds. Additionally, defect Building Information Modeling (BIM) has been developed to visualize and parameterize structural defects. However, limited analysis has been conducted on these defect models. The research gap remains in effectively utilizing the generated defect BIM models to extract information for decision support and maintenance strategies. Furthermore, there are no detailed standards for assessing the impact of defects on the structural integrity of the target infrastructure.

This paper aims to utilize Digital Specification Modeling (DSM) to develop a systematic framework for leveraging the severity of existing defects while considering multiple factors defined in relevant standards. By analyzing the provided defect model, an index for different defect can be calculated, enabling the ranking of severity across different structural areas. Based on this result, maintenance strategies can be optimized for varying situations. The main contribution of this work is directing the traditional experience-based structural condition assessment to a more objective and automated process which can benefit decision-making.

2 Related Work

With the acquired defect information, conducting a thorough defect rating is essential for efficient decision-making and objective asset management over the existing structure. A well-structured rating system allows stakeholders to prioritize maintenance efforts, allocate resources effectively, and mitigate potential structural failures.

2.1 Defect Modeling in BIM

BIM is a process involving collaborating between

different construction stakeholders based on a 3D model. Borrowing the concept, DSM will enable structural analysis, defect ranking, and even assisting decision making.

Borin and Cavazzini [1] recreated the Three-Dimensional (3D) shape of concrete spalling pathology in the BIM model which acts as a decision support system for the built environment. To automate the onsite data collection process and enhance the reliability of diagnosis, Dias, et al. [2] discussed the application of new inspection techniques. They applied severity of degradation to evaluate the global performance of the given façade. Bolourian [3] created a public point cloud dataset for surface defect semantic segmentation and proposed a Deep Learning (DL) approach to detect different types of concrete surface defects in point clouds. Guo, et al. [4] proposed a Convolutional Neural Network (CNN) based approach to detect minor cracks on concrete surface. By facilitating the automated crack detection method, Guo, et al. [5] proposed an innovative approach to use photogrammetry to acquire spatial information to quantify the detected crack on image. Choi, et al. [6] classified the defects as cracks, surface deterioration, displacement, and deformation. Based on the extracted information, they proposed a semiautomated visual approach to filter building condition information and used Dynamo to convert the information into BIM. Yiğit and Uysal [7] generated a Level of Detail 3 (LOD3) Digital Twin (DT) by triangulating the high-resolution images from Unmanned Aerial Vehicle (UAV). Cracks are automatically detected with the aid of DL and converted into vectors. They think the proposed method is suitable for rapid evaluation in terms of Structural Health Monitoring (SHM). Bahreini and Hammad [8] introduced the Ontology for Concrete Surface Defects (OCSD) to provide comprehensive data related to concrete surface defects, encompassing inspection, diagnosis, defect concepts, repair, rehabilitation, and replacement.

2.2 Regulations for Defect Categorizing

Among different methods, United States Army Construction Engineering Research Laboratories (USACERL) appeared to be the most comprehensive standard. Uzarski [9] added descriptions for the USACERL Condition Index. But it is still based on inspectors' experiences when it comes to predicting the condition and repairing time.

Amani, et al. [10] overviewed Component Condition Index System (CCIS) and investigated from technology, measurement, assessment function, and component maintenance. The authors stated that Condition Index (CI) is fundamental for deciding time and cost to invest in repairing or replacing existing facilities. The CI scale rates the status of health from 0 to 100 or D to A based on rating scale theory. It is believed that condition description based on visual guidance is more efficient and it would become an integral infrastructure management system. Queensland-Government [11] suggested that the type, width, location, and orientation of cracks can significantly affect the structure durability. Therefore, accurately measuring cracks is essential for monitoring purposes. The severity is classified as hairline (less than 0.1mm), minor (0.1-0.3mm), moderate (0.3-0.6mm), and severe (more than 0.6mm). According to Queensland-Government [11], the conditions of structure are categorized into five states from good, fair, poor, very poor, to unsafe. The exposure classification is defined as relatively benign, mildly aggressive, aggressive, and most aggressive. Vicroads [12] noted that if the spall is less than 25 mm in depth or 15 cm in diameter, it can be categorized as a small spall.

Although researchers have been working on detecting existing defects and creating BIM based defect models which enhance both efficiency of capturing process and consistency of the data, several gaps remain in the prior studies. Most of the current defect models are used for visualization, while limited research has been allocated to exploit the captured defect data and develop a reproducible assessment system for scoring the condition of building components. In addition, Existing regulations can provide defect classification thresholds but lack a systematic method to quantify the defect attributes and rank the defect accordingly.

Therefore, this study aims to develop a structured defect ranking framework connecting spatial defect information and a transparent scoring method. By evaluating and converting different attributes, a more objective condition assessing method can be achieved and reproduced. Furthermore, the proposed framework can facilitate optimized maintenance and decision making for infrastructure asset management.

3 Research Methodology

This severity scoring framework is developed from structural maintenance and infrastructure inspection standards. By analyzing the provided defect model, a series of defect attributes are obtained and integrated into the proposed framework. The evaluation criterion is normalized ranging from 1 to 10 (least to most severe) which is consistent with infrastructure condition index system. The scoring discipline originates from engineering judgement and widely used inspection standards. Several factors influence the assessment results, including defect type, size, location, exposure, duration of existence and shape. Variations in prioritization can lead to different outcomes, affecting the severity ranking of different structural areas.

A flowchart outlining the assessment process for

individual defects is presented below (see Figure 1). Both the influence of individual defects and the combined effect of multiple factors should be considered as seen in Equation 1, where CS stands for Component Score, IDS stands for Individual Defect Score, GF stands for Group Factor, and CF stands for Combination Factor. Although detailed measurements are presented below, weight and scaling factors will need to be adjusted according to specific cases.

$$CS = \sum (IDS \times GF \times CF) \quad (1)$$

3.1 Individual Effect

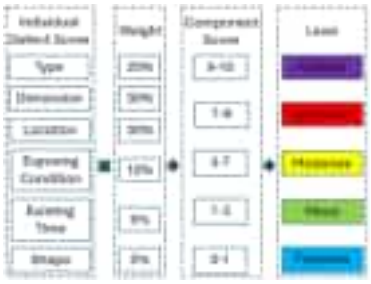

Figure 1. Proposed systematic workflow for individual defect ranking of component.

As seen in Figure 1, the component score is determined based on three key factors: defect ranking criteria, defect score (S_i), and weight (WC_i) (see Equation 2). The defect ranking criteria include defect type, dimensions, location, exposure conditions, and duration of existence. For each criterion, scores are normalized across different conditions using a ten-point scale, where a score of 10 represents the most severe extent, and a score of 1 represents the least severe level.

$$IDS = \sum_{i=1}^{n} S_i \cdot WC_i \quad (2)$$

3.1.1 Defect Type

Different types indicate different levels of potential risk. For example, cracks compromise the structural integrity of the surface, potentially leading to internal damage at early stage. While spalling typically affects a larger surface area and involves internal material exposure, it is more severe than cracking. Overall, if the defect type is more likely to pose danger to structural integrity, the severity score will correspondingly be higher.

3.1.2 Dimension

Defect dimension is one of the most direct factors that represent the level of degradation. For most defects, the affected area serves as the primary measurement criterion, while other dimensions, such as depth, width, and length, are also essential. Defects can be classified into minor, moderate, and major extents according to specific thresholds. Generally, larger defect dimensions correspond to higher severity scores.

3.1.3 Location

The location of identified defects is a significant factor influencing structural stability. Defects near critical components incur higher severity scores. The most critical areas (rated 8-10) include load-bearing components such as joints, columns, beams, and walls, where any flaw can potentially lead to structural collapse. Besides, defects at elevated locations pose significant risks, as falling debris may threaten human safety and the surrounding environment. Moderate-risk locations (rated 4-7) include slabs, floors, and ceilings. Defects in these areas may cause localized hazards but are unlikely to result in global structural failure. Non-load-bearing structures (rated 1-3), such as partition walls and cladding, are considered non-critical, as defects in these areas are less likely to cause severe structural problems.

3.1.4 Exposing Condition

Exposure conditions play a crucial role in the progression of defects. Structures fully exposed to harsh outdoor environments, such as costal erosion, high winds, severe storms, heavy snow, or intense heat, experience the highest severity levels (rated 9-10), as these extreme conditions significantly accelerate degradation and corrosion. Normal outdoor environments (rated 6-8) also have adverse effects on structural integrity, though to a lesser extent. Semi-enclosed areas, such as parking garages, patios, and sunrooms, are less affected by weather conditions and are assigned moderate severity scores (rated 3-5). Indoor environments remain relatively stable, experiencing minimal environmental impact, and therefore receive the lowest defect severity scores (rated 1-2).

3.1.5 Duration of Existence

The duration of a defect's existence is another critical factor influencing structural stability. It can be divided into three phases: emerging, developing, and existing. Developing defects (rated 8–10) are considered more significant than emerging ones, as their progression indicates increasing risk. Emerging defects (rated 4-7) may not be immediately critical. However, if a known defect is detected constantly growing, it poses a greater hazard compared to newly formed defects. In contrast, existing defects (rated 1-3) are the least concerning because they have remained stable over time without posing a major risk.

3.1.6 Shape

Moreover, the shape of a defect plays a crucial role in

surface integrity. For instance, in the case of spalling, the characteristics of its edges can vary. Defects with spiky or sharp edges (rated 6-10) tend to exhibit higher stress concentrations at the corners which can accelerate defect propagation. In contrast, defects with rounded or smooth edges (rated 1-5) are more stable, as the applied forces are more evenly distributed, reducing the likelihood of further deterioration.

3.2 Collective Effect

Apart from the impact of individual defects mentioned in the previous section, the collective effect of multiple defects should also be investigated, as defects often occur in clusters. When multiple defects appear within a single structural unit, various factors, such as intensity influence and center influence, should all be considered. The combined effect of these factors is illustrated in Figure 2.

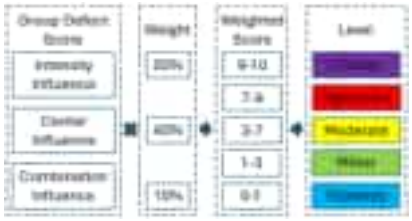

Figure 2. Proposed systematic workflow for group defect ranking of component.

3.2.1 Intensity Influence

Distance is the primary indicator of the combined impact of multiple defects. When defects are densely concentrated within a specific area, the local structural zone becomes more vulnerable, increasing the likelihood of sudden failure. Two approaches can be employed to quantify the level of defect concentration.

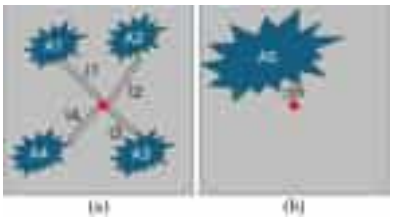

Figure 3. Combined impact factor: (a) adjusted weighted approach, and (b) finding the initial defect.

The first step involves calculating the adjusted weighted intensity factor (see Equation 3) based on a distance function, as illustrated in Figure 3 (a). In this equation, A_i represents the defect area, d_i denotes the distance between two defects, β is the scaling factor, and I_i is the intensity factor when a single defect is positioned at the center. Different initial defect locations may lead to varying results. Since this index is computed with respect to a single center, the outcome may be biased. To enhance scientific accuracy and minimize bias, the weighted intensity factor WI is introduced (see Equation 4). This factor is derived by averaging the individual intensity indices within the same structural component, as shown in Figure 3 (b).

$$I_i = \frac{\sum_1^i A_i e^{-\beta d_i}}{\sum_1^i A_i} \quad (3)$$

$$WI = \frac{\sum_1^i I_i}{i} \quad (4)$$

3.2.2 Center Influence

In addition to the influence of defect density, the group effect on the structural component itself should also be analyzed, as illustrated in Figure 4. In this figure, $A_1 - A_4$ represent defect areas, while $D_1 - D_4$ denote vectors extending from the geometric center of the structural component to the centers of individual defects. The red dot indicates the geometric center of the component.

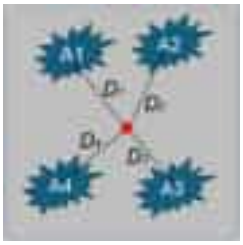

Figure 4. The center impact of the defects towards the center of the component.

The center impact of defects is a key parameter for evaluating their overall effect on a structural component. This index accounts for both the direction and distance of each defect relative to the component's geometric center. The magnitude of the resulting general vector represents the overall impact. The calculation of the center impact index is detailed in Equations 5-7, where k is the scale factor, A_i represents the defect area, D_i is the vector from the component center to defect center, W_i is the weighted vector, V_x is the influence vector in x direction, V_y is the influence vector in y direction, V_z is the influence vector in z direction, and V_i is the gross center influence vector.

$$W_i = D_i \cdot A_i \quad (5)$$

$$V_i = \frac{\sum_1^i k \cdot W_i}{\sum_1^i A_i} \quad (6)$$

$$|V_i| = \sqrt{{V_x}^2 + {V_y}^2 + {V_z}^2} \quad (7)$$

3.2.3 Combination Influence

When more than one kind of defect appears on the same component, combination factor is introduced to calculate the interaction effects between different types of defects. Different combinations of multiple defects can signify varying structural issues. For example, in the case of corrosion, cracking, and spalling, severity increases progressively from the infiltration of greenish deposits to cracks and then to a peeled concrete surface. The presence of both corrosion and cracks generally has a lower CF compared to the combination of cracks and spalling, which directly endangers structural integrity. If only one type of defect is involved in the component, CF is not applied and regarded as the minimum of 1.

4 Case Study

To evaluate the effectiveness of the proposed rating system, a case study is conducted on an aging cooling tower. The study begins with a brief introduction to the background of the cooling tower. High-resolution images were first captured by a UAV (see Figure 5), as well as LiDAR point cloud data using a terrestrial laser scanner (see Figure 6). Subsequently, a spalling BIM model (see Figure 7) is generated in Autodesk Revit using. Finally, a detailed analysis is performed based on the proposed methodology, utilizing the extracted spalling information to assess defect severity.

Figure 5. Captured image of spalling near the top ring of an aging cooling tower.

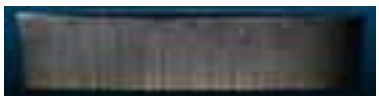

Figure 6. The captured LiDAR point clouds of defective area near the top ring of an aging cooling tower.

Figure 7. The BIM model of the aging cooling tower with spalling spread on the surface.

4.1 Project Background

Since the cooling tower became operational, high-temperature steam has condensed into moisture near the top ring, leading to the gradual corrosion of the concrete surface, as shown in Figure 5. After decades of cyclic exposure, the surface began to swell and eventually detach, resulting in concrete debris falling. These detached fragments pose a significant safety risk to workers on the ground. More critically, the exposure of reinforcement bars accelerates their deterioration, as continuous steam exposure enhances corrosion. Over time, this degradation may damage the stability of the upper structure. Therefore, monitoring the distribution of spalling and assessing its severity across different areas is important for ensuring structural integrity and worker safety.

4.2 Data Analysis

As outlined in Section 3, the individual effects are analyzed in the context of a specific case where spalling is the main defect, and the structure exhibits uniform properties. Additionally, the group effects, primarily including intensity influence and center influence, are quantified according to the conditions observed in the cooling tower. These calculations provide a comprehensive assessment of defect severity.

4.2.1 Individual Effect

The recorded spalling areas, measured in square meters, range from $0.03m^2$ to $4m^2$. These areas are categorized into three groups based on area: minor spalling ($0m^2$-$0.5m^2$), moderate spalling ($0.5m^2$-$1m^2$), and major spalling ($1m^2$-$4m^2$). In this case, a total of 157 minor defects, 54 moderate defects, and 25 major defects were identified. The severity scores assigned to these categories are 3 points for minor defects, 7 points for moderate defects, and 10 points for major defects.

The significance of location is primarily determined by its impact on load-bearing structures. In the case of the cooling tower, the entire structure is axisymmetric, meaning that all concrete panels serve an equivalent functional role. Consequently, height is the key variable influencing location-based importance. The height range is classified into three categories: minor effect (605m-608m), moderate effect (608m-612m), and major effect (612m-615m). Based on these criteria, 17 spalling locations are classified as non-critical (scoring 3 points), 85 locations are categorized as concerning (scoring 7 points), and 134 locations are identified as critical (scoring 10 points).

Regarding shape, no prominent spiky edges were observed among the existing spalling. Instead, most defects exhibit irregular forms. Some examples of these irregular and smooth-edged shapes are presented in Figure 8. Since the defects lack sharp edges, a severity score of 6 is assigned to irregularly shaped spalling, while round-shaped defects are given a lower severity score of 1.

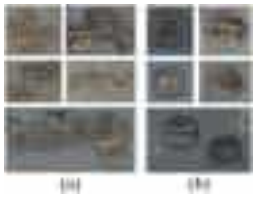

Figure 8. Two shapes of defects: (a) irregular/spiky shapes, and (b) smooth shapes.

As observed in Figure 5, the defects near the top ring primarily consist of spalling. Due to the lack of recorded data, the exact duration of defect existence remains unknown. Similarly, the exposure conditions are largely uniform because all defects are located on the concrete surface at similar heights. Therefore, the indexes for defect type, existing time, and exposure condition can be excluded from the analysis.

As discussed above, three main factors – spalling area, location, and shape are considered in the evaluation. The weighting of assessment criteria represents the relative impact of severity for each type of defect. The weights are determined based on practical inspection experience and engineering judgment in this study. Dimensions of defects are put in the first place as surface material loss is directly related to structural integrity. Location of defects is regarded as the second important factor as the appearance in critical areas can also pose significant safety risks to structural capacity. Shape of defect is allocated a lower weight because the influence is less compared to other two factors. Future studies will adopt more structured approaches or expert surveys to refine the scheme. The weight distribution for these factors is assigned as follows: 50% for area, 40% for location, and 10% for shape. The calculated factors for Panel 1 are provided as an example (see Table 1).

Table 1 Scaled area, location, and shape factors for Panel 1.

Spalling No.	1-1	1-2	1-3	1-4	1-5	1-6	1-7
Area Factor	10	3	3	7	3	7	7
Location Factor	10	10	10	10	10	7	7
Shape Factor	1	1	1	1	1	1	1
Scaled Area Factor	5	1.5	1.5	3.5	1.5	3.5	3.5
Scaled Location Factor	4	4	4	4	4	2.8	2.8
Scaled Shape Factor	0.1	0.1	0.1	0.1	0.1	0.1	0.1

4.2.2 Collective Effect

This section examines the impact caused by multiple defects, specifically focusing on intensity influence and center influence. Since only a single defect type is present, the combination factor is not considered. In this case, the structural unit used for calculating the group effect is a concrete panel. Take Panel 1 as an example, the centers of the identified spalling defects are marked in Figure 9 (a), while the geometric center of the panel is indicated in Figure 9 (b).

Figure 9. Panel 1: (a) numbered centers of spalling, and (b) the center of panel component.

Following Equation 3, the scaling factor β is set to 0.1. The intensity index for different spalling instances is presented in Table 2. As observed, variations in the spalling center result in changes in the intensity index, ranging from 0.7458 to 0.8599. To mitigate potential bias, the derived single intensity indexes are averaged according to Equation 5.

Table 2. Individual intensity factors for spalling on panel 1.

Spalling	Single Intensity Index
1-1	0.8599
1-2	0.7739
1-3	0.8028
1-4	0.8529
1-5	0.8101
1-6	0.7458
1-7	0.7808

For the center index, individual weighted vectors are calculated using Equation 5. Afterward, the scaling factor k is set to 0.2 to obtain the magnitude of the gross center influence index for each concrete panel, as calculated using Equation 6 and 7.

Since only spalling appears on the concrete surface, the combination factor is excluded from the analysis. The group effect factors are weighed as follows: 60% for the intensity influence index and 40% for the center influence index. The intensity influence, center influence index, and combined group effect factors for panel 1 to 10 are listed in Table 3.

Table 3. Calculated influence index for panels 1 to 10.

Panel	Intensity Influence Index	Center Influence Index	Combined Group Index
1	0.8037	0.7155	0.8
2	0.8060	0.8254	0.8
3	0.7568	0.5501	0.7
4	0.7509	0.4367	0.6
5	0.8303	0.4273	0.7
6	0.8111	0.4015	0.6
7	0.8037	0.3436	0.6
8	0.7808	0.5214	0.7
9	0.8368	0.6863	0.8
10	0.8181	0.6571	0.8

To validate the statistics derived, the distribution of spalling on each concrete panel is shown in Figure 10. As previously discussed, the more concentrated the spalling defects are in each area, the higher the value of the intensity influence index. For example, even with a similar amount of spalling, the intensity index of Panel 9 is higher than that of Panel 8 due to the more concentrated spalling in Panel 9. For the center influence index, the value increases as the spalling group moves farther away from the center of the panel. As seen from panel 25 to 27, the center influence index decreases as the defect groups move closer to the panel center.

Figure 10. The projected top ring panels of defects.

4.3 Panel Defect Index

Since both the individual defect scores and group factors are available, the panel defect index can be determined. Figure 11 presents a comparison between the panel defect index obtained using the proposed methodology and the index based solely on the spalling area. The top 10 highest indexes are highlighted in red, the 10 lowest indexes in green, and the moderate values in yellow. The differences in severity rankings indicate that the proposed method offers a more comprehensive assessment by incorporating multiple defect-related factors.

Figure 11. Comparison between the panel defect index and sum of spalling area.

To better understand the distribution of defects, spalling is modeled into different sizes to indicate the affected area (see Figure 12 (a)). The colors represent varying severities, ranging from green (minor) to yellow (moderate) and red (severe). Additionally, the categorized concrete panels based on the defect index are presented in Figure 12 (b). A combined visualization of both the panels and spalling is displayed in Figure 12 (c) to provide a comprehensive overview of the structural condition.

Figure 12. (a) The categorized spalling: green ($0m^2 – 0.5m^2$), yellow ($0.5m^2 – 1m^2$), and red ($1m^2 – 4m^2$), the categorized panel based on defect index: green (minor), yellow (moderate), and red (major), and (c) the categorized panel and spalling

4.4 Validation

The proposed framework is evaluated through comparative analysis and engineering consistency assessment. Compared with the conventional area-based approach, the proposed method derives a more comprehensive result by considering multiple attributes. The assessment is also consistent with engineering deductions, when higher concentration and more critical location can lead to higher scores. Future work is expected to perform a direct comparison with expert assessments.

5 Discussion

The proposed methodology is applied to an aging cooling tower to demonstrate its feasibility. A semantically rich defect specification model is developed, incorporating essential defect and component rating information. To enhance interpretability, the severity of defects is visualized using a color-coded system, facilitating intuitive assessment of structural conditions. This enhanced visualization supports decision-making and maintenance strategy development by leveraging the defect BIM model and parameterized information. The proposed rating system is designed to be adaptable across different projects. Although certain criteria involve limited engineering judgement, explicit scoring rules can maintain repeatability and consistency. One of the main challenges remains the absence of common standards for validating results which can affect the reliability of evaluations. Future research will focus on standardizing the assessment criteria to improve the consistency and robustness of the defect rating system. The integration of Knowledge Graph (KG) could facilitate a more thorough understanding of defect propagation and interdependence.

6 Conclusions

The increasing number of aging infrastructure assets can potentially pose dangers to structural safety and human users. To mitigate the bias introduced by traditional human-based inspections, this study presents a practical workflow - from rating the condition of defects to visualizing categorized defects within a BIM model. A comprehensive assessment criterion is proposed, considering both individual and grouped defect effects. The individual defect assessment includes factors such as type, location, dimension, exposure condition, existing time, and shape. Each factor is assigned a score based on its severity. By multiplying the weights of these factors and summing the scaled values, the overall score for individual defect can be calculated. This score is then aggregated at the component level. Next, group factors – including intensity, center, and combination influences - are evaluated. Integrating both individual and group factors provides a more reasonable defect score for each component.

A Systematic Study on Instance-Level Bridge Point Cloud Segmentation under Cross-Type and Synthetic–Real Training Conditions

Abstract -

Bridge point cloud instance segmentation is essential for digital twin construction and automated bridge management. However, deep learning–based approaches are limited by the scarcity of instance-level annotated real-world data and the domain gap between synthetic and real point clouds. In practical end-to-end Scan-to-Bridge Information Modeling(BrIM) pipelines, segmentation models must operate directly on raw point clouds without assuming prior bridge-specific domain knowledge or relying on domain-driven preprocessing.

To address these challenges, synthetic bridge point clouds for slab and PSC girder bridges were generated using physics-based LiDAR simulation, with a unified component definition applied to both synthetic and real data to construct consistent instance-level annotations. Background elements, including terrain and vegetation, were incorporated into the synthetic scenes to reduce the gap between realistic conditions. Experimental results show that synthetic-only training yields the lowest performance, followed by real-only training, while the best performance is achieved when synthetic and real data are jointly used.

For the Japan dataset, mIoU and mAP improved from 0.253 and 0.131 to 0.531 and 0.638, respectively. For the Cambridge dataset, although mIoU slightly decreased from 0.556 to 0.549, mAP increased from 0.617 to 0.688, indicating improved instance-level performance.

Instance-level segmentation is particularly important in bridge applications, as maintenance and long-term monitoring require component-wise analysis and consistent tracking of *maintenance-relevant structural elements or structural systems*. Given the limited visibility of abutments in real-world and their frequent exclusion in prior studies, we further evaluated performance under scenarios with deck and background components to reflect realistic end-to-end deployment conditions.

Scan-to-BrIM; Instance segmentation; Synthetic point clouds;

1 Introduction

Bridges are critical infrastructure that connects local communities and supports economic activities, making efficient management and maintenance essential. However, conventional bridge management heavily relies on visual inspections and manual operations, which are time-consuming, labor-intensive, and costly [1]. As a result, digital transformation of bridge management has gained increasing attention, with digital twins and Scan-to-Bridge Information Modeling (Scan-to-BrIM) emerging as promising solutions [2].

Within Scan-to-BrIM pipelines, bridge components must be identified from point clouds acquired via laser scanning or photogrammetry and subsequently reconstructed as structured geometric models. Point cloud segmentation therefore plays a central role in enabling downstream modeling and analysis tasks [3]. In particular, instance-level segmentation is required for practical bridge applications, as maintenance, inspection, and long-term monitoring depend on component-wise analysis and consistent tracking of maintenance-relevant structural elements or systems. For this purpose, recent deep learning–based approaches have shown clear advantages over traditional rule-based methods in handling complex bridge geometries and diverse structural configurations [4].

However, the effectiveness of deep learning–based bridge segmentation is fundamentally constrained by the availability and quality of training data. Generating accurate instance-level annotations for real-world bridge point clouds requires substantial domain expertise, manual effort, and time, while large-scale acquisition of real bridge data is often limited by logistical and financial constraints. To address these challenges, many studies have explored training strategies that combine synthetic and real bridge point cloud data, leveraging synthetic data to mitigate labeling costs and data scarcity while incorporating real data to improve realism and generalization.

The synthetic and real data generation pipeline adopted in this study builds upon established workflows in prior literature, while incorporating methodological refinements tailored to bridge point cloud instance segmentation.

Despite recent progress, many existing studies still rely on simplified problem formulations for bridge point

cloud instance segmentation, such as excluding certain structural components (e.g., abutments), merging partially visible elements into dominant instances like decks, or conducting segmentation on pre-filtered point clouds without background points. These simplifications embed strong, often implicit, prior assumptions about bridge geometry and data preprocessing, and therefore depart from realistic end-to-end Scan-to-BrIM workflows, where models must directly process raw, cluttered point clouds acquired from field measurements.

To address this gap, we propose a stepwise experimental framework that explicitly controls and progressively relaxes these assumptions. Rather than treating instance segmentation under a single idealized setting, our framework systematically evaluates model behavior across multiple levels of realism by varying the presence of background points and structurally ambiguous components. This design enables a controlled analysis of how training strategies generalize as the problem formulation transitions from idealized to practically deployable conditions.

2 Related work

2.1 Semantic Segmentation of Bridge Point Clouds

Bridge point cloud segmentation is a fundamental technology for Scan-to-BIM, automated bridge inspection, and digital twin construction, as it enables the identification and separation of structural components from raw 3D point clouds at both semantic and instance levels. Accurate segmentation is a prerequisite for downstream tasks such as structural assessment, deformation analysis, and maintenance planning.

Early studies on bridge point cloud segmentation primarily relied on handcrafted geometric features and rule-based heuristics, including curvature, normal vectors, region growing, and threshold-based clustering [5]. While these approaches achieved reasonable performance in controlled environments, they exhibited strong dependence on manually tuned parameters and limited robustness when applied to complex real-world scenes with occlusions, noise, and varying point densities.

With the rapid advancement of deep learning, data-driven approaches have become dominant in point cloud segmentation. Methods based on PointNet, PointNet++ [6-7], and sparse convolutional networks significantly improved segmentation accuracy by learning discriminative features directly from point cloud data. More recently, transformer-based instance segmentation frameworks have attracted increasing attention due to their ability to model long-range dependencies and global contextual relationships, leading to improved performance in complex and cluttered scenes [8].

Despite these advances, applying deep learning–based segmentation methods to bridge point clouds remains challenging. Bridge datasets often suffer from severe class imbalance, where small components such as abutments or parapets contain significantly fewer points than major components like decks or girders. In addition, acquiring large-scale, labeled bridge point clouds is costly and time-consuming, limiting the availability and diversity of training data [9]. These challenges restrict the generalization capability of existing models when deployed in real-world bridge environments.

2.2 Synthetic Bridge Point Cloud Generation

Deep learning–based bridge point cloud segmentation requires large amounts of labelled data. However, constructing component-level ground-truth annotations for real bridges is extremely costly and labor-intensive. To address this limitation, extensive research has explored the use of synthetic bridge point cloud data.

Early synthetic data generation methods typically sampled point clouds directly from 3D CAD or mesh-based bridge models [10]. Although these approaches enabled efficient data generation and precise labelling, they failed to capture critical characteristics of real-world point clouds, such as sensor noise, non-uniform sampling density, occlusion effects, and background clutter. Consequently, models trained on such data often exhibited limited generalization to real-world scenarios.

To improve realism, subsequent studies adopted physics-based LiDAR simulation or UAV–SfM pipelines to generate synthetic point clouds that more closely resemble real sensor measurements [11-12]. These methods incorporated factors such as scanning geometry, measurement noise, and partial occlusion, leading to improved data fidelity. Nevertheless, many existing approaches remain limited to a small number of bridge types or simplified environmental settings, often neglecting surrounding terrain, vegetation, and background structures.

As a result, a persistent domain gap between synthetic and real bridge point clouds has been widely reported and recognized as a major factor degrading model performance in real-world applications [13]. This limitation has motivated recent research to investigate training strategies that combine synthetic and real data or progressively adapt models across domains. However, systematic comparisons of different training data compositions under controlled experimental settings remain limited, particularly in the context of instance-level bridge segmentation.

3 Methodology

To ground our methodology in existing research

practice, this study first examines six representative prior works that utilize the same real-world bridge point cloud dataset [14-15-16-17-18-19]. From a training-strategy perspective, most previous studies focus on improving segmentation performance by combining synthetic and real data, applying data augmentation to real data, or leveraging pseudo-labeling techniques to exploit unlabeled real-world point clouds [15-16-17]. Other approaches emphasize the generation of synthetic bridge models designed to closely resemble real bridges in order to enhance training effectiveness [8].

Meanwhile, several studies effectively simplify the segmentation task by constraining scene composition or component definitions at the dataset level. For example, in Xia et al. [14], only pier, slab, and background classes are considered, resulting in a highly simplified scene configuration. In the Yang et al. [15] and Yang et al. [17], background and abutment components are excluded altogether, meaning that the input point clouds do not represent raw scanning conditions. Although the Xu et al. [16] partially includes background and abutments, most bridges are truncated around the mid-span region, thereby avoiding complex boundary conditions near abutments.

In the Lin et al. [18], loss functions are strongly tuned based on bridge-specific structural priors, introducing explicit domain assumptions into the learning process. Furthermore, in the Chen et al. [19], abutments and piers are merged into a single category, further reducing component-level granularity and simplifying the segmentation task.

In contrast, practical end-to-end Scan-to-BrIM pipelines operate directly on raw point clouds acquired from field measurements, where background clutter and partially occluded components are inherently present and cannot be reliably pre-filtered. To reflect this practical constraint, this study explicitly distinguishes three training scenarios—synthetic data only, real data only, and combined synthetic–real data—and conducts a comprehensive, stepwise performance comparison using raw point cloud inputs under a unified model architecture and evaluation protocol. Through this analysis, we systematically investigate how training data composition influences bridge point cloud instance segmentation performance in realistic, domain-agnostic settings. A summary of performance comparisons reported in previous studies is presented in Table 1.

Table 1. Segmentation of performance comparisons reported in prior studies

Dataset	mIoU (%)	mAP (%)	OA (%)	Acc (%)
Xia et al. [14]	94.72	-	-	-
Yang et al. [15]	91.84	-	95.56	96.74
Xu et al. [16]	41.4	63.3		
Yang et al. [17]	89.83	-	95.34	94.31
Lin et al. [18]	74.42	-	87.67	86.65
Chen et al. [19]	81.0	-	-	92

3.1 Datasets

To evaluate the performance of the proposed method, two real-world bridge point cloud datasets from Japan and Cambridge were used in this study. By leveraging datasets constructed in different countries, environments, and scanning conditions, we aim to comprehensively assess the generalization capability and practical applicability of the proposed framework. Examples of the real bridge point clouds are shown in Fig. 1.

Figure 1. Representative bridge point clouds from the Japan and Cambridge datasets.

3.1.1 Japan Dataset

Japan Dataset is a proprietary dataset collected in December 2023 from nine reinforced concrete bridges located in rural areas of Japan using a Matterport Pro3 terrestrial laser scanner[20]. The scanner provides a 360° horizontal field of view and a 295° vertical field of view, with a measurement accuracy of ±20 mm at a distance of 10 m and a maximum acquisition rate of 100,000 points per second.

All points were manually annotated into five structural component classes: Abutment, Girder, Deck, Parapet, and Background. For abutment components, parts of the frontal regions were reclassified as Background to account for geometric complexity and severe class imbalance.

For this dataset, following the original bridge IDs provided in the dataset, Bridges 2, 4, 5, 6, 8, and 9 were used for training, while Bridges 1, 3, and 8 were used for testing.

3.1.2 Cambridge Dataset

Cambridge Dataset is a publicly available benchmark dataset, consisting of highway bridge point clouds collected in the Cambridgeshire region of the United Kingdom using a FARO Focus 3D X330 terrestrial laser

scanner[21]. To ensure consistency number in Japan Dataset, a total of nine bridges (Bridges 2–10) were used, excluding Bridge 1 from the original set of ten bridges.

The bridges have total lengths ranging from 55 to 91 m, span lengths of 13 to 35 m, and heights between 5 and 8 m. Structurally, they include multiple piers and horizontally curved deck geometries. All points were annotated into six structural component classes: Abutment, Pier, Girder, Deck, Parapet, and Background.

For this dataset, following the original bridge IDs provided in the dataset. Bridges 3, 4, 5, 7, 8, and 10 were used for training, while Bridges 2, 6, and 9 were used for testing.

3.2 Synthetic and Real Data Generation Pipeline

This study proposes an integrated data generation and annotation pipeline that combines synthetic and real-world data to construct training datasets for 3D instance segmentation of bridge components. An overview of the proposed pipeline is illustrated in Fig. 2.

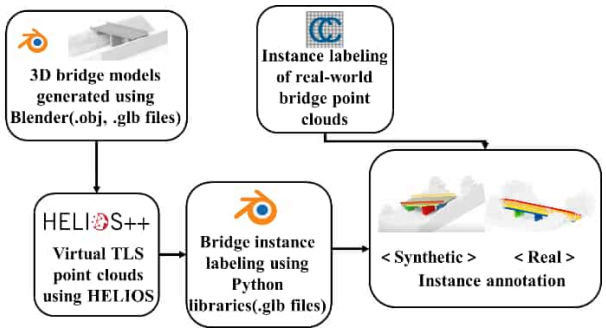

Figure 2. Overview of the proposed data generation and annotation pipeline for bridge component instance segmentation.

Bridge models of slab bridges and PSC girder bridges were first collected from the online repository www.bigdata-eng.com in IFC format and subsequently converted into OBJ files using Blender. Additional structural elements such as piers and surrounding terrain were manually modeled to construct complete 3D bridge scenes in Blender. The synthetic bridge dataset consists of 48 slab bridges and 9 PSC girder bridges, reflecting structural diversity in terms of bridge length (10–45 m for slab bridges and 30–50 m for girder bridges) and pier geometry (rectangular, square, and cylindrical). In addition, terrain-inclusive versions were generated for all bridges to account for realistic topographic conditions. Representative examples of slab and girder bridges are shown in Fig. 3. Virtual terrestrial laser scanning (TLS) was then performed on the generated 3D bridge models using HELIOS++ to produce synthetic bridge point clouds.

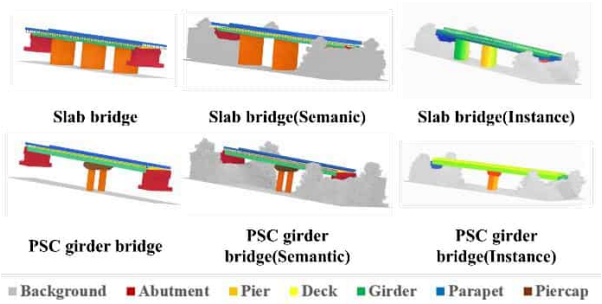

Figure 3. Representative synthetic bridge models used in this study: slab bridges and PSC girder bridges.

To emulate real-world TLS acquisition conditions, scanner placement, field of view, ray distribution, and range attenuation effects were explicitly modeled, and scanner configurations were defined based on the specifications of the RIEGL VZ-400. In particular, TLS scanners were automatically deployed at regular intervals on multiple horizontal planes derived from the bridge bounding box, including planes located above and below the bridge deck in the XY plane and an additional plane positioned 2 m below the structural center. This strategy ensured sufficient coverage of bridge geometries from multiple viewpoints. Scanners that were placed inside the bridge mesh were automatically excluded to prevent unrealistic scanning artifacts. As a result, synthetic point clouds with spatial distributions and point densities comparable to those obtained from real TLS surveys were efficiently generated. The scanner spacing was set to 10 m or 15 m depending on whether background elements were included. Terrain and vegetation were automatically placed to replicate realistic bridge environments. The synthetic dataset was ultimately divided into two variants, with and without vegetation and surrounding hills, while ground surfaces were included in both variants. Detailed HELIOS++ scanner settings are summarized in Table 2.

Following point cloud generation, a Python-based post-processing pipeline was applied to automatically assign component-level instance labels to the synthetic point clouds. Structural component information defined during the Blender modeling stage was preserved in GLB files, and a nearest-neighbor matching process between mesh surfaces and point clouds was used to consistently assign semantic labels and instance IDs to individual points. In contrast, real-world bridge TLS point clouds were manually annotated using CloudCompare.

Table 2. HELIOS++ TLS simulation settings used for synthetic bridge point cloud generation.

Parameter	Value
Pulse frequency	100,000 Hz
Scan frequency	120 Hz
Scan angle	100°

Head rotation speed	10°/s
Vertical FOV	−40° to 60°
Horizontal FOV	−180° to 180°
Trajectory interval	1.0 s

For all point cloud data, RGB values were unified to grayscale to minimize the influence of color information. A voxel down-sampling with a resolution of 0.05 m was applied, followed by spatial cropping into 10 m-sized volumes using a sliding-window strategy. Here, the overlap ratio is defined as the percentage of spatial overlap between adjacent cropped volumes. Overlap ratios of 0%, 12.5%, and 25% were applied, resulting in approximately 100k–300k points per scene. The final dataset includes both synthetic and real bridge point clouds and shares consistent class definitions and instance labeling schemes, enabling direct use for training and evaluating 3D point cloud instance segmentation models.

3.3 Experimental Setting / Evaluation Metrics

All experiments were conducted on a workstation equipped with an AMD Ryzen 7 5800X CPU, an NVIDIA RTX 3090 GPU with 24 GB VRAM, and 32 GB of system memory. The experimental environment was configured on Ubuntu 20.04, using Python 3.8 and CUDA 11.3.

In this study, Relation3D[22] was adopted as the baseline instance segmentation model, and all models were trained for 200 epochs. The training configuration of Relation3D followed the official settings for the ScanNetV2 dataset, except that the batch size was set to 10 and the number of data loader workers was set to 5. In addition, different overlap ratios (0%, 12.5%, and 25%) were applied during data preparation.

Intersection over Union (IoU) measures the degree of overlap between the predicted and ground-truth regions for a given class, indicating how accurately the predicted area matches the reference annotation. Based on IoU, Average Precision (AP) evaluates instance-level segmentation performance by summarizing the precision–recall relationship obtained from IoU-based matching between predicted and ground-truth instances. Mean Intersection over Union (mIoU) is then computed by averaging the IoU values across all classes, providing an overall measure of semantic segmentation accuracy. Finally, mean Average Precision (mAP) is obtained by averaging the AP values over all classes, reflecting the overall instance segmentation performance.

4 Experimental Results

The Japan and Cambridge datasets were used as training sets, while the synthetic dataset consisted of 48 slab bridges and 9 PSC girder bridges. The synthetic dataset was further divided into two variants depending on the presence of surrounding Background. Overlap ratios of 0%, 12.5%, and 25% were applied during data preparation to represent low, moderate, and high levels of spatial redundancy between adjacent subspaces. Specifically, 0% corresponds to a non-overlapping baseline, while 12.5% and 25% introduce progressively increasing overlap within a practical range before excessive redundancy occurs. This design enables a systematic analysis of the trade-off between computational cost and segmentation accuracy. For evaluation, the respective test sets of the Japan and Cambridge datasets were used.

From this perspective, this study compared three training scenarios based on instance segmentation that include vegetation and abutments: training with synthetic data only, training with real data only, and training with a combination of synthetic and real data. Experimental results show that training with synthetic data alone consistently yielded the lowest performance. For the Japan dataset (Table 3), under background-included settings, AP values for overlap ratios of 0%, 12.5%, and 25% were 0.057, 0.088, and 0.078, respectively. When background points were excluded, AP further decreased to 0.045, 0.040, and 0.032 under the same overlap conditions. In contrast, mIoU values were relatively higher under background-excluded settings, reaching 0.291, 0.279, and 0.242, respectively.

Table 3. Accuracies on the Japan dataset for synthetic-only training across overlap ratios (with/without background)

Background\Overlap	0%	12.5%	25%
	mIoU / mAP	mIoU / mAP	mIoU / mAP
Background(0)	0.257 /0.057	0.206 /0.088	0.210 /0.078
Background(x)	0.291 /0.045	0.279 /0.040	0.242 /0.032

Similar trends were observed in the Cambridge dataset (Table 4). When background points were included, AP values at overlap ratios of 0%, 12.5%, and 25% were 0.266, 0.279, and 0.266, respectively, whereas background-excluded settings resulted in mAP values of 0.213, 0.207, and 0.231 under the same conditions. The mIoU values were similar across all settings. Since real bridge environments require the separation of individual components under complex scenes where abutments, ground surfaces, terrain, and surrounding structures are mixed, training with realistic scenes that include

background elements is essential for instance segmentation.

Table 4. Accuracies on the Cambridge dataset for synthetic-only training across overlap ratios (with/without background)

Background\Overlap	0%	12.5%	25%
	mIoU / mAP	mIoU / mAP	mIoU / mAP
Background(0)	0.300 /0.266	0.291 /0.279	0.294 /0.266
Background(x)	0.298 /0.213	0.306 /0.207	0.299 /0.231

Training with real data only led to a clear performance improvement. However, the optimal overlap ratio varied across datasets. For the Japan dataset (Table 5), the highest performance was achieved at an overlap ratio of 12.5%, with an mIoU of 0.253 and an mAP of 0.131. In contrast, the Cambridge dataset (Table 6) achieved its best performance at an overlap ratio of 25%, yielding an mIoU of 0.556 and an mAP of 0.617. This difference is closely related to bridge scale and the crop-based data construction strategy. For structurally smaller Japanese bridges, increasing the overlap ratio can limit the model's ability to sufficiently learn component arrangements and instance-level relationships. In contrast, the longer and more complex Cambridge bridges provide richer spatial contexts, which are more favorable for learning instance boundaries.

Table 5. Accuracies on the Japan dataset under real-data-only training with different overlap ratios.

Overlap	mIoU	mAP
0%	0.075	0.055
12.5%	0.253	0.131
25%	0.181	0.112

Table 6. Accuracies on the Cambridge dataset under real-data-only training with different overlap ratios.

Overlap	mIoU	mAP
0%	0.462	0.485
12.5%	0.415	0.382
25%	0.556	0.617

The most significant performance improvements were observed when synthetic and real data were combined for training. For the Cambridge dataset, applying a 25% overlap ratio and a background-excluded setting for synthetic data resulted in an mIoU of 0.549 and an AP of 0.688. Similarly, for the Japan dataset, an overlap ratio of 12.5% with background-excluded synthetic data achieved an mIoU of 0.531 and an AP of 0.638 (Table 7). In both datasets, better performance was achieved when the synthetic data excluded background elements,

Table 7. Optimal overlap ratio selection for synthetic–real combined training and corresponding performance.

Background \Name(Overlap)	Cambridge (25%)	Japan (12.5%)
	mIoU / mAP	mIoU / mAP
Background(0)	0.530 / 0.668	0.488 / 0.543
Background(x)	0.549 / 0.688	0.531 / 0.638

which can be attributed to the fact that background characteristics were learned primarily from real data. Detailed performance results for each component are presented in Figs. 4 and 5.

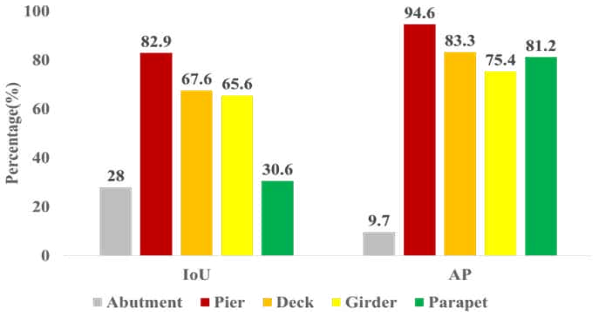

Figure 4. Component-wise instance segmentation performance on the Japan dataset.

These results indicate that synthetic data contributes beyond merely increasing the amount of training data, effectively supporting instance segmentation learning for components that are difficult to sufficiently observe in real TLS data. In particular, abutments, which are adjacent to the ground and structurally complex, often exhibit sparse point distributions and unclear boundaries with background elements, making instance segmentation challenging. Synthetic data provides clear geometric structures and instance boundaries for such components, enabling the model to learn object-level segmentation capabilities required in real end-to-end maintenance pipelines.

Furthermore, when the entire synthetic dataset was combined with real bridge data collected from different regions for training (Table 8), the Japan dataset showed improvements in mAP and mIoU from 0.131 and 0.253 to 0.238 and 0.279, respectively, compared to training with real data only. Similarly, for the Cambridge dataset, mAP and mIoU increased from 0.617 and 0.556 to 0.734 and 0.605. These results outperform the case where training was conducted using real data from the same regional domain only (mAP 0.688, mIoU 0.549), demonstrating that combining background-free synthetic data with multi-domain real data is also effective for improving domain generalization.

Table 8. Performance Comparison of Cross-Domain Real-Data Training with Fixed Synthetic Data

Overlap/Configuation	mIoU	mAP	Abutment	Pier	Deck	Girder	Parapet
			IoU/AP	IoU/AP	IoU/AP	IoU/AP	IoU/AP
Japan(12.5%)	0.279	0.238	0.069/0.002	- / -	0.374/0.138	0.460/0.446	0.214/0.365
Cambridge(25%)	0.605	0.734	0.551/0.223	0.726/0.964	0.659 / 0.834	0.689/0.772	0.402/0.876

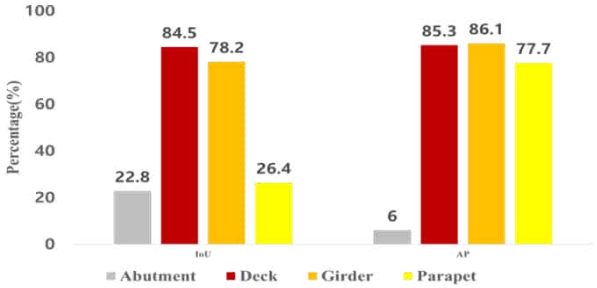

Figure 5. Component-wise instance segmentation performance on the Cambridge dataset.

Instance segmentation results for Bridge 8 in the Japan dataset and Bridge 6 in the Cambridge dataset are visualized in Fig. 6. In the visualization, background points are shown in gray, incorrectly predicted regions are highlighted in red, and correctly segmented instances are distinguished by different colors.

5 Conclusion and Limitation

This study systematically analyzed the performance variations of 3D point cloud–based component-level instance segmentation for bridge maintenance and digital twin construction according to different training data compositions. The fundamental motivation for performing bridge instance segmentation is that, even when components belong to the same category, each component is treated as an independent management unit at an appropriate management level from a maintenance perspective. Multiple piers, parapets, and abutments, which are spatially separable structural units, may be classified into the same semantic class. However, in actual maintenance processes, each component exhibits different damage states, deterioration patterns, inspection histories, and repair records. Therefore, point-wise semantic classification alone is insufficient to satisfy these management requirements, and instance segmentation that identifies individual components as object-level entities is a necessary step in end-to-end Scan-to-BrIM and bridge digital twin pipelines.

Nevertheless, this study has several limitations. First, the experimental scope is limited to slab bridges and PSC girder bridges. Second, although the synthetic dataset reflects variations in component geometry, it is still based on a limited set of component configurations and structural details. Third, some components, such as abutments, still exhibit relatively low performance due to complex geometries and severe class imbalance.

In summary, this study clearly defines bridge instance segmentation as an essential object-level analysis step at the system-management level from a maintenance perspective and demonstrates the performance of training with scenes that include both bridge components and surrounding elements such as background and abutments. The results further show that combining synthetic data with multi-domain real data is an effective strategy for robustly separating individual components in realistic bridge scenes, providing practical guidelines for 3D point cloud–based Scan-to-BrIM and bridge digital twin construction.

Although this study includes both slab-type and girder-type bridges from publicly available datasets in Korea to incorporate structural diversity, the datasets used in this study remain limited. While the effectiveness of the proposed framework is demonstrated, further validation on a broader range of bridge types and real-world datasets is required. In addition, a more comprehensive exploration of training strategies—such as synthetic–real mixing ratios, pretraining versus joint training, and evaluation across multiple models—remains as future work to further enhance generalizability and robustness.

Abstract –

Construction projects generate heterogeneous data from schedules, design models, and site observations. Graph-based data models have recently been adopted to integrate these diverse data sources, but interacting with such models typically requires specialized technical knowledge, which limits their usability in construction practice. This study proposes a schema-aware Graph Retrieval-Augmented Generation (Graph-RAG) framework that enables natural language interaction with construction project graph data models. The framework integrates a large language model with a Neo4j graph database to interpret user queries, retrieve project data through Cypher queries, and generate evidence-grounded responses. A case study integrating schedule data, an IFC design model, and computer-vision-derived site observations produced a project graph with 218 nodes and 377 relationships. Evaluation using six project queries showed that the proposed framework achieved 100% accuracy, outperforming a Text-to-Cypher approach (33.3% accuracy), while direct LLM interaction failed to answer any questions (0% accuracy). These results demonstrate the effectiveness of schema-aware Graph-RAG for reliable natural language access to construction project data.

Keywords –

Construction Projects; Knowledge Graph; Graph-RAG; LLMs; Construction Data Interaction; Natural Language Interaction

1 Introduction

Construction projects generate large volumes of heterogeneous data throughout their lifecycle, including schedules, design models, site observations, and as-built records [1, 2]. Integrating these diverse data sources in a meaningful and consistent manner remains a significant challenge for project management and decision-making [3]. In recent years, graph-based data models and knowledge graphs have emerged as a promising solution for construction data integration [4]. By representing project entities such as activities, infrastructure elements, resources, and observations as interconnected nodes and relationships, graph models enable heterogeneous data sources to be linked in a semantically meaningful way, supporting richer representation of project knowledge and improved data integration across different project systems [5, 6].

Despite their strong capability for integrating heterogeneous construction data, interacting with graph-based data models often requires specialized technical knowledge. Accessing and querying graph databases typically require graph query languages and database technologies that are more familiar to computer scientists than to construction practitioners [7]. As a result, many project stakeholders may find it difficult to directly interact with graph-based project data models, limiting their usability in everyday construction management. This creates a gap between the availability of integrated project data and the ability of practitioners to effectively access and interpret that information.

Recent advances in large language models (LLMs) offer a promising opportunity to bridge this gap by enabling natural language interaction with complex data systems [8]. Because graph data models organize project information through semantically connected entities and relationships [9], LLMs can potentially serve as an interface that translates user questions into meaningful interactions with the project graph. Motivated by this potential, this study proposes a framework that leverages LLMs to enable natural language interaction with construction project graph data models. By allowing users to query project information using natural language while grounding responses in graph-based data, the proposed approach aims to improve the usability of

graph-based construction information systems and make integrated project knowledge more accessible to construction stakeholders.

2 Related Work

This section reviews prior research on construction information modelling, LLMs, and retrieval-augmented generation, highlighting current practices and limitations in construction-phase applications.

2.1 Construction Information Models and Graph-based Representations

Construction projects have traditionally relied on Building Information Modelling (BIM) platforms and relational databases to manage project information [10]. BIM has been widely adopted to support design coordination, quantity take-off, and visualization[11], while relational databases have been used to store schedules, cost records, and inspection data [12, 13]. For example, Heidary et al. [14] used a 4D BIM environment to link 3D design models with construction schedules, enabling improved visualization of planned activities over time and supporting hazard identification and safety management during construction, whereas Palomar et al. [15] implemented a relational database–based platform using SQL Server to centrally store and synchronize structured project data across multiple disciplines. Although these approaches have improved information organization, they typically operate in isolated silos and rely on predefined schemas that limit flexibility when project conditions change [3]. As construction progresses and new data sources emerge, such as site observations and as-built records, maintaining consistency and traceability across systems remains challenging [1, 2].

To address these limitations, recent research has explored graph-based data models and knowledge graphs for construction information management [4]. Graph representations allow entities such as activities, resources, building elements, and observations to be explicitly linked, supporting richer semantics and more flexible querying than traditional tabular models [5]. In this context, Sun et al. [16] reviewed text-based automatic knowledge graph construction for road infrastructure operations, demonstrating how document-centric sources can be transformed into structured knowledge graphs to support querying and reasoning across lifecycle activities. Knowledge graphs have been applied to integrate BIM data, schedules, safety information, and regulatory knowledge, enabling reasoning over relationships rather than isolated attributes [6, 17]. These approaches have demonstrated advantages in representing complex dependencies and enabling inference across heterogeneous data sources [18, 19].

Despite these advances, interaction with graph-based construction data models typically relies on predefined dashboards or fixed query templates [7]. Such interfaces are designed around anticipated information needs and require backend development when new questions arise [9]. As a result, responding to emerging or unexpected information demands during the construction phase remains difficult, limiting the practical usability of graph-based systems for day-to-day decision-making by project teams.

2.2 Large Language Models in Construction Projects

LLMs are generative AI systems trained to predict and produce natural language, enabling tasks such as question answering, summarization, and drafting based on learned linguistic patterns [8]. Recent evaluations show that ChatGPT-style models can perform competitively on domain problem-solving tasks, motivating their exploration as decision-support tools in construction management [20]. In the construction context, LLMs are increasingly positioned as conversational interfaces that can translate complex technical content into more accessible, actionable narratives for practitioners [21].

In construction applications, Prieto et al. [22] investigated ChatGPT for construction scheduling, examining how well it can generate schedule-related outputs and support planners through natural-language interaction. For project documentation, Xiao et al. [23] combined computer vision with ChatGPT to convert construction videos into automated daily reports, aiming to reduce manual reporting effort while preserving site progress details. For compliance, Yang and Zhang [24] proposed a prompt-based pipeline to transform building code text into structured representations usable for automated checking.

However, the direct use of LLMs also introduces important limitations. LLMs generate responses based on statistical patterns learned from training data rather than verified, project-specific information [24], which can lead to hallucinations, incorrect assumptions, or missing contextual constraints [25]. In construction projects, where decisions are often time-sensitive and safety-critical, such behavior poses significant risks. These limitations highlight the need for complementary mechanisms that can ground LLM outputs in authoritative, traceable, and project-specific information sources.

2.3 Retrieval-augmented Generation in Construction

Retrieval-augmented generation (RAG) has recently been adopted in construction research to improve the reliability of large language model (LLM) outputs by grounding responses in external knowledge sources. Lee et al. [26] compared a RAG-based approach with a fine-tuned LLM for construction safety knowledge retrieval by integrating GPT-4 with a safety knowledge graph derived from guidelines, demonstrating improved consistency in answering safety queries. Similarly, Baek et al. [27] developed a RAG-enhanced framework that retrieves activity- and equipment-specific cases from a construction accident repository to generate tailored safety risk management guidance, showing that domain-adapted embeddings improve retrieval quality. Beyond safety applications, Zheng et al. [28] integrated LLMs with a nested contract knowledge graph to improve the accuracy and interpretability of automated contract risk identification.

Recent studies have further extended RAG and LLM-grounded approaches to different construction tasks and data modalities. Guo et al. [29] proposed a multimodal framework combining a visual language model with a two-stage RAG pipeline to support automated safety compliance monitoring from site images. Zhou et al. [30] integrated an external construction engineering management knowledge base with general-purpose LLMs to enable question answering in construction management contexts when domain training data are limited. Related work has explored alternative grounding strategies, such as long-context LLMs for building code interpretation [31], RAG-based systems for generating personalized feedback in construction management training [32], and multimodal multi-agent frameworks for geotechnical design tasks involving both text and images [33]. In addition, recent work by Pan et al. [34] proposed an LLM-enabled multi-agent framework that enables natural language interaction with graph-based digital twins of existing buildings, where an agent pipeline interprets user queries, generates graph database commands, and retrieves information from the digital twin graph to produce grounded responses for facility management scenarios.

Nevertheless, existing applications of RAG in construction largely focus on static knowledge sources, such as codes, regulations, historical documents, or predefined training materials. The use of RAG to interact with live, evolving project data during the construction phase has received limited attention. In particular, the potential of Graph-RAG to enable natural language access to project knowledge graphs that represent the current state of construction activities and site conditions remains underexplored. Addressing this gap requires frameworks that combine graph-based project data with retrieval-grounded language models to support reliable natural language interaction with construction-phase project information.

3 Research Methodology

This study proposes a Graph Retrieval-Augmented Generation (Graph-RAG) framework to enable natural language interaction with a construction project graph data model. The system integrates a large language model (LLM) with a graph database so that users can query project information using natural language while responses remain grounded in structured graph data. When a user submits a question, the framework first retrieves the schema and ontology from the project graph to provide structural context. Using this information, the LLM decomposes the user query into simpler sub-questions aligned with the graph structure. For each sub-question, the LLM generates a Cypher query to retrieve relevant information from the graph database. The retrieved graph data are then used to generate grounded answers for each sub-question, which are finally synthesized by the LLM to produce a unified response to the original user query. The overall workflow of the proposed Graph-RAG framework is illustrated in Figure 1.

The LLM in the proposed framework performs three key tasks: (1) question decomposition, (2) graph query generation for retrieval, and (3) response generation and synthesis. These components enable the system to bridge natural language user queries and structured project graph data, allowing complex project information to be accessed through intuitive natural language interaction.

3.1 Schema-aware Question Decomposition

When a user submits a natural language query, the system first retrieves the schema and ontology information from the project graph database. This information describes the available node types, relationships, properties, and semantic structures within the project data model. The schema is provided as contextual input to the LLM to ensure that the query interpretation is consistent with the structure of the graph.

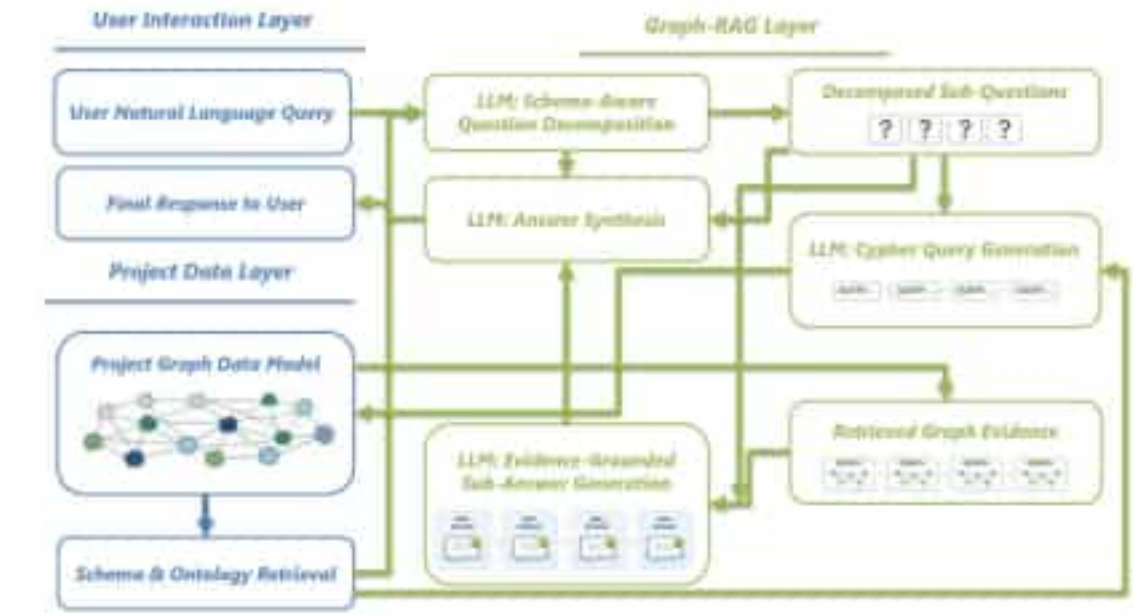

Figure 1. Overview of the proposed Graph-RAG framework for natural language interaction with construction project graph data.

Using this schema-aware context, the LLM refines the user query and decomposes it into a set of simpler sub-questions. Each sub-question represents a specific information retrieval task that can be mapped to graph entities and relationships. This decomposition step helps transform complex user queries into structured information retrieval tasks that align with the project graph schema.

3.2 Graph Query Generation and Retrieval

For each decomposed sub-question, the LLM generates a Cypher query that retrieves the relevant information from the graph database. The generated queries follow the structure of the project graph schema and are designed to retrieve entities, relationships, and contextual attributes required to answer the sub-question.

The Cypher queries are executed against the Neo4j graph database, and the retrieved results are returned as structured graph evidence. This retrieval step ensures that the responses generated by the LLM are grounded in actual project data rather than relying solely on language model inference.

3.3 Evidence-Grounded Response Generation and Synthesis

Once the relevant graph data are retrieved, the LLM generates a response for each sub-question using the retrieved evidence. The model is instructed to base its reasoning only on the retrieved graph information to ensure factual consistency and transparency.

Finally, the LLM synthesizes the responses to the individual sub-questions together with the original user query to generate a unified answer. This synthesis step enables the system to provide coherent explanations that integrate multiple pieces of graph-retrieved information into a final response for the user.

4 Case Study

To evaluate the proposed framework in a real-world scenario, a case study was conducted on an ongoing road intersection upgrade project in New South Wales, Australia. Construction of the project commenced in late 2023 and is scheduled for completion in 2027. The project involves multiple construction activities, resources, and observational data collected during the construction phase. These heterogeneous data sources provide a suitable environment for examining how a graph-based data model combined with large language models can support natural language interaction with project information.

4.1 Case Study Project Graph Data Model Preparation

In this case study, three types of project data were

integrated to construct the project graph data model: the project schedule (structured data), an IFC design model (semi-structured data), and construction site images (unstructured data). These heterogeneous data sources were mapped into a graph structure using ten top-level entities representing key concepts of the construction domain. Through predefined semantic rules, information from the schedule, design model, and site observations was linked to form a unified project graph.

Construction site images were processed using the YOLOv8 computer vision model to detect relevant construction elements. The detected elements were then matched with corresponding elements in the IFC design model based on spatial location and linked to the related construction activities defined in the project schedule. By connecting activities, design elements, and observed site conditions, the different data sources were semantically integrated into a single project graph data model. After processing one project schedule, one IFC model, and 32 construction site images (two images per observation date across 16 different dates), the resulting graph contained 218 nodes and 377 relationships representing the project state (Figure 2).

Figure 2. Snapshot of the dynamic construction project graph in Neo4j on 5 September 2025.

4.2 Developing the Graph-RAG Pipeline

The Graph-RAG pipeline was developed and implemented in Python by integrating the Neo4j graph database with the OpenAI GPT-4.1 model through the OpenAI API. The developed pipeline first retrieves the schema of the project graph and converts it into a structured text summary that can be provided to the LLM as contextual input. Based on this schema-aware context, the framework processes the user question through several LLM-driven stages. First, the LLM decomposes the user question into simpler sub-questions while considering the schema and ontology of the project graph. Second, for each sub-question, the LLM generates a Cypher query to retrieve relevant data from the Neo4j database. Finally, the retrieved graph evidence is used by the LLM to generate grounded responses for each sub-question, and these are then synthesized into the final answer returned to the user. Prompt engineering was used throughout these stages to control the LLM behavior and keep the outputs aligned with the graph structure and project semantics.

In the implemented prompts, each stage was guided by a specific instruction logic. For question decomposition, the LLM was instructed to act as an ontology-aware planning assistant that refines the user question conservatively, decides whether decomposition is needed, and creates schema-consistent sub-questions without introducing unsupported graph elements. For Cypher generation, the LLM was instructed to produce read-only Cypher queries, follow project-specific semantic rules, use only valid retrieval patterns, and avoid any write or administrative operations. For evidence-grounded answering, the LLM was instructed to answer each sub-question only from the retrieved graph evidence, explicitly mention uncertainty when evidence is incomplete, and avoid inventing unsupported facts. In the final synthesis stage, the LLM was instructed to answer the original user question directly by combining the sub-question answers while clearly preserving the distinction between graph-supported findings and uncertain information.

4.3 Testing Setup

To evaluate the effectiveness of the proposed framework, six questions were designed to test the system's ability to retrieve project information under different reasoning scenarios. These questions include temporal status queries, progress tracking queries, resource matching queries, and delay detection queries.

- Q1 — What was the construction status of the activity "8 Columns A – FW" on 2 June 2025?
- Q2 — What was the construction status of the activity "8 Columns A – FW" on 21 May 2025?
- Q3 — What was the construction status of the activity "8 Piles A" on 23 April 2025?
- Q4 — What was the construction status of the activity "8 Piles A" on 7 May 2025?
- Q5 — Which observed machinery types match the machinery planned for the associated construction activities?
- Q6 — Based on the latest available observations, which construction activities are currently identified as delayed?

Four different question-answering methods were evaluated:

- Direct LLM – only the user question is given to the LLM.
- LLM + Full Graph Data – the LLM receives the question and the entire project graph data model as input.
- Text-to-Cypher Retrieval – the LLM generates a Cypher query directly from the question and retrieves graph data in a single step.
- Proposed Graph-RAG Method – the schema-aware decomposition and retrieval framework proposed in this study.

A Python-based testing interface was developed to allow a user to submit a question and automatically generate responses from all four evaluation methods simultaneously for comparison, as illustrated in Figure 3.

Figure 3. Screenshot of the Python testing environment showing simultaneous outputs from the four evaluation methods.

4.4 Results

The experimental results demonstrate clear differences between the evaluated methods. When only the question was provided to the LLM, the model was unable to produce correct answers for any of the questions because it had no knowledge of the specific project data. This outcome is expected since general-purpose LLMs are trained on broad datasets and do not contain information about a particular construction project.

When the entire project graph data model (218 nodes and 377 relationships) was provided as input to the LLM, the API request exceeded the tokens-per-minute (TPM) rate limit of GPT-4.1, producing the following error:

Error: request exceeds the allowed token limit (429 rate limit error).

This indicates that processing the entire project graph as input exceeded the TPM rate limit of the GPT-4.1 API, making this approach impractical for real-world applications due to computational and processing constraints.

The remaining two approaches were able to produce responses. The one-step Text-to-Cypher method correctly answered only the last two questions (2/6), while it failed to correctly interpret the temporal context required for the first four questions. In contrast, the proposed Graph-RAG framework successfully answered all six questions while also providing evidence retrieved from the project graph. A summary of the performance of the four evaluated methods is presented in Table 1, demonstrating the improved accuracy and reliability of the proposed Graph-RAG framework in retrieving project-specific information.

Table 1. Accuracy comparison of the evaluated question-answering methods.

Method	Accuracy
Direct LLM	0/6 (0 %)
LLM + Full Graph Data	Not executable under standard API rate limits
Text-to-Cypher	2/6 (33.3 %)
Proposed Graph-RAG	6/6 (100 %)

5 Discussion and Conclusions

This study proposed a Graph Retrieval-Augmented Generation (Graph-RAG) framework to enable natural language interaction with construction project graph data models. By integrating a large language model with a graph database, the framework allows users to query project information in natural language while ensuring that responses are grounded in structured project data. The case study shows that the approach can effectively retrieve project-specific information from heterogeneous data sources integrated into a unified project graph. Compared with alternative approaches such as direct LLM interaction and one-step Text-to-Cypher retrieval, the proposed framework achieved higher accuracy and produced responses supported by explicit graph evidence.

Nevertheless, this study has some limitations. The evaluation was conducted on a single case study with a relatively small project graph, which may not fully represent the scale and complexity of larger construction projects. Future work will extend the framework to support multi-query conversations, causal and predictive

reasoning, and broader evaluation across different project types. Further research will also examine the performance, scalability, and user adoption of the proposed framework in larger construction project environments.

Acknowledgments

This research is supported by funding from the Australian Research Council (ARC) Research Hub for Resilient and Intelligent Infrastructure Systems (IH210100048), and the ARC Research Hub for Human-Robot Teaming for Sustainable and Resilient Construction (IH240100016). We also extend our sincere appreciation to GeoAI, in particular Mr. Alastair Linke, Chief Executive Officer, Dr. Youheng Guo, and Mr. Barber Cameron, for providing access to the case study data and for offering valuable technical feedback throughout the project.

Abstract -

Autonomous navigation in cluttered construction environments is challenging due to unstructured obstacles, GPS-denied conditions, and operational constraints on onboard computation. Optimization-based planners such as Covariant Hamiltonian Optimization for Motion Planning (CHOMP) offer obstacle-avoidance capabilities but are often unsuitable for high-frequency control due to their computational cost and sensitivity to local minima. This study investigates a safety-regularized imitation learning framework that integrates residual policy learning, a learned safety critic providing probabilistic risk estimates, and Conditional Value-at-Risk (CVaR) regularization. Through systematic evaluation in a procedurally generated PyBullet construction environment featuring dense scaffolding and debris, we show that safety-oriented loss shaping alone is insufficient to mitigate covariate shift in behavioral cloning, resulting in low task success despite conservative trajectories. In contrast, incorporating Dataset Aggregation (DAgger) enables the learned policy to acquire effective recovery behaviors, improving navigation success to 80% while maintaining safety margins comparable to the expert planner. The primary contribution of this work is an empirical demonstration that dataset aggregation, rather than safety regularization alone, is critical for robust imitation learning in cluttered construction environments. The proposed framework provides a foundation for distilling optimization-based planners into lightweight, reactive policies suitable for simulated aerial navigation in construction-like environments, while real-world deployment remains future work.

Imitation Learning; Drone Navigation; Control Barrier Functions; Robust Control; PyBullet; Robotics

1 Introduction

Construction sites are dynamic and hazardous environments for robotic deployment, characterized by narrow corridors, hanging scaffolding, and scattered debris such as pallets, pipes, and steel beams. These conditions limit the effectiveness of standard GPS-based waypoint following or map-heavy global planners for aerial robots tasked with site inspection, progress monitoring, or surveillance [1]. Therefore, navigation in such environments often requires a reactive controller that supports real-time and online obstacle avoidance control.

While optimization-based motion planners such as CHOMP [2] can generate feasible trajectories in cluttered environments, their computation costs can limit use in real-time control. Running such optimizers online at the control frequency required for quadrotors (often > 50 Hz) is difficult on standard embedded hardware [3]. Furthermore, these planners may generate trajectories with high jerk due to gradient-based updates on non-convex cost landscapes, potentially imposing mechanical loads on the airframe.

Given the computational load of optimization based motion planners, Imitation Learning (IL) has been explored as a practical alternative method for distilling the capabilities of a heavy planner into a lightweight neural policy. In this work, IL is used to learn a reactive policy from expert demonstrations [4]. However, common IL approaches, such as standard Behavioral Cloning (BC), are known to suffer from two flaws. First, it is susceptible to covariate shift, where small errors accumulate, which can drive the robot into unvisited states where the policy is undefined [5]. Second, BC mimics the expert directly; if the expert minimizes time by grazing obstacles (as CHOMP often does), the student policy inherits this behavior.

To address these limitations, this project implemented a safety-regularized imitation learning for cluttered construction environments. The approach combines residual policy learning, a learned approximation to a control barrier function, and risk-sensitive loss terms. The implementation focused on the following components:

1. A meta-residual policy learning architecture that combines a classical nominal controller with a learned neural correction to improve tracking performance and obstacle avoidance in cluttered environments.
2. A latent safety critic inspired by control barrier functions that estimates proximity to unsafe regions directly from raw LiDAR observations.
3. A risk-sensitive training objective incorporating Conditional Value-at-Risk (CVaR) to emphasize rare but

critical failure cases arising from complex obstacle geometries.

4. A systematic evaluation in a procedurally generated PyBullet construction environment to empirically demonstrate dataset aggregation, rather than safety regularization alone, is critical for robust imitation learning in highly cluttered spaces.

2 Research Background

2.1 Autonomous Navigation in Cluttered Construction Environments

Construction sites are challenging for autonomous navigation due to dense structural elements, narrow passages, unstructured debris, and frequent layout changes. These environments can be GPS-denied or unreliable, complicating GPS-dependent navigation [6]. UAVs are increasingly used for construction tasks such as site inspection, image- or video-based 3D mapping, and performance monitoring, motivating robust navigation in complex settings [7].

UAV navigation is commonly categorized into map-based and map-less (reactive) strategies. Map-based methods (e.g., SLAM and occupancy mapping) build an environment representation to support planning, whereas map-less methods react directly to sensor observations [8]. Prior work has extensively studied sampling-based and optimization-driven planners for collision-free trajectory generation, but these methods often assume stable environment representations and can be computationally demanding for onboard use on resource-constrained platforms [9].

In cluttered, dynamic settings, maintaining accurate and up-to-date maps is difficult due to layout changes, sensing artifacts, and moving obstacles, which can reduce the effectiveness of map-heavy global planning. This motivates reactive control approaches that map observations to actions without expensive online optimization. Learning-based navigation, including imitation learning, provides one such approach by distilling expert behavior into reactive policies [10]. However, robustness and safety remain challenging under distribution shift and rare failure cases, motivating imitation learning methods that incorporate safety constraints and distribution-alignment mechanisms [11].

2.2 Imitation Learning and Meta-Learning

IL has evolved beyond simple BC. While BC [12] treats control as a supervised regression problem, it lacks long-horizon stability due to covariate shift. DAgger [5] addresses this by querying the expert on student-induced states, a strategy employed in this project for data aggregation. Recent work has explored meta-learning formulations (e.g., MAML [13]) to improve adaptation across navigation tasks. While these methods enable rapid parameter updates, they primarily adjust the behavior of an underlying planner rather than altering the optimization landscape.

In highly cluttered environments, local minima often affect planner performance. Residual Policy Learning (RPL) [14] provides a complementary approach by enabling the learned component to modify the effective vector field guiding the trajectory. Generative Adversarial Imitation Learning (GAIL) [15] seeks to align occupancy measures between expert and learner but may produce unsafe behavior when expert demonstrations approach obstacle boundaries. Diffusion-based policies [16] have demonstrated multimodal action modeling; however, their iterative denoising procedure incurs computational overhead, presenting challenges for high-frequency aerial control loops.

2.3 Trajectory Optimization: CHOMP

The expert demonstrator used in this study is based on CHOMP (Covariant Hamiltonian Optimization for Motion Planning) [2]. While Model Predictive Control (MPC) [17] and sampling-based methods like RRT* are standard in local planning, MPC requires solving convex optimization problems at every timestep, which can be computationally demanding. RRT* produces probabilistically complete but often non-differentiable paths.

CHOMP treats trajectory generation as a functional gradient descent problem. It handles cost maps (ESDFs) and produces smooth trajectories, though it is prone to local minima and requires gradient computations. Our approach uses CHOMP as a *nominal* prior to guide the student policy training.

2.4 Safe Control and Barrier Functions

Control Barrier Functions (CBFs) [18] provide a method to ensure forward invariance of a safe set. If a valid barrier function $h(x)$ exists, safety can be enforced by constraining the control input u:

$$\dot{h}(x) + \alpha(h(x)) \geq 0 \tag{1}$$

Defining an analytical $h(x)$ for a raw point cloud is difficult in unstructured environments. Recent work [19] learns CBFs from data. This project implements a latent safety critic inspired by CBFs to estimate the safety margin directly from LiDAR features.

3 Preliminaries

This section defines the robot dynamics, environmental representation, and safety formulation used in the implementation.

3.1 Quadrotor Dynamics

The quadrotor is modeled as a kinematic system controlled by velocity commands. Let state $s_t \in \mathcal{S} \subset \mathbb{R}^n$ include the robot's position $p_t \in \mathbb{R}^3$, velocity $v_t \in \mathbb{R}^3$, and sensor observations o_t (LiDAR scans). The control input $u_t \in \mathcal{A} \subset \mathbb{R}^3$ specifies the target velocity vector.

$$p_{t+1} = p_t + u_t \Delta t \tag{2}$$

This kinematic model is used for high-level trajectory planning, assuming a lower-level flight controller handles the rotor dynamics.

3.2 Euclidean Signed Distance Fields (ESDF)

The expert planner relies on an implicit surface representation of the environment. An ESDF, denoted as $\phi(x)$, maps a point $x \in \mathbb{R}^3$ to the distance to the nearest obstacle boundary ∂O.

$$\phi(x) = \begin{cases} d(x, \partial O) & \text{if } x \notin O \\ -d(x, \partial O) & \text{if } x \in O \end{cases} \tag{3}$$

This representation allows for gradient computation $\nabla\phi(x)$, which is utilized by the CHOMP optimizer. In the simulation, this is computed from the LiDAR point cloud.

3.3 Control Barrier Functions (CBF)

A Control Barrier Function $h(s)$ is a scalar function defined over the state space such that the set $C = \{s \in \mathcal{S} : h(s) \geq 0\}$ represents the safe region. The boundary $\partial C = \{s : h(s) = 0\}$ represents the limit of safety. For a control system $\dot{s} = f(s, u)$, the safety condition is maintained if the control input u satisfies:

$$\frac{\partial h}{\partial s} f(s, u) \geq -\alpha h(s) \tag{4}$$

where $\alpha > 0$ determines how aggressively the system is allowed to approach the boundary. In this study, this condition is incorporated as a penalty term in the loss function rather than being solved online via QP.

3.4 Conditional Value-at-Risk (CVaR)

To address rare collision scenarios, CVaR is employed. For a loss distribution Z and confidence level $\alpha \in (0, 1)$, CVaR is defined as the expected loss in the worst α-percentile of cases:

$$\text{CVaR}_\alpha(Z) = \mathbb{E}[Z \mid Z \geq \text{VaR}_\alpha(Z)] \tag{5}$$

where VaR_α is the Value-at-Risk threshold. This term is intended to robustify the policy against outlier scenarios.

4 Methodology

4.1 System Architecture

The system consists of three main components: a global planner (providing the goal), a local expert planner (CHOMP), and the learning-based student policy. The student policy processes raw LiDAR data and state information to generate velocity commands.

4.2 Residual Policy Learning

We employed Residual Policy Learning (RPL) rather than mapping observations directly to absolute actions. The final control command u_t is given by:

$$u_t = v_{curr} + \pi_\theta(f(s_t)) + u^z_{PID} \tag{6}$$

where v_{curr} is the current velocity, π_θ predicts a delta-velocity correction (Δv) in the xy-plane, and u^z_{PID} is a fixed PID controller for altitude maintenance.

4.2.1 Feature Extraction

Raw LiDAR scans are converted into a local occupancy grid and processed into an Euclidean Signed Distance Field (ESDF) patch (size 7×7) centered on the drone. The policy network input is a concatenation of:

- The flattened ESDF patch (49 dimensions).
- Current velocity vector (3 dimensions).
- Goal delta vector (3 dimensions).

4.2.2 Network Architecture

The policy network π_θ is a Multi-Layer Perceptron (MLP) with two hidden layers of 256 units each, using LeakyReLU activations (slope 0.2).

4.3 Learned Safety Critic

A neural network $r_\phi(s)$ (Safety Critic) was trained to approximate the risk of a state. The ground truth risk R_{gt} is computed during expert data collection using an exponential decay of the minimum LiDAR clearance d_{min}:

$$R_{gt}(s) = \exp(-\gamma \cdot d_{min}) \tag{7}$$

where $\gamma = 2.0$. This signal is bounded in $[0, 1]$. The critic network mirrors the policy architecture but outputs a single scalar value through a Sigmoid activation, trained via Mean Squared Error (MSE):

$$\mathcal{L}_{critic} = \|r_\phi(s) - R_{gt}(s)\|^2 \tag{8}$$

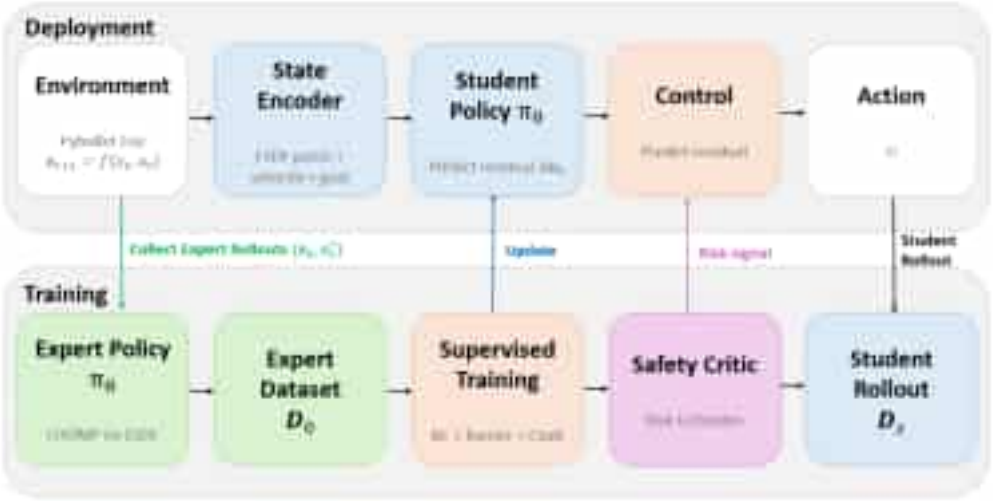

Figure 1. System architecture. The student policy learns a residual correction to the current velocity, guided by the expert's demonstrations and regulated by the Safety Critic.

4.4 Loss Function

The training process utilized a Safety-Regularized loss function, combining behavioral cloning with barrier-based regularization and risk sensitivity.

$$\begin{aligned}\mathcal{L}_{total} = & \underbrace{\|\pi_\theta(s) - \Delta u^*_{target}\|^2}_{\text{BC}} \\ & + \lambda_1 \underbrace{\mathbb{E}[B(s,u)]}_{\text{Barrier Mean}} \\ & + \lambda_2 \underbrace{\text{CVaR}_\alpha(B(s,u))}_{\text{Robust Safety}}\end{aligned} \tag{9}$$

where the Barrier Cost $B(s,u)$ is defined as:

$$B(s,u) = r_\phi(s) \cdot \|u_{final}\|^2 \tag{10}$$

This term penalizes high kinetic energy ($\|u\|^2$) when the estimated risk $r_\phi(s)$ is high. The $\text{CVaR}_{0.1}$ term calculates the mean of the top 10% of barrier costs in the batch. Parameters were set to $\lambda_1 = 0.01$ and $\lambda_2 = 0.05$ for the experiments.

4.5 Training Pipeline: DAgger

The DAgger algorithm was utilized to address distribution shift. The pipeline proceeds as follows:

1. **Expert Collection:** Collect initial trajectories using the CHOMP teacher.
2. **Pre-training:** Train π_θ and r_ϕ on expert data.
3. **Iterative Rollout:** Execute the student policy π_θ in the environment to collect new observations $s_{student}$.
4. **Expert Labeling:** Query the teacher for the optimal action u^* at these new states.
5. **Aggregation & Retraining:** Add the new (s, u^*) pairs to the dataset and retrain.

5 Experimental Setup

5.1 Simulation Environment

A custom simulation environment was developed using the PyBullet physics engine. The environment, "Construction Site," spans a $22m \times 22m$ area.

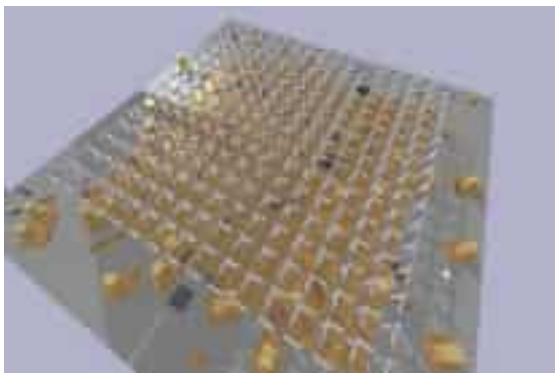

Figure 2. The PyBullet simulation environment featuring procedurally generated scaffolding and debris.

The scene generation is procedural to explicitly model the structural variability found across different construction scenarios. It consists of:

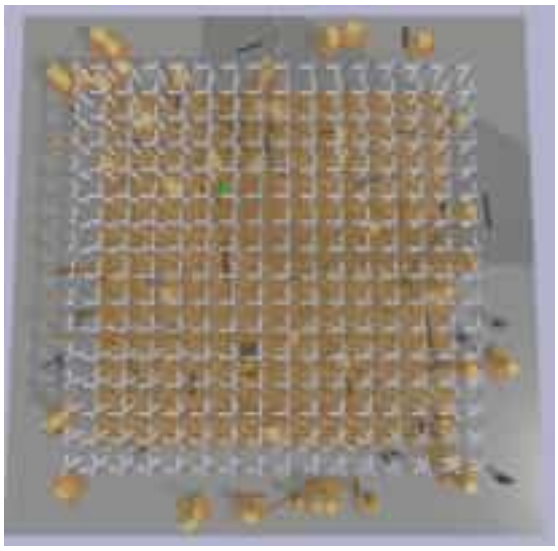

Figure 3. Top-down view of a generated episode. Red indicates the goal, blue indicates the start. Note the density of the scaffolding grid.

- **Scaffolding Grid:** A 15×15 grid of bays ($1m \times 1m$) constructed from vertical uprights and horizontal ledger pipes (radius $0.06m$).
- **Debris Scattering:** 40 wooden pallets ($0.6m \times 0.5m$) and 80 random debris items (steel beams, cylinders, pipes) scattered across the floor.
- **Spawn Logic:** The drone and goal are often spawned inside the scaffolding structure or atop debris piles.

5.2 Sensors and Robot Model

The robot is modeled as a quadrotor with a $0.18m$ radius, equipped with a simulated LiDAR sensor:

- **Range:** 10.0 meters.
- **Resolution:** 72 azimuth rays $\times$ 5 elevation layers (Total 360 rays).
- **Update Rate:** 60 Hz.
- **Feature Space:** Raw point cloud rasterized into a 7×7 ESDF patch.

Camera inputs were not used to reduce computational overhead, relying on geometric depth data. These procedurally generated scenes are intended to represent a type of cluttered construction-like layouts rather than all construction scenarios, and the present evaluation is limited to short-horizon navigation in dense obstacle fields.

5.3 Expert Demonstrator

The expert policy is based on CHOMP, utilizing the instantaneous ESDF to compute a velocity gradient minimizing:

$$\mathcal{U}(traj) = w_{obs}\mathcal{U}_{obs} + w_{smooth}\mathcal{U}_{smooth} + w_{att}\mathcal{U}_{att} \tag{11}$$

Parameters were tuned to $k_{att} = 1.5$ (goal attraction) and $k_{rep} = 0.8$ (obstacle repulsion).

6 Results

6.1 Quantitative Comparison

Five comparative baselines were evaluated to systematically analyze the performance of Imitation Learning variants against the optimization-based expert. The baselines are:

1. **Teacher (CHOMP):** The optimization-based expert.
2. **Vanilla BC:** Behavioral Cloning on expert data.
3. **BC + CVaR:** BC with risk-sensitive loss.
4. **BC + CVaR + CBF:** Full loss function on static expert data.
5. **BC + CVaR + CBF + DAgger:** The full method with iterative dataset aggregation.

Five comparative baselines were evaluated to systematically analyze the performance of Imitation Learning variants against the optimization-based expert.

Table 1 summarizes the results averaged over 15 evaluation episodes.

6.2 Observation of "Drift" Failure Mode (Methods 2-4)

Our initial hypothesis was that a robust loss function (CVaR + CBF) might enable training a safe policy from expert data alone. However, methods trained purely on static expert datasets (Methods 2, 3, and 4) yielded success rates below 15%. While these methods produced smooth trajectories (Jerk $< 8m/s^3$) and maintained high safety margins (Clearance $> 0.3m$), they consistently failed to reach the goal. Flight logs indicate these failures were due to covariate shift. The expert trajectories lie on a specific manifold; when the student drifted due to approximation error, it entered unvisited states. Lacking data in these regions, the policy output defaulted to passive behaviors, causing the drone to freeze or drift until timeout. This observation suggests that loss shaping alone was insufficient to resolve the distribution shift problem in this environment.

6.3 Impact of DAgger (Method 5)

Implementing DAgger (Dataset Aggregation) improved the success rate to 80%. By iteratively collecting data where the student operates and the expert corrects, the policy learned recovery behaviors. Notably, the jerk metric increased significantly (from 7.8 to $30.2m/s^3$). This

Table 1. Failure Analysis and Final Success (Averaged over 15 Episodes)

Method	Success	Jerk (m/s^3)	Min Clearance
Teacher (CHOMP)	100%	42.4	0.06 m
Vanilla BC	13.3%	4.3	0.55 m
BC + CVaR	6.7%	4.8	0.69 m
BC + CVaR + CBF	6.7%	7.8	0.34 m
Ours (with DAgger)	**80.0%**	**30.2**	**0.07 m**

suggests that the "smoothness" observed in the static-data policies was a result of passivity. The DAgger-trained policy exhibited more aggressive control behavior (closer to the Teacher's 42.4 jerk) to actively correct errors and navigate the clutter.

6.4 Flight Smoothness

The Teacher policy exhibited high jerk ($\approx 42.1 m/s^3$) due to the discrete nature of the ESDF gradient updates and the repulsion forces in the potential field. The policy with DAgger reduced jerk to $\approx 30.2 m/s^3$. This reduction indicates that the neural network effectively filtered some of the high-frequency optimization noise from the expert while maintaining the trajectory intent.

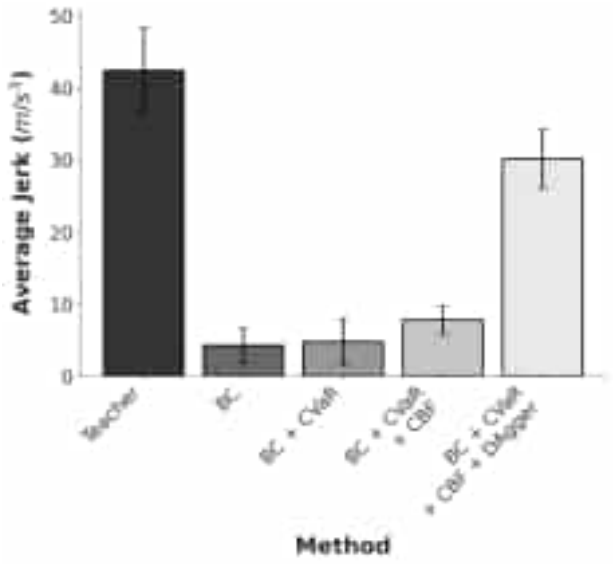

Figure 4. Comparison of average jerk. Lower values indicate smoother flight.

6.5 Safety Margins

The minimum clearance distance to obstacles was tracked during flight. The Teacher policy occasionally violated the safety margin, potentially due to local minima. The policy maintained a comparable clearance ($0.07m$ vs $0.06m$). The inclusion of the CVaR term was intended to penalize proximity to obstacles, though in the DAgger-trained model, the clearance remained tight due to the complexity of the environment.

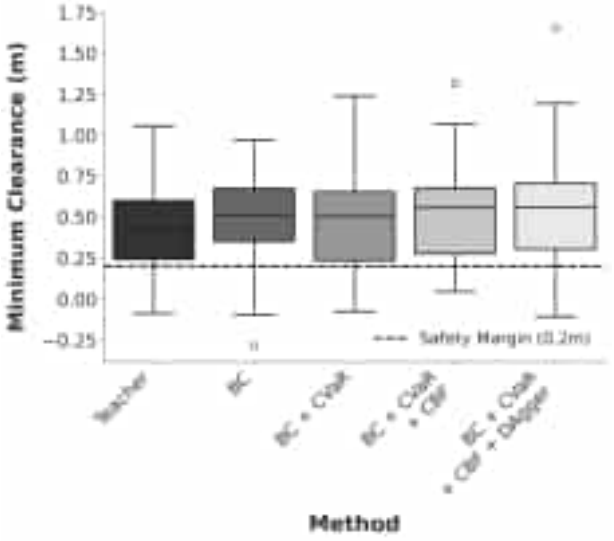

Figure 5. Distribution of minimum clearance distances.

7 Discussion

The quantitative evaluation highlights the challenges inherent in learning from static expert demonstrations. Despite incorporating safety-oriented regularization, methods trained without dataset aggregation consistently failed to achieve reliable goal-reaching performance. These failures are attributable to covariate shift: the expert trajectories occupy a narrow region of the state space, whereas deviations during execution place the learner in states for which no corresponding supervisory labels exist. Under these conditions, the policy exhibited unreliable corrective behavior.

Incorporating DAgger mitigated this issue by explicitly collecting supervisory signals in learner-induced states. This procedure enabled the policy to acquire effective recovery strategies and resulted in an improvement in success rate. The observed increase in jerk relative to static-training methods reflects a shift from conservative, low-

mobility behavior toward active correction, aligning more closely with the expert's operational characteristics. This suggests a trade-off where robustness requires active correction, which inherently increases control effort. The residual-learning formulation integrated the nominal controller with the learned correction. This structure allowed the system to default to the nominal controller when the residual was near zero, though the drift issues in static training suggest the residual component is critical for navigation in complex clutter.

7.1 Scalability

The results have implications for deployment on embedded hardware. The constant-time inference $O(1)$ of the neural policy contrasts with the scaling complexity of CHOMP. This efficiency is relevant for MAVs with limited onboard compute. Additionally, the Latent CBF operates on raw depth features rather than visual textures, which visual-domain dependence in future sim-to-real transfer to physical hardware using depth cameras.

7.2 Limitations

The current method relies on a static world assumption. The ESDF is computed instantaneously, ignoring the velocity of dynamic obstacles. Extending the method to dynamic environments would require a temporal component. Additionally, the LCBF provides a probabilistic estimate rather than a formal control-theoretic guarantee of safety. The present study is limited to simulation in PyBullet and does not include real-world UAV experiments, so the results should be interpreted as controlled empirical evidence rather than deployment-ready validation.

8 Conclusion

This paper presented a safety-regularized imitation learning framework for autonomous navigation in cluttered construction environments. By combining a residual policy architecture with a learned approximation of a control barrier function and a risk-sensitive objective, the method integrates safety considerations directly into policy learning for reactive aerial navigation. Experimental results demonstrate that, although safety-aware loss terms improve clearance behavior, they are insufficient to resolve covariate shift when trained solely on static expert demonstrations. Incorporating dataset aggregation through DAgger significantly improved task success by enabling the policy to learn recovery behaviors in learner-induced states. These findings highlight the importance of distribution-alignment mechanisms in imitation learning for risk-aware robotic navigation in cluttered environments.

Beyond the simulated evaluation presented in this study, several directions are particularly relevant for construction-oriented deployment. Future work will extend the environment complexity to include a broader range of construction clutter types, such as partially assembled structural elements, temporary formwork, and moving equipment. Additional sensing degradations common to construction sites, including dust, occlusion, sparse geometry, and sensor noise, will be incorporated to better reflect real-world operating conditions. Integrating prior information from Building Information Models (BIM) as structural or semantic priors may further improve navigation robustness and enable tighter coupling with construction workflows such as progress monitoring and safety inspection. Together, these extensions aim to bridge the gap between learning-based navigation research and practical deployment of aerial robots in active construction environments.

Abstract -

As digital fabrication systems in construction become more sensorized and controllable, they expose growing opportunities for data-driven process understanding that remain largely underutilized. Consequently, additive manufacturing workflows continue to rely on expert intuition and trial-and-error, which limits their industrial adoption in dynamic environments, such as construction sites. This paper presents PFAB, an open-source Python-based framework that enables predictive fabrication workflows by structuring data, coordinating learning tasks, and guiding parameter selection. PFAB formalizes fabrication as a data-driven process that generates predictive models through active learning methods and supports performance-based optimization of process parameters. Its modular, schema-first design separates framework-level orchestration from fabrication-specific logic, allowing the same predictive workflow to be applied across fabrication systems. The framework is demonstrated through Learning–by–Printing, an exemplary implementation for extrusion-based additive manufacturing, and is complemented by an executable reference implementation illustrating end-to-end usage.

Predictive fabrication; Data-driven additive manufacturing; Active learning; Learning by printing

1 Introduction

1.1 Motivation

Additive Manufacturing (AM) for construction is widely regarded as a promising technology to address long-standing challenges in productivity and sustainability. By connecting parametric design with automated fabrication and machine control, AM offers unprecedented flexibility and enables the efficient fabrication of bespoke components for reduced material use [1]. Yet despite rapid growth in academic activity and high-visibility demonstrators, AM has not realized this potential in practice [2]. Most systems continue to depend on expert intuition and iterative trial-and-error, resulting in a lack of first-time-right manufacturing and limiting broader industrial adoption.

A central difficulty emerges from the interaction of multiple interdependent factors, including design parameters, material behavior, environmental conditions, and machine settings. Small variations in any of these aspects can produce disproportionately different results [3]. This coupling and variability make AM processes difficult to model explicitly and challenging to control using traditional methods. As a result, there is a growing need for approaches that can leverage the digital nature of AM not only for automation, but also for acquiring, structuring, and interpreting process data to enable more predictable and robust fabrication [4].

1.2 A layered view on digital fabrication

Digital fabrication workflows can be understood as a sequence of tightly connected layers. At the design layer, geometric intent, structural considerations, and material selection are defined using computational and parametric tools. The fabrication layer translates this intent into a task plan governed by process parameters and converts it into machine-executable instructions for physical execution. These two layers form the basis of current practice and are well supported by existing digital toolchains.

Modern digital fabrication systems increasingly operate as cyber-physical systems (CPS): sensors capture the *as-fabricated* reality, data feedback is used to synchronize fabrication tasks, monitor quality, and maintain stable operation [5]. However, the use of this data remains largely reactive. Data is collected, inspected, or used for post-process corrections, but rarely interpreted in a way that reveals the underlying relationships between the design, material, process, and environmental factors that shape fabrication outcomes. As a result, current workflows still lack a systematic mechanism for learning from data, and the potential of cyber-physical systems remains underutilized.

To fully exploit the data feedback provided by modern CPS architectures, a predictive layer is proposed (Fig. 1). The Predictive Fabrication (PFAB) framework introduces this layer through a modular and generalizable architecture that orchestrates the entire data-processing and learning pipeline. PFAB models the general behavior of a fabri-

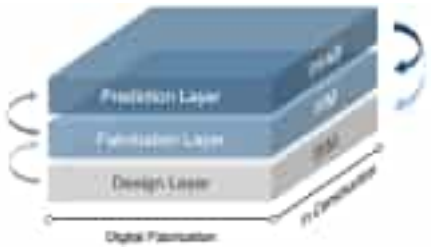

Figure 1. Layered view of digital fabrication in construction.

cation system to enable performance-driven optimization of process parameters. The resulting prediction model can be integrated into the fabrication layer for experiment-specific refinement and into the design layer for outcome-informed decision-making. This perspective provides the conceptual foundation for the generic software framework presented in this work.

2 Related Works

Recent work in digital fabrication highlights the strong coupling between design geometry, material behavior and process parameters, underscoring the need for structured process descriptions [6]. Frameworks such as Fabrication Information Modeling (FIM) formalize the digital-physical data flows required for cyber-physical operation [5]. Building on this foundation, data-driven approaches in AM have focused on feature extraction and learning methods to interpret sensing data and enable predictive modeling [4].

2.1 Data-driven additive manufacturing

Additive manufacturing processes build components layer by layer through controlled material deposition, giving rise to sensor measurements that are inherently spatially and temporally structured. Feature extraction forms a foundational component of data-driven workflows, as the performance of downstream learning processes is ultimately bounded by the quality and relevance of the extracted features. Wolfs et al. synthesized key quality indicators across scales and emphasized the importance of in-line and on-line measurement for achieving first-time-right manufacturing [7]. Versteege et al. demonstrated how knowledge-driven feature engineering can transform high-dimensional sensor data into compact, physically meaningful representations suitable for monitoring and learning [8, 9].

Complementary efforts use machine learning across a range of AM technologies to predict specific outcomes, such as buildability constraints [10] or microcrack investigations for the optimization of material performance [11]. Physics-informed and hybrid modeling strategies demonstrate how physical principles can be embedded into learning models, as shown in co-driven approaches that incorporate physical equations to improve rheological prediction and parameter selection [12]. Zhao et al. highlight the need for real-time monitoring to capture process deviations in-situ, as demonstrated by transformer-based detectors for in-process defect identification and analysis [13].

2.1.1 ML-oriented frameworks in related domains

Other fields have recognized the need for modular learning workflows that structure data processing, model training and deployment. In computational design, AIXD provides a low-code environment that integrates surrogate modeling and inverse design within an orchestrated pipeline [14]. General AutoML frameworks such as TPOT and Auto-Sklearn 2.0 [15, 16] further exemplify this principle by automating feature preprocessing, model selection, and validation within standardized pipelines. These frameworks demonstrate how modular architectures coordinate data, models and decisions, lowering the barrier to deploying data-driven techniques in complex learning workflows.

2.2 Summary of related works

Existing research shows that robust feature extraction remains fundamental, as predictive accuracy depends critically on the information derived from process measurements. However, current sensing, prediction, and hybrid modeling efforts address specific components of the fabrication process, leaving substantial potential in unifying these contributions within a holistic framework. More recently, studies have pointed to the need for real-time monitoring and adaptation during fabrication, where deviations must be addressed as they emerge to enable first-time-right manufacturing. At the same time, most approaches remain tightly coupled to specific materials, machines, or sensing setups, limiting their applicability across the diverse and variable characteristics of digital fabrication methods.

3 PFAB Framework

PFAB is a generic software framework for predictive fabrication that unifies data structuring, learning methods, and optimization routines within digital fabrication workflows. This transforms fabrication experiments into a systematic learning process, supporting parameter calibration and establishing the architecture for predictive closed-loop control. The PFAB framework is released as open-source software under the MIT license and cited as a versioned research artifact [17].

3.1 Overview

General-purpose machine learning frameworks assume the availability of static datasets and do not address a defining characteristic of fabrication systems: the ability to actively generate high-quality data through controlled physical experiments. PFAB is built around this capability, emphasizing targeted experimentation to maximize information acquisition while limiting resource expenditure.

The `PfabAgent` initiates this process by orchestrating the fabrication system through a structured data acquisition and evaluation workflow across an arbitrary number of sensing modalities. The resulting dataset enables the training of predictive models that support holistic, data-driven optimization of process parameters for unseen experimental configurations. The framework is built upon three architectural pillars:

- **Modular system architecture:** PFAB distinguishes between a core layer that defines the data object structure, a logic layer hosting fabrication-specific and internal processing, and an orchestration layer that integrates these components into a unified workflow.
- **Schema-first design:** To manage heterogeneous data, PFAB enforces a strict schema contract that guarantees consistency and enables automated validation across all downstream learning tasks.
- **Stateless agent:** The logic and orchestration are encapsulated in a stateless agent that operates as a pure function of the dataset, ensuring reproducibility and allowing robust recovery from interruptions.

Building on this architecture, PFAB structures parameter selection across three calibration modes: a *baseline mode* that proposes initial experiments through maximin spacing, an *exploration mode* focused on systematic information gain, and an *inference mode* that leverages trained models for performance-driven parameter optimization.

3.2 System requirements

PFAB assumes a digitally controlled fabrication system in which design intent, process parameters, and machine instructions are explicitly parameterized and programmable. Parameter configurations proposed by the predictive layer must be executable without manual intervention. The system must further provide sensor-based feedback capturing *as-fabricated* process information. This may include visual sensing, force or torque measurements, energy consumption, acoustic signals, or laser-based measurements. No specific sensing modality is required, as PFAB operates on derived features rather than raw signals.

3.3 Predictive layer workflow

The PFAB workflow consists of a sequence of stages that connect data structuring, user-defined logic, model training, and parameter calibration. While these steps can vary depending on the fabrication setup, their core structure follows a consistent pattern that integrates fabrication logic with PFAB's learning and calibration mechanisms. The key stages are outlined below.

3.3.1 Problem formalization

PFAB follows a schema-first architecture inspired by AIXD [14], in which all dimensions, parameters, features and performance attributes are defined explicitly before any data is collected. These data objects form a hierarchical structure: `Dimensions` describe the component structure, `Parameters` describe all inputs of the fabrication system, `Features` represent processed sensory information, and `PerformanceAttributes` score the extracted features to evaluate experiment outcomes. `DataBlocks` group these objects into coherent categories, and the resulting `Schema` serves as a strict contract that governs validation, storage and all downstream learning tasks. Once the schema is defined, a `Dataset` instance acts as a lightweight container that stores structured `ExpData` objects, one per fabrication experiment, and automatically manages their storage across local and external data sources (Listing 1).

# Define Schema and initialize Dataset objects
schema = Schema("name", params, domains, feats, attrs)
dataset = Dataset(schema, local_folder="local/")
```

Listing 1. Initialization of schema and dataset.

Fabrication-specific logic is introduced by defining how raw sensor measurements are transformed into structured features and how these features are scored against task-specific target values to evaluate fabrication outcomes. Since the appropriate learning algorithm depends on the structure of the data, PFAB allows users to configure an appropriate prediction model. Once these components are specified and validated against the schema, the `PfabAgent` initializes the systems that orchestrate all subsequent evaluation, learning, and parameter calibration steps (Listing 2).

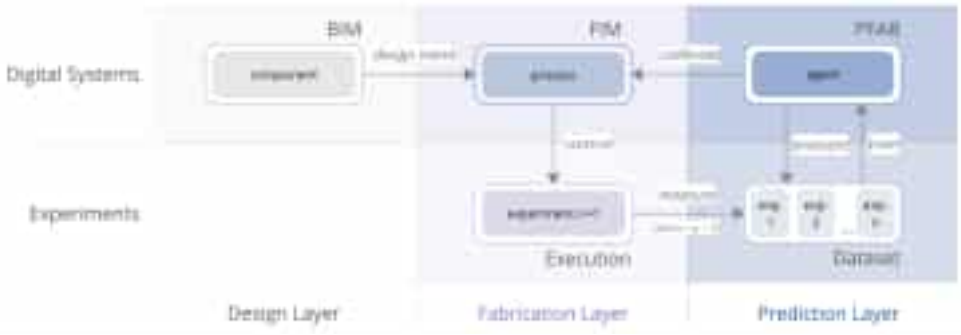

Figure 2. Illustration of the fabrication–learning loop with respect to the design, fabrication and prediction layers.

```python
# Initialize PfabAgent
agent = PfabAgent()

# Import and register user-defined models
import FeatModel, EvalModel, PredModel
agent.register_model(FeatModel)
agent.register_model(EvalModel)
agent.register_model(PredModel)

# Initialize agentic systems and validate against schema
agent.initialize_systems(schema)
```

Listing 2. Agent initialization and user-defined model integration.

3.3.2 Calibration modes

PFAB structures parameter proposal across three named calibration modes that differ only in their objective function, all executed through a single optimization engine, the `CalibrationSystem`. This allows the framework to guide fabrication from the first experiment until production-ready deployment within a unified interface.

Mode	Prediction model	Objective
Baseline	-	Maximin spacing
Exploration	Surrogate	Information-driven
Inference	Trained	Performance-driven

Table 1. Modes of the `CalibrationSystem`.

Baseline mode. Before active model development can start, PFAB generates an initial dataset using the `PfabAgent.baseline_step`, which proposes experiment configurations by maximizing spacing within the defined parameter bounds, requiring no predictive model. The fabricated experiments form an initial schema-based `Dataset` that enables subsequent calibration steps to operate on empirical observations rather than priors.

Exploration mode. The structured dataset is interfaced with the `DataModule`, which handles normalization, batching, and dataset splitting according to the schema and user inputs, ensuring consistent preprocessing across all learning steps. In the exploration mode, the user invokes `PfabAgent.exploration_step` on the current datamodule, and PFAB proposes the most informative next parameter configuration within the defined bounds. The proposed experiment is fabricated and added to the dataset, incrementally improving data coverage and predictive fidelity. This closes the fabrication–learning loop illustrated in Fig. 2, yielding a progressively enriched dataset promoting predictive generalization. The prediction model is periodically trained and validated on the growing dataset using the datamodule via `PfabAgent.train_step`. Once sufficient data coverage and validation accuracy are achieved, the predictive layer is considered production-ready.

Inference mode. The trained prediction model is queried through `PfabAgent.inference_step` to map a given design intent, expressed through its parametric representation, to an optimized set of process parameters for fabrication. Unlike exploration, inference is guided by a performance-driven optimization objective rather than information acquisition. The objective is defined through weighted performance attributes, which encode task-specific trade-offs and are passed directly to the inference step, preserving the stateless nature of the agent while allowing objectives to be adjusted without corrupting the workflow.

3.4 Executable Reference Implementation

An executable reference repository is provided as the primary entry point to the framework. It instantiates the required fabrication-specific interfaces and executes the full agentic workflow using synthetic data, enabling end-to-end execution without hardware or sensing dependencies. The repository is publicly available at `https://github.com/luca-bettermann/pred-fab-mock/tree/release/isarc-2026`.

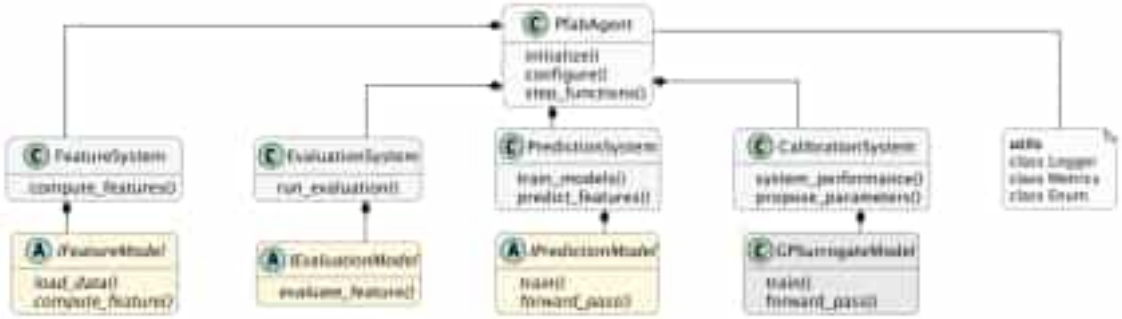

Figure 3. Schematic illustration of the modular `PfabAgent` system architecture.

3.5 Cross-layer integration

The predictive layer described in Sec 3.3 is self-contained and constitutes the methodological scope of this paper. However, as indicated in Fig. 1, the PFAB architecture is explicitly designed to leverage the predictive capabilities in preceding layers of the digital fabrication pipeline. These integrations reuse the foundational data structures and agent abstractions described in this section, and are briefly discussed to clarify the architectural intent of PFAB.

Fabrication-time adaptation. In principle, predictive models trained within the PFAB workflow can be fine-tuned and queried incrementally during fabrication as new *as-fabricated* data becomes available. By operating on explicit dimensions (e.g., printing layers), such integration would enable localized parameter recalibration and predictive closed-loop control. While architecturally supported, the methodology of fabrication-time adaptation is not detailed in this paper.

Design-time prediction. Similarly, trained prediction and evaluation models can be integrated in the design layer to estimate expected features and performance without physical execution. This enables outcome-informed design decisions, but remains outside the scope of this work.

4 Methods

The PFAB architecture is separated into framework-level orchestration and user-defined fabrication logic, as illustrated by Fig. 3. The `PfabAgent` serves as the single entry point and coordinates exploration, training and inference by delegating execution to specialized orchestration systems. These systems automatically manage any number of feature, evaluation and prediction components while keeping the core workflow unchanged.
Fabrication-specific logic is integrated through the highlighted abstract interfaces. Feature extraction is implemented via the `IFeatureModel`, which transforms raw sensor data into structured features. The `IEvaluationModel` maps these features to normalized performance attributes. Predictive models defined through the `IPredictionModel` contract are trained on the resulting dataset and queried during calibration. Together, these interfaces define the low-level extension points of PFAB, enabling fabrication-specific implementations while preserving a fixed orchestration flow.

4.1 Dimensional Domains

In digital fabrication, scalar process parameters are defined per experiment, whereas sensor-derived features are inherently dimensional, measured at specific positions within the fabrication structure (e.g., per layer, per path segment, or per structural node). PFAB formalizes this through the concept of a *Domain*: a named, ordered iteration space composed of *Dimension* objects, each representing one structural axis of the fabrication system (Listing 1). Features declare the domain they belong to, clearly defining their dimensional structure. The schema enforces that all user-defined models contain a coherent domain declaration, validated at system initialization (Listing 2). This explicit structure makes the agent's systems directly tailored to the structural element being fabricated, and forms the architectural basis for fabrication-time adaptation and predictive closed-loop control.

4.2 Calibration strategy

PFAB treats parameter selection as a constrained numerical optimization problem executed by a single solver orchestrated by the `CalibrationSystem`. In both the exploration and inference modes, the system calibrates process parameters by solving the same optimization problem, differing only in the objective function being optimized.
Calibration objectives are expressed through the scalar system performance $S(\cdot)$ that aggregates multiple task-specific performance attributes into a single normalized score. Each attribute is assumed to be normalized to $[0, 1]$

and assigned a user-defined weight w_i reflecting its relative importance. The system performance is computed as

$$S(\mathbf{a}) = \frac{\sum_i w_i \, a_i}{\sum_i w_i}, \tag{1}$$

where $\mathbf{a}$ denotes the vector of performance attributes.

4.2.1 Active learning objective

During dataset generation, calibration is driven by an active learning approach that reduces epistemic uncertainty while maintaining alignment with the user-defined system performance. PFAB employs a lightweight Gaussian Process-based surrogate model `GPSurrogateModel` that maps input parameters directly to expected performance attributes, while providing the required uncertainty estimates. The acquisition function follows an Upper Confidence Bound (UCB) formulation [18]:

$$\alpha(\mathbf{x}) = (1 - \kappa)\, S\big(\boldsymbol{\mu}(\mathbf{x})\big) + \kappa\, S\big(\boldsymbol{\sigma}(\mathbf{x})\big), \tag{2}$$

where $\boldsymbol{\mu}(\mathbf{x})$ and $\boldsymbol{\sigma}(\mathbf{x})$ denote the predicted mean and uncertainty, respectively, and $\kappa \in [0, 1]$ controls the exploration–exploitation balance *within the exploration mode*. The aggregation function $S(\cdot)$ is applied consistently to both quantities to prioritize information gain in regions relevant to the task objective.

4.2.2 Performance-driven objective

In the inference mode, calibration switches from the surrogate model to the full prediction pipeline to prioritize accuracy over uncertainty. The `PredictionSystem` maps input parameters $\mathbf{x}$ to predicted physical features $\mathbf{y}$, which are scored by the `EvaluationSystem` and aggregated into a scalar system performance:

$$J(\mathbf{x}) = S\big(E\big(f_\theta(\mathbf{x})\big)\big)\,, \tag{3}$$

where f_θ denotes the prediction model and $E(\cdot)$ the evaluation mapping.

5 Case Study: Learning–by–Printing

While PFAB is designed as a fabrication-agnostic predictive framework, this paper grounds its concepts through an instantiation in extrusion-based additive manufacturing. In this context, predictive fabrication manifests as Learning–by–Printing (LbP), in which fabrication outcomes are evaluated and used to calibrate process parameters such as nozzle speed and layer height. PFAB provides the structured data representation, learning pipeline, and calibration logic required to implement the fabrication–learning loop (Fig. 2).

5.1 Proof of Concept

The feasibility of Learning–by–Printing was demonstrated in a prior study on data-driven parameter calibration for extrusion-based 3D printing in construction [19]. That work aimed to validate whether a physical printing system can autonomously improve fabrication quality with respect to a defined objective using sensor data and predictive models.

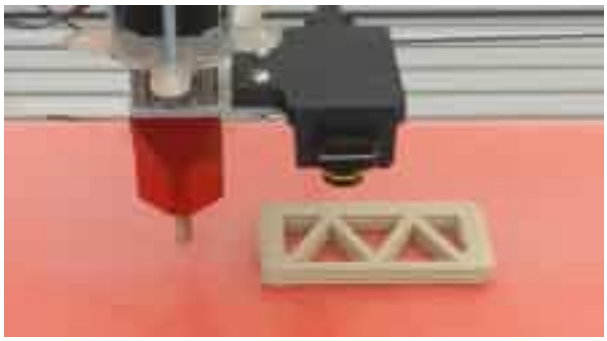

Figure 4. Extrusion-based clay 3D printing setup used in the Learning–by–Printing proof of concept [19].

The study executed the fabrication–learning loop in inference mode. A prediction model was trained from structured fabrication data and subsequently used to calibrate process parameters for future prints. Repeated fabrication trials demonstrated measurable improvements in geometric accuracy and structural consistency, validating the practical effectiveness of embedding predictive models directly into the fabrication workflow.

The Learning–by–Printing study is implemented using PFAB's schema-first formulation. Table 2 summarizes the parameters, features, and performance attributes used in the case study.

Table 2. Schema instantiation in the Learning–by–Printing case study [19].

Parameters	Features	Performance Attrs.
layer time	node overlap	p_{node}
layer height	filament width	$p_{filament}$
path offset	print time	$p_{process}$

Fabrication logic was implemented by extracting geometric features from computer vision-based models and evaluating them against task-specific target values derived from the intended print geometry. These steps directly realize PFAB's `IFeatureModel` and `IEvaluationModel` interfaces, while the `IPredictionModel` was instantiated using Gaussian Process Regression.

The calibration objective is formulated as the weighted

system performance,

$$S(\mathbf{a}) = \frac{w_1 * p_{node} + w_2 * p_{filament} + w_3 * p_{process}}{w_1 + w_2 + w_3}, \tag{4}$$

with weights $w_1 = 3.0$, $w_2 = 2.0$, and $w_3 = 1.25$ reflecting the relative importance of the performance terms. Optimizing this objective enabled automatic parameter calibration toward improved fabrication quality without any manual intervention.

6 Discussion and Conclusion

Prior research in data-driven digital fabrication has established sensing, feature extraction, prediction, and monitoring as key enablers for improving process reliability. However, these contributions typically address isolated aspects of the fabrication pipeline and remain tightly coupled to specific machines, materials, or experimental setups. This fragmentation limits their applicability to first-time-right manufacturing beyond the predefined setting of individual studies. Robust digital fabrication therefore requires jointly addressing process complexity and sensitivity to local, context-dependent disturbances in a generalizable manner.

PFAB contributes a unifying software framework that formalizes predictive fabrication as a structured, end-to-end process linking data acquisition, learning, and parameter calibration. By enforcing consistent data structures and modular interfaces, PFAB enables the development of predictive models that capture general fabrication behavior across experiments. The presented proof of concept in extrusion-based additive manufacturing demonstrates that such models, when embedded directly into the fabrication workflow, can guide parameter calibration and measurably improve fabrication outcomes without manual intervention.

At a conceptual level, PFAB addresses fabrication complexity by modeling the interactions between design, material, process, and environment in a data-driven manner. While this paper focuses on the predictive layer and its calibration workflow, the framework's architecture is explicitly designed to support fabrication-time adaptation as well as design-time prediction. Predictive closed-loop control targets local, non-generalizable sensitivities during execution, while an outcome-informed design stage promotes desirable fabrication outputs. In this way, PFAB provides a foundation for systematically addressing both complexity and sensitivity across the layers of digital fabrication systems.

The framework is presented as a conceptual and architectural contribution referencing an initial proof of concept; extensive empirical validation will be reported in upcoming publications. In practice, predictive performance remains bounded by the quality of feature extraction and evaluation criteria, which cannot be fully standardized and must remain customized to the fabrication context. Extending the predictive layer to fabrication-time adaptation introduces constraints on sensing latency and computational cost, which scale with the complexity of the prediction model's forward pass. These challenges are intrinsic to digital fabrication and reinforce the need for a system-level framework that makes such dependencies explicit and manageable. By standardizing how data, models, and fabrication systems interact, PFAB promotes modularity, transferability, and reproducibility across fabrication contexts. We argue that such data-driven frameworks form a necessary foundation for advancing digital fabrication toward reliable, first-time-right manufacturing in construction.

Abstract-
Facilities management teams encounter complex HVAC maintenance scenarios as faults propagate across interconnected subsystems. This study presents HVACONNECT, a text-enriched heterogeneous graph learning framework for HVAC-related maintenance triage. Using six years of CMMS work orders and BAS signals from a 19-building campus, a heterogeneous graph capturing building hierarchies, HVAC systems, and work orders was constructed. A large language model (LLM) pipeline was used to extract semantic data from raw work order text. A relation-aware heterogeneous GATv2 was then used to generate node embeddings via masked feature reconstruction. Feature ablation showed that removing text features reduced clustering quality by 44%, highlighting the critical value of semantic context. Downstream priority prediction achieved an operationally useful 83% precision despite severe class imbalance, and the learned component embeddings enabled meaningful maintenance-zone clustering.

Keywords-
Graph Deep Learning, GNNs, Priority Prediction, Maintenance Triage

1 Introduction

Heating, ventilation, and air conditioning (HVAC) systems dominate commercial building operational loads, requiring proactive maintenance to prevent comfort complaints and energy waste [1]. Traditionally, Fault Detection and Diagnosis (FDD) relies on Building Automation System (BAS) sensor streams. However, scaling BAS analytics across diverse portfolios is hindered by cross-building variability, inconsistent instrumentation, and high operational overhead [2].

Computerised Maintenance Management Systems (CMMS) offer a highly accessible alternative. Work orders routinely capture symptoms, actions, and priority signals without needing extra sensors. While recent Natural Language Processing (NLP) based methods can mine this text for triage, they typically treat records independently, ignoring the interconnected nature of building subsystems [3,4]. Graph learning naturally models these interdependencies. Graph Neural Networks (GNNs) couple equipment topology, operational context, and text-based maintenance events into a unified formulation. Heterogeneous graph architectures, in particular, allow the integration of mixed node and edge types while preserving narrative semantics [5,6].

To bridge this gap, this study introduces HVACONNECT (Heating Ventilation and Air Conditioning Operations Network for Node Embedding, Clustering, and Triage). By unifying BAS signals and CMMS work orders into a heterogeneous graph, our framework learns robust node representations. We demonstrate its operational utility through a three-level priority prediction task and maintenance zone clustering. Therefore, Section 2 reviews related work, followed by the proposed methodology in Section 3. Section 4 presents experimental results, and Section 5 concludes the paper.

2 Related work

BAS-driven fault detection and diagnosis has been widely studied using both domain-informed modelling and data-driven learning. However, persistent organisational and technical barriers exist, including inconsistent data quality, portfolio

variability, and weak alignment between algorithm outputs and actionable maintenance workflows, which are explored below.

2.1 CMMS work order analytics

Maintenance logs were repeatedly shown to contain predictive signals when analysed using text mining and machine learning. Work order narratives support component-level fault frequency analysis, while portfolio benchmarking indicates that these could be used to distinguish maintenance scenarios by building user populations [3,7] More recent work that applied NLP to automate labour assignment used neural networks for priority prediction, while clustering and taxonomy generation supported structured knowledge discovery from unstructured records [4,8]. However, these approaches rarely modelled explicit relationships between assets, symptoms, and interventions as a unified relational system.

2.2 Graph learning for maintenance representation

GNNs were progressively used to encode relational structure for diagnostics and prognostics [5]. In HVAC-specific settings, semi-supervised Graph Convolutional Networks (GCNs) improved fault diagnosis under limited labels, which indicated that topology and relational neighbourhood signals were beneficial when data were scarce [6]. Broader graph learning methods, including neighbourhood aggregation, attention-based message passing, relational convolutions, and heterogeneous graph transformers, enabled scalable modelling of multi-typed nodes and edges [9]. Text-based graph learning further demonstrate the capabilities of integrating text narratives into embeddings [10]. Together, these methods motivate our approach of treating maintenance planning as learning over a heterogeneous, text-bearing building graph rather than as isolated prediction over sensors or tickets.

3 Methodology

3.1 Data set

The data set covered BAS variables with CMMS work orders from a North American university complex as summarised in Table 1.Work orders were available in text format as exported tabular records. Each record contained a text description field alongside structured metadata fields such as dates, component identifiers, and cost values, which were directly ingested into the processing pipeline.

The scope focused on centralised HVAC assets aligned with Uniformat II[11] and Whitestone specifications [12]. Work orders were organised by system, subsystem, and component using unified identifiers for cross-building consistency, and each work order was originally linked to a HVAC component. Only reactive maintenance events were analysed.

Table 1.Work order dataset characteristics

Dataset attribute	Description
Data collection timeline	2014-2019 (6 years)
Institutional distribution	19 Buildings
Dataset volume	2999 distinct work order records
HVAC classification architecture	System, Subsystem, Component
Performance metrics	Labour hours, Material costs, Total maintenance costs
BAS Data	Temperature, Humidity, Atmospheric pressure, Wind Conditions

3.2 Analysis of unstructured work order descriptions

CMMS descriptions used inconsistent terminology and documentation styles. A data extraction step was applied to recover problem and action narratives, floor designations, and room markers, as illustrated in Figure 1. A 300-row gold standard was constructed by two domain experts with over five years of facilities management experience, who independently extracted problem and action labels from raw CMMS descriptions. Disagreements were resolved by a third expert. Four extraction sources were scored against this gold standard. LLM variants comprised three Gemini 2.5 Pro [13] prompt configurations (zero-shot, one-shot, and few-shot, with an increasing number of examples) and an open-source model Qwen3-30B-A3B-Instruct [14]. Each row was scored as correct when all fields matched the gold standard. The few-shot Gemini prompt achieved 99.7% accuracy, with similar performance from Qwen. The few-shot Gemini was retained as the production configuration. Across the full dataset, only 9 rows were flagged for manual checks, confirming that the pipeline operates reliably at scale with minimal human intervention.

Two candidate embedding models, OpenAI text-embedding-3-large [15] and Gemini embedding-001 [15], were evaluated across five metrics to be used as the text embedding model. While Gemini achieved higher thematic cohesion (0.730 vs 0.586), OpenAI demonstrated stronger inter-theme separation (0.646 vs 0.840, lower is better) and higher negation contrast (0.309 vs 0.198). OpenAI was selected as separation and negation sensitivity are more critical for distinguishing opposite system

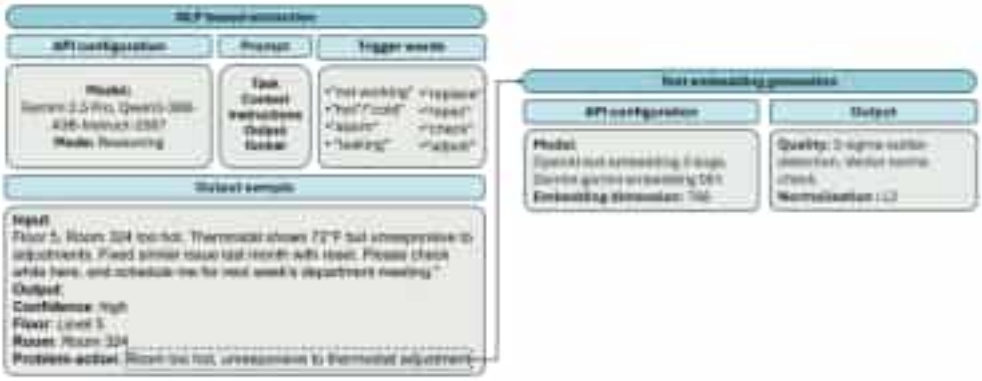

Figure 1. NLP extraction and text embedding generation workflow with other leading models used for comparison of extraction and embedding quality

states, such as “no airflow” versus “adequate airflow” in HVAC maintenance records. 768 embedding dimension is chosen as a standard widely used sentence transformer dimension [16]

3.3 Heterogeneous graph and fault propagation modelling

A heterogeneous HVAC operations graph was constructed to represent potential fault propagation through spatial, functional, and temporal relationships. The design followed a tripartite framing that aligned the representation with standards for system classification, maintenance documentation, and control mapping. The physical infrastructure layer encoded six containment levels, linking buildings to floors, floors to rooms, rooms to HVAC systems, systems to components, and components to work orders. Beyond containment, system-to-system edges captured control interactions and functional flow, and work order-to-work order edges captured temporal adjacency. Edge types and semantics are listed in Table 2.

Table 2. Graph edges and relationships

Source node	Target node	Relationship type
Building	Floor	contains floor
Floor	Room	contains room
Room	System	has system
System	Component	has component
Component	Work Order	has workorder
System	System	controls system
System	System	flows to system (flow type)
Work Order	Work Order	temporal (time difference)

An HVAC-specific flow topology was encoded using system flow edges to reflect service delivery pathways. Cooling generation supplied distribution networks that served downstream terminals, and heat generation followed a similar structure, while control edges represented feedback relationships. Temporal edges linked work orders within a seven-day window to reflect operational interdependence. The median inter-event time between consecutive maintenance events on related components is 4.2 days, with 62.4% of events falling within seven days. Temporal edge weights follow a linear decay from 1.0 at same-day to near-zero at the window boundary. A sensitivity analysis across 3, 7, 14, and 30-day windows confirmed stable results, with chain counts ranging from 225 to 357 and the functional similarity threshold having negligible effect, confirming that the seven-day window is a balanced operating point rather than an arbitrary choice.

3.4 Heterogeneous graph feature engineering

After graph construction, feature sets were assigned to each node type using BAS and CMMS data, as summarised in Table 3. Work order nodes combined text embeddings with numeric attributes representing problem diversity, thermal context, cost signals, and priority information. Features were normalised to stabilise message passing using z-score standardisation for scalar features and L2 normalisation for text embeddings.

Table 3. Summary of feature engineering

Node type	Feature groups	Representation
Building	Size, age, condition and cost indicators	Normalised numerics
Floor	Floor index, room count, subsystem counts	Normalised counts
Room	Floor index, subsystem presence	Indices, binary flags

System	System category, component count	One hot, normalised counts
Component	System family, component class	One hot, categorical codes
Work order	Text semantics, environment, priority, cost, problem diversity	Embeddings, engineered numerics, frequency features

3.5 Graph representation learning and downstream evaluation

Standard graph attention on homogeneous graphs does not preserve relation-specific semantics, therefore a customised heterogeneous GATv2 was implemented to learn embeddings under edge-type attention and multimodal feature integration. The building mask (BM) module given in Eq. (1), (2) reduces cross-building information leakage for within-building analyses. The overall architecture is shown in Figure 2.Figure 2. HVACONNECT model architecture

3.6 Heterogeneous graph attention architecture

Each message passing layer applied relation-specific GATv2 operators and aggregated relation-wise messages using a mean operator to avoid domination by high-degree relations. Four edge categories, building hierarchy, HVAC system structure, HVAC flow, and temporal linkage, were handled by separate operators. Each operator used four attention heads with 32 dimensions per head, producing 128-dimensional hidden representations after concatenation. Work order nodes used a two-stage projection with increasing dropout, while other node types used a single projection to 128 dimensions.

3.7 Domain-informed learning objective

The model was trained transductively using masked feature reconstruction. During training, subsets of input features were masked and the model reconstructed only masked positions, which encouraged reliance on neighbourhood information and reduced identity mapping. Masking rates were 30% for 768-dimensional language features and 10% for engineered scalar features. Reconstruction loss in Eq. (3) used mean squared error on masked indices only. A diversity regulariser Eq. (4), adapted from redundancy reduction principles in Barlow Twins [17] and VICReg [18], maximised mean pairwise Euclidean distance across all component embeddings to counteract global embedding collapse. A separation loss Eq. (6), grounded in supervised contrastive learning [19], operated on building-masked embeddings using cosine similarity to increase within-building alignment while reducing across-building similarity, preserving building-level identity distinct from the global geometric spread enforced by the diversity term. Total loss is given in Eq. (7).

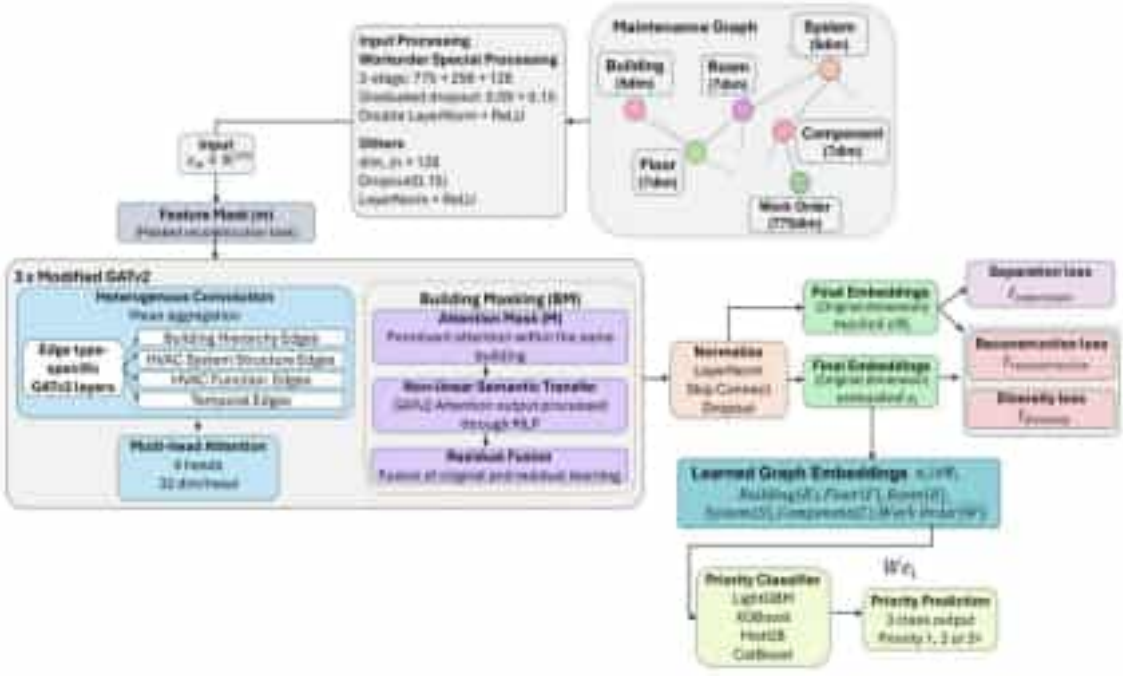

Figure 2. HVACONNECT model architecture

$$M_{ij} = \begin{cases} 0, & b(i) = b(j) \\ -\infty, & b(i) \neq b(j) \end{cases} \quad (1)$$

$$\alpha_{ij}^{BM} = \text{softmax}_j(e_{ij} + M_{ij}) \quad (2)$$

$$\ell_{\text{reconstruction}} = \frac{1}{|m|} \sum_{i \in m} \| D_t(e_i) - x_i^{in} \|^2 \quad (3)$$

$$\ell_{diversity} = -\frac{1}{N(N-1)} \sum_{i \neq j} \| e_i - e_j \|_2 \quad (4)$$

$$\tilde{e}_i^M = \frac{e_i^M}{\|e_i^M\|_2}, S_{ij} = (\tilde{e}_i^M)^\top \quad (5)$$

$$\ell_{\text{separation}} = -\text{mean}(S_{ij} \mid b(i) = b(j), i \neq j) + \text{mean}(S_{ij} \mid b(i) \neq b(j)) \quad (6)$$

$$\ell_{total} = \sum_t w_t \, \ell_{reconstruction}^{(t)} + \lambda + \gamma \, \ell_{separation} \quad (7)$$

Here, $b(i)$denotes the building membership of node i, $e_{ij}$the raw GATv2 attention score, and $\alpha_{ij}^{BM}$the attention weight after building masking. The set $m$contains the masked feature positions, $x_i^{in}$is the original input feature of node i, $e_i$and $e_i^M$are the node embeddings before and after masking, $D_t$is the decoder associated with node type t, $N$is the number of nodes, $S_{ij}$is the cosine similarity between L2-normalised masked embeddings, and $w_t$is the reconstruction weight for node type t. In total loss, $w_t$is the reconstruction weight for node type t, and λand γare the weights for the diversity and separation losses, respectively.

4 Experiments and results

4.1 Priority triage

The applicability of GNN-derived embeddings was first analysed using a priority prediction task using downstream classifiers. Raw CMMS priority values were grouped into three classes to reduce sparsity while retaining operational distinctions of urgent, high, and all remaining priorities.

Models were evaluated using two splits as given in Table 4. Priority labels were severely imbalanced, with 1,186 urgent work orders, 1,731 high-priority work orders, and 82 work orders in the remaining group. Under the stratified split, gradient boosting models achieved strong discrimination. With XGBoost, macro precision reached 0.832 and macro AUROC reached 0.837, indicating that the embedding representation separated classes despite macro averaging penalising minority performance. Under the temporally ordered split, performance decreased modestly. A text-only baseline trained on problem action embeddings underperformed the full HVACONNECT representation, which indicated that triage benefited from combining text semantics with relational and contextual signals learned through heterogeneous message passing.

4.2 Embedding validation and ablation evidence

Ablation analysis (Figure 3) reveals that removing problem and action text features causes the largest degradation in clustering quality, followed by thermal context feature Figure 3. Feature ablation. All changes are sign-normalised (negative:degradation). Baseline: Silhouette:0.896, DB:0.352, IBC:0.221, IBD:0.189. Overall is the unweighted mean of all four metrics. Removing priority deviation has minimal impact, confirming the model does not rely on it as an implicit shortcut. Clustering metrics, namely Intra-Building Cohesion (IBC), Inter-Building Distinction (IBD), Silhouette, and Davies-Bouldin (DB), confirm the embeddings successfully capture building context while maintaining coherent, well-separated structure.

Table 4. Priority prediction metrics

Model	Precision (weighted)	Recall (weighted)	F1 (weighted)	Precision (macro)	Recall (macro)	F1 (macro)	AUROC (macro)
80/20 Split							
LightGBM	0.7652	0.7650	0.7622	0.7958	0.6454	0.6925	0.8349
XGBoost	0.7615	0.7583	0.7563	0.8316	0.6424	0.6961	0.8374
HistGB	0.7612	0.7583	0.7558	0.8325	0.6415	0.6959	0.8340
Temporal Split							
CatBoost	0.7189	0.7200	0.7192	0.5622	0.5381	0.5473	0.7779
XGBoost	0.7349	0.7480	0.7409	0.4958	0.5002	0.4976	0.7950
LightGBM	0.7314	0.7427	0.7362	0.4935	0.4957	0.4940	0.7694
Text embedding only (CatBoost)	0.6252	0.6275	0.6239	0.4412	0.4399	0.4384	0.7050

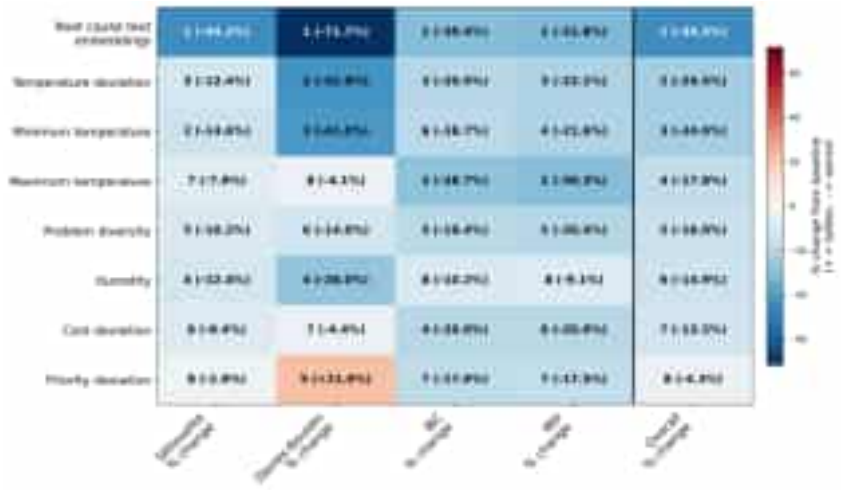

Figure 3. Feature ablation . All changes are sign-normalised (negative = degradation). Baseline: Silhouette:0.896, DB:0.352, IBC:0.221, IBD:0.189. Overall is the unweighted mean of all four metrics

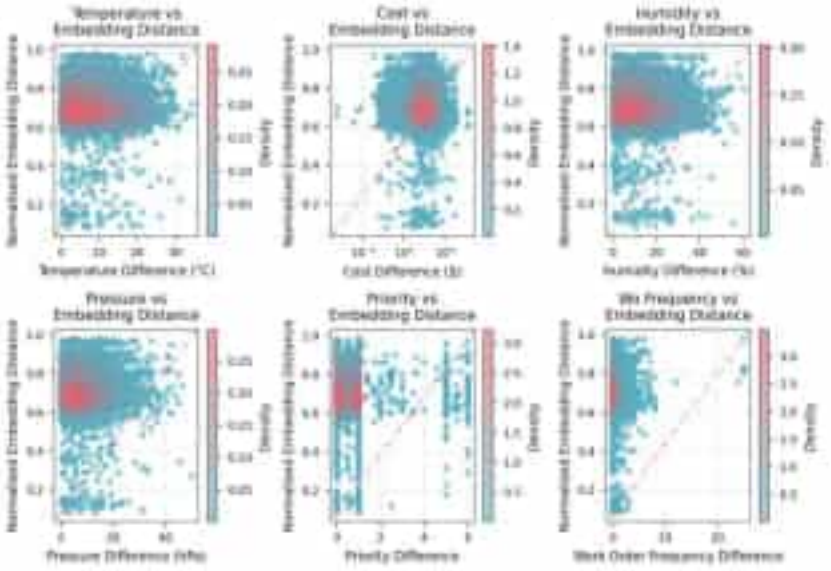

Figure 4. Embedding distance visualisation for feature reconstruction using HVACONNECT

Figure 4 maps pairwise operational attribute differences against normalised embedding distances. Most points sit above the hypothetical y = x line (where a single attribute would explain separation), proving HVACONNECT integrates multiple features simultaneously. Dense clusters with near-zero attribute differences but high embedding distances confirm that contextual factors, such as spatial location, component type, and message-passing dependencies, heavily drive the representations. Additionally, the log-scaled cost subplot shows components with drastically different maintenance costs can remain close in embedding space. This demonstrates that the attention mechanism effectively balances environmental, operational, and economic attributes without allowing any single feature to dominate.

4.3 Maintenance zone identification

A further application of the learned HVACONNECT component embeddings focused on optimising maintenance zones. Traditional zone-based strategies often relied on static, generalised boundaries that were not sensitive to operational conditions or functional interdependencies, which could create inefficiencies and overlapping responsibilities [20]. HVACONNECT addressed this gap by deriving data-driven maintenance zones directly from learned embeddings.

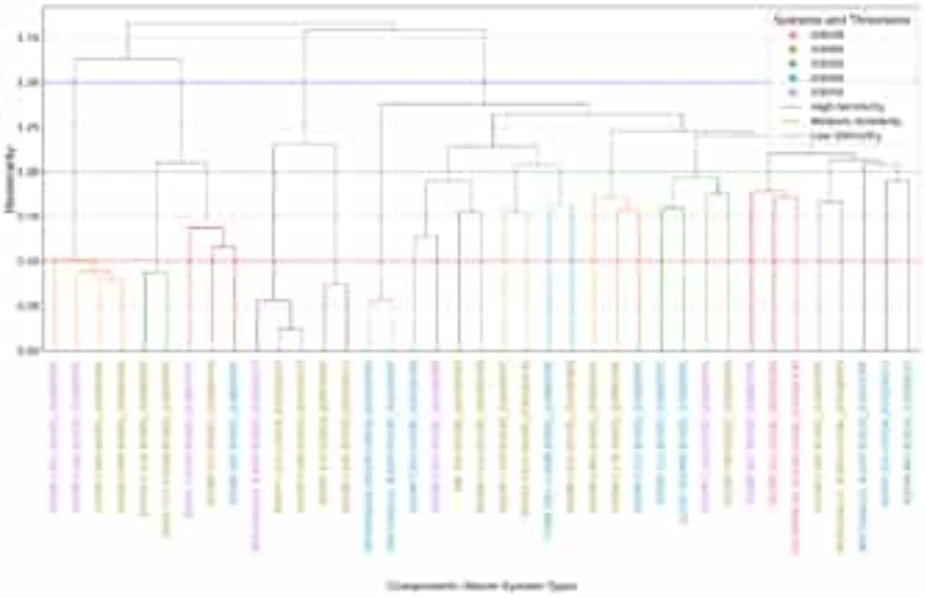

Figure 5. Hierarchical component relationships in building F280

4.4 Portfolio-scale zoning

Portfolio-scale zones were formed by applying DBSCAN to L2-normalised component embeddings using cosine-based dissimilarity. A semantic cut-off of $\theta \geq 0.80$ was used, corresponding to a neighbourhood radius of $\varepsilon = 1 - \theta$, which yielded $\varepsilon = 0.20$ in cosine distance. This configuration produced five dense and well-separated zones that broadly aligned with HVAC subsystem groupings, including heating, cooling, distribution, terminal units, and controls. Location attributes and work order history were attached after clustering to characterise each zone for scheduling and resourcing, while ε remained adjustable to match the operational setting.

The derived zones offered a compact view of resource demand and historical patterns. For example, a controls-centric zone captured a large share of thermostats and panels and exhibited substantial historical labour and cost, while a critical cooling zone isolated a small number of chillers and cooling towers that required specialist coverage despite a comparatively low cost profile.

4.5 Granular building-level relationships

To support building-specific planning, hierarchical clustering was applied to building-masked component embeddings using Ward's method to generate per-building dendrograms. This analysis provided a more granular view of how components clustered based on maintenance histories, and it supported three operational tiers defined by dendrogram distance thresholds (Figure 5). Tier A captured near-identical relationships for $0 \leq d \leq 0.50$, Tier B captured moderate coupling for $0.50 < d \leq 1.00$, and Tier C captured weak coupling for $d > 1.00$. The dendrogram visualisation was reported per building in a Room-System-Component format, which supported rapid inspection of within-system structure and cross-system relationships.

4.6 Limitations and future work

The framework's reliability depends on the quality of historical CMMS data, as inconsistent documentation can degrade the extracted semantics and embedding quality. Validation is limited to a single campus. While operational deployment requires pilot testing with facility management teams, the framework's outputs support several potential workflows. For reactive maintenance, priority predictions and nearest-neighbour searches could enable dispatcher triage and ticket bundling for co-located or similar components. In terms of planned maintenance, aggregated priority predictions by zone could inform labour and inventory forecasting. Additionally, for strategic maintenance, annual summaries of zone workloads could support threshold reviews and long-term replacement planning. Future work should evaluate model transferability across diverse portfolios, integrate real-time sensor attributes, and apply temporal graph learning to capture evolving operational states.

5 Conclusion

This study presented HVACONNECT, a text-enriched heterogeneous graph representation of

HVAC maintenance that unified physical hierarchy, operational relations, and work order history. The learned work order embeddings supported triage through priority prediction under severe class imbalance, while ablation evidence indicated that problem-action text contributed strongly to meaningful embedding structure. Beyond triage, the same embedding space supported data-driven maintenance zoning at portfolio scale and more granular building-level relationship inspection through dendrograms. Together, these outputs suggested a single representation learning backbone that could support reactive routing, planned scheduling, and strategic review of maintenance activities when deployed with human-in-the-loop processes.

Abstract –

Recent studies have highlighted the necessity for a conceptual cost prediction model for Modular and Offsite Construction (MOC) projects. Barriers such as high costs and the absence of scientific methods for justifying cost comparisons between MOC and conventional construction methods impede the adoption of MOC. This study presents an ensemble machine learning (ML) technique that assesses the performance of three distinct algorithms: linear regression, support vector machine regression, and random forest. It illustrates the effectiveness of this approach for preliminary cost predictions in the conceptual stage. The analysis of predicted versus actual costs demonstrated strong correlation, with R^2 approximately 0.78, root mean square error (RMSE) around 13340 (0.053 when normalized), and mean absolute error (MAE) approximately 10331 (0.041 when normalized). Additionally, the implementation of the synthetic minority oversampling technique (SMOTE) eliminated data-related stochasticity, while the timeline-based data collection addressed time-related stochasticity. This ensemble machine learning technique serves as a foundational database for subsequent learning-based models in MOC projects.

Modular and Offsite Construction; Ensembled Machine Learning; Conceptual Cost Prediction

1 Introduction

Modular and Offsite Construction (MOC) is acknowledged as a superior approach for improving sustainability and productivity compared to conventional on-site construction. MOC is a procedure wherein diverse building elements, including walls, floors, roofs, and staircases, are manufactured in a controlled environment and subsequently transported to the construction site for assembly. In this study, MOC or modular refers to factory-produced housing units manufactured in controlled environments and transported to site for final assembly, typically consisting volumetric modules and panelized structural components. However, the execution of MOC has been obstructed by uncertainty concerning the costs and advantages of employing these novel approaches in the construction industry. MOC approaches, including prefabrication, panelization, and modularization, utilize lean manufacturing principles to tackle conventional in-situ building issues, such as productivity, logistics, safety, emissions, waste, quality, and the trade-offs between environmental limitations and prices [1]. Notwithstanding these advantages, there have been increasing obstacles to the adoption of MOC as an alternative in nations such as Canada, Hong Kong, Singapore, the United Kingdom, and the United States. The recent threats to Canada's construction industry resulting from post-pandemic inflation highlight the necessity of adopting MOC as a potential solution to mitigate the negative impacts of inflation in this vital sector. However, progress is impeded by the absence of a cost database that can effectively illustrate the feasibility of MOC compared to conventional methods [2]. The primary obstacle to MOC in Canada is its inadequate comprehension. In the United Kingdom, prefabricated houses have not achieved commercial success due to obstacles such as elevated costs and restricted opportunities for clients and designers to customize [3]. Researchers have observed that ambiguity surrounding initial expenses, capital expenditures, payback timeframes, and supply chain challenges has impeded the implementation of MOC in China [4]. The principal challenges related to insufficient information for adopting MOC include: (1) the conceptual ambiguity surrounding MOC costs, (2) the perception that offsite solutions incur higher costs than traditional alternatives, (3) the absence of cost data and information regarding MOC, and (4) the uncertainty regarding methods to

reduce construction costs while enhancing efficiency.

To tackle with the cost related problems, researchers have followed traditional approaches, statistical methods, machine learning (ML) techniques and hybrid approaches. Traditional cost estimating methods employ detailed quantity take-offs, whereas comparative cost estimates depend on parameters including type, size, capacity, time, material, and other related factors. Traditional cost estimating relies on blueprints and specification breakdowns, which are time-consuming. Additionally, comparative cost estimates, such as case-based reasoning (CBR), assume a linear relationship between the final cost and fundamental design variables of the project. The assumption of a linear relationship is problematic and frequently leads to inaccurate cost estimates [5, 6]. Recent studies have increasingly focused on machine learning and deep learning algorithms with multiple layers, which are effective for comprehending the non-linear patterns inherent in the data [7, 8]. Stochastic parameters include temporal factors such as inflation rates and discount rates, as well as elements like missing data and outliers, which contribute to uncertainty in learning models. Researchers have employed methods such as Monte Carlo Simulation and Fuzzy Logic Theory to address these types of problems by completing the missing data [9, 10].

To address all these problems together, this study employs an ensemble machine learning-based cost prediction methodology, utilizing data from the US Census Bureau survey and RSMeans Square Foot Costs Book, to fulfill the following objectives: (1) to create a conceptual stage MOC project cost prediction model, (2) to establish a model for cost comparison between MOC and traditional alternatives, (3) to compile an initial cost database for MOC projects in Canada, and (4) to analyze the cost savings realized through the application of lean manufacturing techniques in previously completed projects across the U.S. The cross-country data were used because no complete dataset from the Canadian Modular Industry was available, and both the US Census Bureau and RSMeans have been widely adopted as international reference benchmarks in construction cost research. RSMeans provides normalized cost indexes that are transferable across regions and have been directly adopted in this study using two cross-country datasets. RSMeans Square Foot Cost data for Canada are already internally normalized using Canadian labor rates, material pricing, and provincial location factors. The objective of this study is not to establish absolute cost parity between the U.S. and Canada, but to examine whether the learned cost relationships from modular construction data remain valid when applied to region-specific Canadian baseline costs. Section 2 delineates the study approach employed to attain these aims. Section 3 delineates the findings and discourse of this investigation.

2 Methodology

As illustrated in Figure 1, the proposed methodology consists of following five steps: (1) data collection for modular buildings in U.S., data collection for conventional buildings in U.S., and data collection for conventional buildings in Canada; (2) data pre-processing stage combining preparation of data, exploratory data analysis, principal component analysis and mandatory pre-processors for a machine learning model such as one hot encoding and normalization; (3) developing the machine learning model using an ensembled approach with three algorithms; (4) data augmentation using the synthetic minority oversampling technique (SMOTE) and (5) model evaluation and validation. The following sections describe each step of the overview of the research framework.

2.1 Data Collection

The data collection step was mainly conducted through two major data sources which are the manufactured houses survey from US Census Bureau [11] and RSMeans Square Foot Costs Book [12]. 528 data points were collected from the survey results of U.S. Census Bureau ranging from houses 874 square feet gross area to 1879 square feet gross area. The survey was conducted across 44 states of U.S. from 2018 to 2023. Majority of the buildings were constructed using vinyl siding wood frame with concrete blocks and pressure treated wood as the foundation. Average buildings had 2 to 3 bedrooms as per the published information available. The price collected was the average sales price up to transportation to the client site excluding taxes and land acquisition fees. Depending on the available data from the survey results, required data were collected from the RSMeans Square Foot Costs Book for conventional houses in U.S. and conventional houses in Canada. 4483 data points were collected for conventional houses in U.S. ranging from 874 square feet gross area to 1879 square feet gross area to match the available manufactured housing data pattern, from 2018 to 2023. The data was collected for three different material types; wood siding wood frame, brick veneer wood frame, and stucco on wood frame. The data included three different number of floor representatives as in 1 floor, 1.5 floor and 2 floor as per RSMeans data set. The type selected was the single-family residential houses of average grade with continuous RCC footing and average mechanical and

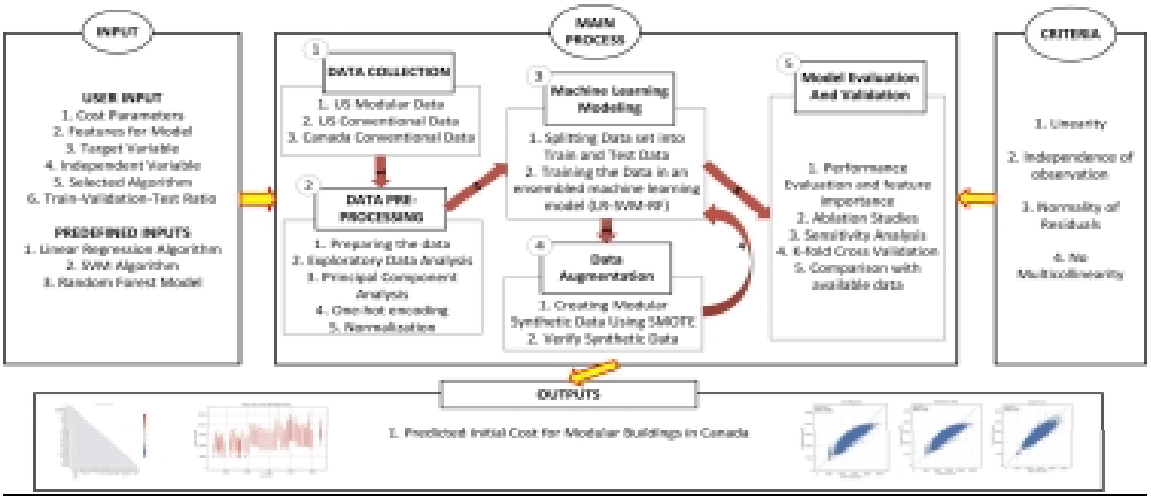

Figure 1: Overview of the research framework.

electrical equipment. The price collected was a sales price with general contractor overhead and profit without tax, which resembles a similar pattern from the conveyed survey results from U.S. Census Bureau. Similarly, conventional house price was collected for the 10 Provinces in Canada as well with a similar pattern of parameters such as area, floors, material and average building details. The total dataset was divided into 80:20 training and testing set ratio. The training dataset was used for model learning and hyperparameter tuning, while remaining 20% was used for independent model evaluation. Table 1 shows the statistical distribution of the collected data across different parameters.

Table 1: Summary of Dataset Distribution and Characteristics

Description	Details
Total Data Points	8738
Location	44 States/10 Provinces
Country	U.S. and Canada
Year	2018-2023
Material	4 Types
Number of Floors	1, 1.5, 2.0
Average Building	Single Family Single Section
Dataset Distribution	
Category	Number of Samples
Modular (U.S.)	528
Conventional (U.S.)	4483
Conventional (Canada)	3727
Total	8738
Model Training Configuration	
Parameter	Value
Train-Test Split	80:20

The Canadian dataset for conventional buildings collected using RSMeans was not used to train the final machine learning model, rather it was used up to data augmentation as a baseline cost for conventional buildings with Canadian parameter. This helped the dataset to learn cost pattern differences among U.S. and Canada regional barrier and the U.S. modular and conventional data helped to learn cost patterns between modular and conventional buildings.

2.2 Data Pre-processing

The second step included preparation of data according to the requirement for the model, exploratory data analysis to understand the existing relationship and patterns, principal component analysis to find out influential parameters connected to the target variable and finally one hot encoding along with normalization before feeding the data into the machine learning model.

2.3 Machine Learning Modeling

A three-algorithm ensemble machine learning model was selected to execute the core methodology. The three algorithms utilized were linear regression, support vector machine, and random forest. The objective of choosing these three algorithms was to furnish a list with diverse capabilities for capturing both linear and nonlinear patterns in the dataset. Linear regression forecasts cost by representing the linear increase or decrease of the target variable as a function of the independent variables. A support vector machine can be optimized by the selection of the kernel and hyperparameters to accommodate variations in the dataset's pattern. Furthermore, random forest is a tree-based algorithm that has recently demonstrated efficacy in identifying high-dimensional

nonlinear patterns inside datasets [13]. Figure 2 illustrates the architecture of the generated machine learning model.

Figure 2: ML model architecture.

2.4 Data Augmentation

The data augmentation process was executed to address some gaps in the U.S. Census Bureau survey data. Data for gross areas ranging from 1202 to 1452 square feet and from 1576 to 1768 square feet were absent. The initial model exhibited subpar performance due to an inadequate variation in the distribution of the chosen independent variable. As some ranges of modular housing sizes were missing in the U.S. Census Bureau data, to ensure a balanced dataset and avoid bias toward certain building sizes, the Synthetic Minority Oversampling Technique (SMOTE) was used to generate additional samples for the underrepresented ranges. At first more data were collected from RSMeans for the underrepresented ranges for conventional U.S. and conventional Canada buildings. Finally, data augmentation was applied to generate synthetic data for the missing ranges in the U.S. modular data as well as some data for Canada modular so that the model is not overfitting to any independent variables. Various data augmentation approaches were examined, including the SMOTE, random oversampling technique, adaptive synthetic oversampling technique, TOMEK under-sampling technique, and k-means and k-medians imputation. Given the availability of real-world datasets pertaining to conventional buildings in RSMeans as a primary data source, the SMOTE was selected for the data augmentation phase. This method generates synthetic data by establishing neighbors within the existing minority data, while a custom relationship logic can elucidate the observed relationships between the majority and minority data throughout the entire dataset. The generated synthetic data was assessed by distribution skewness, correlation preservation tests (such as Pearson and Spearman), and the Kolmogorov-Smirnov (KS) test of the cumulative distribution function [14]. Table 2 shows the data type ratio before and after augmentation process.

Table 2: Data type ratio for collected and augmented dataset

Dataset	Data Type	Ratio
Collected Data (8738)	Real Modular: Real Conventional	6:94
First Augmented Data (36042)	Real Modular: Synthetic Modular: Real Conventional Including Missing Area Ranges	1.5:48.5:50
Final Model Dataset (18153)	Real Modular: Synthetic Modular	2.9:97.1

2.5 Model Evaluation and Validation

The model evaluation and validation phase commenced with an assessment of the created models' performance regarding correctness and errors, with the resultant feature importance in relation to the original principal component analysis. Upon attaining the requisite performance level, multiple ablation tests were undertaken, including the elimination of existing outliers in the dataset, to ascertain whether performance could be enhanced further or if the outliers were merely noise. The building type was concurrently utilized as a variable across all accessible data, including conventional data, to evaluate potential enhancements in model performance and to ascertain the presence of overfitting. A sensitivity analysis was conducted to assess variations in the target variable and to identify any excessively sensitive elements within the model. K-fold cross-validation was ultimately conducted to confirm that the final model was neither overfitting nor underfitting. To make sure the synthetic data behaved like real data, statistical tests such as Pearson, Spearman, and Kolmogorov-Smirnov were used to compare distributions. The results showed no significant difference between real and synthetic samples, meaning the added data followed the same patterns as the original dataset.

3 Results and Conclusions

To assess the proposed machine learning-based cost prediction model, various evaluation methodologies were employed at this stage such as the coefficient of determination (R^2), mean absolute error (MAE), and root mean square error (RMSE) to yield a thorough comprehension of the model and identify the optimal algorithm as shown in Figure 3. Subsequently, feature importance, ablation experiments, sensitivity analysis, and k-fold cross-validation were conducted.

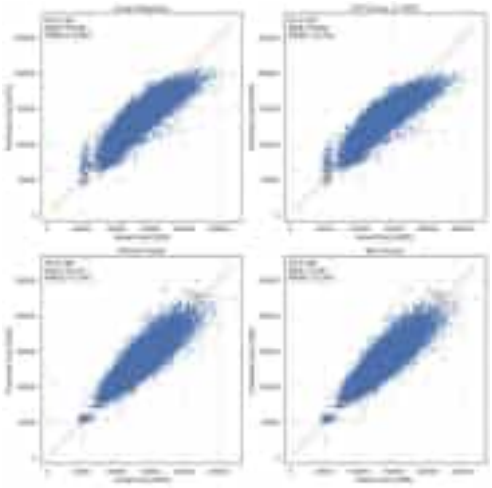

Figure 3: Performance of the machine learning model.

3.1 Performance Evaluation and Feature Importance

As per the ensembled model architecture, random forest is chosen as the optimized algorithm for the dataset. Random forest feature importance was conducted to analyse the influential features that influence the final model. Table 3 shows the performance comparison against existing conceptual cost studies in conventional construction as there is no comparable study in modular construction till date.

Table 3: Performance Comparison

Article	Algorithm	R^2	Dataset
[15]	LR and ANN	0.69 – 0.98	Historical Residential Buildings from Germany
[16]	LR	0.95	Historical Care Retirement Facility
[17]	ANN	0.89	Water Rehabilitation Projects
[8]	GB	0.99	RSMeans Structural Assemblies
Proposed Study	RF	0.78	Combined US Census Bureau and RSMeans

The ensemble architecture was initially developed to evaluate three candidate algorithms' (LR, SVM and RF) performance on the final dataset. As shown in Figure 3, RF was the best performer as per developed ensembled architecture, so final feature importance was conducted for RF. Depending on internal pattern of the dataset, and hyperparameter tuning, the best performer can change in case of any other dataset or this dataset when additional data from Canada modular industry is available. Testing the model's performance on any other dataset is considered outside the scope of this study. Figure 4 shows the output for the random forest feature importance test. Area and year appear as dominant predictors because construction cost estimation is inherently dependent on building size and temporal cost escalation. However, other variables such as location, material type, and number of floors also contributed to model predictions. The scope of this study is within the prediction for a conceptual stage cost for modular buildings, and with the availability of more granular data regarding phases and components future work can investigate more into the dominant predictors such as specific modular building parameters like module sizes, panel sizes and joints.

3.2 Ablation Studies

Two varieties of ablation investigations were performed subsequent to the selection of the final machine learning model. The final model dataset had 18,153 data points, encompassing both actual and synthetic modular building data. The dataset had outliers across various model features, including area, location, material, and year. Subsequent to the final model selection, these outliers were eliminated from the final dataset to ascertain if the model's performance would

improve. The outliers were identified using interquartile range (IQR) method, where observations outside 1.5xIQR from the first and third quartiles were considered potential outliers. The R^2 value decreased from 0.78 to 0.75, suggesting that the remaining outliers in the sample represented significant distributional variance rather than mere noise, and their removal led to underfitting. A dataset with typical RSMeans data included 36,042 data points. The inclusion of "building type" as an additional training feature was examined, yielding an R^2 value of 0.95 and the maximum importance for this feature suggesting overfitting, which resulted in the model's exclusion. The inclusion of "building type" resulted in a significant increase of R^2 value because the model captured dataset-specific correlations rather than generalizable patterns. This is expected since RSMeans data encodes strong cost differences directly through building type (e.g., economy, average etc.). A comparison between initial principal component analysis and this model's random forest feature importance revealed that "building type" did not consistently appear as dominant contributor on principal component analysis explaining overall data variance, however in this model it emerged as an overly dominant predictor, suggesting potential bias. Therefore, instead of applying explicit regularization, a feature exclusion strategy was adopted to improve model generalizability.

3.3 Sensitivity Analysis

A sensitivity study was conducted to evaluate the model's performance across all chosen features. The primary objective of this test was to identify any oversensitive characteristics within the designed model and to ascertain whether the model remained susceptible to uncertain parameters, such as absent outliers, incomplete data, temporal variables like inflation, and other deficiencies.

Figure 5 illustrates the outcomes of the sensitivity analysis. The final model demonstrated a balanced sensitivity across all selected features. The previously observed unclear behavior, stemming from ambiguous parameters, was largely mitigated in the final model.

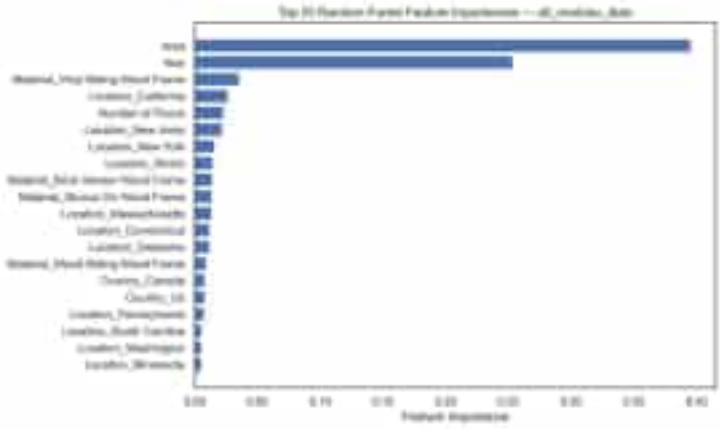

Figure 4: Random Forest feature importance of the final tested model.

3.4 K-fold Cross Validation and Comparison with Available Data

The predictions from the machine learning model were ultimately confirmed by 5-fold cross-validation and by comparing them with the cost data available from the U.S. Census Bureau survey results and the RSMeans database. Figure 6 illustrates that there were no significant alterations in the R^2 value during the 5-fold cross-validation, demonstrating that the model was not overfitted to any subset of the dataset and performs consistently on unseen data. The model achieved a mean R^2 value of 0.779 with a standard deviation of 0.008 and standard error of 0.0036. The 95% confidence interval of the mean R^2 was estimated as [0.77, 0.79], indicating low variability and stable performance across different data partitions.

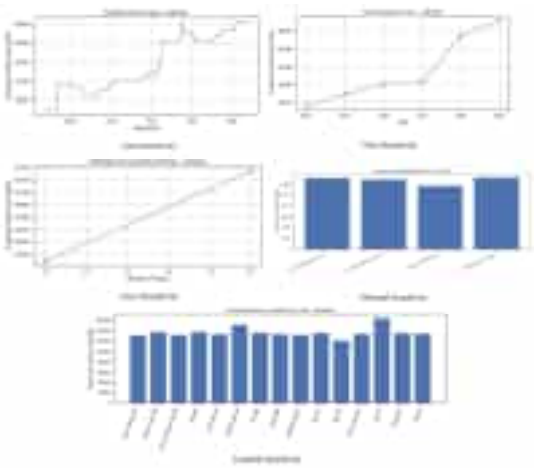

Figure 5: Sensitivity analysis results from the final model.

Subsequently, the projected modular construction cost data was compared with the actual data. The comparison involved analyzing the cost data disparity between modular and conventional buildings from the U.S. Census Bureau survey and contrasting it with the conventional costs from RSMeans in Canada and the projected modular costs derived from the model.

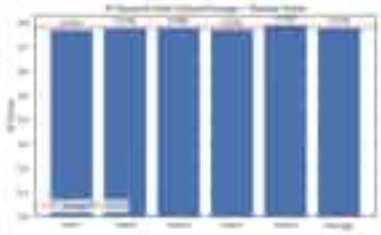

Figure 6: 5-fold cross validation results.

The comparison of analogous features among the selected independent variables in the U.S. and Canada revealed a mere 0.9% discrepancy between the two. This further demonstrates that the model has discerned the relational patterns present in the empirical data. The objective of the comparison in Table 4 is not statistical inference but illustrative comparison of cost patterns between modular and conventional construction. A detailed statistical hypothesis testing framework is considered outside the scope of this conceptual stage study and will be explored in future research. The purpose of this cross-country comparison is also not to establish exact cost parity but to evaluate whether learned cost relationships remain consistent across datasets. Full economic normalization between U.S. and Canadian markets is considered outside the scope of this conceptual model.

Table 4: Comparison with real world data for similar features

Building Type and Country	Area (Sq. ft.)	Cost (US $)	Average % Difference
Conventional, U.S.	1777	239138	-
Modular, U.S.	1777	141200	40%
Conventional, Canada	1777	299350	-
Predicted Modular, Canada	1777	176892	40.9%

3.5 Conclusion

This paper presents an ensemble machine learning strategy to tackle current cost-related issues in conceptual cost prediction for MOC. The proposed framework establishes a thorough methodology to create a verified learning-based cost prediction tool for the MOC sector in Canada.

This study's contributions are as follows. A complete strategy for creating a conceptual-stage cost estimation tool for MOC projects is provided. This framework tackles the dual aims of forecasting modular construction expenses and establishing a preliminary database for MOC projects, which may be utilized for subsequent cost prediction models. This study determines the most significant cost parameters for a conceptual cost prediction model by the integration of comprehensive feature selection and feature importance analysis. This model does not differentiate between specific cost components rather, it illustrates the cost reductions of a MOC project relative to a conventional project. Nevertheless, it can acquire and convey information and expertise from one regional research to another by employing conceptual cost factors. This may prove efficient for future research in sectors lacking data, but notable advancements have occurred in other regional areas. Knowledge and information produced in one region can be effectively assimilated and disseminated using a comparable machine learning model to enhance the designated industry.

Moreover, the established machine learning model can be calibrated to function as a cost-comparison tool between MOC and traditional projects. The ambiguity regarding the advantages of MOC projects can be alleviated. Despite the initial overhead expenses associated with establishing factories and machines potentially surpassing those of traditional projects, the elimination of waste, enhancement of quality, and acceleration of timelines can markedly decrease costs, hence boosting sustainable construction practices.

Applying cross-country normalization is considered outside the scope of this conceptual-stage model. Future

work will investigate explicit cross-country normalization once sufficient real modular cost data become available in Canada. Moreover, although synthetic data were used to fill missing ranges, the model was carefully validated to ensure these data did not distort results. Future work will include more real modular housing data from Canadian projects to further verify model robustness. As the objective of this study is conceptual-stage cost prediction rather than detailed cost breakdown modeling, component-level decomposition such as production, transportation and overhead cost will be addressed in future work when more granular modular factory data become available.

This research facilitates the creation of a viable machine learning-based cost predictor by the implementation of methodologies including timeline data collection, data augmentation, and synthetic data synthesis, which mitigate uncertainties stemming from inflation rates, absent data, and outliers. While the model is proficient in making certain predictions, enhancements can be implemented to evaluate its capacity to address uncertainties. The model could be expanded to function as a more detailed cost breakdown structure for MOC projects when analogous data is accessible from factories. Ultimately, the model may be employed to formulate a multi-objective optimization problem whereby cost serves as either a constraint or the objective function of the favored methodology.

Abstract –

Large language models (LLMs) evolve rapidly, yet their probabilistic generation is inherently non-traceable and leaves a persistent bottleneck in domain knowledge cognition. Retrieval augmentation via texts or knowledge-graphs (KGs) improves coverage and factual accuracy, but existing studies still depend largely on static knowledge structures and manually governed updating, so the obstacle to sustained and reliable domain knowledge cognition remains. This study therefore proposes a synergized LLM–KG framework for domain knowledge, centered on ontology-governed KG automatic generation (AutoGen) and update, and hybrid vector–graph retrieval for clause-grounded reasoning. Specifically, guided by a manually developed ontology, the KG is automatically constructed, incrementally enriched, and jointly used with vector retrieval to ground each query against both textual evidence and graph structure. A case study is conducted in construction contract management. Results demonstrate the robust KG AutoGen performance with average F1 scores of 0.904 for entity extraction and 0.856 for triple extraction. Across three query stages, the framework further improves multi-hop reasoning and clause-grounded accuracy, with its F1 advantage over GraphRAG widening from 0.00 to 0.37 and that over LLM-only prompting increasing from 0.25 to 0.45. This study provides a traceable route to deeper, more reliable, and continually refined domain knowledge cognition.

Keywords –

LLM; Knowledge graph; Domain knowledge; Knowledge cognition

1 Introduction

Recent advances in large language models (LLMs) have remarkably improved machines' natural language processing performance even in general but complex contexts. However, when application scenarios shift from general-purpose settings to domain-specific environments, the performance is no longer determined solely by interpretative and generative ability [1]. Rather, it fundamentally depends on domain knowledge cognition, defined as the processes by which input information is transformed, processed, stored, retrieved, and used [2]. Despite their strong parametric memory, LLMs remain susceptible to hallucinations due to their probabilistic generative nature, so factual reliability remains a concern in specialized domain knowledge. More importantly, LLMs do not naturally convert unstructured evidence into reusable, explicit knowledge representations, and dependable domain deployment remains difficult [3].

As structured representations of entities and their relationships, knowledge graphs (KGs) are widely regarded as a promising approach to domain knowledge cognition due to their support for logical reasoning and cross-task reuse [4]. Nevertheless, constructing and maintaining high-quality KGs remains costly, and practical deployments often suffer from limited coverage and delayed updates, and high maintenance effort. To address these limitations, increasing attention has been devoted to integrating LLM and KG. Existing studies largely fall into two categories: (i) LLM for KG, where LLMs are leveraged to accelerate entity alignment and relation extraction for automated KG construction; and (ii) KG for LLM, where KGs serve as external knowledge sources that enhance LLM reasoning through approaches such as Graph-based Retrieval-Augmented Generation (GraphRAG) and Think-on-Graph (ToG) [5]. Despite progress along both directions, most existing work focuses on isolated stages of the cognitive process. LLMs are typically used for one-off triple extraction and KG construction, whereas KGs primarily serve as static or manually updated stores for retrieval. As domain evidence is often ambiguous and context-dependent, there is an increasing need for a synergized LLM–KG framework that leverages their complementarity to update domain cognition through query-driven interaction, in a manner akin to human experts [6].

To address this gap, this study proposes a synergized LLM–KG framework tailored for domain knowledge cognition, which integrates ontology-governed KG

AutoGen and update with hybrid retrieval-augmented reasoning. Departing from conventional functionally isolated designs, this framework aims to construct a continuously improving cognitive system that synergizes KG and LLM. Specifically, the domain ontology is first manually established as the governing schema and representational boundary for domain knowledge. Building on this, an LLM-driven and ontology-governed KG AutoGen pipeline is developed to support domain KG initialization and incremental update. At the query stage, the framework can acquire relevant external resources online, update the vector database (DB), and incorporate domain knowledge via KG AutoGen into KG DB. More importantly, it introduces a hybrid reasoning mechanism, in which the ontology schema, vector DB, and KG DB are jointly leveraged to ground evidence and strengthen reasoning capability.

A construction contract management case study is conducted to evaluate the proposed framework. Using the Public Sector Standard Conditions of Contract for Construction Works 2020 (PSSCOC CW 2020) in Singapore as the source corpus, this study excerpts 3 subparts for the comparative experiment. To ensure a fair comparison with baseline methods, online search is excluded. Instead, the first subpart is used for initialization, while the remaining two are introduced sequentially in two query-driven update stages. The evaluation focuses on two aspects: the accuracy and stability of KG AutoGen, assessed against manually annotated entity- and triple-level gold standards for each subpart; and reasoning performance, evaluated through a 15-question hierarchical benchmark with manually defined gold-standard references, in comparison with LLM-only prompting and GraphRAG under the same information setting at each stage. After systematic examination, the results demonstrate both the reliability of ontology-governed KG construction and update, and the advantage of hybrid retrieval in improving multi-hop reasoning and clause-grounded answering during query stage.

The remainder of this paper is organized as follows. Section 2 reviews related work on LLM-KG integration for domain knowledge cognition. Section 3 presents the proposed methodology. Section 4 describes the construction contract management case study and the corresponding experimental evaluation. Section 5 concludes the paper and discusses future work.

2 Related work on domain knowledge augmentation for LLM

Among existing domain knowledge augmentation research for LLM, domain knowledge cognition can be treated as an operational capability that supports (i) perception of domain evidence, (ii) memory organization and reliable recall, (iii) reasoning over constraints and relational structure, and (iv) decision-oriented use of the derived knowledge [7]. Building on this, existing approaches can be positioned into four representative paradigms: prompting engineering, Naive RAG, Graph RAG, and synergized LLM–KG, as shown in Figure 1.

Figure 1. Comparison of Prompt engineering, Naive RAG, Graph RAG and Synergized LLM-KG.

(1) Prompt engineering

Prompt-based methods treat cognition primarily as an in-model process, with manual prompt construction based on scaffolds, including few-shot exemplars and structured reasoning instructions, to elicit task behavior. Their main advantage is low cost and rapid adaptation, since no external memory layer is required. However, domain knowledge remains inadequate, largely implicit and non-auditable, its reliability depends heavily on manual prompt design and the model itself, and systematic provenance tracking is typically unavailable.

(2) Naive RAG

Naive RAG grounds cognition in external text source materials, i.e., vector database (Vector DB), utilizing retrieval mechanisms as a proxy for memory recall. While this approach effectively mitigates hallucinations and supports efficient retrieval over large document collections, it relies on unstructured, fragmented text chunks. Consequently, the system often lacks the connectivity required for cross-document consistency, struggling to reconstruct the complex causal chains necessary for robust knowledge reasoning [8].

(3) Graph RAG

Exemplified by approaches like GraphRAG and ToG, this paradigm introduces a structured memory in the form of a KG to act as a semantic index. By retrieving entities, navigating relational paths, and aggregating neighborhood contexts alongside text, these methods significantly enhance precision and support for compositional queries. While this improves explainability and reasoning depth, conventional pipelines often treat the KGs as static DBs with high maintenance costs, lacking a mechanism for dynamic, user-driven updates to the knowledge state.

(4) Synergized LLM–KG

This paradigm integrates LLMs and KGs as mutually complementary components in domain knowledge cognition. The KG serves as structured domain memory that preserves entities, relations, and constraints, while the LLM supports extraction, retrieval orchestration, and reasoning over the grounded evidence. Although prior studies have demonstrated the promise of combining LLMs with structured knowledge, most focus on either KG-assisted reasoning or LLM-assisted KG construction in isolation. Much less attention has been given to ontology-governed KG automatic generation and incremental update under newly introduced evidence [6]. Consequently, existing synergy remains largely static at the retrieval stage, rather than extending to controlled knowledge expansion.

Motivated by these observations, the unresolved issue is not simply how to retrieve more evidence, but how to support a continuous domain cognition process in which knowledge can be structured, queried, verified, and selectively updated. This study accordingly tries to address this through two coupled capabilities: ontology-governed KG AutoGen and update, and hybrid vector-graph retrieval for clause-grounded reasoning.

3 Methodology

To operationalize the proposed paradigm, this study develops a synergized LLM-KG framework to support domain knowledge cognition, as illustrated in Figure 2. The framework comprises three parts: document parsing, ontology-governed KG AutoGen and update, and QA with hybrid reasoning. Operationally, the framework starts from a parsed corpus and a manually prepared ontology. The domain ontology is manually developed to provide a consistent schema of concepts, relations, and constraints. Document parsing then converts raw documents into a cleaned corpus and a vector database for retrieval. Governed by the ontology, KG AutoGen transforms extracted evidence into ontology-aligned entities and triples, which are consolidated into the KG as structured domain memory and incrementally updated when new evidence is introduced. At the query stage, the QA module jointly exploits the ontology schema, vector DB, and KG DB to support clause-grounded reasoning, with agentic external search activated when internal evidence is insufficient.

3.1 Document parsing

The process begins with document parsing, where domain documents are uploaded as raw sources. The system first applies structural segmentation to preserve the original information organization, such as section boundaries and figure-related content, so later retrieval can return evidence in coherent units rather than fragmented text. After segmentation, text cleaning and normalization will be conducted to reduce noise introduced by formatting and heterogeneous layouts. The cleaned text is then tokenized and stored in a vector DB, which serves as the retrieval substrate for later evidence access. In short, document parsing turns unstructured materials into a normalized corpus and a vector index, which later supports both ontology construction and evidence grounding in QA.

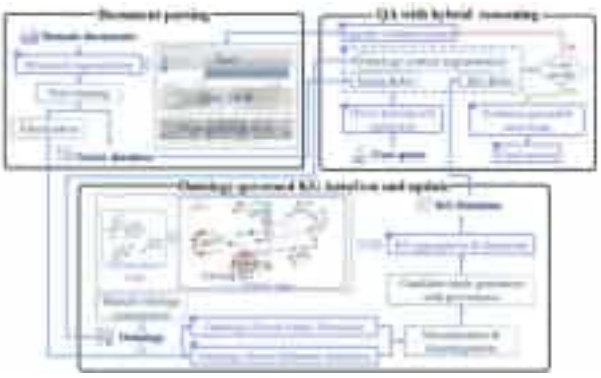

Figure 2. Research methodology.

3.2 Domain ontology manual development

Domain ontology is developed to provide a stable semantic boundary for KG AutoGen and update by defining the admissible classes, relation types, and constraints required for the target domain. The development process follows four steps: identifying core domain concepts from existing domain ontology (such as IfcOWL for BIM/IFC semantics; BOT for building structure; Brick for building systems) or authoritative domain sources (IFC for BIM data structure; bSDD for the built environment; OSHA 29 CFR 1926 for construction safety; FIDIC/NEC for construction contract); defining relation types and semantic constraints to capture domain logic; normalizing synonymous or ambiguous expressions into controlled labels and stable identifiers; and formalizing the resulting schema in RDF/OWL as a machine-readable governance layer. The ontology is then evaluated through competency questions to verify its adequacy for entity typing, relation extraction, and reasoning support. Once established, it serves as the schema boundary for KG extraction and validation, while the KG is incrementally constructed and updated under its governance.

3.3 KG AutoGen

The ontology specifies the normative schema and constraints, while the KG serves as the instance-level memory populated and governed under this schema for subsequent retrieval and reasoning. Given the ontology,

KG AutoGen therefore provides a systematic pathway to transform dispersed textual evidence into a structured and auditable KG. The ontology is maintained in RDF/OWL to provide a formally specified schema of concepts, relations, and constraints, and it functions as a constraint layer that steers extraction toward schema-consistent structures. Specifically, entities are extracted in an ontology-driven manner so that mentions are typed by predefined professional concepts rather than ad hoc labels, and relations are derived under the ontology's relation schema to reduce structural drift and improve constraint consistency. To ensure global consistency across sources and iterations, normalization and disambiguation are performed so that variant surface forms resolve to stable identifiers.

During implementation, the operational KG is stored in Neo4j as a labeled property graph (LPG), enabling efficient subgraph operations and low-latency incremental updates through Cypher queries [9]. Candidate triples are generated with provenance, including source documents and evidence spans, which supports traceable verification before consolidation. To enforce ontology governance over an LPG-based KG, KG AutoGen applies a lightweight schema mapping and validation layer that projects ontology classes and properties to Neo4j labels, relationship types, and admissible property constraints, and uses these constraints to gate triple insertion. Importantly, the generation and consolidation behavior evolve between iterations. In the first run, no existing KG is available, and the newly generated triples are connected and organized to form an initial KG structure. In other runs, the system operates in an incremental mode: newly generated triples are aggregated and aligned against the existing KG, where entity matching, relation alignment, and duplicate resolution enable integration, refinement, and expansion of the graph. Finally, evaluation and validation filter out inconsistent or weakly supported triples before accepted updates are committed to the KG database. Through this iterative construction-and-alignment process, KG AutoGen establishes a validated memory substrate that the QA module can reliably retrieve and reason over, while also enabling controlled assimilation of domain knowledge over time.

3.4 QA system with hybrid reasoning

When user makes a query, the framework runs a QA pipeline that tightly couples synergized retrieval and structured reasoning. A user query is first parsed and expanded into retrieval-ready representations, including key entities, constraints, and decomposed sub-questions. Based on this structured interpretation, the system launches two complementary retrieval streams. The first stream follows a vector-led Naive RAG workflow that retrieves semantically relevant text segments from the vector database. The second stream follows GraphRAG on the KG DB, where Cypher queries retrieve query-conditioned communities and construct a task-specific subgraph that captures relational structure and constraint dependencies that plain text retrieval does not expose. This study further augments the LLM with ontology text, which supplies schema and constraint information to enforce schema-consistent interpretation and reduce structurally invalid inferences. During the process, the LLM acts as an orchestrator that aligns text evidence with graph evidence, checks consistency against ontology constraints, and resolves mismatches between retrieved passages and KG assertions.

When internal evidence is insufficient or outdated, external evidence retrieval is activated. Agentic web search acquires supplementary sources, which are subsequently processed through document parsing and ontology-governed KG AutoGen to produce query-relevant structured evidence. This evidence is then cross-checked against the existing subgraph and ontology constraints before entering the reasoning pipeline. On this basis, the final answer is generated through evidence-grounded synthesis, with explicit reconciliation between text-derived evidence and graph-derived structure.

Reasoning is not treated as a terminal step when externally retrieved evidence is verified. Instead, the framework performs a controlled update, under which only qualified statements are written back to the KG DB. Specifically, a candidate statement is committed to the KG only when (i) its supporting evidence is traceable to concrete sources, (ii) it does not contradict existing KG facts or the evidence base, and (iii) it complies with the ontology-defined schema and constraints. Through this update process, each interaction not only produces an evidence-grounded response but also incrementally improves the knowledge base, increasing coverage and precision over repeated use while preventing unverified errors from being written back and amplified.

4 Case study

To evaluate the proposed framework, a construction contract management case study is conducted using the Public Sector Standard Conditions of Contract for Construction Works 2020 in Singapore (PSSCOC CW 2020). This corpus is well suited to the study because contract reasoning is clause-intensive, procedurally constrained, and inherently multi-hop: practical questions often require navigation across notices, causal events, entitlement conditions, payment procedures, and dispute routes.

4.1 Experimental design

Three subparts are excerpted from PSSCOC CW 2020. Subpart A covers time, claims, loss and expense,

and payment workflow; Subpart B adds instructions, contract documents, ambiguity, and delay causation; and Subpart C further adds variations, valuation, dispute routes, and service of notices. To ensure fair comparison, online search is excluded. The system is initialized with Subpart A only, then updated with Subpart B in the first growth stage and with Subpart C in the second growth stage. This design makes knowledge expansion explicit and allows the effects of KG update on reasoning depth to be examined stage by stage.

4.2 Experimental setting

The evaluation follows two tracks. First, KG AutoGen is assessed against manually annotated gold standards at the entity and triple levels for each subpart. The gold annotations cover 20 entities and 18 triples in Subpart A, 15 entities and 12 triples in Subpart B, and 15 entities and 12 triples in Subpart C. Second, reasoning performance is evaluated using a 15-question hierarchical benchmark with manually defined gold-standard clause references. The benchmark contains five Stage-1 questions over Subpart A only, five Stage-2 questions over Subparts A+B, and five Stage-3 questions over Subparts A+B+C. Their reasoning depth increases from single-chain 3-4 hop, to cross-subpart 5-6 hop, to multi-subpart 7-9 hop, while the number of gold-standard sections rises from 8-10 in Stage 1, to 12-14 in Stage 2, and to 18-24 in Stage 3. LLM-only prompting and GraphRAG are adopted as baselines, and all models receive the same information at each stage. Precision, recall, and F1 are reported for both KG AutoGen and reasoning experiments. Figure 4 illustrates the implemented interface for clause-grounded answering and graph inspection.

4.3 Results and discussion

For the construction contract management case, the domain ontology was manually developed as a contract-variant-specific governance layer for KG AutoGen and update. Rather than aiming to cover construction contracts in general, the ontology was bounded to the conceptual and procedural scope of the target corpus, namely the Public Sector Standard Conditions of Contract for Construction Works 2020 in Singapore (PSSCOC CW 2020), with emphasis on the three selected subparts used in the staged experiment: time extension, claims and payment workflow; instructions, document hierarchy, ambiguity, and delay causation; and variations, valuation, disputes, and notice service. Within this boundary, it specifies the main entity classes, relation types, and semantic constraints needed for clause-grounded reasoning, including actors such as Contractor and Superintending Officer, instruments such as notices and instructions, events such as delay and ambiguity, and procedural objects such as claims, payment certificates, variations, valuation steps, and dispute routes. The ontology was formalized in RDF/OWL and validated through competency questions derived from the benchmark, such as whether the schema could represent the notice and substantiation chain for time and loss-and-expense claims, the contractual effectiveness of oral instructions, the resolution path for ambiguity-linked delay and cost, the variation-to-valuation-to-payment route, and the effect of service-of-notice rules on later dispute procedures.

Building on the ontology, KG AutoGen constructs the knowledge graph through staged initialization and incremental update. In the initialization stage, ontology-typed entities and schema-consistent relations are extracted from the initial contract corpus, transformed into provenance-backed triples, and consolidated into an initial KG. In later stages, when additional contract subparts are introduced, KG AutoGen performs incremental consolidation by aligning newly generated triples with the existing graph through entity matching, relation alignment, and duplicate resolution. In this way, the KG grows progressively with the expanding corpus while remaining governed by the same ontology-defined schema and constraints. Figure 3(a) visualizes the resulting graph at the final stage, and Figure 3(b) shows a representative clause-centered subgraph.

Figure 3. Visualization of (a) the 3rd update stage KG and (b) the detailed subgraph.

The framework is implemented as an end-to-end operational system, where LLM services via the DeepSeek API are used to orchestrate query interpretation, evidence alignment, and verification, while the KG is stored in Neo4j to support efficient subgraph retrieval and incremental updates. As illustrated in Figure 4, users interact with the system through a QA interface. For each query, the system retrieves both passage-level evidence from the vector database and structure-level evidence from the KG, constructs a query-conditioned subgraph, and generates an evidence-grounded answer with clause-linked support. In parallel, the interface exposes the retrieved related

knowledge as an interpretable graph view and triple list, enabling users to inspect the reasoning substrate rather than receiving a black-box response. For more details, please check the demo exhibition video from the website: https://www.youtube.com/watch?v=IDWH5f-LsZE.

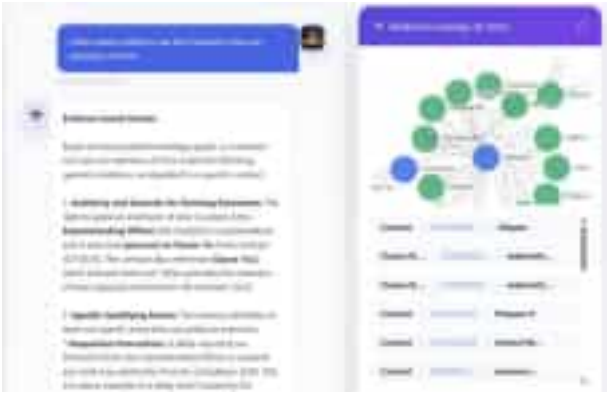

Figure 4. The synergized LLM-KG cognition system.

To further assess hybrid reasoning performance, the proposed framework is compared with two baselines: DeepSeek (LLM-only) and Neo4j GraphRAG (GraphRAG). To ensure a fair comparison, the LLM-only systems operate without access to the internal KG or any online search; the same base LLM and embedding model are used across GraphRAG and the proposed framework, while the difference lies in whether ontology-governed KG AutoGen, KG incremental update, and ontology-augmented retrieval are enabled. All methods are evaluated on the same set of contract management questions under the same staged information setting.

Tables 1 and 2 summarize KG AutoGen performance across the three subparts. Entity extraction remains strong across all stages, with F1 scores of 0.927, 0.903, and 0.882 for Subparts A, B, and C, respectively, yielding an average F1 of 0.904. Triple extraction is more demanding but still robust, with F1 scores of 0.889, 0.800, and 0.880 and an overall average of 0.856. These results show that ontology governance provides a stable extraction boundary not only during initialization but also during incremental update, even when later subparts introduce more cross-clause and procedural relations.

Table 1. Performance of machine annotated entity across subparts.

Subpart	Precision	Recall	F1
A	0.905	0.950	0.927
B	0.875	0.933	0.903
C	0.833	0.938	0.882

Table 2. Performance of machine annotated triple across subparts.

Subpart	Precision	Recall	F1
A	0.889	0.889	0.889
B	0.769	0.833	0.800
C	0.846	0.917	0.880

Table 3 shows that the reasoning advantage of the proposed framework becomes more evident as the knowledge state grows and the questions become more multi-hop. At initialization, the proposed method matches GraphRAG at F1 = 0.76 and already exceeds LLM-only prompting by 0.25. After the first update, its F1 rises to 0.79, outperforming GraphRAG (0.55) and LLM-only prompting (0.43). After the second update, the advantage widens further to 0.82 versus 0.45 for GraphRAG and 0.37 for LLM-only prompting. This trend indicates that the main benefit does not lie merely in storing more information, but in updating the KG under ontology governance and then retrieving evidence jointly from vector space and graph structure.

Table 3. Results of evaluation metrics for compared models.

Stage	LLM-only			GraphRAG			Ours		
	P	R	F1	P	R	F1	P	R	F1
Startup	0.42	0.66	0.51	0.72	0.81	0.76	0.72	0.82	0.76
Update 1	0.36	0.53	0.43	0.49	0.62	0.55	0.75	0.84	0.79
Update 2	0.31	0.46	0.37	0.39	0.52	0.45	0.78	0.86	0.82

In qualitative terms, LLM-only can produce fluent but weakly grounded answers, whereas GraphRAG improves structural retrieval but remains limited when the graph is incomplete and processing capability is limited at one time. By contrast, the proposed framework returns clause-linked answers together with an inspectable subgraph, making the reasoning path auditable. This is particularly important for contract management, where whether a claim succeeds often depends on the exact interaction among notice clauses, evidentiary requirements, and procedural escalation.

5 Conclusion

This study proposes a synergized LLM-KG framework for domain knowledge cognition, centered on ontology-governed KG automatic generation and update, and hybrid vector-graph retrieval for clause-grounded reasoning. Unlike conventional approaches that treat KG construction, updating, and querying as isolated functions, the proposed framework connects these stages within a unified workflow, in which structured knowledge can be automatically constructed from domain evidence, incrementally expanded under

ontology governance, and jointly exploited with vector retrieval during reasoning. In this way, the framework provides not only evidence-grounded answers, but also a traceable and continuously improvable knowledge base.

To ensure reliability, the framework uses a manually developed ontology as the schema boundary for entities and triples extraction and validation, thus KG is constructed and updated through provenance-backed and schema-consistent triples. At the query stage, textual evidence and graph structure are jointly retrieved to support clause-grounded reasoning. The construction contract management case study demonstrates that the proposed framework achieves robust KG AutoGen performance across initialization and update stages, while also improving multi-hop reasoning and clause-grounded answering over both LLM-only prompting and GraphRAG baselines. These results indicate that the main advantage lies not merely in storing more domain knowledge, but in governing KG growth through ontology constraints and integrating vector-based and graph-based evidence during reasoning.

Several limitations also remain. Future work will further validate the framework compared to broader advanced LLMs and retrieval frameworks with real-world dynamic document settings. Other important directions include more systematic handling of conflicting evidence, more principled criteria for ontology refinement, and broader evaluation of long-term knowledge growth under repeated updates. In addition, future research may explore closer integration between external evidence acquisition and internal KG consolidation, so that domain knowledge can be expanded in a more timely and trustworthy manner.

Abstract –

This study explores the integration of Building Information Modeling (BIM)-based selective disassembly planning with robotic automation to facilitate the efficient and autonomous retrieval of building components, addressing critical challenges in the construction industry's transition toward a Circular Economy (CE). The BIM-based disassembly planning system developed in previous studies forms the core of this framework, generating optimized sequences for disassembly while considering environmental impacts, cost efficiency, and structural dependencies. This information is processed and utilized by robotic operating systems to execute precise disassembly tasks, as demonstrated through virtual simulations and pilot tests. The results indicate the technical feasibility of robotic selective disassembly for simple building archetypes, highlighting the potential for scaling this approach to more complex scenarios. The proposed method offers substantial decarbonization benefits by enabling material recovery and reuse, reducing reliance on virgin resources, and minimizing waste generation. These advancements directly contribute to reducing greenhouse gas emissions associated with material extraction, processing, and disposal. Additionally, this approach aligns with CE principles by extending the lifecycle of building components and promoting sustainable construction practices. Future work will focus on validating the framework in real-world applications, addressing challenges such as variability in building systems, structural interdependencies, and environmental constraints. The integration of advanced robotics, including AI-driven perception and adaptive control, will further enhance scalability and robustness. Moreover, potential applications in extreme environments, such as extra-terrestrial construction, underscore the versatility of this approach.

1 Introduction

Selective disassembly sequence planning (SDSP) is emerging as a transformative technology in the disassembly of buildings, offering several advantages. It facilitates the efficient retrieval of reusable building components and materials [7,9], supports adaptive reuse [15], renovations [16], and maintenance [16], and contributes to the development of superior life-cycle strategies like Design for Disassembly (DfD) [1,5,10,12] and the concept of buildings as future material banks [1,14]. Simultaneously, the field of robotic automation for assembly and disassembly in construction is gaining momentum [8]. The deployment of robotics in this context is proving to increase the efficiency and quality of work, demonstrate both technical and economic feasibility, and address labor shortages in response to the substantial current and future demand for buildings worldwide [4].

The need for implementing SDSP in a systemic manner is critical in today's context for a transition towards a Circular Economy (CE) in the built environment. The construction industry is currently responsible for the depletion of 40% of global natural resources and generates approximately 40% of waste ending up in landfills [1]. These issues are largely due to the fact that the existing built environment was not designed with disassembly, reuse, adaptation, or transformation in mind [12,16]. Additionally, practical SDSP methods and tools have been lacking [14]. However, recent advances have seen the implementation of SDSP [15] and robotic automation [18] using Building Information Modeling (BIM). This convergence has created a clear pathway for leveraging the combined benefits of both technologies to achieve optimized, systemic disassembly of building structures, thereby supporting the decarbonization of the built environment.

The primary aim of this study is to develop a framework for the integration of BIM-based SDSP into robotic automation processes. The framework focuses on the information processing using a previously developed BIM-based SDSP system for enriching the intelligence of robots for the autonomous disassembly of targeted

structure components. The information processing will be elucidated for the technical implementation using different types of robotic solutions (e.g. robotic arms and wheeled robots) and virtual simulations (e.g. robotic arm simulator). A functional demonstration has been created to showcase the preparation, processing, and integration of information necessary for the BIM-based SDSP system and the operating system of a robotic solution.

2 Background

2.1 Selective disassembly for buildings

Selective disassembly sequence planning (SDSP) is the process of recognizing the required consecutive steps for dismantling targeted building components, defining deconstruction activities, and ordering them logically. While SDSP for manufacturing products has been developed over the past five decades, SDSP for buildings has gained more attention only in the last decade due to the growing need for a CE in the built environment [15]. In 2018, the BIM-based Sequential Disassembly Planning for Buildings (SDPB) method was developed for the selective disassembly of building components. The SDPB method analyses the disassembly capacity of building assemblies by generating optimized sequences for retrieving targeted components, considering environmental impact, building cost, and rule-based analysis [14]. Mahmoudi and Hosseini Nourzad [9] developed the Hybrid Disassembly Sequence Planning (HDSP) method and tested it with the same building archetypes presented in the SDPB model. Denis et al. [5] developed the Disassembly Network Analysis (DNA) method for selective disassembly planning by applying network analysis. In a subsequent study, Vandervaeren et al. [16] developed the Material Flow Analysis for Demountable buildings (MFAD) method to evaluate the effect of the disassembly capacity on the building material flow. In 2024, Allam and Nik-Bakht [2] proposed a deconstruction planning method using Knowledge Graph (KG) technology to facilitate the evaluation of disassembly sequences for targeted components. In their work, Abu-Ghaida, et al. [1] developed a disassembly network-based approach for accounting for product recovery potential in building life cycle assessments. The primary distinction between the KG technology [2] and the closed-loop lifecycle information flow [18] lies in their respective structures and flexibility. The KG framework is centered on data integration for lifecycle modeling within a structured and organized arrangement, whereas the closed-loop lifecycle information flow illustrates the circulation of data within a dynamic, circular system. Collectively, these data structuring models are complementary, as KGs can facilitate the utilization of closed-loop lifecycle information flows for continuous enhancement and incorporation into BIM. In 2021, Beurskens [3] presented an assessment method to evaluate the reuse potential of buildings and building products. The author proposed the use of Design Structure Matrices (DSM) for establishing the relationships among building components, with the purpose of identifying the disassembly sequence of the components using Steward's algorithm.

2.2 Robotics for disassembly of building structures

The field of construction robotics has predominantly focused on assembly processes, with numerous successful implementations such as the DFAB House project at ETH Zurich demonstrating robotic fabrication of concrete walls, the SAM100 (Semi-Automated Mason) robot for bricklaying, and the Japanese construction giant Obayashi Corporation's automated systems for steel beam assembly. In contrast, relatively limited research has been directed towards robotic disassembly, particularly in the context of selective disassembly operations [13]. Unlike total disassembly, which involves the complete deconstruction of a structure, selective disassembly represents a more sophisticated approach requiring precise targeting of specific components while preserving the integrity of surrounding elements [14,15]. This strategic methodology, when combined with robotic automation, holds significant potential for enabling adaptive reuse, reconfigurability, and transformability of buildings. Recent advances in robotic technology, particularly when integrated with BIM-based SDSP systems, are beginning to address the complexities inherent in selective disassembly operations, offering promising solutions for more sustainable and circular approaches to building modification and material recovery. However, significant challenges remain in developing robust systems capable of handling the variability and complexity of building disassembly tasks, particularly in terms of component recognition, manipulation strategies, and real-time adaptation to changing site conditions.

Little of the existing literature regarding the integration of robotics with on-site construction activities has focused on disassembly or similar topics. Meta-analyses of robotics in construction (RiC) focused on revealing trends in the technology's implementation, but did not identify disassembly as a significant topic of recent research [6,17]. In addition, human-robot collaboration (HRC) literature sees a much heavier importance placed on construction than deconstruction [11]. Opportunities for the integration of robotics in total disassembly and selective disassembly are relevant. The use of BIM in building design creates a network of spatial data regarding building materials and assemblies that can

be utilized by robotic operating systems for robot assisted selective disassembly. The primary contribution of this paper is the structuring of the SDPB output as an information package compliant with the Industry Foundation Classes (IFC) schema for robotic operating systems, alongside a pilot demonstration of this pipeline simulation.

3 A framework for robot assisted selective disassembly for buildings

The framework is centred on information processing using a BIM-based SDSP system to enhance the intelligence of robots for the autonomous disassembly of targeted components, leveraging a system developed in earlier studies (see Figure 1). This system provides crucial information for autonomous selective disassembly, including optimized sequences for disassembling building parts (components and connections), geometrical and topological information for building parts, three-dimensional coordinates for each part (x, y, z), hosted components, hosted connections, connection type, physical interface characterization, structural composition relationship, graph data structure, extraction directions for each building part ($+x$, $-x$, $+y$, $-y$, $+z$, $-z$), and physical constraining parts in each extraction direction. All this information is used and managed by the robot operating system for developing the disassembly tasks.

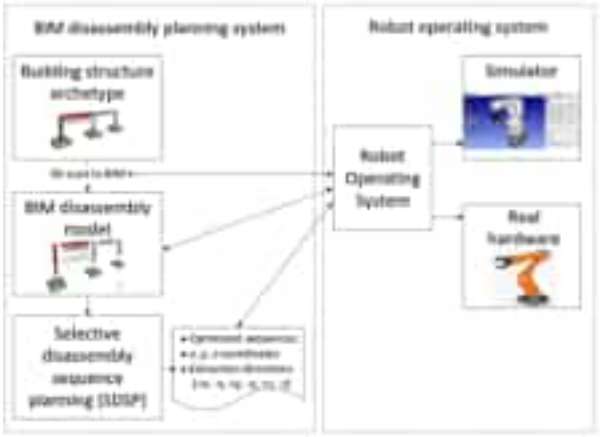

Figure 1. Framework for the integration of BIM-based SDSP for robotic automation

3.1 BIM-based disassembly planning

The BIM-based SDSP system selected for this research is the Sequential Disassembly Planning for Buildings (SDPB) method developed in previous studies. The SDPB method is based on an approach developed for product manufacturing, namely the Disassembly Sequence Structure Graph (DSSG) method. The SDPB method is used to generate optimized disassembly sequences for retrieving targeted components from BIM-based models by considering environmental impact, building cost, and rule-based analysis. The information generated by the system is as follows:

- Optimized sequences for disassembling building components.
- Geometrical and topological information for building parts is the information related to the geometrical characteristics of the disassembly parts. This information is fundamental to the creation of an analytical disassembly model that is consistent with the real conditions of the objects in the space as well as for determining the physical constraints among objects.
- Three-dimensional coordinates for each part (x, y, z) define the origin of a 3D Cartesian coordinate system associated with all the parts of the disassembly model. This characteristic is mainly associated with selective disassembly methods that evaluate extraction directions in a free 3D space, such as matrix-based methods and petri net methods.
- Hosted components and hosted connections register the parts that structurally depend on a host component. This characteristic is exclusive to buildings' disassembly models, in which the static equilibrium plays a critical factor to be able of estimating realistic disassembly patterns.
- Connection type indicates the condition of a fastener for being removed in one direction (e.g. $+x$) or multiple directions (e.g. $+x$, and $-x$).
- Physical interface characterization defines the geometrical and mechanical specifications associated with different types of connections (e.g., bolts, screws, rivets, washers, welding). The physical interface characterization plays a critical role in the accurate study of the disassembly properties of a connection type and the technical feasibility for disassembly.
- Structural composition relationships are an important characteristic for disassembly models of buildings. This characteristic indicates the structural connectivity among parts inside a disassembly model. For manufacturing products, any fastener can be removed from the disassembly model if the fastener is physically accessible. In comparison, in a building composition, some fasteners could be physically accessible but without them, the structural stability of the assembly would be compromised.
- The graph data structure is necessary for establishing the mathematical configuration of the disassembly model. A graph data structure is the

abstract representation of a disassembly model through nodes (vertices) and liaisons (edges).

- Extraction directions are the possible paths for removing any disassembly part. As a generality for SDSP methods, the extraction directions are four in a 2D environment (+*x*, -*x*, +*y*, -*y*) and six in a 3D environment (+*x*, -*x*, +*y*, -*y*, +*z*, -*z*). However, the extraction directions can be increased by adding as many extraction directions as necessary and by adding compounded extraction paths.
- Physical constraining parts are the physical restrictions of a disassembly part in any extraction direction (contact constraints, motion constraints, and projection constraints).

In this study, we tested the BIM-based SDSP system in a building archetype. The BIM-based disassembly model was developed, and the information package was structured according to the IFC. IFC is the most important international standard for open BIM data exchange. IFC is a standardized and continuously expanded data model that facilitates the exchange of BIM data in the AEC domain. Figure 2 shows the building archetype under study, as well as the information package generated by the system.

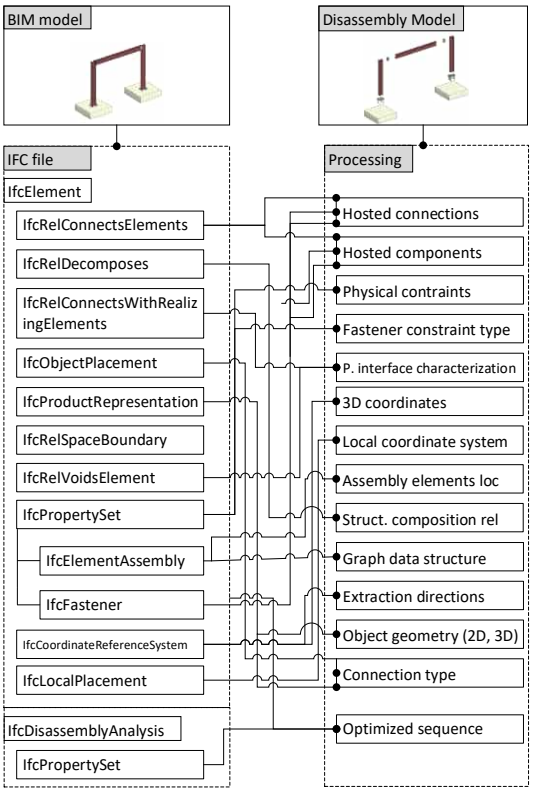

Figure 2. Disassembly sequence IFC information package

3.2 Robotic control architecture for selective disassembly

At the current stage of this research, the BIM-based SDSP framework has been implemented to automatically generate a structured disassembly information package for targeted building components. The robotic simulation and control architecture, however, is proposed as the next stage of development and is therefore presented here as an implementation pathway. The purpose of this phase is to transform the SDSP-generated information into robot-readable commands and environment representations. In this framework, the SDSP output serves as the high-level task planner, while the robotic platform is responsible for motion planning, collision detection, execution logic, and state updates during the disassembly process.

A central motivation for the proposed method is that while IFC preserves rich building information, such as component identities, geometry, spatial relationships, and semantic properties, it is not designed for robot control. Specifically, direct IFC export lacks robot-oriented parameters required for task execution, leaving the challenge of autonomous disassembly unresolved. The proposed SDSP framework addresses this limitation by enriching and reorganizing the BIM-derived data into a structured disassembly information package. In this regard, the SDSP layer acts as an intermediate semantic translation step between the building information model and the robotic execution environment.

The robotic system proposed for this phase consists of a fixed-base articulated manipulator operating within a physics-based simulation. A medium-reach, six-degree-of-freedom (6-DoF) robotic arm is considered appropriate for the initial implementation, as the pilot study involves localized disassembly actions on a simple frame and requires controlled positioning, directional extraction, and manipulation of structural and connection elements. The software stack integrates Gazebo as the simulation environment, ROS 2 as the middleware layer, and MoveIt 2 as the motion planning and manipulation framework. Within this architecture, Gazebo maintains the world model and physics-based actuation, ROS 2 manages inter-node communication for task planning and control, and MoveIt 2 handles collision-aware trajectory planning, kinematic feasibility, and scene updates.

To support this integration, the SDSP information package is translated into a robot-oriented task model. For each component or connection to be removed, the package should provide, at minimum, a unique identifier, sequence index, pose data, end-effector orientation, approach and extraction vectors, dependency list, clearance requirements, and obstacle data. It should also maintain status variables indicating whether an element is intact, detached, grasped, or removed. For connections, attributes such as type, disengagement mode, and any required motion constraints are included. Although some

of these fields may be partially inferred from the BIM model, the key contribution of the SDSP framework is that it assembles them into a task-centered representation that is aligned with robotic disassembly planning.

The proposed control architecture follows a hierarchical structure. At the top level, the SDSP module provides the ordered sequence of disassembly actions and inter-component dependencies. At the middle level, a task-planning node in ROS 2 interprets each action and decomposes it into motion primitives such as approach, align, engage, detach, extract, retreat, and place. At the lower level, MoveIt 2 generates feasible trajectories subject to workspace constraints, while the controller executes joint-space or Cartesian commands in Gazebo. After each successful disassembly action, the planning scene and simulation state are updated to reflect the removal of the corresponding component, allowing the next step in the sequence to be planned against the modified environment.

While a full perception layer is outside the scope of the current study, the framework is designed to ultimately incorporate vision and force sensing for closed-loop execution. Vision will confirm component identity and pose consistency relative to the digital model, while force-torque sensing will monitor contact conditions during extraction. In early simulation-based development, these functions will be approximated through perfect-state feedback; later stages can replace these assumptions with simulated depth cameras, joint feedback, and force-sensitive control. Therefore, the proposed system will function as an integrated architecture that bridges BIM-derived disassembly logic with robot-level planning and execution.

3.3 Proposed validation approach for robot assisted selective disassembly

For functional demonstration, a pilot study was developed for robot-assisted selective disassembly of a simple frame (see Figure 3). The BIM model was structured according to the specified needs for a robot operating system. The information package was created automatically for the selective disassembly of the component c_1 (structural column). The optimized disassembly path is: f_1-f_2-c_1. The information package was exported to the robot operating system for the disassembly task. To maintain scope, the current study focused on the BIM-to-simulation information flow, treating robotic execution as a conceptual demonstration rather than a fully implemented control pipeline.

Consequently, the next development stage involves validating the BIM-to-robot workflow in a simulated environment. In this phase, the disassembly environment will be represented in Gazebo, the robot manipulator will be integrated through ROS 2 and MoveIt 2, and the SDSP information package will be used as the task-level input for robotic execution. Under this workflow, the robotic arm executes the prescribed disassembly sequence step-by-step, updating the simulation and planning scene after each completed action. For the frame example, the robot will first perform the task associated with f_1, then update the environment to reflect its removal, then proceed to f_2, and finally execute the extraction of c_1 once the prerequisite steps have been completed. This will allow the proposed framework to test whether the SDSP-generated information can be correctly interpreted and executed within a robotic simulation.

The initial simulation-based validation targets three technical objectives. The first is data interoperability, namely whether the SDSP package can be translated into simulation and motion-planning inputs. The second is kinematic feasibility, namely whether the robot can generate valid, collision-free motions for each step in the prescribed sequence. The third is state consistency, namely whether the simulation environment can be updated correctly after each removal to reflect the evolving disassembly state. Assessment metrics will include sequence completion status, motion-planning success rate, collision occurrences, and any violations of the prescribed extraction or dependency constraints. Additional qualitative observations will be recorded regarding failure modes, such as unreachable approach poses, geometric interference, or inconsistencies between the SDSP representation and the simulation environment.

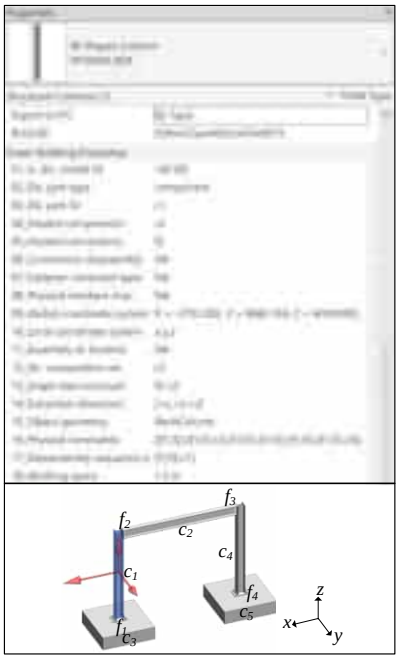

Figure 3. BIM-based Sequential Disassembly Planning for Buildings (SDPB)

The pilot study highlights the framework's ability to

integrate BIM-based SDSP data with robotic control systems, enabling the autonomous execution of selective disassembly. These findings underscore the importance of robust data structuring and compatibility with IFC standards to ensure seamless data exchange between BIM models and robotic systems. Future validation efforts will extend the proposed framework to more complex building structures with diverse materials, connection types, and architectural configurations. Additionally, subsequent physical implementations with real-world robotic solutions will address challenges such as unstructured environments, sensor integration, and scalability. These advancements will refine the SDSP framework and support the application in practical construction and deconstruction scenarios.

4 Conclusions and Future work

The study's findings indicate that the BIM-based SDSP system is highly effective in enriching a robot's ability to process information, sense, plan, and execute the retrieval of specific components from a building structure. In this study, we propose the information package that can be automatically produced by a BIM-based SDPB system for performing the disassembly works in an autonomous way by a robotic solution. The results demonstrate the technical feasibility of implementing SDSP with robotic solutions for simpler building structures. This approach offers significant benefits for decarbonization in the construction industry by enabling the efficient recovery and reuse of building materials, thus reducing the demand for virgin resources and minimizing waste. By integrating robotics with BIM-based selective disassembly, the method supports sustainable construction practices and aligns with Circular Economy principles, directly contributing to the reduction of greenhouse gas emissions associated with material extraction, processing, and disposal.

Looking forward, the next steps involve applying this approach to more complex building archetypes with diverse subsystems in real-world scenarios. This entails addressing challenges such as increased variability in component types, structural interdependencies, and environmental constraints. The integration of advanced robotic capabilities, including AI-based perception and adaptive control systems, will be crucial in overcoming these challenges and enhancing the system's scalability and robustness. Additionally, this methodology has potential applications in futuristic scenarios, such as the disassembly of building structures designed for extra-terrestrial construction (e.g., space infrastructure and settlements). Such applications would benefit from the autonomous and precise nature of the proposed approach, specifically through the expansion of the system's future operational capacity to function in extreme conditions.

Future research will also focus on improving the integration between BIM-based SDSP systems and robotic solutions, particularly in terms of real-time data exchange and dynamic task optimization. Exploring human-robot collaboration for selective disassembly tasks could further enhance safety and efficiency. Lastly, validating the proposed framework through experimental testing with physical robotic systems and expanding its application to larger-scale projects will be critical to demonstrating its practical viability and impact on advancing Circular Economy principles in the built environment.

Abstract -

Spraying processes, such as shotcrete, painting, and abrasive blasting, are critical to construction but remain labor-intensive, hazardous, and challenging to automate. Realistic and computationally efficient simulation models are crucial for supporting robotic process planning, training, and control. However, existing approaches are typically process-specific and lack generality across different material systems. This study presents a unified, physics-informed particle system-based simulation that can represent diverse spraying processes within a single computational model. The formulation integrates stochastic adhesion and rebound mechanisms with process-dependent material parameters, enabling the reproduction of characteristic behaviors—from cohesion and detachment in shotcrete to smooth deposition in painting and particle scattering in abrasive blasting. The framework operates in near real-time and has been quantitatively validated for the shotcrete process using published experimental datasets, while additional spraying processes such as painting and abrasive blasting are demonstrated qualitatively to illustrate the generality of the modeling approach. The results demonstrate that only a limited set of parameter adjustments is required to emulate distinct process dynamics, establishing a scalable foundation for robotic spraying and trajectory optimization.

1 Introduction

A wide range of spraying processes is used in construction, including surface protection and coatings, sprayed concrete (shotcrete), insulation and sealant foams, spray painting, adhesive sprays, and abrasive blasting. All of these processes are highly dynamic: material is ejected from the nozzle and projected onto a target surface, requiring the operator to both control deposition and continuously adjust based on visual feedback. Despite their importance, most of these processes are inherently hazardous—exposing workers to dust, rebound, chemical agents, or physical strain. Combined with a severe labor shortage and a declining skilled workforce in the construction sector [1], the need for robotics and automation to support, augment, or partially replace human operators becomes urgent.

To achieve human-level expertise autonomously, a robotic system must first acquire a reliable understanding of the underlying spraying process. Developing such understanding requires robust simulation models. Shotcrete provides a compelling example: it is a complex and skill-intensive process that requires operators to undergo rigorous training and certification. However, physical shotcrete tests are costly, wasteful, and unsustainable, whereas simulation-based training (e.g., [2]) offers a safer and more scalable alternative. Beyond training, simulation models enable technical analysis, waste reduction, and process optimization, provided they are sufficiently reliable and accurate.

The main contribution of this study is the extension of our previously developed shotcrete simulation model [3] to a broader class of construction spraying processes. The underlying particle-based framework has been quantitatively validated for shotcrete deposition against experimental data [4, 5]. Building on this foundation, the present work investigates whether the same physics-based simulation architecture can be generalized to other spraying applications, including painting and abrasive blasting.

Unlike prior work that focused exclusively on concrete spraying, we show that these processes can be represented within a unified particle-based framework by adjusting a limited set of material and process parameters governing adhesion, cohesion, and rebound behavior. This enables the reproduction of distinct spraying regimes while preserving a consistent simulation architecture. The additional processes considered in this study are, therefore, intended to demonstrate the generality of the framework through parameter adaptation, rather than to provide independent quantitative validation.

The remainder of this article is organized as follows. Section 2 reviews the state of the art in simulation technologies and robotic advancements relevant to each process. A theoretical overview of particle methods is provided in

Section 3. Section 4 details our simulation model, including the parameter settings and ranges for each process. The corresponding results are presented in Section 5, followed by a discussion and concluding remarks in Section 6.

2 Background

Spraying processes have long been the subject of engineering analysis and robotics research. From concrete placement to protective coatings and abrasive blasting, each domain has developed its own simulation methods and automation strategies. However, most of the existing work has remained domain-specific, with few attempts at unifying frameworks that can handle multiple processes under a standard methodology. This section reviews the state of the art in simulation in three representative applications: shotcrete, spray painting, and abrasive blasting.

2.1 Sprayed concrete

Shotcrete simulation has attracted considerable attention due to the complex interactions between aggregates, mortar, and substrate surfaces. Early work applied the Discrete Element Method (DEM) to explicitly represent aggregate and mortar phases, modeling collision, rebound, and packing effects in sprayed layers [6]. DEM-based formulations have also been extended to capture rheological behavior and yield-stress effects of fresh concrete mixtures by combining particle kinematics with macroscopic rheology models [7, 8].

Coupled Computational Fluid Dynamics–Discrete Element Method (CFD–DEM) approaches later emerged to approximate both the granular and fluid aspects of fresh concrete [9]. Nevertheless, DEM and CFD–DEM remain computationally intensive and struggle to meet real-time constraints. Velez et al. [10] traded physical realism for speed (via ray-casting adhesion) and proposed a real-time training simulator. More recently, particle system-based models have been proposed to strike a balance between realism and efficiency [4], introducing a physics-informed particle system capable of reproducing spray dynamics and cohesive failure phenomena. A voxel-based model [11], capable of modeling material evolution in real time, further underscores the growing interest in bridging the divide between computational efficiency and fidelity. These developments highlight a spectrum of approaches, from high-fidelity but slow solvers to simplified, high-performance models.

2.2 Spray painting

Spray painting is among the most extensively studied spraying processes, primarily due to its widespread use in the automotive and manufacturing industries [12]. Simulation models have been developed to analyze droplet transport, deposition, and film formation, typically by resolving the airflow field using CFD [13]. However, accurately predicting paint thickness on complex geometries remains a challenge and requires the development of advanced coupled CFD models.

Coupling CFD with a Lagrangian particle-tracking approach enables the prediction of droplet trajectories and the final film thickness. Earlier, Böttner and Sommerfeld [14] developed a comprehensive CFD–DEM model for electrostatic powder painting, combining a finite-volume approach for the airflow field with discrete particle tracking and the solution of the Laplace equation to incorporate electrostatic effects. Later, Fogliati et al. [15] employed the time-averaged Navier–Stokes equations, comprising the k–ϵ turbulence model, to predict deposition outcomes across various geometries and operating conditions.

In robotics, automated spray-painting systems often integrate simulation or predictive modeling into offline path-planning and optimization pipelines. These systems aim to achieve uniform coating thickness, minimize material waste, and improve process efficiency through model-based trajectory optimization [16, 17].

2.3 Abrasive blasting

Abrasive blasting (sandblasting) is a jet-cleaning process used for surface preparation, roughening, or coating removal. It involves high-velocity particles impacting a target surface, typically modeled as a purely particulate flow with negligible adhesion. Classical simulations of abrasive blasting have predominantly relied on the DEM. To achieve greater physical realism, Longmore et al. [18] employed DEM and represented each granule as a tetrahedral lattice of four particles, implicitly capturing static friction through the interlocking of neighboring granules. Alternative approaches have utilized CFD to analyze the influence of parameters such as particle size, blasting pressure, and nozzle distance [19].

Across all three domains, notable progress has been achieved in either high-fidelity process simulation or task-specific robotic automation. However, the literature remains fragmented: most simulation tools are tailored to a single material system, and their formulations are not readily transferable across different spraying processes. This limitation motivates the present work, which seeks to unify shotcrete application, spray painting, and abrasive blasting within a single, particle-based simulation framework—distinguished only by their process parameters.

3 Particle methods

Particle methods are a broad family of mesh-free numerical techniques in which a continuum or system is modeled through discrete entities—"particles"—whose motion and

interactions collectively approximate the behavior of the underlying process. In contrast to grid-based (Eulerian) schemes, particle methods adopt a Lagrangian viewpoint that follows material motion, thereby reducing numerical diffusion during advection, simplifying the treatment of free surfaces and interfaces, and naturally handling complex boundaries and heterogeneous materials without the need for complex mesh generation. These properties make particle methods well-suited to highly dynamic processes, such as sprays, splashes, fragmentation, and other multiphase phenomena. These advantages, however, come at a cost: particle methods generally demand greater computational resources, careful implementation and tuning, and extensive validation to achieve predictive reliability.

Following the formalization proposed by [20], particle methods can be described in terms of five foundational concepts:

1. **Representation:** the basic unit or object that is being manipulated (particle, point, droplet).
2. **Interaction:** the ability of particles to affect one another (e.g., via collisions, constraints, or forces).
3. **Neighborhood:** the criterion that determines when and with which neighbors interactions occur.
4. **Evolution:** changes to a particle's state governed by external physics, independent of neighbors.
5. **Iteration:** the system's progression through discrete timesteps.

They further distinguished three levels of description for particle methods:

- A `general algorithmic framework`, including the data structures and functions common across particle-based approaches.
- A `particle method instance`, which specifies the problem or application context to which the method is applied.
- A `state transition function`, which governs how an instance evolves from its initial state to later states through repeated application of the algorithm.

This layered definition separates the abstract algorithmic design from application-specific implementations, providing a general foundation for particle-based simulation in a wide range of domains.

4 Simulation model

The proposed simulation model is implemented as a modular, physics-informed particle system in C++. Designed for generality, the same core framework can simulate a wide range of spraying processes—shotcrete, painting, sandblasting, and others—by modifying only material parameters and process-specific plugins. Figure 1 presents a Unified Modeling Language (UML) class diagram that organizes the framework into a particle emitter, particle data structure, surfaces, obstacles, and a physics engine for integration and collision handling.

At the core lies the `Swarm`, which manages all active and inactive particles. Each particle is represented by a lightweight structure containing its position, velocity, and lifetime, which are updated at discrete timesteps (default: $\Delta t = 0.01\,\mathrm{s}$). The swarm handles activation, deactivation, and efficient culling of particles outside the domain, enabling scalability to tens of thousands of particles and supporting real-time simulation.

Particle generation is handled by the `Emitter`, derived from an abstract interface. Emitters are parameterized by particle spawn rate, velocity range, shape, aperture, and angular spread, allowing them to replicate the behavior of different nozzle types. For example, paint spraying can be represented by high emission rates with a point emitter (near-zero aperture) for air spray guns, a rectangular emitter for a fan-shaped airless spray guns, or an annulus for rotary bell atomizers. Sandblasting, by contrast, is modeled with a circular emitter, coarser particles than spray paint, and higher initial velocities. Each emitter initializes particles with randomized attributes sampled from empirical distributions.

Within the modular framework, particles emitted by the `Emitter` are managed by the `Swarm` and updated under external forces. Each particle is represented as a geometric, massless point with optional user-defined attributes (e.g., shape, size, color) that affect only visualization. Motion evolves under external forces such as gravity, aerodynamic drag, or viscoelastic effects; in the simplest configuration, trajectories are purely ballistic. The `PhysicsEngine` advances motion explicitly using forward Euler integration at discrete timesteps, ensuring deterministic, computationally efficient updates suitable for real-time use. For collision handling, trajectories are approximated as straight-line segments per timestep, and intersections are tested against geometric obstacle primitives (planes, cylinders, boxes, spheres) using algebraic methods [21]. Impacts are then resolved through specular reflection with attenuation by a coefficient of restitution, rather than by DEM-style contact solvers. This abstraction deliberately omits particle–particle interactions to maintain scalability and real-time performance while retaining sufficient fidelity for spray-process simulation.

Whether a particle adheres or rebounds upon impact is a stochastic process. In shotcrete, a rebound probability $p_r(\theta)$ is computed from the particle's impact angle θ rel-

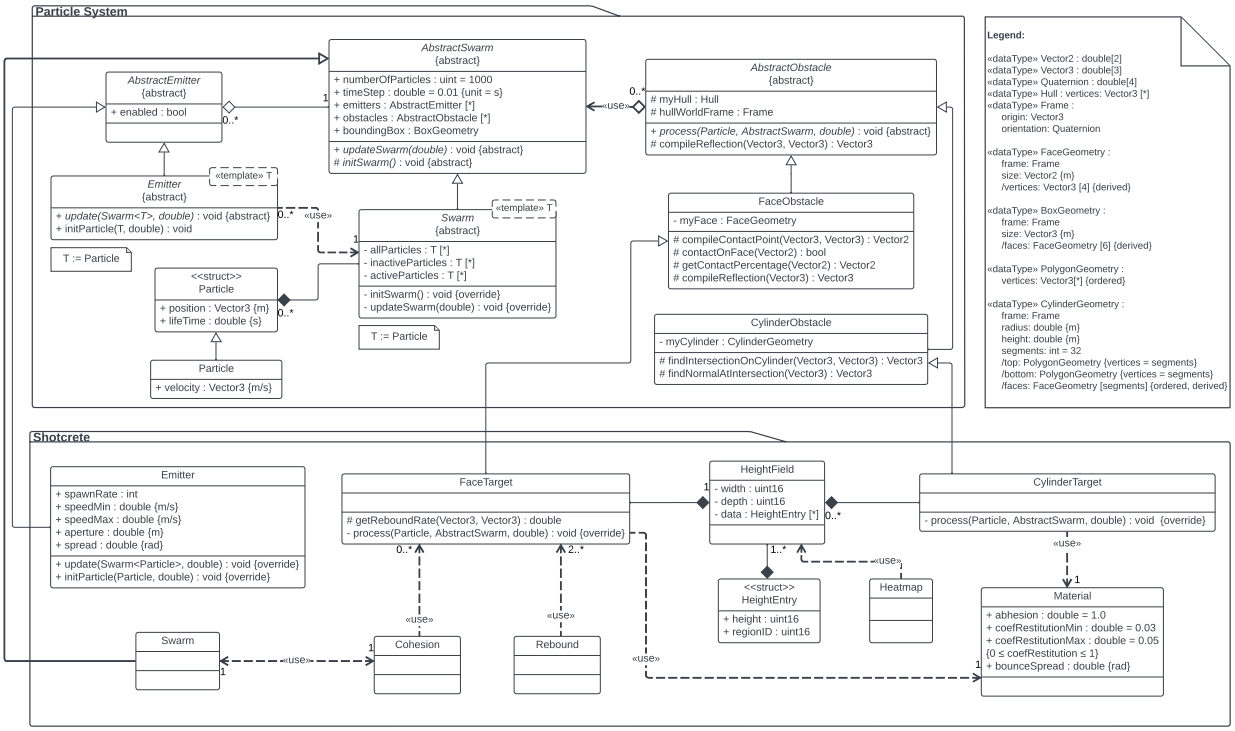

Figure 1. Unified Modeling Language (UML) class diagram of the particle system library, together with an example shotcrete extension. The model specifies abstract and concrete classes for particle emission, swarm management, and obstacle handling, conforming to the UML 2.5.1 specification.

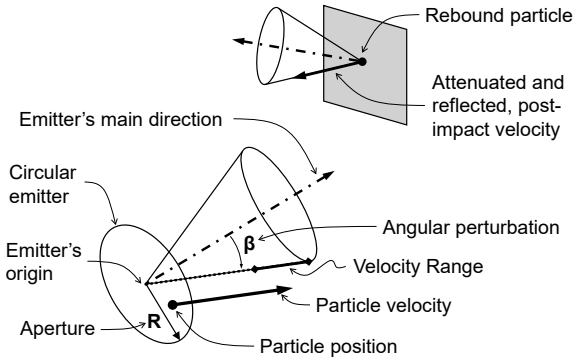

Figure 2. Circular particle emitter model. Particles are stochastically initialized within the emitter aperture and assigned velocity vectors perturbed from the primary emission axis. Perturbations are constrained by angular and magnitude bounds, thereby controlling the spread of the emission. Post-impact dynamics are represented by a reflected direction about the local surface normal, with the speed attenuated to account for energy dissipation.

ative to the surface normal using an empirical polynomial fit to Melbye's curves [22]. A uniform variate $u \sim U[0,1]$ is drawn and scaled by a material-specific *abhesion* (i.e., anti-adhesion) factor $\alpha \in [0,1]$; the outcome is obtained by comparing this draw with $p_r(\theta)$. For shotcrete, we use $\alpha = 1$, so the angle–dependent probability governs adhesion/rebound; for paint, we set $\alpha = 0$, suppressing rebound so that all impacts adhere. For abrasive blasting, we do *not* increase α; instead, we bypass the angle curve by setting $p_r(\theta) \equiv 1$, which forces every impact to rebound regardless of angle. Rebounding particles leave with the specularly reflected direction and an attenuated speed given by the coefficient of restitution, with a small random scatter added to match experimental spread.

Surfaces and obstacles are implemented through an abstraction hierarchy. The `AbstractObstacle` interface provides collision detection and reflection utilities, with concrete implementations such as `CylinderObstacle` and `FaceObstacle`. Targets like `FaceTarget` extend this functionality by recording deposition into a `HeightField`, a grid structure that tracks layer thickness and identifiers for cells lacking adequate support. This enables both visualization and quantitative analysis (e.g., thickness uniformity, rebound ratio), supported by a

`Heatmap` utility for graphical overlays.

Cohesion—a key sprayability parameter for achieving satisfactory in-situ properties of shotcrete mixes [23]—quantifies mesoscale structural stability and is modeled through post-processing of the heightfield. At user-defined intervals, cells that exceed local support thresholds are flagged and clustered into connected regions, identifying potential cohesive failure zones. This approach provides a computationally efficient surrogate for more detailed rheological modeling, enabling real-time analysis of failure risk while omitting costly particle–particle or fluid–structure interactions. In painting, analogous effects such as dripping or sagging can be represented but are generally negligible, whereas abrasive blasting does not exhibit cohesive failure at all. A summary of the default parameters for these three processes is provided in Table 1.

The recommended heightfield resolution depends on the target size; nevertheless, higher values such as 1024×1024 are generally advised. Since the simulation model decouples resolution from runtime performance, increasing resolution improves the accuracy of adhesion (i.e., material accumulation) and cohesion analysis without incurring significant computational penalties [4].

The simulation timestep Δt was selected in the range of 10^{-4}–10^{-2} s to balance accuracy and throughput. To avoid missed collisions, Δt must be small enough that the maximum particle displacement per step is less than the smallest obstacle. A default timestep of 10^{-3} s is recommended, with adjustments possible depending on performance and accuracy requirements.

The model achieved near real-time performance without employing common acceleration strategies, despite the availability of effective and well-established techniques such as spatial hashing [25] and data-parallel computation [26]; in typical configurations involving on the order of 10^4–10^5 active particles, real-time execution was achieved on standard computing hardware, consistent with previously reported benchmarks [3, 4]. Incorporating such methods in future work could further extend scalability to simulations involving millions of particles.

5 Results

As described in Section 4, emission directions are sampled from probability distributions constrained by the spray cone angle. Figure 3 compares two sampling strategies: a uniform distribution and a truncated normal distribution. The uniform distribution produces a stronger concentration of particles near the spray cone axis, whereas the normal distribution allows the spread to be adjusted via its mean (μ) and standard deviation (σ). In earlier work [4], we reproduced on-target accumulation profiles of wet-mix shotcrete reported by Ginouse and Jolin [27] by setting $\mu = 0.255$ and $\sigma = 0.102$. The simulation achieved errors of approximately **5%**, **3%**, and **2.8%** for maximum absolute, root-mean-square, and mean absolute error, respectively, relative to empirical data.

Figure 4 demonstrates four representative runs of the same robotic spraying task under different process models and obstacle configurations, highlighting the simulator's flexibility and the qualitative effects of process physics and geometry. Panel (a) illustrates shotcrete with reinforcements, showcasing pronounced shadowing and underdeposition behind reinforcement bars. Rebounded particles are visible in flight and are deposited on the ground heightfield, while cohesive buildup and detachment are possible. Panel (b)—shotcrete without reinforcements—exhibits a largely radially symmetric accumulation pattern with far fewer localized voids, demonstrating how obstacles strongly affect coverage even for identical nozzle kinematics. Panel (c) depicts spray painting, displaying near-complete immediate adhesion and a uniformly covered surface, consistent with high-adhesion, no rebound, and negligible sagging. Abrasive blasting is illustrated in Panel (d), which contrasts sharply: adhesion is suppressed, nearly all particles rebound with significant scattering, and no material accumulates on the target; the heatmap therefore represents hit coverage and suggests erosion intensity.

All simulations were executed using process parameters derived from Table 1; specifically, cohesion and the angle-dependent rebound model were enabled for the shotcrete cases, rebound was suppressed for the painting, and forced

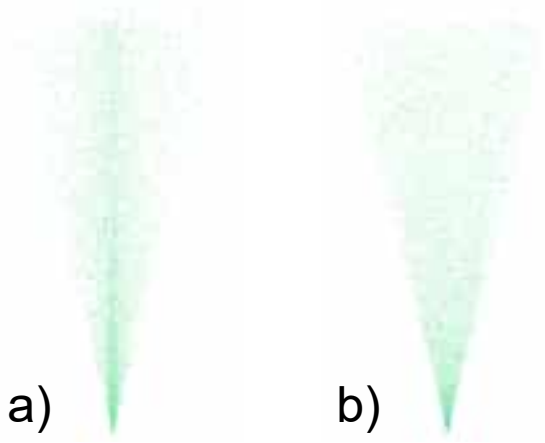

Figure 3. Comparison of particle emission patterns when directions are sampled from **a)** a uniform distribution and **b)** a truncated normal distribution ($\mu = 0.255$, $\sigma = 0.102$). The normal distribution offers tunable control over spread, enabling closer alignment with empirical spray patterns. All other parameters were held constant.

Table 1. Default simulation parameters for three spraying processes.

Parameter (units)	**Shotcrete**	**Spray painting**	**Abrasive blasting**
Emitter type	Circular	Point / rectangular / annulus	Circular
Particle spawn rate (particles/s)	10^4	10^4–10^5	10^3–10^5
Particle size*	3.0 (aggregate)	0.05 (droplet)	0.5 (grain)
Particle velocity (m/s)†	20–30 (wet-mix)	20–60	100–200
Emitter aperture (mm)	32–76	0.5–2.0 (point emitter)	3.2–19.1
Spray cone angle (°)	9–18	15–120+	15
Abhesion α	1.0 (angle-based)	0.0 (rebound suppressed)	N/A (bypassed, forced rebound)
Rebound model	Angle-dependent polynomial	N/A	forced rebound ($p_r = 1$)
Coefficient of restitution	0.03–0.05	N/A	0.6–0.9
Cohesion enabled?	Yes	No (optional drip)	No
Scattering spread	Small angular noise	Negligible	Moderate–large
Notes	High cohesion, angle rebound	Near-instant adhesion	Elastic impacts, erosion

* Particle size refers to the rasterized diameter (in pixels) of points drawn with `GL_POINTS`, stored as a floating-point value.
† Particle velocity is highly affected by input airflow, air pressure, and aggregate size [24].

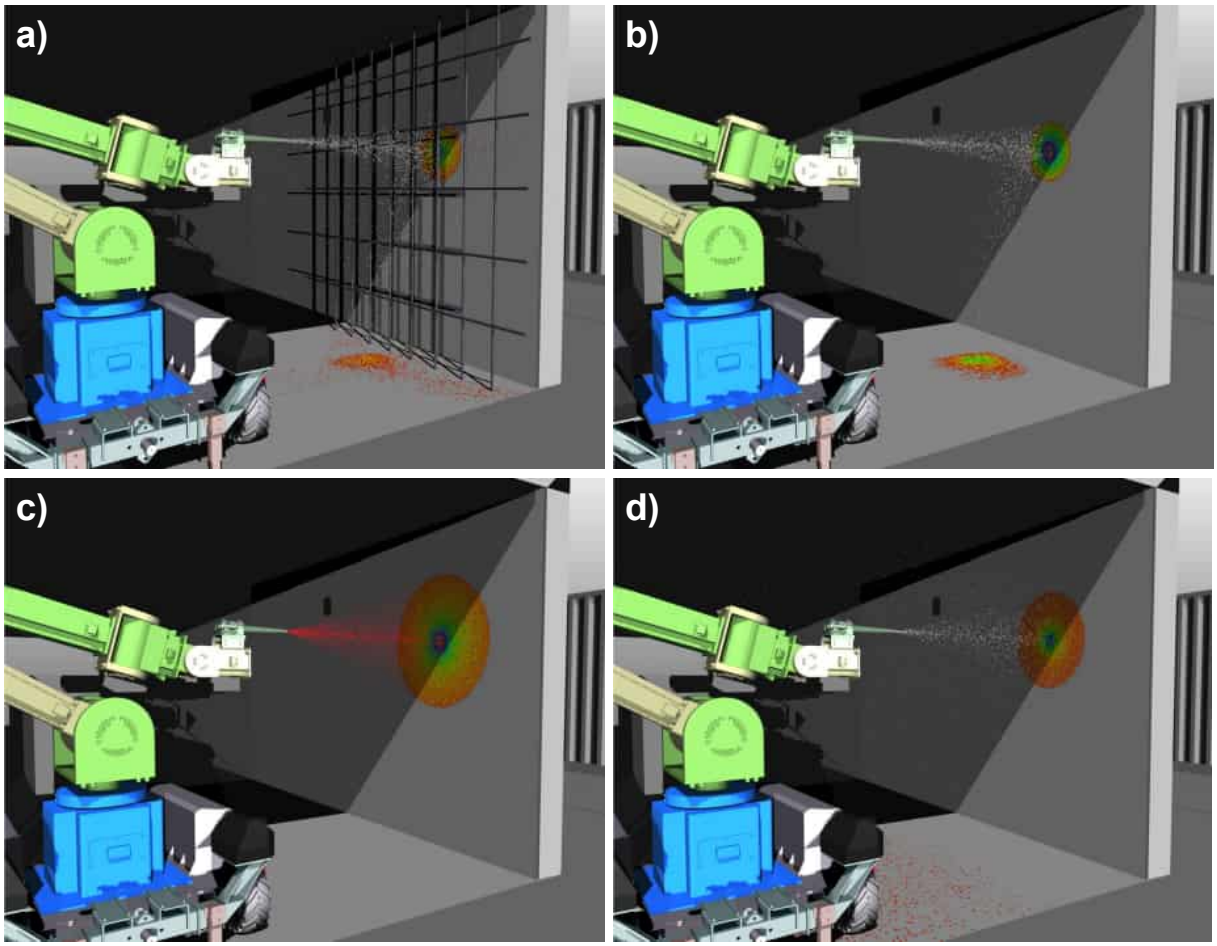

Figure 4. Comparison of robotic spraying simulations across four processes: **a)** shotcrete with reinforcement elements, **b)** shotcrete deposition without reinforcement, **c)** spray painting, and **d)** abrasive blasting, where adhesion is disabled, and all particles rebound with high scattering. Parameters for each scenario were selected according to Table 1.

rebound (high restitution and scatter) was used for blasting. These visual comparisons demonstrate that changing only plugin parameters (while keeping the same emitter/nozzle kinematics) produces distinct, physically interpretable outcomes.

6 Discussion and conclusion

The results confirm that the unified framework can simulate characteristic behaviors in different spraying processes. For instance, in the shotcrete configuration, the model successfully captures cohesive failure and material detachment phenomena, which are absent in the painting mode. Conversely, in painting mode, high adhesion and low rebound parameters produce a smooth surface finish; however, sagging may still occur. In abrasive blasting, the system exhibits purely particulate scattering without accumulation. These qualitative distinctions are consistent with the expected physical behavior of each process, supporting the generality of the proposed model. In this context, variations in physical sprayer characteristics such as flow rate, nozzle geometry, and supply pressure are implicitly captured through emitter parameters (particle spawn rate, velocity distribution, and angular spread), whose influence on deposition behavior has been previously analyzed for the shotcrete process [4], while further process-specific validation under controlled operating conditions remains a direction for future work.

A key advantage lies in the modular software architecture. The same core simulation engine operates across all modes, with behavior determined solely by parameter sets that define material and process properties. This demonstrates the feasibility of our central objective: to enable a single, physics-informed particle system to emulate diverse spraying processes by varying only their governing parameters. Such an approach can be directly embedded into robotic programming environments or Digital Twins, enabling engineers to switch between simulation-based design and control processes seamlessly.

The automation potential of this unified approach is substantial. A robotic cell could employ simulation-in-the-loop optimization to refine spray patterns until predicted deposition or coverage meets desired criteria. Similarly, robotic abrasive blasting systems could test and evaluate different nozzle trajectories in simulation to maximize cleaning efficiency while minimizing material loss. Because the simulation executes in near real time, it also provides a practical foundation for machine learning–based process control or operator training in virtual environments.

The current formulation also excludes several classes of physical phenomena, including particle–particle interactions in dense flow regimes, complex fluid behaviors such as splashing and droplet coalescence, and post-deposition volumetric evolution such as lateral flow or expansion (e.g., in foam-based materials). As a result, the model is most appropriate for particle-dominated spraying processes where deposition is primarily governed by particle–surface interactions, including adhesion, rebound, and accumulation, and where a heightfield representation provides a sufficient approximation of material buildup. This limitation also prevents simulating processes characterized by significant post-deposition evolution, such as expanding foam. Transitioning to a three-dimensional cellular automaton (3D CA) would substantially enhance geometric expressiveness and enable simulation of time-dependent material behavior, including lateral motion and post-impact spreading. Overall, while the framework is robust and extensible, advancing its fidelity will require volumetric modeling, physically grounded parameter calibration, and broader experimental validation. These developments will further strengthen its applicability as a tool for robotic construction, process optimization, and virtual skill assessment across diverse spraying applications.

Abstract

Heritage buildings exhibit complex and irregular legacy environments that pose significant challenges for conservation. This study introduces a framework grounded on high-precision terrestrial laser scan, which serves as input for both semantic segmentation of structural components and fine-grained surface feature extraction. Leveraging the TLS scans, the proposed approach supports 3D scene understanding of heritage buildings, including structural segmentation of walls, floors and ceilings, as well as extracting surface-level details (e.g., cracks) that are layered onto the main structural components. The framework (1) integrates 3D point cloud-based geometric representation of heritage buildings and (2) displays the primary building 3D geometry with updated surface attributes (crack spatial pattern) to uncover new insights. This method improves spatial interpretation in complex heritage environments, offering a platform for analysing potential heritage conservation issues.

Heritage Building; Scene Understanding; Semantic Segmentation; Fine-Grained Surface Feature

1 Introduction

Heritage buildings serve as vital touchstones of cultural identity; yet their conservation faces challenges such as weathering, material aging, and urban development pressures that accelerate deterioration. The shophouse is a predominant heritage building typology in Southeast Asia and Southern China [1, 2]. Singapore is one of the most significant centres for shophouse development [2]. Figure 1 shows a typical shophouse (i.e., NUS Baba House), featuring a ground floor designated for retail or commercial use and upper floors reserved for residence. Compared to modern commercial complexes, shophouse architecture is a less spatially efficient typology for commercial operation. Furthermore, it is characterised by fragile building materials that present unique vulnerabilities to age-related degradation. Such surface conditions may occur independently on specific floors or manifest in combination within particular areas, making the intensive monitoring of shophouse conditions increasingly important to preserve and sustain their cultural and historical significance.

Figure 1. Sample point clouds of shophouse obtained from terrestrial laser scanning

In Singapore, there are over 6,000 conserved shophouses required on-site monitoring and surveying which is a tremendous work [3]. Nowadays, reality capture technologies such as LiDAR or photogrammetry have been adopted to provide a digital archive of the shophouse. But these methods require intensive human labour and time to accurately scan and document the building information and geometry in digital format [4], followed by evaluating the surface conditions and recording relevant conservation issues.

To solve this problem, many studies have attempted to integrate scanning to support as-built data capture as well as automated structural segmentation and fine-grained surface feature extraction (material change,

surface pattern etc.). Applying 3D point clouds for building surface feature extraction and assessment (such as cracks) has been attempted by many studies [5-7]. The studies could achieve defect identification accuracy from 42.5% to 99.7%. To achieve this level of accuracy, close-range scanning of the defect area and high-resolution scanned data are simultaneously required [5, 6]. However, digital documentation at such level-of-detail is impracticable for thousands of heritage buildings. For example, a typical 3-storey shophouse has 8 to 12 rooms, which require 16 to 36 scans to generate comprehensive point clouds. Manual labelling of point clouds in this level-of-detail across different structural vulnerabilities like cracks, spalling, moisture infiltration could be tedious and time consuming. More importantly, methods that directly use 3D point cloud data to undertake semantic segmentation or other related tasks are restricted by inherent quality limitations, including the inability to capture local structural details, sensitivity to non-uniform sampling densities, and a lack of translation invariance, which limits their generalisability to complex, irregular geometries often found in heritage sites [8, 9].

As such, more studies nowadays intend to leverage image-based sensing to address the semantic segmentation in heritage buildings. Image segmentation offers several advantages. First, computational efficiency is improved as they require less processing power and memory compared to direct processing of point clouds, making them more efficient and light-weighted for practical applications. Secondly, image-based methods are more flexible as the collection and labelling of images is inherently more straightforward and cost-effective than processing 3D point clouds [10-13]. Additionally, the abundance of open-source dataset, pretrained models and well-established networks provides a robust foundation for transfer learning specific to heritage buildings.

Other studies explored image semantic segmentation with foundational models introducing robust capabilities for segmenting objects in images and videos [14, 15]. Further advancements have focused on open-vocabulary segmentation [11, 12, 16]. Since heritage buildings present more complicated architectural and ornamental elements than modern architectures, adopting open vocabulary models allows the network to understand the various unseen or arbitrary elements present in heritage building environments.

While image-based methods significantly improve efficiency for rapid data acquisition and are easier to deploy at scale, they still face challenges in fully capturing the heterogeneous materials and diverse surface conditions present in historical architecture. Compared with LiDAR-based scanning, image-based methods often exhibit lower geometric fidelity and weaker spatial representation, making it difficult to integrate fine-grained surface details into a precise spatial context, particularly for depth-related features. This limitation reduces their ability to quantify defect dimensions or reveal underlying spatial patterns and their potential impacts for heritage buildings.

This study introduces a framework that utilises high-precision terrestrial laser scanning (TLS) as the primary input for both structural semantic segmentation and fine-grained surface feature extraction. By leveraging TLS, the approach enables comprehensive building 3D scene understanding, encompassing semantic segmentation of structural components like walls, floors, and ceilings alongside fine-grained surface feature extraction that layers onto the structural components. The framework achieves this by (1) integrating point cloud-based 3D geometric representation of heritage buildings and (2) displaying primary building geometry with fine-grained surface attributes. The 3D integration enhances interpretability and enables spatial-level structural analysis by providing a quantified crack dimensions and localization within the building's coordinate system.

2 Methodology

The methodology of this work is shown in Figure 2. For each individual scan, the TLS generates a panoramic colormap for colour point clouds. The colormap contains abundant information about the scene and can be used for 3D scene understanding.

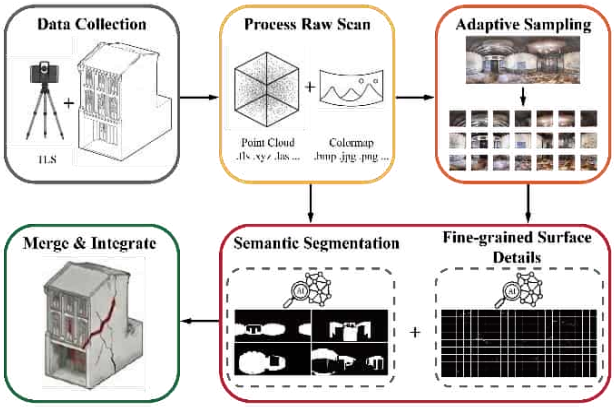

Figure 2. Overview of proposed method

This study uses two pipelines dedicated to processing the colormap to segment structural walls, floors, and ceilings alongside fine-grained surface detail extraction that is layered onto the main structural segmentation results. The colormap overlay embeds surface-level labels, allowing each point to carry both the structural component type and its surface condition through updated surface attributes. The resulting masks from both pipelines are integrated to provide a unified point cloud-based 3D geometric representation of the heritage

building, updated with surface attributes on the segmented structural components such as cracks on walls etc. to reveal their spatial patterns. This method can be extended to other surface features such as openings, material transitions and surface patterns, thereby enhancing 3D scene understanding tasks.

2.1 Dataset Collection and Processing

To enable automatic crack identification and semantic segmentation of structural components on panoramic colormap, experiments are conducted on a shophouse to collect its point cloud using TLS. The dataset consists of the following: point clouds, panorama colormaps that are extracted from point clouds, and ground truth colormaps. They are processed to align the requirement of machine learning pipelines.

2.1.1 On-site Scanning

The point cloud dataset is acquired by scanning a heritage shophouse, the NUS Baba House. This building was built around 1895 and undergone several renovations [17]. To capture a comprehensive dataset, the shophouse is scanned from 24 positions (shown in Figure 3) to cover all interior surfaces and façade elevation.

A FARO® TLS was used to acquire the point cloud data. Scanner parameters were set at indoor 10 meters for interior scenes and outdoor 20 meters for exterior and semi-exterior scenes. The acquired raw point clouds are processed and the colormap of each scene is exported. Figure 4 shows the registered point cloud and on-site scanning operation photo.

2.1.2 TLS Panoramic Colormap

The machine learning pipeline for fine-grained surface feature extraction exhibits varying constraints regarding input resolution; while some architectures support native resolution processing via internal slicing, others require fixed dimensions or down-sampling. However, relying on down-sampling is problematic because pixel density is a critical determinant of prediction accuracy; reducing colormap quality inevitably leads to information loss and compromises feature extraction results. Furthermore, preserving the exact original resolution is essential for the subsequent accurate integration of 2D predictions back into the 3D point cloud. Consequently, to bypass the resolution constraints of specific networks and standardize testing across diverse pipelines without sacrificing fidelity, a systematic slicing and tiling approach was implemented. This process partitions the original panoramic colormap into a grid of unified patches. A significant challenge in standard tiling is the "boundary effect," where semantic information is corrupted because object instances (e.g., cracks) traversing tile borders are severed, leading to incomplete feature extraction.

To mitigate this issue, an overlap sampling mechanism is applied. This principle introduces a defined overlapping area between adjacent tiles, ensuring that objects located at boundaries are captured fully within the receptive field of at least one tile, thereby increasing model sensitivity. The tiling logic is mathematically defined as follows: for a colormap of dimensions $w \times h$, with tile size T, overlap distance d, and step size $s = T - d$, each tile is indexed by its column x and row y. Given these parameters, the total number of tiles required to cover this colormap is computed as $Nx = \lceil (w - d) / (T - d) \rceil$ along the horizontal direction and $N_y = \lceil (h - d) / (T - d) \rceil s$ along the vertical direction.

2.1.3 Test Scenes

Indoor scans 07 (1F atrium), 13 (2F front hall), 16 (2F corridor), 19 (3F front hall), 21 (3F staircase), 22 (3F corridor), 23 (3F atrium), 24 (3F rear hall) shown in Figure 4 are selected to test the defect feature extraction methods' performance. These scenes are selected considering the complexity of background context. The simplest scene 19 features one significant crack on an unobstructed wall. Scene 23 contains multiple cracks on multiple walls, while the background context is increased but the defect area is relatively clean. Scene 07 includes many defect types and is captured in higher resolution, bringing challenge to the computing. Scene 24 features insignificant crack and spalling, the background context is extremely complex, introducing many interferences to the scene.

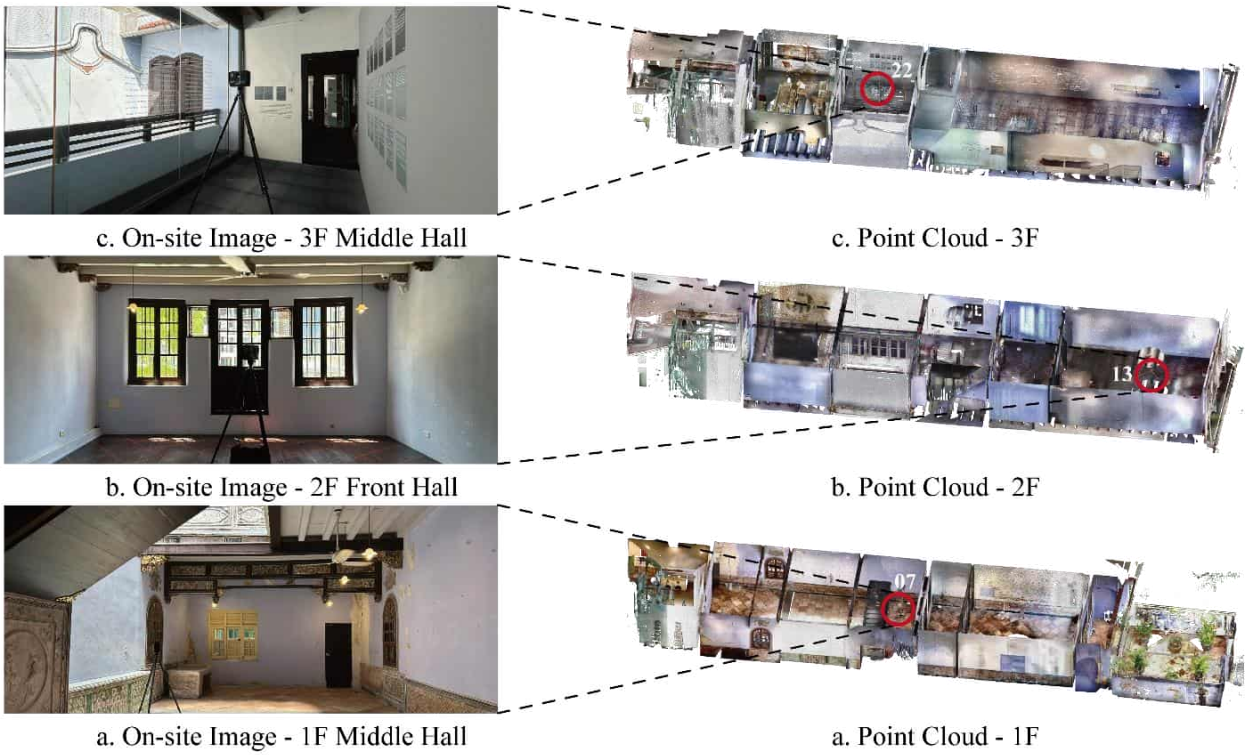

Figure 4. On-site scanning photo and corresponding registered point cloud

2.2 Fine-Grained Surface Feature Extraction

Identification of fine-grained surface features has achieved remarkable performance in structural health monitoring domains [18-22]. Advanced architectures like Vision Transformers (ViTs) significantly outperform traditional CNNs in capturing fine-grained crack details. While widely applied for precise segmentation, these methods remain restricted by application limitations, as existing models often exhibit limited generalisability, struggling to maintain accuracy when facing domain shifts caused by diverse lighting conditions, complex surface textures, or unseen structural materials.

In this study, crack identification is undertaken using multiple pipelines, each applied to tiled colormap. The pipelines generate complementary crack masks that highlight varying crack widths, orientations, and intensities across different surface conditions. The results are analysed using Precision (Pr), Recall (Re), F1-score (F1) and IoU to compare and evaluate all tested pipelines under all scenes and test settings, the metrics are defined in Equations (1)-(4).

$$\text{Precision} = \frac{\text{TP}}{\text{TP} + \text{FP}} \tag{1}$$

$$\text{Recall} = \frac{\text{TP}}{\text{TP} + \text{FN}} \tag{2}$$

$$\text{F1} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \tag{3}$$

$$\text{IoU} = \frac{\text{TP}}{\text{TP} + \text{FP} + \text{FN}} \tag{4}$$

2.3 Segmentation of Structural Components

When applying crack identification methods to the panoramic colormaps together with 3D point clouds, numerous false positive predictions are generated due to the complexity and scale of the scanned scenes. Successfully identifying the true positive predictions from the false alarms is critical for increasing the accuracy of crack identification. Incorporating the segmentation of structural components-such as walls and columns-facilitates the removal of false predictions detected in the non-structural area. In this study, the 3D scene is semantically interpreted using a semantic segmentation masking network, whereby structural components are extracted as combined masks to exclude false predictions that are detected on irrelevant elements.

Structural component segmentation is achieved using semantic masking generated by state-of-the-art segmentation networks [16, 23]. These masks restrict the crack identification process to structural regions, effectively suppressing noise and reducing false positives. This approach enables more accurate crack identification across complex indoor environments characterized by

occlusions and elements geometrically similar to cracks.

2.4 Crack Identification in Point Clouds

Mapping crack extraction results in 3D point cloud representation provides an intuitive visualisation of the surface conditions, revealing the crack's spatial distribution patterns and their potential structural implications. To achieve this, detected defects are labelled on the panoramic colormap, which replaces the original colormap. Since the colormap is inherently pixel-to-point aligned with the XYZ coordinates, this replacement automatically colourizes the corresponding 3D points to highlight defects. These colour labelled scenes are subsequently registered into a holistic 3D model of the building. Following registration, redundant low-resolution overlapping regions are removed to preserve only the high-resolution in the final point cloud.

3 Results and Discussion

3.1 Crack Identification

Tables 1 and 2 show the Recall and IoU of crack identification [19-22]. Figure 5 shows the results which reveal insight into the proposed tile and merge method. Initial testing of the crack identification revealed a dichotomy in performance. While high accuracy and specificity were observed in 75% of the raw colormap, the models struggled significantly in scenes where cracks pixels are minute relative to total pixels. Despite the successful identification of certain cracks, the overall quantitative metrics for Precision, Recall, and IoU are severely limited by scene complexity. Across all unmasked test scenes, the baseline maximum precision peaked at only 25.44%, with a maximum IoU of 20.75%. These limited results are primarily attributed to an excessive amount of false positive pixels generated from background noise and non-structural elements. Therefore, a robust mechanism is required to filter the noise and retain only valid predictions on relevant building surfaces for subsequent 3D integration. While overlap sampling is applied to preserve the cracks on tile boundaries, its contribution to the correct identification of true defects was limited.

3.2 Structural Wall Segmentation

To address the limitations identified in the baseline crack extraction, a two-stage optimisation strategy involving semantic masking and overlap sampling is implemented. Semantic segmentation networks [16, 23] are utilised to generate semantic masks, as illustrated in Figure 6, based on specific structural prompts, including "wall," "brick wall," "plaster wall," "column," and

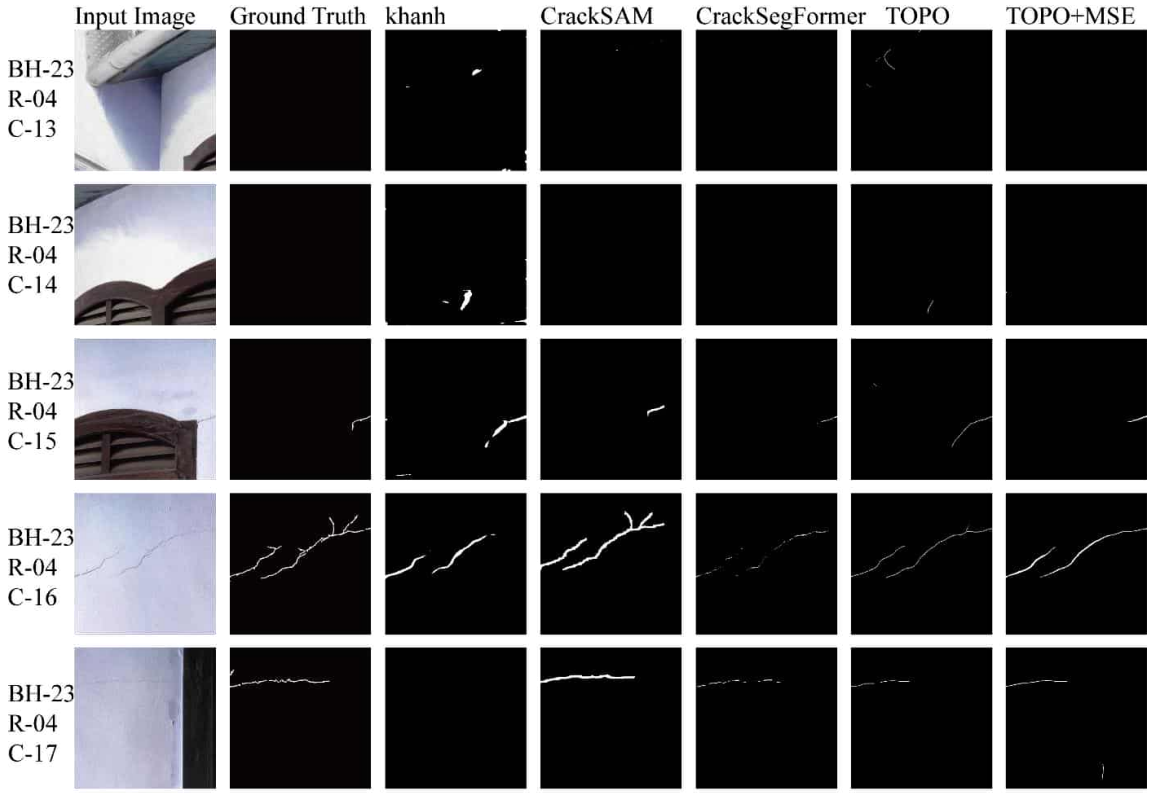

Figure 5 Examples for crack extraction using overlap sampling

"building surface." Among the evaluated networks, masks generated by GroundedSAM2 [16] were selected for its superior stability and prediction accuracy.

Experiment results show that semantic masking and overlap sampling combined approach enhances robustness in prediction. The introduction of semantic masking layer could significantly improve the overall mean precision across all methods from 4.55% to 21.18% and the mean IoU from 3.48% to 10.88%.

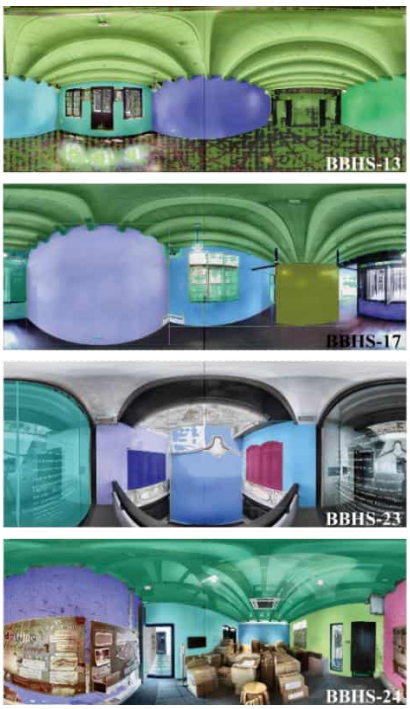

Figure 6. Semantic masks of structural components

The efficiency of this optimisation approach is most evident in complex scenes where baseline prediction generates more false positives. For instance, in test scene bbhs-22 using the CrackSegFormer method, the application of semantic masking combined with overlap sampling raised precision from 8.25% to 63.68%, marking a substantial recovery from the noise-dominated baseline. Similarly, CrackSAM in scene bbhs-21 increased IoU by 37.20% from a negligible 0.33% to 37.53%. These results confirm that introducing semantic masks effectively eliminates false positives on non-structural elements, fundamentally improved the precision and efficacy of the crack extraction pipeline. However, the improvement in Precision and IoU involves a trade-off in Recall. Because the semantic masks are isolating the predicted structural elements, some true defect pixels located at the boundaries of these surfaces could be excluded. While this leads to reductions in Recall depending on the architectural complexity of the scene, the trade-off is considered justifiable for structural health monitoring. Rather than pursuing pixel level accurate detection, the introduction of semantic masks significantly reduces background noise to improve the global detection reliability.

3.3 Surface Attributes in Point Clouds

Figure 7 displays representative results from the pipeline, illustrating fine-grained crack extraction within the segmented structural walls. Beyond visual inspection, the integration of these detections into a 3D point cloud environment enables several critical downstream tasks.

First, it allows quantification of defect length and area, providing a basis for severity evaluation. Second, visualizing surface defects in 3D reveals their spatial

4 Conclusions

This study presents a structural semantic segmentation and fine-grained surface feature extraction for heritage buildings. The proposed method addresses the inherent challenges of conducting structural health assessments on point cloud data captured in complex heritage environments. By incorporating semantic understanding of the scanned scenes, the method isolates structural components, refining crack identification on 3D point cloud data. The research was validated through experiments on a shophouse, benchmarking automated predictions against human visual inspections. Experimental results highlight the feasibility of TLS-derived point clouds for structural health assessment, confirming improvements in defect identification metrics in real-world heritage environment.

The proposed method has certain limitations for improvement. As the prediction was deployed using default parameters and generic datasets, fine-tuning these models on a dedicated heritage defect dataset could significantly bolster identification performance and robustness against domain-specific noise. Furthermore, current state-of-the-art networks predominantly focus on single-defect extraction (i.e., cracks), often yielding suboptimal results for multi-defect scenarios. Integrating diverse defect datasets with open-vocabulary semantic understanding models offers a promising pathway toward a holistic, multi-objective structural health assessment framework. Finally, while the high-resolution data provided by TLS is essential for detecting minute cracks, it introduces a trade-off in computational efficiency, the inherent operational constraints of TLS also limit its scalability in rapid field deployments. To bridge the gap between precision and operational practicality, future research will adapt this framework for data derived from mobile SLAM. Successfully adapting this pipeline to mobile data would not only mitigate the operational limitations of data acquisition, but also ready the framework for efficient structural health monitoring.

A scalable reinforcement learning framework for task allocation in flexible construction scenarios

Yifan Wang[1], Bin Yang[1]

[1] College of Civil Engineering, Tongji University, China

Abstract

The construction process requires close collaboration among multiple crews, which relies fundamentally on efficient task allocation. However, the performance and efficiency of existing scheduling approaches remain limited and are insufficient to support fine-grained decision-making. This paper proposes a scalable Reinforcement Learning (RL) framework for Multi-Crew Task Allocation (MCTA) in flexible construction scenarios. First, a disjunctive graph is developed to model construction tasks and their internal constraints, upon which the MCTA problem is formulated as a Markov Decision Process. Then, a four-module RL network architecture is designed to address the MCTA problem, and the overall policy is trained using Proximal Policy Optimization (PPO). Case study shows that the proposed framework can effectively allocate tasks, achieving a 8.63% reduction in project duration and a 15.88% decrease in crew idle time compared with existing methods.

Keywords –

Construction scheduling; Task allocation; Reinforcement learning; Disjunctive graph; Proximal policy optimization

1 Introduction

The construction process involves multiple work crews that can independently execute specific tasks. The completion of these tasks collectively leads to the final delivery of the entire project. The organization of the construction workflow plays a crucial role in ensuring project efficiency[1,2]. Construction Schedule Optimization (CSO) aims to enhance this organization by systematically planning and coordinating the timing and sequence of construction activities. In this process, the overall project is decomposed into several manageable and analyzable task units, commonly referred to as the Work Breakdown Structure (WBS). Based on this, the sequence of task execution is determined under the constraints of process precedence and resource availability, and each task is assigned to corresponding work crews for execution.

The problem of determining the optimal start times together with executor assignment under resource and precedence constraints is defined as the Flexible Resource-Constrained Project Scheduling Problem (FRCPSP)[3,4], which is known to be NP-hard[5]. In existing studies, such problems are primarily addressed using mathematical methods[6,7], heuristic methods[8,9] and metaheuristic approaches[10,11]. With the increasing complexity and expanding scale of modern construction projects, the construction process has evolved into a dynamically changing complex system characterized by intricate spatiotemporal constraints[9,12] and expansion of project scale. However, these methods rely on static rules or complex computational mechanisms, resulting in insufficient performance and generalization in flexible construction scenarios with strong dynamics of tasks and resources[13,14].

Reinforcement Learning (RL) is an effective approach for solving sequential decision-making problems in dynamic environments. Several studies have applied RL to determine construction project schedules[15–17]. However, these studies exhibit two key limitations: (1) they suffer from limited scalability, which leads to the curse of dimensionality in large-scale problems and an inability to handle variable problem sizes caused by dynamic changes or unexpected events; (2) they often fail to explicitly model the internal spatiotemporal constraints among construction tasks, forcing the neural network to implicitly learn project-specific decision rules in a black-box manner. These limitations hinder the practical applicability of RL in complex and flexible construction scenarios and restrict its ability to generate high-quality, fine-grained schedules.

To address these limitations, this study proposes an RL framework for modeling and solving fine-grained construction scheduling problem Multi-Crew Task Allocation (MCTA) problem from the perspective of Multi-Agent Simulation (MAS)[18]. The main contributions of this study are summarized as follows: (1)

A disjunctive graph is developed to model MCTA by explicitly representing spatiotemporal constraints among tasks. (2) A scalable RL framework is proposed to learn scheduling policies over the disjunctive graph, integrating Relational Graph Convolutional Network (RGCN) [19] and self-attention-based aggregation.

2 Related Work

2.1 Mathematical methods for construction scheduling

Early studies addressed the CSO problem using mathematical methods, among which the most common and influential is the Critical Path Method (CPM)[20]. CPM is a project scheduling technique that predicts the total project duration and identifies critical activities by locating the longest path of dependent tasks within a project. However, CPM has proven insufficient to handle the multi-objective, multi-constraint nature of modern scheduling problems, particularly in balancing resource continuity and cost trade-offs.

Consequently, Integer Programming (IP) and Linear Programming (LP) have been introduced to solve CSO problems. For example, Mattila et al.[21] proposed an integer linear programming-based linear scheduling model for resource leveling. Gomar et al.[22] developed a linear programming model to optimize the allocation of multi-skilled labor resources, minimizing labor costs while satisfying project demands. Ipsilands et al.[23] formulated a multi-objective linear programming model for scheduling linear and repetitive projects. To address the dynamic nature of the construction process, Robinson[24] applied a Dynamic Programming (DP) approach to determine project schedules that minimize overall duration, enabling the optimal allocation among activities with arbitrary cost – time functions.

2.2 Heuristic and metaheuristic methods for construction scheduling

Large-scale CSO problems are typically NP-hard, making it difficult for exact algorithms to obtain optimal solutions within a reasonable computation time. Heuristic methods, on the other hand, can efficiently produce near-optimal and satisfactory solutions by designing problem-specific decision rules. For example, Elazouni[25] proposed a heuristic algorithm that enumerates and ranks parallel project schedules under credit constraints, aiming to minimize project duration while maintaining real-time cash flow matching. Gajpal and Elazouni[26] introduced an enhanced heuristic algorithm based on a polynomial-shifting strategy, which replaces exhaustive search and reduces computation time from exponential to polynomial order without compromising solution accuracy. Similarly, Al-Shihabi et al.[27] developed a heuristic method that balances project duration and financial progress through a dual-priority rule enabling rapid generation of feasible scheduling solutions.

Metaheuristic methods improve candidate solutions through iterative computation based on predefined criteria, without requiring strong assumptions about the underlying CSO problem. Chan et al.[28] proposed a Genetic Algorithm (GA)-based construction resource scheduling method, which learns the structural features of project networks through selection and recombination mechanisms. Elazouni et al.[29] employed GA, Simulated Annealing (SA), and the Shuffled Frog-Leaping Algorithm (SFLA) to solve project scheduling problems under financial constraints, achieving the shortest total project duration with SA in large-scale networks. Ye et al.[11] further developed a two-stage task allocation framework for multiple heterogeneous construction robots based on an improved genetic algorithm, effectively enhancing collaboration efficiency in multi-robot systems.

2.3 RL for construction scheduling

The reliance of heuristic and metaheuristic approaches on predefined rules and static optimization limits their adaptability to the dynamic construction processes. RL is an effective approach for solving dynamic decision-making problems[30], and has been applied to address CSO challenges. Soman et al.[16] proposed a hybrid method that integrates RL with Linked-Data to automatically generate look-ahead schedules for construction projects. Kedir et al.[17] combined RL with agent-based modeling to obtain practical solutions that support decision-making in construction activity sequencing. Yuan et al.[15] considered both process precedence and resource constraints in bridge construction and employed RL to generate construction schedules. In addition, Agrawal et al.[31] developed a novel approach integrating Proximal Policy Optimization (PPO) with Monte Carlo sampling, which enables automatic generation of optimized assembly sequences and schedules for prefabricated buildings. These studies did not decompose construction projects into fine-grained task units and thus overlooked the precedence and spatial overlap constraints among tasks. Liu et al.[32] propose a Construction Markov Decision Process framework that leverages multi-agent RL to evaluate goals and plan paths, reducing project duration and labor idle time. However, they did not provide a systematic formulation of the scheduling problem, and therefore the methods still exhibit limitations in both performance and practical applicability.

3 Methodology

3.1 Problem formulation

This study focuses on a flexible construction process involving multiple crews, each possessing distinct skill sets, and models each crew as an agent. The entire project is decomposed into multiple tasks using WBS[33], and all agents collaboratively complete the construction through interleaved task execution, following the workflow illustrated in Figure 1. In this research, the MCTA problem incorporates three types of constraints, which are designed to explicitly capture the interactions among the three key elements in MCTA: tasks, labor resources, and workspace. Specifically, capability constraints reflect the matching relationship between tasks and crew skills, precedence constraints model the logical dependencies among tasks, and spatial overlap constraints characterize the conflicts arising from limited workspace.

(1) Capability constraint: Each crew can only execute tasks corresponding to its specific trade (e.g., a rebar-tying crew cannot perform formwork installation tasks).

(2) Precedence constraint: A task cannot be started until all its adjacent predecessor tasks are completed (e.g., formwork installation must precede concrete pouring).

(3) Spatial overlap constraint: If the workspace of a target task overlaps with that of a neighboring ongoing task, the target task cannot be initiated.

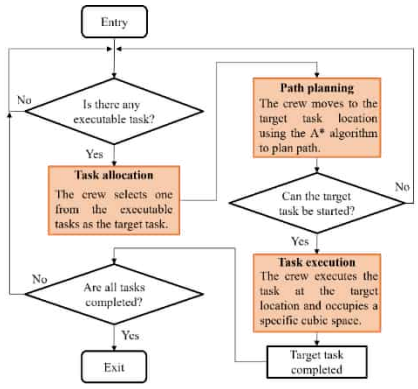

Figure 1 Workflow of crew agents

3.2 RL mathematical Model for MCTA

To address the MCTA problem, we adopt a RL approach, which requires formulating the scheduling process as a Markov Decision Process (MDP). The MDP can be formally described by a tuple $\langle \mathbf{S}, \mathbf{A}, \mathrm{P}, \mathrm{R}, \gamma \rangle$. $\mathbf{S}$ and $\mathbf{A}$ denote the state and action spaces, respectively, while P is the state transition probability function. R represents the reward function used to evaluate task allocation performance, and γ is the discount factor.

3.2.1 State

The state of the MCTA is defined by tasks attributes, agent attributes, and relationships among tasks. Attributes of tasks and agents are categorized into static and dynamic attributes, as illustrated in Table 1. $\mathbf{S}_{\mathrm{loc}}^{\mathrm{task}}$ and $\mathbf{S}_{\mathrm{loc}}^{\mathrm{agent}}$ are represented by two-dimensional coordinates on the plane. $\mathbf{S}_{\mathrm{type}}^{\mathrm{task}}$ and $\mathbf{S}_{\mathrm{type}}^{\mathrm{task}}$ are encoded as one-hot vectors, with the element corresponding to its type set to 1 and all others set to 0. $\mathbf{S}_{\mathrm{dur}} = [d]$ is determined based on the task quantity and the corresponding crew productivity rate. Four task pools—$task_{\mathrm{wait}}$, $task_{\mathrm{queue}}$, $task_{\mathrm{on}}$, and $task_{\mathrm{end}}$—are used to represent the execution status of tasks[9]. $\mathbf{S}_{\mathrm{po}}$ is represented as a one-hot encoded vector, where the element corresponding to the current pool of a task is set to 1 and all others are set to 0.

Table 1 Summary of state space

Temporality	Attribute	Symbol	Representation
Static	Task location	$\mathbf{S}_{\mathrm{loc}}^{\mathrm{task}}$	2D vector
	Task type	$\mathbf{S}_{\mathrm{type}}^{\mathrm{task}}$	One-hot vector
	Execution time	$\mathbf{S}_{\mathrm{dur}}$	1D scalar
	Agent type	$\mathbf{S}_{\mathrm{type}}^{\mathrm{agent}}$	One-hot vector
Dynamic	Task pool	$\mathbf{S}_{\mathrm{po}}$	One-hot vector
	Agent location	$\mathbf{S}_{\mathrm{loc}}^{\mathrm{agent}}$	2D vector

The relationships between tasks can be represented with a disjunctive graph[34] $G = (T, P, S)$, as shown in Figure 2. Here, T denotes the set of all tasks (nodes in black). P is a set of directed edges representing the precedence constraints between consecutive tasks, directed from each predecessor task to its successor (illustrated in orange). S is a set of undirected edges, in which each edge connects a pair of tasks that have a spatial overlap relationship (illustrated in blue).

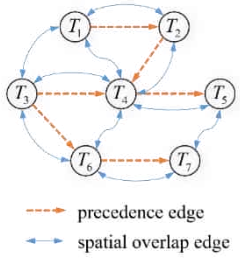

Figure 2 Disjunctive graph for MCTA

3.2.2 Action

Each crew agent outputs one discrete action a_t at a decision step t, where each optional action corresponds to a task. The dimensionality of the action space equals the total number of tasks. Due to the three types of constraints mentioned in Section 3.1, a large portion of the action space consists of invalid actions, which may lead to inefficient exploration during the agent's learning process. To address the problem, this study introduces action mask technique to handle a variable action space. Specifically, the logits of invalid actions are set to negative infinity at the output layer of the policy network, ensuring that their probabilities become zero after the softmax operation. Consequently, action sampling is performed only among valid actions, effectively improving exploration efficiency and training stability.

3.2.3 State transition

The state transition P of MCTA corresponds to the update of the overall construction progress. When an agent reaches an available task location, the task is moved from $task_{\text{queue}}$ to $task_{\text{on}}$. Upon task completion, the task transitions from $task_{\text{on}}$ to $task_{\text{end}}$, while its adjacent successor tasks are simultaneously moved from $task_{\text{wait}}$ to $task_{\text{queue}}$, thereby becoming eligible for execution.

3.2.4 Reward

The objective of MCTA is to minimize the total project duration, with all crew agents sharing a common reward defined as $\mathrm{R} = \mathrm{R}_{\text{finish}} + \mathrm{R}_{\text{time}}$. Here, $\mathrm{R}_{\text{finish}}$ is a terminal reward granted to all agents upon the completion of all construction tasks, while R_{time} is a stepwise penalty applied at each simulation timestep to encourage faster overall project completion.

3.3 Scalable RL network architecture for MCTA

This study proposes a scalable network architecture comprising four modules: a feature extraction module, a global representation module, a task scoring module, and a decoder model as illustrated in Figure 3.

3.3.1 Feature extraction module

The disjunctive graph represents precedence and spatial overlap constraints through different types of edges, thereby transforming spatiotemporal dependencies into connection features. To process such a heterogeneous graph with multiple edge types, a RGCN (parameterized by θ_{R}) is employed to extract task-level relational features.

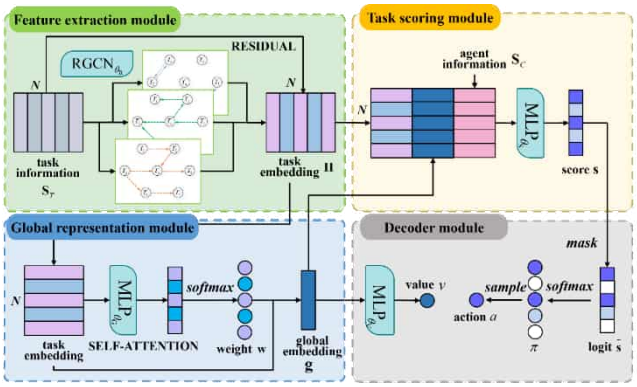

Figure 3 RL network architecture for MCTA For a given task T_i, its raw features can be defined as:

$$\mathbf{S}_{T_i} = (\mathbf{S}_{\text{loc}}^{\text{task}} \,\|\, \mathbf{S}_{\text{type}}^{\text{task}} \,\|\, \mathbf{S}_{\text{dur}} \,\|\, \mathbf{S}_{\text{po}}) \tag{1}$$

where $\|$ is the vector concatenation operator. To mitigate over-smoothing problem during multi-layer information aggregation, the original features are concatenated with the RGCN output (Equation (2)) to form the d-dimensional embedding of n tasks $\mathbf{H} = (\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_n)^{\mathrm{T}} \in \mathbb{R}^{n \times d}$, completing the feature extraction process.

$$\mathbf{h}_i = (\mathbf{S}_{T_i} \,\|\, \mathrm{RGCN}_{\theta_{\mathrm{R}}}(\mathbf{S}_{T_i}; \theta_{\mathrm{R}})) \tag{2}$$

3.3.2 Global representation module

The amount of information increases linearly with the number of tasks, so task-level information must be compressed into a graph-level representation to prevent dimensionality explosion. This study proposes a self-attention–based global representation method to identify critical tasks and reduce information loss A multi-layer perceptron (MLP) parameterized by θ_{G} is used to compute the attention weight $\boldsymbol{\alpha} = (\alpha_1, \alpha_2, ..., \alpha_n)^{\mathrm{T}}$ of each task based on its task embedding (Equation (3)(4)), after which a weighted average of all task embeddings is performed to obtain a global embedding $\mathbf{g}$ with the same dimensionality as each individual task embedding (Equation (5)).

$$w_i = \mathrm{MLP}_{\theta_{\mathrm{G}}}(\mathbf{h}_i; \theta_{\mathrm{G}}) \tag{3}$$

$$\alpha_i = \frac{\exp(w_i)}{\sum_{j=1}^{n} \exp(w_j)} \tag{4}$$

$$\mathbf{g} = \sum_{i=1}^{n} \alpha_i \mathbf{h}_i \in \mathbb{R}^d \tag{5}$$

3.3.3 Task scoring module

We designed a scalable task-shared scorer, which shares feature-mapping parameters across all tasks. For

each task T_i, its task embedding $\mathbf{h}_i$ is concatenated with the global embedding $\mathbf{g}$ obtained from the global representation module and information $\mathbf{S}_c = (\mathbf{S}_{\text{type}}^{\text{agent}} \,\|\, \mathbf{S}_{\text{loc}}^{\text{agent}})$ of the agent, and then passed through an MLP scorer parameterized by θ_S to compute its score s_i. (Equation (6)).

$$s_i = \text{MLP}_{\theta_S}(\mathbf{h}_i \,\|\, \mathbf{g} \,\|\, \mathbf{S}_c; \theta_S) \tag{6}$$

Task scoring module not only preserves the independent comparability of individual nodes but also allows the network to learn the relative importance among tasks through backpropagation.

3.3.4 Decoder module

The decoder module utilizes the encoded information from upstream modules to generate both the value and action outputs. The value decoder maps the global information contained in the global embedding $\mathbf{g}$ into a scalar value v using MLP parameterized by θ_V:

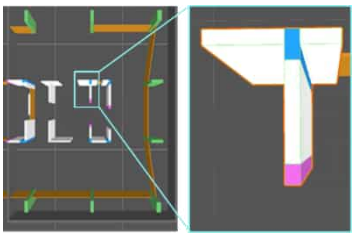
$$v = \text{MLP}_{\theta_V}(\mathbf{g}; \theta_V) \in \mathbb{R} \tag{7}$$

The action decoder receives the task scores $\mathbf{s} = (s_1, s_2, ..., s_n)^T$ from the shared scorer. To handle the variable action space, invalid tasks are masked by setting their corresponding logits to negative infinity. Then softmax function is then applied to obtain the action probabilities. Finally, the selected action a_t is sampled from this probability distribution.

3.3.5 PPO for MCTA

PPO[35] is a widely used RL algorithm that improves training stability and efficiency by introducing a clipped objective function to limit abrupt policy updates. It alternates between sampling trajectories through agent–environment interaction and performing several epochs of gradient-based optimization, making it simple to implement yet highly effective for scheduling problems like MCTA. This study employs PPO to train agent strategy.

4 Case study



4.1 Case description and modeling process

To validate the effectiveness of the proposed method, we adopts a case study based on vertical component construction for a prefabricated structure. The case involves 7 construction crews (N=7) across 5 trade types, and a total of 86 construction tasks (n=86) associated with 36 structure components(Table 2). The 7 crews consist of one Joint cutting and Cleaning Crew (JCC), one Hoisting and Installation Crew (HIC), one Grouting Crew(GC), two Reinforcing Crews (RC1 and RC2), and two Form-work Crews (FC1 and FC2). Under capability constraints, each crew can only perform tasks corresponding to its trade. The simulation parameters are configured in strict accordance with reference[32]. We developed an RL environment based on Unity 3D.

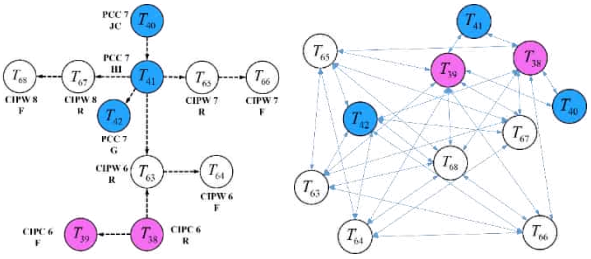


Table 2 Basic attributes of components

Component type	ID	Required tasks
Prefabricated columns	PCC 1-6	JC,HI,G
Cast-in-place columns	CIPC 1-5	R,F
Prefabricated walls	PCW 1-8	JC,HI,G
Cast-in-place walls	CIPW 1-17	R,F

A local structure segment (shown in Figure 4(a)) is selected to demonstrate the disjunctive graph modeling process. Within this segment, 11 tasks are involved, connected by 10 precedence relations, which are directed from predecessor tasks to successor tasks to represent precedence constraints, as shown in Figure 4(b). These precedence relationships are derived not only from general construction knowledge but also from the connection relationships among components and the specific technical requirements of the project. The 34 spatial overlap edges are illustrated in Figure 4(c). Each edge indicates that the corresponding tasks have overlapping bounding volumes and therefore cannot be executed simultaneously under the spatial overlap constraint. In Figure 4(b) and (c), the nodes are arranged using different layouts to better visualize the distinct connection patterns of the two relations.

(a) Selected segment of the structure

(b) Precedence relations (c) Spatial overlap relations

4.2 Configurations

The simulation experiments were conducted on a computer equipped with a 13th Gen Intel® Core™ i9-13900K CPU (3.00 GHz), 64 GB RAM, an NVIDIA GeForce RTX 4090 GPU, and a 64-bit Windows 11 Professional operating system. In the simulation environment, each time step corresponds to 2.5 seconds, and each spatial unit represents one meter in the real-world project. Key network parameters are summarized in Table 3.

Table 3 Network parameters

Parameter	Value
Task feature dimension	12
Agent feature dimension	7
Number of RGCN layers	3
Hidden layer dimension of RGCN	64
Output layer dimension of RGCN	64
Embedding dimension	64+12=76
Number of MLP_{θ_G} layer	2
Hidden layer dimension of MLP_{θ_G}	64
Number of MLP_{θ_S} layer	3
Hidden layer dimension of MLP_{θ_S}	512
Number of MLP_{θ_V} layer	3
Hidden layer dimension of MLP_{θ_V}	512
Activation function	ReLU
Learning rate	0.0001
Epsilon	0.2
Number of epoch	3
Max step	330000
Buffer size	1280
Batch size	128

4.3 Results

Through iterative interaction with the environment (Figure 5), the proposed method successfully generated a fine-grained construction schedule for the case project. All 86 tasks were finished without constraints violated. Reference [36] evaluated 12 rules for task sequencing, from which we select three well-performing rules that are suited to MCTA as baselines. (1) First In First Out (FIFO): Tasks that enter the task pool $task_{\mathrm{queue}}$ earlier are given higher priority, reflecting a fairness-oriented scheduling strategy based on task availability. (2) Shortest Operation Time (SOT): Tasks with the shortest execution time are prioritized to improve efficiency. (3) Shortest Distance (SD): Tasks that are geographically closest to the crew agent are prioritized, aiming to reduce travel time. In addition, we import the Priority Rule (PR)[9], that comprehensively considers multiple factors.

Among metaheuristic methods, we selected GA as a baseline, as it is widely applied in scheduling research. Following the approach in [37], each gene represents the priority of a task, and the total project duration is used as the fitness function. The population size is set to 100. The optimization process is terminated after 80 generations, as the best fitness value shows no improvement for 20 consecutive generations. Also, an RL-based method in construction scheduling, FC-PPO[32], is included as a baseline. For fair comparison, this baseline adopts the same number and dimension of hidden layers as the scorer and value networks proposed in this study, and is trained for the same number of steps.

Figure 5 Runtime visualization of the simulator

Three performance indicators are defined to quantitatively evaluate the efficiency and stability of the MCTA system (as shown in Table 4), including:(1) Project Duration (PD): the total duration of the construction process.(2) Average Idle Time (AIT): the average idle time of crews caused by the unavailability of executable tasks.(3) Crew Utilization Rate (CUR): the ratio of working time to total time for crews. The results are averaged over 30 simulation runs with different random seeds.

Among the heuristic methods, FIFO, SOT, and SD each focus on a single factor and lack adaptability to complex construction scenarios. For highly dynamic construction scenarios, the GA method based on pre-calculated task priorities struggles to achieve reliable performance within limited iterations, with an average PD of up to 19.83 h. Among all seven evaluated methods, the proposed approach achieves the shortest average PD of 14.40 h, representing a 8.63 % reduction compared with the best competing method (FC-PPO). Moreover, its standard deviation is only 0.35 h, demonstrating excellent stability in performance. AIT and CUR reflect the utilization of human resources in the MCTA problem. The proposed method significantly reduces AIT of crews, achieving a 15.88 % reduction compared with the best among the other seven methods (FC-PPO), while also attaining the highest CUR. These results strongly demonstrate the superior performance of the proposed approach.

Table 4 Performance comparison of different methods

Method	PD (h)	AIT (h)	CUR (%)
FIFO	19.98±0.45	6.85±0.36	50.63±1.21
SOT	19.57±0.37	6.48±0.29	50.54±0.89
SD	16.30±1.04	4.88±0.61	56.68±2.15
PR	16.64±0.63	4.99±0.37	54.93±1.18
GA	19.83±0.27	6.79±0.23	50.75±0.65
FC-PPO	15.76±0.75	4.22±0.34	56.39±1.49
Ours	**14.40**±0.35	**3.55**±0.27	**60.29**±0.88

To further investigate whether the learned representations effectively capture real-world construction conditions, an additional analysis is conducted from two perspectives. (1) An ablation study is performed to evaluate the contribution of the graph-based representation. Specifically, the RGCN is replaced with a task-wise MLP that directly processes raw features. The results show that the cumulative reward does not exhibit an increasing trend during training, indicating that features extracted from the disjunctive graph are indispensable for decision-making. (2) A correlation analysis is conducted to examine the relationship between extracted features and the task importance reflected by the self-attention mechanism. The attention weights, together with the task scores, provide an indication of which features are most relevant to the construction conditions. The results show that the extracted features achieve an average Spearman rank correlation coefficient ρ of 0.46, with 70.0 % of feature dimensions exhibiting moderate or higher correlation ($\rho >$ 0.4), and 17.5 % showing strong correlation ($\rho >$ 0.7). In contrast, the raw features yield an average ρ of only 0.05, indicating a very limited contribution to representing construction conditions.

5 Conclusion and future work

This study proposes a disjunctive graph–based representation for flexible construction processes, together with a scalable RL framework to address the MCTA problem. The core network architecture integrates a feature extraction module, a task scoring module, a global representation module, and a decoder module. Within this architecture, a RGCN is employed to capture multi-relational features from the disjunctive graph, while a self-attention mechanism aggregates global information in a scale-agnostic manner. These designs enable the learned policy to generate high-quality task allocation decisions that shorten overall project duration and significantly improve labor resource utilization.

Future research should focus on developing large, standardized datasets for various construction types to learn generalized scheduling policies with stronger transferability and robustness. Advancing these directions will further strengthen the proposed framework's capability to support practical, real-time decision-making in complex construction management environments.

Abstract -

Robotic bridge inspection systems are emerging as crucial technologies to improve efficiency and safety in infrastructure maintenance, particularly in accessibility-constrained environments. However, the challenge of processing multi-view data and integrating detection, quantification, and report generation into a unified workflow remains unresolved. To address this challenge, this paper proposes an integrated inspection framework using multi-view RGB-D image sequences for a robotic bridge inspection. The framework supports multi-scale inspection by enabling both wide-area inspection and local-area inspection, while employing a two-stage voting mechanism to mitigate duplicate detections and false positives in 3D space. Experiments at a Precast Segmental Method (PSM) concrete box-girder bridge demonstrated that the framework successfully detected nine defect types, generated 2D inspection maps, and produced millimetre-scale quantification results. This work demonstrates the feasibility of an integrated robotic bridge inspection system that encompasses multi-view data analysis and quantification for practical workflows.

Keywords –

Bridge inspection; Multi-view integration; Defect detection; Quantification; Multi-scale inspection

1 Introduction

Surface defect inspection of concrete bridge structures is critical for ensuring structural safety and supporting maintenance decision-making. In South Korea, the proportion of bridges in service for over 30 years has been increasing [1], with surfaces such as box-girder interiors and exterior abutments representing typical hard-to-access regions due to their locations and structural characteristics [2]. Practical bridge inspection requires multi-scale approaches combining wide-area inspection of the overall structure and local-area inspection of defect-concentrated regions [3]. Beyond detection, defect measurement and quantification are essential components of concrete bridge inspection [4]. Obtaining quantitative measurements in physical units is essential for condition assessment and maintenance decision-making in practical bridge inspection. However, existing processes rely heavily on visual observation by inspectors, causing persistent issues including subjectivity, lack of consistency, and labour-intensive procedures [5]. Accordingly, there is growing need for automated inspection technologies providing objective and consistent quantitative results even in environments with limited accessibility.

In response to these demands, recent research has actively employed deep learning techniques for bridge surface defect detection and quantification [6, 7]. Torok et al. [8] investigated methods to identify global defect location and distribution through Structure-from-Motion (SfM), while Deng et al. [9] explored image-based Simultaneous Localization and Mapping (SLAM) approaches. Research on surface defect detection using Light Detection and Ranging (LiDAR) sensors has also been presented. Feng et al. [10] quantified crack geometry and location in 3D space through sensor fusion SLAM combining LiDAR and camera. Lin et al. [11] proposed surface defect detection methodologies utilizing 2D projection of LiDAR-acquired point clouds, demonstrating image and point cloud integration in defect inspection. However, these prior efforts have been primarily limited to specific defect types such as cracks and have not addressed comprehensive quantification across multiple defect types or inspection report generation. Furthermore, multi-scale inspection strategies encompassing both wide-area and local-area inspection have been largely overlooked.

Meanwhile, research on robot-based data acquisition systems for accessibility-constrained environments has also been conducted [12], and quadruped robots have demonstrated stable mobility and continuous image sequences acquisition across various environments [13]. However, these robotic data

acquisition technologies and defect analysis algorithms have been developed independently, and methodologies to systematically address duplicate detections and false positives arising from multi-view image sequences remain insufficient.

This paper proposes an integrated inspection framework for multi-scale defect detection, quantification, and report generation using bridge surface image sequences data. The proposed framework addresses the detection, classification, and quantification of nine defect types specified in Korean regulations [14], while mitigating duplicate detections and false positives. To validate the proposed framework, experiments were conducted using data acquired by a quadruped robot at an exterior abutment of a box-girder bridge. Additionally, a multi-scale inspection strategy was validated through experiments using interior diaphragm data captured by a handheld camera. These experiments demonstrated the practical applicability of the framework in real inspection environments.

2 Methodology

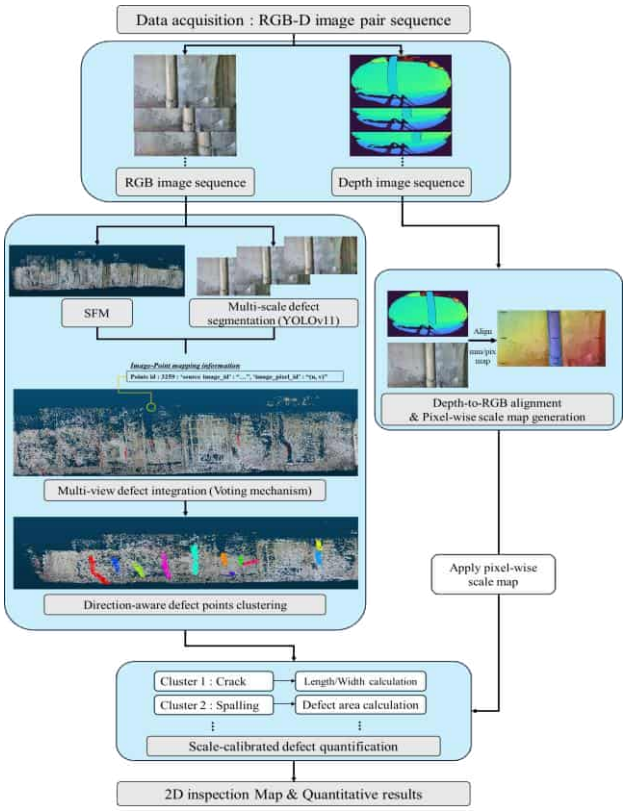

Figure 1. Overall Framework

Figure 1 shows the overall workflow of the proposed framework. The framework processes RGB-D image sequences, leveraging both 2D information from RGB images and 3D spatial information from depth data. Each processing module is described in detail in the following subsections.

2.1 SfM-based 3D reconstruction

SfM-based reconstruction is performed to integrate 2D RGB images into 3D space. The key advantage of SfM is that it establishes 2D-3D correspondence by identifying which pixel in which source image generated each point in the reconstructed point cloud. In overlapping regions between images, a single 3D point is mapped to multiple images, which forms the basis for multi-view integration. The proposed framework utilizes this 2D-3D correspondence to address duplicate detections and false positives arising from multi-view image sequences, as well as to support defect clustering and quantification. In addition, the reconstructed point cloud serves as the foundation for generating a 2D inspection map that visualizes the relative spatial distribution of defects within the inspected area.

2.2 Multi-scale defect detection

A YOLOv11x-seg model [15] is applied to each RGB image to detect and segment defects. The model was trained on nine types of surface defects in the dataset: crack, detachment, spalling, rebar exposure, material separation, damage, leak, lifting, and efflorescence. This paper used datasets from AI-hub [16]. All images are processed at the standard input resolution of 640 by 640 pixels. The model outputs a defect mask in polygon format for each detected defect, enabling the identification of defect type and boundary information within each RGB image.

To support both wide-area inspection and local-area inspection, the proposed framework provides two detection modes. Standard Mode uses the original image as input to the YOLOv11 model and detects defects directly. In contrast, Crop Mode divides the image into a grid of user-specified dimensions and performs YOLOv11 model for inference independently on each cropped image. To prevent defects from being split across crop boundaries, adjacent cropped images are overlapped by a specified number of pixels. For example, when using a 2 by 2 grid with 150-pixel overlap, defects detected in each cropped image can be geometrically merged. The continuous shape of defects that span multiple crops is then restored by computing the geometric union of overlapping defect polygons. While the grid size in Crop Mode can be selected flexibly without compromising detection performance, larger grids increase computational cost. Users can therefore choose the grid size based on site conditions and required detection precision.

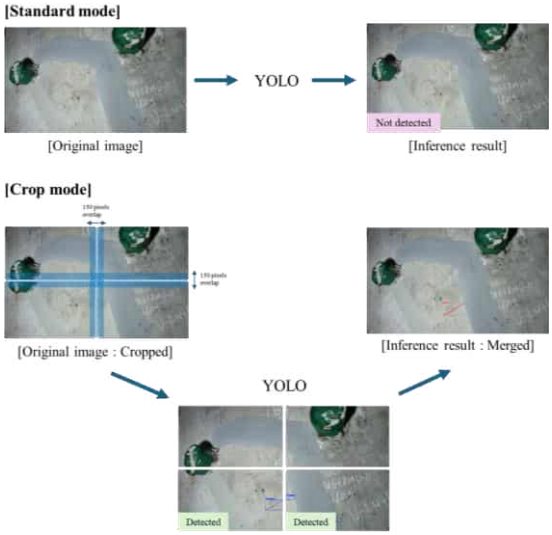

Figure 2. Standard Mode and Crop Mode for multi-scale defect detection (2×2 grid example)

2.3 Pixel-wise scale map generation

Since SfM-based reconstruction is inherently scale-free, depth information is required to convert pixel-based measurements into real-world physical units. To address the perspective-induced scale variation where the same physical dimension is represented by different numbers of pixels depending on the camera-to-surface distance, a pixel-wise scale map is generated for each image using depth information obtained from the RGB-D camera. This scale map computes the physical dimension per pixel (in millimetres per pixel) at each location in the image based on the depth value and camera focal length.

First, the depth image is aligned to the coordinate frame of the corresponding RGB image. This process is performed through coordinate-transformation and resolution matching using the extrinsic parameters between the RGB and depth cameras and the intrinsic parameters of each camera.

Each pixel (u_d, v_d) in the depth image and its corresponding depth value Z_d are back-projected to a 3D point $\mathbf{P}_d = (X_d, Y_d, Z_d)^\top$ in the depth camera coordinate frame using the depth camera intrinsic parameters. The depth camera intrinsic parameter matrix $\mathbf{K}_d$ is defined as:

$$\mathbf{K}_d = \begin{bmatrix} f_{x,d} & 0 & c_{x,d} \\ 0 & f_{y,d} & c_{y,d} \\ 0 & 0 & 1 \end{bmatrix}$$

where $f_{x,d}$, $f_{y,d}$ are the focal lengths of the depth camera and $c_{x,d}$, $c_{y,d}$ represent the principal point. The back-projection process is expressed as:

$$\begin{bmatrix} X_d \\ Y_d \\ Z_d \end{bmatrix} = Z_d \cdot \mathbf{K}_d^{-1} \begin{bmatrix} u_d \\ v_d \\ 1 \end{bmatrix}$$

The 3D point $\mathbf{P}_d$ expressed in the depth camera coordinate frame is then transformed to the RGB camera coordinate frame. This transformation is performed using the extrinsic parameters between the depth and RGB cameras, consisting of a rotation matrix $\mathbf{R}_{d\to r}$ and a translation vector $\mathbf{t}_{d\to r}$:

$$\mathbf{P}_r = \mathbf{R}_{d\to r}\,\mathbf{P}_d + \mathbf{t}_{d\to r}$$

where $\mathbf{R}_{d\to r} \in \mathbb{R}^{3\times 3}$ is the rotation matrix that rotates the depth camera coordinate frame to the RGB camera coordinate frame and $\mathbf{t}_{d\to r} \in \mathbb{R}^3$ is the translation vector representing the relative position difference between the two cameras.

The 3D point $\mathbf{P}_r = (X_r, Y_r, Z_r)^\top$ which has been transformed into the RGB camera coordinate frame, is projected onto the RGB image plane using the RGB camera intrinsic parameter matrix $\mathbf{K}_r$:

$$\begin{bmatrix} u_r \\ v_r \\ 1 \end{bmatrix} = \frac{1}{Z_r}\mathbf{K}_r \begin{bmatrix} X_r \\ Y_r \\ Z_r \end{bmatrix}$$

Through this process, each pixel in the depth image is mapped to a corresponding pixel (u_r, v_r) in the RGB image coordinate frame, establishing pixel-level correspondence between the RGB and depth images.

From the aligned depth map, the physical scale $s_x(u_s, v_s)$, $s_y(u_s, v_s)$ at each pixel is computed using the depth value $d(u_d, v_d)$ (in millimetres) and the RGB camera focal lengths f_x , f_y :

$$s_{x\,or\,y}(u_s, v_s) = \frac{d(u_d, v_d)}{f_{x\,or\,y}}$$

The pixel-wise scale map generated in this manner is created for each RGB image and is subsequently used in the defect quantification stage to convert pixel-based measurements into physical units.

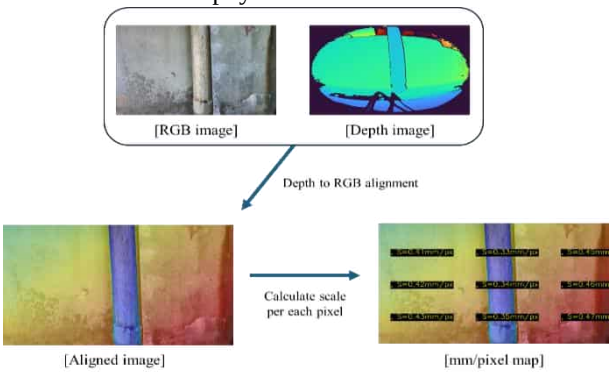

Figure 3. Scale map generation process

2.4 Multi-view defect integration in 3D space via two-stage voting mechanism

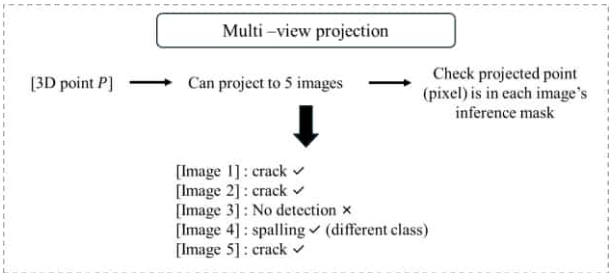
Defect polygons detected by the YOLOv11 model in each RGB image are integrated into 3D space through projection onto the point cloud generated by SfM. Using the 2D-3D correspondence established in the SfM database, each 3D point is back-projected to all RGB images in which it is visible. If the projected pixel coordinate falls inside a detected defect polygon, the point is designated as a defect point candidate. Through this process, each 3D point receives semantic information regarding defect presence and defect class from multiple RGB images. Since each 3D point uniquely represents a specific spatial location, the same defect can be represented as a single entity in 3D space even when observed in multiple images or captured in fragmented views.

During the projection process, false detections from the defect segmentation model must be considered. When acquiring numerous image sequences for inspection, false detections can occur frequently due to variations in lighting conditions and viewing angles. False detections can manifest in two forms: false positives where non-defect regions are incorrectly identified as defects, and misclassifications where defect classes are incorrectly predicted. To mitigate these issues, a two-stage voting mechanism is designed to leverage the multi-view nature of robotic inspection.

In Stage 1, the Detection Voting stage, the presence or absence of a defect at each point is determined. Each 3D point P_j has an associated set of images $\mathcal{I}_j$ in which it is observed. For each image $I_i \in \mathcal{I}_j$, the 3D point P_j is projected onto the image, and it is verified whether the projected pixel location falls inside any defect mask (including all defect classes). The defect presence voting ratio $v_d(P_j)$ for point P_j is defined as:

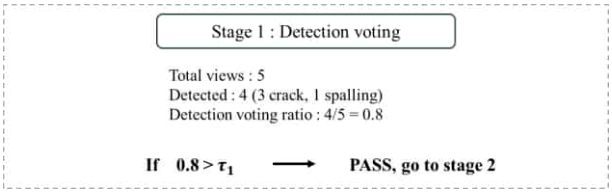
$$v_d(P_j) = \frac{1}{|\mathcal{I}_j|}\sum_{I_i \in \mathcal{I}_j} \mathbb{1}_{mask}(I_i, P_j)\ ,\ \tau_1 = 0.5$$

where $|\ \mathcal{I}_j\ |$ is the number of images in which point P_j is observed, and $\mathbb{1}_{mask}(I_i, P_j)$ is an indicator function that returns 1 if the projected location of point P_j in image I_i falls inside any defect mask, and 0 otherwise. In the proposed framework, a threshold τ_1 is applied, and only points satisfying $v_d(P_j) \geq \tau_1$ are selected as defect-present 3D points.



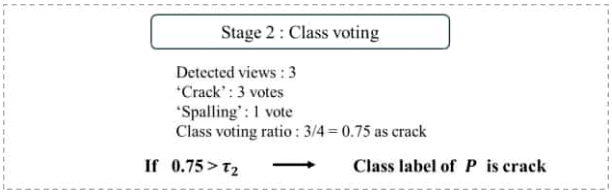
In Stage 2, the Class Voting stage, the final defect class is determined for each defect-present 3D point selected from Stage 1 by aggregating the observation frequency for each defect class. The voting ratio $v_c(P_j, c)$ for point P_j to be classified as class c is defined as:

$$v_c(P_j, c) = \frac{1}{|\mathcal{I}_j|}\sum_{I_i \in \mathcal{I}_j} \mathbb{1}_{mask}(I_i, P_j, c)$$



where $\mathbb{1}_{mask}(I_i, P_j, c)$ returns 1 if the projected location of point P_j in image I_i, falls inside a defect mask of class c, and 0 otherwise. The final defect class is determined through the following condition, which eliminates cases where defect classes are inconsistently predicted:

$$v_c(P_j, c) \geq \tau_2\ ,\ \tau_2 = 0.5$$



This two-stage voting mechanism mitigates false detections and misclassifications by labelling each point in the point cloud with a defect class based on the projection results. Through this process, multi-view defects are integrated into a unified 3D representation. Figure 4 illustrates this process.

(a)

(b)

(c)

2.5 Direction-aware defect points clustering

The 3D defect points selected through voting stages must be clustered into individual defect instances. For defects such as cracks, conventional distance-based clustering using Density-Based Spatial Clustering of Applications with Noise (DBSCAN) can erroneously merge intersecting cracks into a single cluster. To address

this issue, a direction-aware clustering strategy that leverages local orientation information is applied.

First, density-based primary clustering is performed using DBSCAN to remove noise and extract candidate defect regions. Second, the local orientation of points within each cluster is estimated using Principal Component Analysis (PCA) and point groups exhibiting large orientation differences are separated to split intersecting defects into independent instances. Finally, remerging is performed based on centroid distance and principal component orientation similarity to restore contiguous defects that may have been inadvertently separated. This direction-aware clustering approach overcomes the limitations of simple distance-based clustering, enabling more accurate clustering of complex defect geometries in multi-view environments. Figure 5 illustrates the differences between clustering methods.

Through this process, the final defect clusters can be visualized in 3D space, and this information is subsequently utilized to generate a 2D inspection map. This 2D inspection map provides the spatial locations of defects within the structure and can be used in practical inspection workflows.

(a) (b) (c)

Figure 5. Differences by clustering method; (a) DBSCAN clustering, (b) proposed clustering, (c) original crack RGB image.

2.6 Scale-calibrated defect quantification

Using the pixel-wise scale map established in Section 2.3, each clustered defect instance is quantified in millimetres. Since point cloud cluster data lacks clear boundary definition and exhibits sparsity, leading to potential measurement errors, defects are quantified using the RGB images associated with points in each cluster through the 2D-3D correspondence. As illustrated in Figure 6, each 3D point within a defect cluster can be projected to multiple RGB images through the 2D-3D correspondence. By aggregating these projection relationships, the image most frequently associated with the cluster points is selected as the measurement source. This image selection process is independently performed for each defect cluster, ensuring that every cluster is quantified from its own most representative image. The selected image's pixel-wise scale map and defect mask are then loaded, and different measurement strategies are applied depending on the defect type.

2.6.1 Crack measurement: length and width

For cracks, the segmentation mask is narrow, requiring measurement of length and width, but direct calculation from the mask is impractical. Therefore, the single-pixel-width crack centreline skeleton extraction and measurement algorithm proposed by [6] is adopted to measure length and width. However, [6] presented a measurement approach for single images. In the proposed framework, the image with the highest number of point observations from the 3D crack cluster is selected, and measurement is conducted on that image. Furthermore, while [6] used a fixed scale factor, the proposed approach applies the spatially varying scale map to convert pixel-based measurements into real-world units, thereby reducing measurement errors arising from depth changes and perspective effects.

2.6.2 Non-crack defect measurement: Area

For non-crack defects such as detachment, spalling, and rebar exposure, area is used as the primary quantification metric. In the selected image for the defect instance, the physical area of each pixel within the defect mask is computed by multiplying the scale values in the u and v directions from the pixel-wise scale map, and the total defect area is obtained by summing these individual pixel areas in square millimeters. Unlike cracks, non-crack defects do not require single-pixel-width precision, allowing the segmentation mask to be used directly.

The quantification results for each defect are stored in JSON format. Using the 2D inspection map and defect quantification results, the final inspection report is generated.

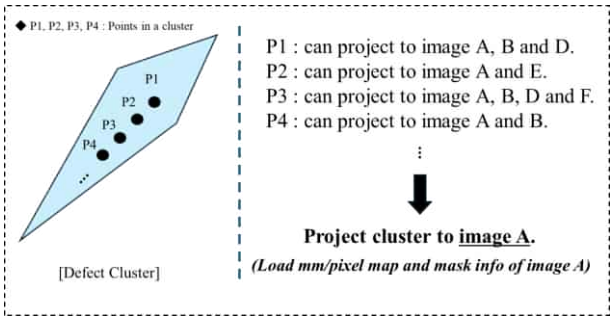

Figure 6. Scenario of image selection for defect cluster quantification

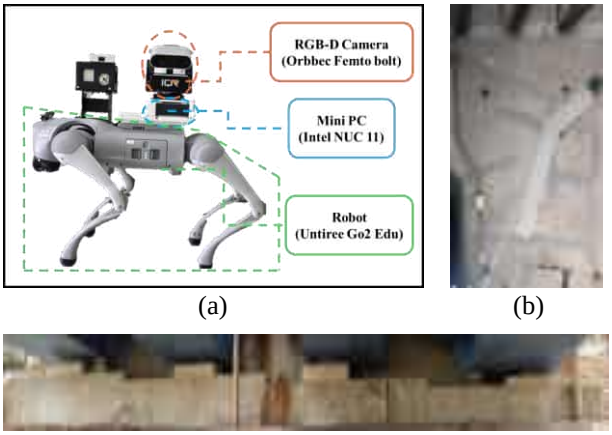
3 Experiments and Results



3.1 Data acquisition

For the experiments, data were collected using an RGB-D camera (Femto Bolt by Orbbec). In robot-based acquisition, the RGB-D camera was mounted on a quadruped robot (Go2 Edu by Unitree Robotics), with a mini-PC (Intel NUC 11) also equipped to store and manage the captured RGB-D image sequences (Figure 7(a)). In handheld acquisition, image sequences were acquired using the same camera model.

RGB and depth image sequences were captured as synchronized pairs. To ensure overlap for SfM-based 3D reconstruction, pairs were acquired at 0.5-second intervals. RGB-D images were captured at different resolutions per camera specifications (RGB: 3840 by 2160 pixels, depth: 512 by 512 pixels). Additionally, the RGB and depth lenses had different Fields of View (FOV). These characteristics and the extrinsic and intrinsic parameters were incorporated into the scale map generation described in Section 2.3.

3.2 Experiment Site

Images were acquired at an exterior abutment and an interior diaphragm of a Precast Segmental Method (PSM) concrete box-girder bridge (Figure 7 (b), (c)). Both sites represent different inspection scales within the multi-scale framework. At the abutment site, requiring wide-area inspection, the entire wall surface was captured using a quadruped robot, acquiring 698 RGB-D image pairs. At each position, images were taken at three camera orientations (upward, horizontal, downward tilt) from 50 to 70 centimetres standoff distance, advancing less than one metre between positions with five-second stationary periods to prevent motion blur. The diaphragm site represents a critical area where load-bearing prestressing tendons run through, requiring local-area inspection. A total of 212 RGB-D image pairs were acquired using a handheld camera. Since the diaphragm is inside the bridge structure, images were acquired with supplementary lighting due to limited natural lighting.

(a) (b)

(c)

Figure 7. (a) Hardware configuration on quadruped robot, (b) diaphragm site, (c) abutment site

3.3 Results

3.3.1 Abutment site

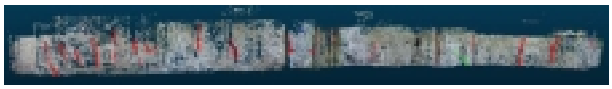
Figure 8 presents the wide-area inspection results obtained by applying the proposed framework to the exterior abutment. Figure 8(a) shows the 3D point cloud of the abutment reconstructed through SfM using the RGB-D image sequences acquired by the quadruped robot. This reconstruction enables verification of the overall geometry and inspection coverage of the target structure at a structure-wide scale. Figure 8(b) presents the integrated defect information obtained through multi-view integration and clustering of detections from multi-view image sequences. While defects may be observed repeatedly or captured in fragmented views across different viewpoints, the proposed framework consolidates them into single defect instances, mitigating duplicate detections. Different colours are assigned to each cluster for visualization purposes.

Figure 8(c) shows the 2D inspection map generated based on the identified 3D defect instances. The map visualizes defect locations and types in a structured format, enabling clear visualization of wide-area inspection results. Figure 8(d) presents quantification results for each defect type in tabular form.

To quantitatively evaluate the detection performance, 33 unique defects were manually identified across the abutment surface and used as Ground Truth (GT). YOLO alone produced 1,762 detection masks across 689 images, where duplicate detections from multi-view image sequences make it impossible to determine the actual number of unique defects without 3D projection. When detections were projected into 3D space and clustered without the voting mechanism, the framework achieved a Precision of 0.429, Recall of 0.758, and F1 Score of 0.556. With the multi-view voting mechanism applied, Precision improved to 0.889 with an

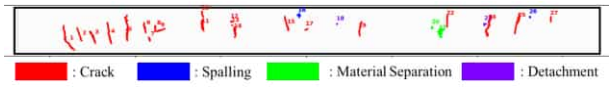
F1 Score of 0.781, demonstrating that the voting mechanism substantially reduces false positives while maintaining comparable Recall (0.697).

3.3.2 Diaphragm site



The diaphragm site represents a localized surface and requires finer inspection detail. Figure 9 demonstrates the effectiveness of the multi-scale inspection strategy at the interior diaphragm of the PSM box-girder bridge.

Figure 9 (a) shows the results obtained by applying Standard Mode to identify the overall defect distribution across the structure. In contrast, Figure 9 (b) presents the results of applying Crop Mode of the proposed framework to the region requiring local-area inspection. This comparison was conducted with all processing steps identical except for the detection scale. Based on YOLOv11 model inference on cropped images, defects that were not detected in Standard Mode were additionally detected.



These results demonstrate that the proposed framework can accommodate both wide-area inspection and local-area inspection within a unified framework, as required in practical inspection environments.

4 Discussion

The experimental results demonstrated that the proposed framework operates as a robotic inspection system for real concrete bridge surfaces. In inspection environments using multi-view images, issues such as duplicate detections, fragmented observations, and false positives frequently occur. The proposed framework mitigates these issues in 3D space and subsequently performs defect quantification. As shown in Section 3.3.1, the quantitative evaluation confirmed that the multi-view voting mechanism substantially reduces false positives while maintaining comparable Recall. However, direct comparison with the manual inspection map remains limited because the manual inspection was conducted at a different time than the experimental data acquisition.

Meanwhile, 3D reconstruction through SfM was advantageous in establishing explicit 2D-3D correspondence but is limited by the scarcity of extractable features in the acquired images. Sparse point clouds were generated in feature-poor regions, such as areas covered with repair tape on the interior diaphragm of the box girder, due to the lack of distinctive visual features or motion blur. To overcome these limitations, future work could explore RGB-D Visual SLAM or fusion with LiDAR sensors. Additionally, while the diaphragm site experiments demonstrated the effectiveness of multi-scale inspection, the use of handheld camera data can also be considered a limitation.

While the detection performance has been quantitatively evaluated in Section 3.3.1, further validation of the quantification process remains necessary. Ground truth measurements of defect dimensions should be obtained through manual inspection conducted concurrently with robotic data acquisition to enable direct comparison with the framework's quantification outputs.

5 Conclusion

This paper proposed an integrated framework that unifies defect detection, quantification, and report generation into a continuous workflow for accessibility-constrained concrete bridge surfaces using multi-view RGB-D image sequences. The framework addresses multi-scale inspection by supporting wide-area and local-area inspection while systematically mitigating duplicate detections and false positives in 3D space.

Experiments at the exterior abutment and interior diaphragm of a PSM box-girder bridge confirmed reliable operation in real environments, generating quantification results and 2D inspection maps for various defect types. This work demonstrates the feasibility of advancing robotic bridge inspection from simple data acquisition to an integrated system encompassing multi-view analysis and quantification.

Future research should address the limitations identified in Section 4. More robust reconstruction approaches must be developed to ensure stable 3D reconstruction. Rigorous validation of the quantification process is required to demonstrate that the proposed framework provides reliable results.

Abstract –

Inspection of concrete box-girders is essential for ensuring the structural performance of a PSM bridge throughout its service life. With advances in 3D sensing and point cloud processing, 3D data-based approaches have been increasingly applied to bridge inspection. This paper presents a 3D reconstruction pipeline for concrete box-girder interiors that generates CAD models directly from scan data. Point cloud data of girder interiors acquired by a quadruped robot equipped with a LiDAR sensor are preprocessed and then semantically segmented into interior components using a deep learning model. Segmented point cloud data is subsequently converted into a 3D CAD model through a sliced patch-based reconstruction algorithm. The proposed method was validated on real concrete box-girder interior data. Point cloud segmentation achieved a mIoU of 94.1%. The geometric accuracy of the generated CAD models was evaluated using mesh-to-point cloud distance, yielding mean distances of 0.025 m against point cloud data. These results demonstrate that the proposed pipeline can effectively construct as-built 3D models of concrete box-girder interiors, supporting efficient data-driven inspection.

1 Introduction

Bridge inspection is essential for ensuring structural performance throughout the entire service life. In particular, the internal inspection of bridges constructed using the Precast Segmental Method (PSM) has become an issue of growing concern. In 2016, corrosion and rupture of tendons were observed inside the concrete box-girder of Jeongneungcheon Overpass [1], and in 2020, tendon corrosion was identified at Cheongdam 1st Bridge [2]. Such cases of inadequate internal inspection have shown the critical importance of interior inspection for concrete box-girders.

Recent advances in 3D sensing technologies and point cloud processing have highlighted the potential of Scan-to-BIM and digital twin approaches for improving bridge inspection [3]. Jing et al. [4] proposed a method for semantic segmentation of masonry bridge components using a segmentation model trained solely on synthetic data, followed by instance segmentation using the DBSCAN algorithm. Kim et al. [5] applied SuperPoint Transformer to segment bridge point cloud data acquired by UAV-mounted LiDAR, training the model on both synthetic and real data. Yang et al. [6] presented a Scan-to-BIM framework for highway bridges, in which a deep-learning segmentation model trained on both synthetic and real datasets segments LiDAR-acquired point clouds into individual components, and the resulting segmented point clouds are then projected to extract component outlines that are subsequently parameterized and instantiated as BIM elements. Shu et al. [7] proposed an automated method to generate geometric digital twins of box-girder bridges, using a model trained on synthetic and TLS point clouds for component segmentation and cross-section key point extraction, and aligning internal structures generated from design drawings to the global coordinate system. Zhu et al. [8] proposed a method for cable-supported bridges with girders that uses TLS to scan the girder interior and processes interior and exterior point clouds to estimate the girder volume, including the internal void geometry.

Existing research have primarily focused on reconstructing external geometry or have relied on design drawings to model internal structures. Despite the importance of concrete box-girders, research on 3D data-driven inspection of box-girder interiors remains limited.

This highlights the need for methodologies to construct as-built 3D models specifically for concrete box-girder interiors.

This paper proposes a 3D reconstruction pipeline for concrete box-girder interiors based on point cloud semantic segmentation and a sliced patch-based 3D reconstruction algorithm. The proposed pipeline semantically segments structural components from interior scan data and reconstructs them into 3D models. Figure 1 illustrates an overview of the proposed pipeline. First, interior point cloud data are obtained from raw scans acquired by a LiDAR sensor mounted on a quadruped robot. Second, wall surfaces are extracted and reconstructed as parametric models to define the interior geometry. Third, the remaining interior components are semantically segmented using a deep learning-based segmentation model. Fourth, 3D CAD models of the segmented components are generated through a sliced patch-based algorithm.

2 Methodology

2.1 Point Cloud Data Acquisition and Preprocessing

As shown in Figure 1(a), interior data were acquired using a quadruped robot (Unitree Go2) equipped with a LiDAR sensor (Livox Avia) and a mini computer (Intel NUC). The acquired data were registered into a global map using FAST-LIO2 [9], and a loop-closure module was additionally integrated to correct accumulated drift and improve global consistency [10]. First, roll and pitch correction and axis alignment are performed to align the coordinate system such that the longitudinal direction of the girder is parallel to the X-axis. Then, the diaphragms at both ends of the girder were manually removed.

2.2 Wall Extraction and 3D CAD Model Generation

To extract wall surfaces from the preprocessed point cloud, this paper developed an alpha shape-based wall extraction algorithm. Figure 2(a) illustrates the stages of the proposed algorithm. First, the point cloud is projected

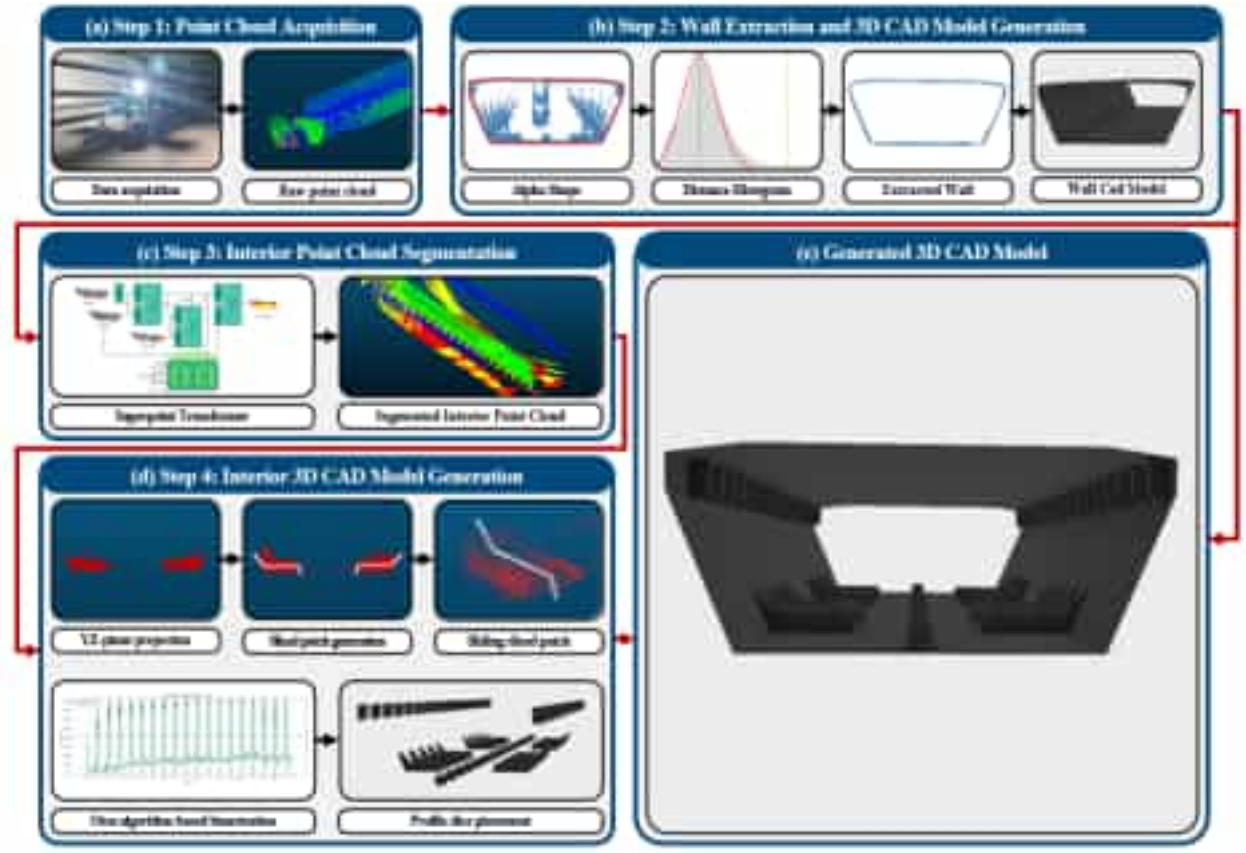

Figure 1. Overview of the proposed framework; (a) acquisition of box-girder interior point cloud data using a quadruped robot, (b) wall extraction and 3D CAD model generation, (c) point cloud segmentation using SuperPoint Transformer, (d) 3D CAD model generation of segmented components, (e) generated 3D CAD model.

onto the YZ plane, and the alpha shape algorithm is applied to estimate the outer contour of the girder cross-section. Statistical Outlier Removal (SOR) is applied prior to prevent errors caused by outliers. Second, the minimum Euclidean distance from each point in the full point cloud to the contour is computed. Third, the distribution of wall point distances is modeled as a Gaussian distribution. The peak of the distance distribution is defined as the mean μ. Since the portion of the histogram beyond the peak contains interior points, the Gaussian distribution is fitted only to the portion up to the peak. A threshold is then set at $\mu + n\sigma$ to separate wall points from interior points. In this study, a threshold of $\mu + 6\sigma$ was used, corresponding to a 99.99% inclusion probability. Finally, points within this threshold are classified as wall points, while the remaining points are classified as interior points. Figure 2(b) illustrates the generation of a 3D CAD model based on the extracted wall points. RANSAC-based line feature extraction [11] is first applied to the contour to extract parametric line segments representing the wall surfaces. The extracted line segments are then inwardly offset to μ to align them with the actual wall surface location. Finally, the cross-section is extruded along the longitudinal axis by the length of the girder to produce a parametric 3D model of the wall surfaces.

2.3 Point Cloud Segmentation

The preprocessed point cloud data is semantically segmented using SuperPoint Transformer, a deep learning-based 3D segmentation model [12]. SuperPoint Transformer (SPT) processes large-scale point clouds by first computing a multi-scale hierarchical partition of the scene into geometrically homogeneous superpoints. At each partition level, adjacent superpoints are connected to form a superpoint graph. The network then performs sparse self-attention on these graphs to propagate information at each scale, enabling large receptive fields and context aggregation while predicting semantic labels at the finest superpoint level. The interior components of the concrete box-girder are classified into five categories: deviator block, tendon, top temporary Post Tensioning (PT) bar anchor block, bottom temporary PT bar anchor block, and cable tray. A deviator block is a concrete block installed to redirect the alignment of external tendons, with embedded ducts through which tendons pass. The top and bottom temporary PT bar anchor blocks are used to apply compressive stress when joining segments during construction and are located at the top and bottom of the girder, respectively [13]. A tendon is a steel strand, and a cable tray is a metal structure that accommodates electrical and communication cables.

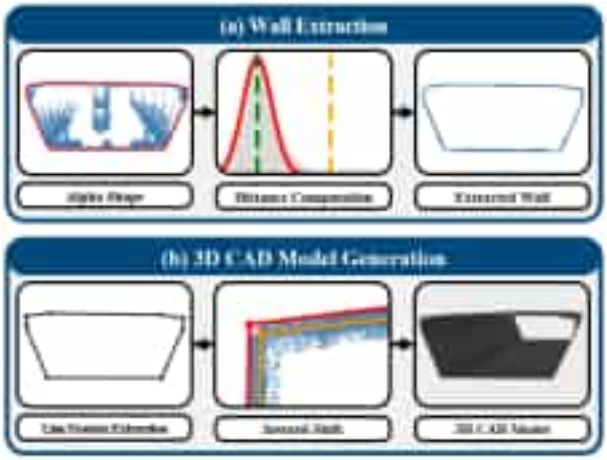

Figure 2. Extraction of the wall point cloud and 3D CAD model generation; (a) wall extraction, and (b) 3D CAD model generation.

2.4 Interior 3D CAD Model Generation

Among the five segmented classes, the deviator block, top temporary PT bar anchor block, and bottom temporary PT bar anchor block were converted into CAD models.

For 3D model generation, this paper developed a sliced patch-based 3D reconstruction algorithm. This algorithm is based on the patch-based component matching algorithm proposed by Kim et al. [14]. In their approach, a 3D patch similar in size and shape to each

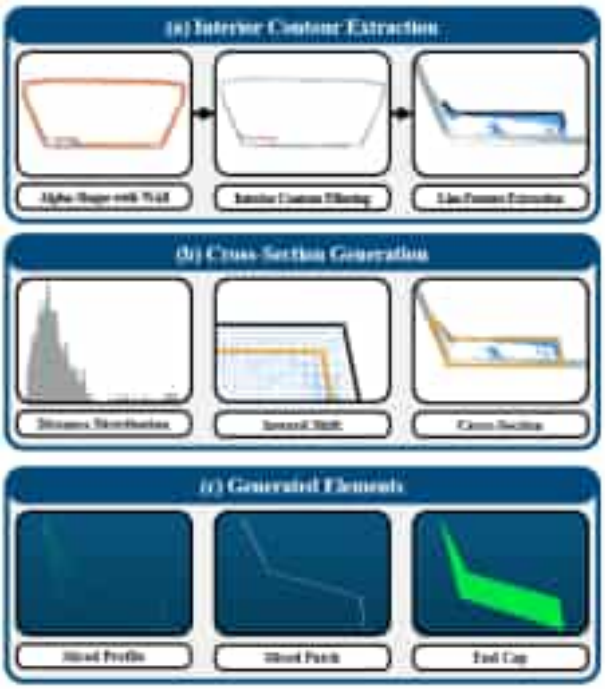

Figure 3. Generation of the three elements used in this study; (a) extraction of the interior contour, (b) cross-section generation, and (c) generated elements.

component is generated and traverses across the target region within the point cloud data. If the distance between points in the patch and the target point cloud data falls below a predefined threshold, the presence of the component is confirmed. This algorithm was originally proposed for detecting standardized components within scaffolding structures. In this paper, the algorithm was modified to a sliced patch-based approach.

Figure 3 illustrates the generation of patch elements used in the proposed algorithm, consisting of interior contour extraction, cross-section generation, and element generation. In Figure 3(a), the segmented point cloud of each component is projected onto the YZ plane and individual instances are separated using DBSCAN-based clustering. The wall point cloud is also projected, and the alpha shape algorithm is applied to the combined point cloud of the component and wall to extract the outer contour. Boundary edges for which either endpoint belongs to the wall point cloud are then removed, retaining only the edges corresponding to the interior surfaces. RANSAC-based line feature extraction [11] is applied to the remaining edges to extract parametric line segments Figure 3(b) shows the cross-section generation step, in which the distances from all points to the extracted contour are computed, and the line segments are inwardly offset to μ to align them with the actual surface location. The outermost line segments are then extended to the wall polygon to form a closed polygonal cross-section. Figure 3(c) shows the three elements generated from the refined cross-section: the sliced profile, created by extruding the contour with a thickness of 1 cm in the X-axis direction; the sliced patch, generated by sampling 4,000 points from the interior surface; and the end cap, generated by filling the interior of the contour with a mesh.

Figure 4 illustrates the procedure for generating 3D CAD models of components using the proposed algorithm. As shown in Figure 4(a), the segmented point cloud data of each class is projected onto the YZ plane along with its corresponding sliced patch to obtain a 2D point cloud data. For components arranged in two rows, such as the deviator block and top temporary PT bar anchor block, the left and right sides are separated using DBSCAN-based clustering (Figure 4(b)). Figures 4(c), (d), and (e) show the generated sliced patch for each component. The sliced patch is slid along the X-axis in increments of 1 cm, corresponding to the thickness of the sliced profile (Figure 4(f)). The sliding range is defined as the X-axis extent of the clustered segment with a 1 m padding on each side. At each position, the number of points $C(\tau)$ within a threshold distance τ between the sliced patch and the segmented point cloud data is calculated. $C(\tau)$ is defined by the following function:

$$C(\tau) = \sum_{i=1}^{N} 1[d(a_i, B) \leq \tau] \quad (1)$$

Where N is the number of points in the sliced patch, a_i is the i-th point in the sliced patch, B is the segmented point cloud, $d(a_i, B)$ is the distance from a_i to the nearest point in B, and $1[\cdot]$ is an indicator function that returns 1

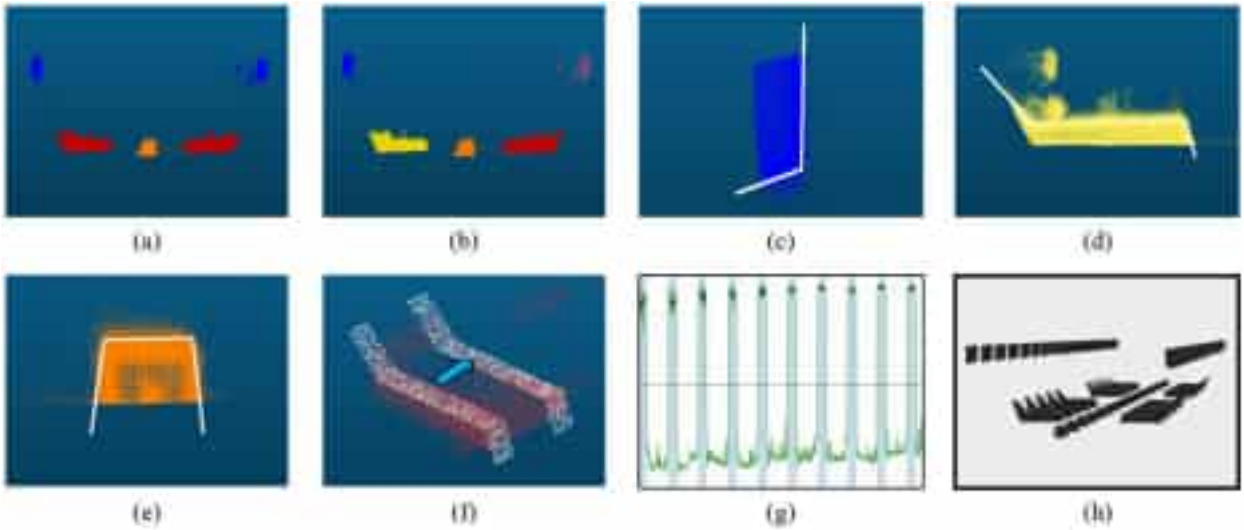

Figure 4. Sliced patch-based 3D reconstruction algorithm; (a) projection of the segmented point cloud onto the YZ plane, (b) left–right separation of the deviator block and top temporary PT bar anchor block using DBSCAN clustering, (c) generated sliced patch of the left top temporary PT bar anchor block, (d) generated sliced patch of the right deviator block, (e) generated sliced patch of the bottom temporary PT bar anchor block, (f) sliding of the sliced patch along the longitudinal direction, (g) binarization of the position– $C(\tau)$ graph using Otsu's algorithm, and (h) 3D reconstruction of individual components.

if the condition is satisfied and 0 otherwise. In this paper, τ was set to 4 cm.

This yields a position– $C(\tau)$ graph along the X-axis. As shown in Figure 4(g), the graph exhibits high point counts when the sliced patch passes through regions where actual components are present. To separate regions where components are present from those where they are absent, the graph is binarized using Otsu's algorithm. Sliced profiles are placed at positions along the sliding axis identified as containing components. Since components composed only of sliced profiles form an open shape at both ends, end caps are added to complete a closed solid geometry. Figure 4(h) shows the 3D reconstruction results of individual components. This algorithm is applied to the deviator block, top temporary PT bar anchor block, and bottom temporary PT bar anchor block. The final combined model is saved as a 3D CAD file.

3 Experiments and Results

3.1 Datasets

To validate the proposed method, interior point cloud data were acquired from three concrete box-girders. A total of 10 interior sections were scanned: 8 from Girders A and B, which contain 18 deviator blocks each, and 2 from Girder C, which contains 20 deviator blocks. In Girder A, deviator blocks are distributed with 10 on the east side and 8 on the west side relative to the cross-sectional center, while Girder B has the opposite distribution with 8 on the east and 10 on the west. Girder C has 10 deviator blocks on each side, totaling 20.

The acquired point cloud data underwent reprocessing. For each dataset, roll and pitch correction was performed, the longitudinal direction of the girder was aligned parallel to the X-axis, and wall points were removed. For datasets with complete boundary contours, wall removal was performed using the proposed wall extraction algorithm — specifically, two datasets from Girder A and one from Girder C. For the remaining datasets, wall removal was performed manually. All other preprocessing steps were performed manually.

For training SuperPoint Transformer, the 10 datasets were split into training, validation, and test sets. The training set consists of 6 datasets: 5 from Girder A and 1 from Girder B. The validation set includes 1 dataset from Girder A and 1 from Girder B. The test set consists of 2 datasets from Girder C, which has a different geometry, to evaluate generalization performance on girders with a different number of deviator blocks. Each point cloud data was manually labeled with the five classes.

Model training was conducted on a workstation running Ubuntu 20.04, equipped with an NVIDIA GeForce RTX 3090 GPU and an Intel Xeon Gold 6240M CPU. The parameters for SuperPoint Transformer were set as follows: voxel size of 1.5 cm, tiling of 2, and batch size of 2. Regularization strength values were set to (0.1, 0.2, 0.3). The maximum number of training epochs was set to 600.

3.2 Experimental Results

3.2.1 3D Semantic Segmentation Results

Table 1 presents the 3D semantic segmentation results. The evaluation metrics used are Intersection over Union (IoU), precision, recall, and F1 score, defined as follows. Here, TP, FP, and FN denote the number of true positive, false positive, and false negative points, respectively.

$$IoU = TP/(TP + FP + FN) \quad (2)$$

$$Precision = TP/(TP + FP) \quad (3)$$

$$Recall = TP/(TP + FN) \quad (4)$$

$$F1\ score = \frac{2(Precision \cdot Recall)}{Precision + Recall} \quad (5)$$

The segmentation achieved a mean IoU (mIoU) of 94.1% and a mean F1 score of 96.9%. Figure 5 shows the segmented test data.

Table 1. Segmentation performance for concrete box-girder interior point cloud data.

Class	IoU	Precision	Recall	F1 score
Deviator block	82.5%	84.2%	97.6%	90.4%
Tendon	97.9%	99.8%	98.1%	98.9%
Top temporary PT bar anchor block	92.7%	92.7%	100.0%	96.2%
Bottom temporary PT bar anchor block	98.5%	99.2%	99.3%	99.2%
Cable tray	98.9%	99.0%	99.9%	99.5%
Average	94.1%	95.0%	99.0%	96.9%

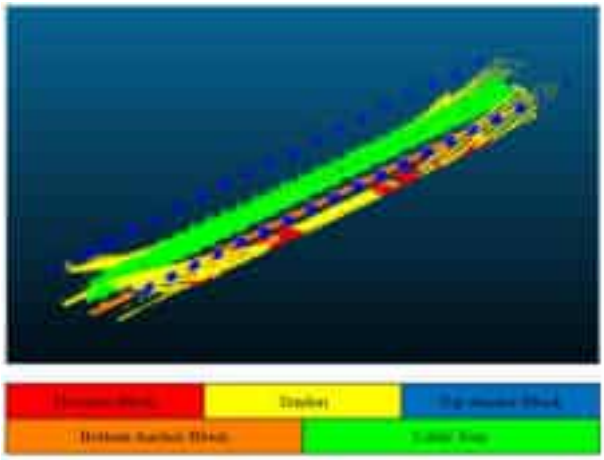

Figure 5. Segmentation result.

3.2.2 3D CAD Model Generation Result

Sliced profiles, sliced patches, and end caps for each component were generated from the segmented point cloud and applied to the 3D reconstruction. Table 2 presents the mean mesh-to-point cloud distance. For each point in the segmented point cloud, the distance to the nearest polygon of the generated mesh was calculated. The proposed method achieved mean distances of 0.025 m against the point cloud data. Figure 6 shows the 3D CAD model generation results.

Table 2. Mean mesh-to-point distance results for the generated 3D CAD models compared with the point cloud.

Class	Mesh-to-point cloud distance
Wall	0.007 m
Deviator block	0.002 m
Top temporary PT bar anchor block	0.080 m
Bottom temporary PT bar anchor block	0.010 m
Average	0.025 m

Figure 6. Generated 3D CAD model of the concrete box-girder interior.

4 Discussion

4.1 Point Cloud Segmentation

The point cloud segmentation results showed that the Top temporary PT bar anchor block, Bottom temporary PT bar anchor block, and Cable tray achieved high IoU values of 92.7%, 98.5%, and 98.9%, respectively.

These classes have minimal physical connections with other components in the concrete box-girder interior point cloud after wall removal, resulting in clear boundaries between classes. This is considered to have contributed to stable segmentation performance. Furthermore, the model demonstrated high performance on test data with a different deviator block arrangement compared to the training data, indicating potential for generalization.

In contrast, the deviator block showed relatively lower IoU values of 82.5%. As shown in Figure 7(a), tendons in contact with deviator blocks were found to be misclassified as deviator blocks. Since tendons structurally pass through deviator blocks and are physically in contact with them, tendon points were misclassified as deviator blocks. Additionally, Figure 7(b) shows cases where tendons were misclassified as cable tray. This is attributed to the tendons extending upward and approaching the locations where the cable tray is present.

4.2 3D CAD model generation

The proposed sliced patch-based 3D reconstruction algorithm achieved mean mesh-to-point cloud distances of 0.025 m against the point cloud and successfully generated 3D CAD models by separating components at the instance level from semantically segmented point cloud data. Notably, the proposed method reconstructed 3D CAD models using only the point cloud data.

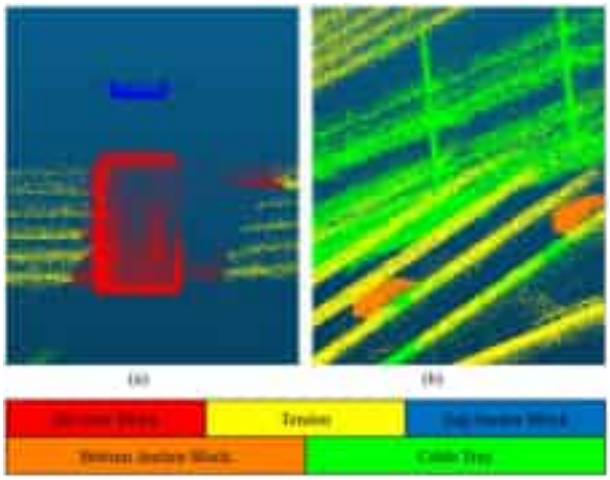

Figure 7. Examples of misclassification in point cloud segmentation results; (a) tendon misclassified as a deviator block, and (b) tendons misclassified as a cable tray.

However, cases were observed where the generated 3D CAD models differed from the actual geometry. Figure 8(a) shows a case where multiple 3D CAD models were generated for a single component. This occurred due to variability in the position– $C(\tau)$ graph constructed from nearest-neighbor relationships between the patch and point cloud, causing the Otsu-based binarization to segment a single continuous component into multiple fragments. Figure 8(c) shows a case where a 3D CAD model was generated for only a partial region of a component rather than the entire geometry. This is attributed to sparse points on all surfaces of the segment during scanning, resulting in missing points in certain regions.

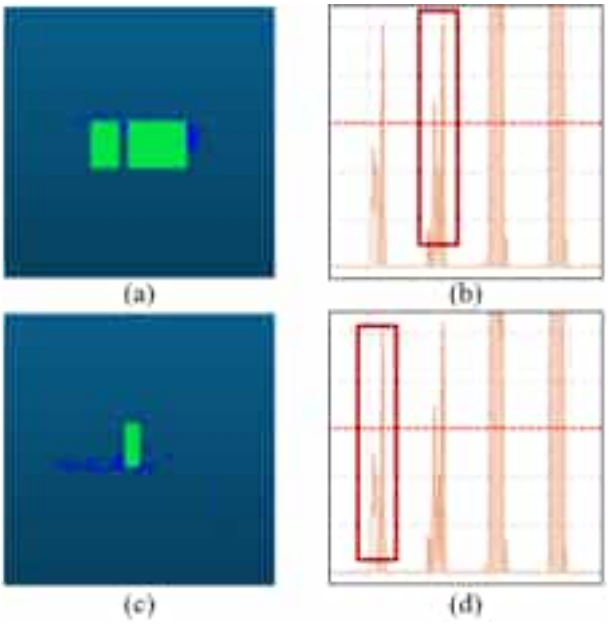

Figure 8. Examples of incorrect 3D reconstruction; (a) a top anchor block fragmented into two parts, (b) a segment split by Otsu algorithm-based binarization (highlighted by the red box), (c) a model generated only on the right-side surface, and (d) an excessively thin segment remaining after Otsu algorithm-based binarization (highlighted by the red box).

4.3 Future Development

This paper presented a procedure for segmenting concrete box-girder interior point cloud data using SuperPoint Transformer and reconstructing 3D CAD models from the segmented results. The proposed framework was applied to actual bridge girder data, demonstrating its potential applicability to concrete box-girder inspection by performing semantic segmentation and 3D reconstruction on girder data with different interior environments. However, several aspects require further improvement.

First, the proposed framework does not include a 3D reconstruction methodology for tendons. Considering the significance of a tendon in a concrete box-girder, it is necessary to develop a parametrization method for tendons and integrate it into the proposed framework.

Second, the validation of the proposed methodology was limited to data acquired from a single bridge. Therefore, it is necessary to verify the generalization performance on bridges with different internal structures. Additional concrete box-girder interior data from multiple bridges with varying interior geometries, component configurations, and scan qualities should be acquired, and performance should be validated by applying the same pipeline to enhance practical applicability.

Third, several steps in the proposed pipeline were performed manually. Roll and pitch correction and axis alignment, and diaphragm removal were conducted manually, and the parameters for SOR-based noise removal, the alpha shape algorithm, and RANSAC based line extraction were heuristically determined. Automating these procedures is necessary.

Fourth, the proposed sliced patch-based algorithm is applicable only to components that are linear and have a constant cross-sectional profile along their length. For components with varying cross-sections or curved geometries, alternative reconstruction approaches would be required.

5 Conclusion

This paper presents a framework for semantic segmentation of point cloud data acquired from the interior of a concrete box-girder and 3D CAD model reconstruction of individual components. The proposed methodology was validated on actual concrete box-girder data, achieving a semantic segmentation performance of 94.1% mIoU. The mean mesh-to-point cloud distance was 0.025 m against the point cloud data, demonstrating the feasibility of the proposed approach. By addressing the identified limitations and refining the methodology in future work, this paper is expected to contribute to the establishment of 3D data-driven inspection systems for interiors of a concrete box-girder.

Abstract -

Simulation-based optimization (SBO) for energy-efficient building design exemplifies a typical design-change process that remains disconnected from open BIM-enabled collaboration. The gap stems from IFC’s limited capacity to represent the information generated by SBO. To overcome the limitations, this study proposes a novel IFC schema extension for LLM Agent-enhanced SBO, named *IfcSboExtension*, that enriches incremental IFC updates with contextual metadata capturing not only what changed, but also why the change occurred and how it was derived. The proposed extension model enables exchangeable and traceable SBO iterations by embedding decision rationale and methodological provenance directly into incremental IFC updates. The feasibility and value of the extension are demonstrated through a case study on building energy efficiency optimization, in which an LLM agent enhances the interpretability of design changes.

Keywords –

Building information modelling (BIM), Industry Foundation Classes (IFC), Incremental IFC updates, Simulation-based optimization (SBO), Large language model (LLM)

1 Introduction

Building information modelling (BIM) is recognized as a digital integration of information throughout a building lifecycle, and increasingly mandated in the AEC (Architecture, Engineering, and Construction) industry [1]. BIM-based collaboration has progressively grown to level 2, namely “open BIM”, which signifies a fully integrated, collaborative environment for project stakeholders through federated discipline models and open exchange standards [2]. Industry foundation classes (IFC), and ISO 16739-1:2018 standard, are *per se* open BIM that provides a vendor-neutral data format for seamless data exchange between various BIM applications [3].

However, the scalability and adoption of IFC are constrained by the monolithic, file-based exchange paradigm. In practice, BIM stakeholders receive the modified model as a new monolithic file from collaborators and check manually to identify the potential impact on their own disciplines, which is intensive in labor and prone to errors.

IFC 5, the upcoming modular version, plans to implement incremental IFC updates to address these issues [4]. From a theoretical perspective, the transition toward incremental IFC updates aligns with the process-centric knowledge philosophy [5], which emphasizes that construction knowledge is dynamic, iterative, and context-sensitive regarding knowledge dissemination among project partners. Consequently, the modular architecture of IFC 5 is expected to better support both operational efficiency and effective knowledge management in construction projects.

Simulation-based optimization (SBO) is a typical design-change process in which design parameters are iteratively adjusted, leading to modifications to model design. Recent studies have leveraged large language models (LLM) to promote the interpretability of traditional black-box SBO workflows [6]. However, the information generated by the LLM-enhanced SBO remains neither exchangeable nor traceable within the context of sustainable, collaborative design based on open BIM. To address the gap between LLM-enhanced SBO and open BIM, this paper proposes an IFC extension for LLM-enhanced SBO, which explicitly answers ‘why’ and ‘how’ in addition to ‘what’ to enrich such incremental IFC updates.

The remainder of this paper is organized as follows: Section 2 reviews the state-of-the-art research on incremental IFC updates and simulation-based optimization. Section 3 introduces the proposed IFC schema extension for incremental update. Section 4 demonstrates the implementation of the extension

through a case study employing large language model (LLM) agents for building energy efficiency optimization. Section 5 provides the conclusion.

The primary contributions of this study are twofold. First, the proposed IFC schema extension emphasizes that the 'why' and 'how' dimensions are essential to the 'what' of incremental IFC updates. Second, the feasibility of the proposed extension was validated through a real-world project.

2 Literature Review

2.1 IFC and schemas for changes

IFC was originally conceived as a monolithic, object-oriented schema based on the EXPRESS data modelling language [7]. As an object-oriented data schema, the IFC schema contains several classes, namely "entities", and serves as "templates" to describe building information. The semantic meaning and the implementation of entities are generalized through inheritance mechanisms. Each entity declares a set of local attributes, in addition to the global attributes inherited from its supertype. There are two types of IFC entities, namely rooted and non-rooted entities, which contain or do not contain a globally unique identifier (GUID). In practice, the instantiated IFC entities are transformed into ASCII text rows in the text-based IFC-SPF (STEP Physical File) formatted file [8]. An IFC-SPF file is exchanged in a snapshot-based exchange paradigm, which means each IFC-SPF file represents a complete state of a model at a given time, regardless of actual changes. This exchange paradigm leads to inefficiencies in data transmission, version control, and change impact analysis for decision making in the collaborative, multi-disciplinary environment [9].

To overcome the limitations of holistic IFC file exchange, recent research and standardization efforts have shifted toward change-based IFC exchange approaches. In the literature, three categories of difference (or delta) computation methods have been developed to capture changes between two IFC models, which are (1) GUID-based; (2) flattening-based; and (3) graph-based approaches.

The GUID-based approach recognizes two IFC instances as identical if they share the same GUID, which is widely adopted by commercial BIM platforms such as Autodesk Revit, Navisworks and Graphisoft ArchiCAD. However, a significant limitation of this approach is that GUIDs may not remain consistent across different BIM authoring tools, rendering GUID-based comparison unreliable. The flattening-based approach eliminates randomly referenced identifier numbers (i.e., the "#"-IDs) in IFC files. The "flattening" process is to replace all the "#"-IDs with specific instant IDs, such as content-based hash ID [10][11]. Therefore, flattening-based approaches enable deterministic textual comparison.

Both the GUID-based and flattening-based methods are fundamentally text-oriented. In contrast, the graph-based approach leverages graph-based algorithms to compute semantic differences between two graph-represented IFC models. There are two main steps involved in the graph-based approach. First, the graph representation of IFC models is developed, such as RDF (resource description framework) graph and directed property graphs. Then, graph-based algorithms, such as graph transformation [12], are implemented to capture the changed part of two IFC models.

2.2 Knowledge engineering applications of changes in construction

The dynamic theory of knowledge creation developed by Nonaka and Takeuchi [13], namely the SECI model, posits that knowledge is created, transferred, and applied through the creative tension between tacit and explicit know-how. The SECI model reveals a significant source of knowledge, that knowledge is generated from continuously combined, refined, and reconfigured explicit assets. This definition aligns with the iterative development processes of construction projects [1]. Accordingly, changes in a construction project, such as design iterations, site conditions, and stakeholder feedback, are recognized as a knowledge source which has great influence on successful project delivery [14].

Knowledge engineering (KE) is the process of designing, building, and maintaining knowledge-based systems by identifying relevant domain knowledge, representing it in formal structures (such as ontologies, or knowledge graphs), and implementing reasoning mechanisms that can use the knowledge to make inferences, decisions, or recommendations [15]. A core KE approach is the development of domain ontologies that explicitly define change types, actors, causes, and impacts. Early work by Beetz et al. [16] transforms the EXPRESS schema of IFC into an OWL ontology, namely IfcOWL, and paves the way to change detection as ontology alignment. The following work of Oraskari and Törmä [17] introduces a signature algorithm for RDF diff computation. Furthermore, a domain ontology for pumped storage hydropower system was developed by Zhang et al. [18] to support design changes management.

IFC also can be serialized into various data structures, such as ifcJSON and labelled property graph, to support algorithmic reasoning for change detection. For example, A semantic differential transaction (SDT) approach and the following traceable SDT approach were developed based on the JSON-format IFC to capture the semantic changes through structure matching [10][11].

2.3 Simulation-based optimization as a typical change

Simulation-based optimization (SBO) is widely applied to building design by iteratively tuning design parameters towards sustainable objectives [19]. The generic SBO workflow comprises iterative simulations that are evaluated through objective functions defined in optimization algorithms. SBO constitutes a typical design-change process in which the design parameters vary across iterations, producing corresponding modifications in design. For example, energy performance optimization is a key task in SBO for early stage building design, aiming to reduce the environmental impact of future buildings. SBO involves tuning design parameters such as window-to-wall ratio and building materials. In each iteration, these parameters are adjusted to gradually improve energy performance.

Traditional SBO is challenged by high computational complexity and low interpretability. A recent study by Zhou and Xue [19] introduces an Automatic Information Gain-guided Convergence (AIGGC) method to refine critical design parameters through interpretable information gain analysis. Subsequent research integrated the large language model (LLM) to further enhance the interpretability and efficiency of complex SBO [6].

However, the information produced by LLM-Agent enhanced SBO is neither exchangeable nor traceable within the context of sustainable, collaborative design based on open BIM. Existing literature characterizes BIM-supported SBO as a one-way workflow that portions of the required parameter data are extracted from BIM [20], yet the SBO iteration results are not embedded back into BIM for collaborative use. The limitation arises for two reasons. First, contemporary SBO practices are predominantly implemented on visual programming platforms such as Grasshopper, which do not natively support IFC. Secondly, the IFC schema lacks the capacity to represent the information generated by LLM-Agent enhanced SBO, such as design parameters, constraints, and convergence analysis. The proposed IfcSboExtension uniquely encode the decision rationale, optimization provenance, and LLM interaction context to support change-based IFC exchange for traceable and interpretable collaborative design.

3 IFC extension for LLM agent-enhanced SBO

To extend IFC's capability of representing information of LLM Agent-enhanced SBO, an IFC extension model named '*IfcSboExtension*' was proposed. The extended schema illustrates 'what' data should be involved, 'why' the IFC schema should be extended, and 'how' to capture the incremental IFC changes within the LLM Agent-enhanced SBO. A general IFC extension workflow is illustrated in Figure 1, which constitutes three steps: (1) Information requirements in LLM Agent-enhanced SBO, (2) *IfcSboExtension* model development, and (3) verification and implementation for incremental IFC updates.

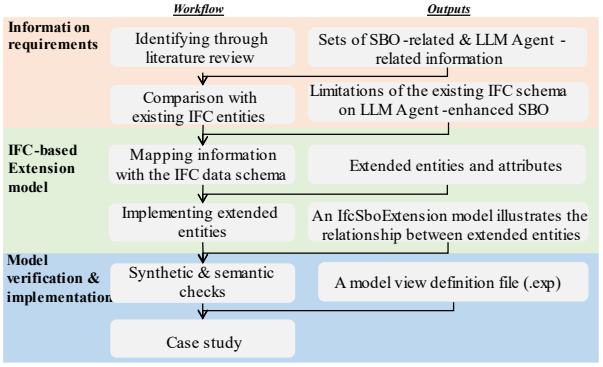

Figure 1. IFC extension workflow

The first step answers 'what' and 'why' the IFC schema should be extended to LLM Agent-enhanced SBO. Table 1lists the crucial data of two categories: (1) SBO-related data such as design parameters and optimization constraints, as well as (2) LLM Agent-related data such as prompts and structured responses.

A meticulous comparison with the existing entities within IFC4 ADD3 revealed that both SBO-related and LLM Agent-related information required extension to enable seamless data exchange. For example, *IfcProcess* is defined in existing IFC schema to represent one individual activity that has sequence relationships with other processes. Three subtypes of *IfcProcess*, namely *IfcTask*, *IfcEvent*, and *IfcProcedure* do not contain the semantics such as parameters, constraints, and objective functions. One compromise approach supported by IFC schema is identifying specific property sets, such as *Pset_SBO*. However, this approach converts SBO semantics to unstructured strings and leads to semantic ambiguity and semantic loss.

3.1 The *IfcSboExtension* model

According to the required data listed in Table 1, three rooted entities and two non-rooted entities were extended align with the IFC4 ADD3 schema. As Figure 2 shows, the extended entity *IfcSboWorkflow* and *IfcAiAgentInteraction* are two subtypes of the abstract *IfcControl*, and *IfcOptimizationIteration* is a subtype of the abstract *IfcProcess*. The reason lies in the semantic definition of *IfcControl* and *IfcProcess*. In IFC4 ADD3, *IfcControl* represents all concepts that control or constrain the utilization of products, processes, or

resource, whereas *IfcProcess* is defined as one individual activity or event. According to the definition, *IfcControl* and its subtypes are suitable for representing a workflow, whereas *IfcProcess* and its subtype focus on one specific process. In LLM Agent-enhanced SBO, SBO is a workflow that contains a set of 'simulation-optimization' iterations, and the interaction between stakeholders and LLM Agent is also recognized as a set of communications rather than single process. One optimization iteration aligns with the definition of *IfcProcess* which transforms input in output. *IfcObjectiveFunction* and *IfcSboOptimizationDirection-Enum* are two non-rooted entities extended at the resource layer. These two non-rooted entities cannot exist independently but can only exist if referenced by the rooted entity *IfcSboWorkflow*. Due to page limits, only the extended *IfcSboWorkflow* entity and relevant attributes is present in Figure 3, which illustrates the EXPRESS representation of *IfcSboWorkflow* to ensure both machine and human readability.

Table 1. Crucial data in LLM Agent-enhanced SBO

	Crucial Data	Data type (in IFC)	Example
SBO-related	SBO parameters	SET [1: *n*] of REAL	(0.45,0.45,1.1,2,5.0733)
	SBO constraints	STRING	$\left\|FAR_{ori} - FAR_{opt}\right\| \leq 0.05$ (FAR for floor area ratio)
	SBO objectives	STRING	EUI = 112.684 $kWh/m^2 \cdot yr$
	SBO results	STRING or BINARY	JSON or CSV

3.2 Model verification

For verification, the official IFC documentation toolkit *IfcDoc* and a test software platform APSTEX were employed. The verification procedure involves two steps: syntactic verification and semantic verification. As summarized in Table 2, syntactic verification ensures compliance with the formal grammar of the EXPRESS language. The extended IFC entities were documented using *IfcDoc* to verify their compliance with EXPRESS language grammar. The exported use-case model view definition, designated as *IfcSboExtension*, incorporates 19 existing IFC entities and 5 newly defined IFC entities.

In the second stage, semantic verification was performed by compiling the extended *IfcSboExtension* model into Java classes using the Apstex IFC Framework. Additionally, accessor methods of explicit, derived, and inverse attributes of the extended IFC entities are developed. Critically, domain rule enforcement methods were developed, and corresponding unit tests were designed to verify the *IfcSboExtension* model based on the created Java classes.

```

Figure 4. Examples of domain rule checking method and unit test for "HasObjectives" of the IfcSboWorkflow entity

Figure 4 presents an example of a domain rule checking method and its associated unit test. For efficient compilation, so-called “lambda expressions” were used to implement the domain rule checks. The example ‘whereRuleCheck’ is defined to check the applicable objectives of the extended entity *IfcSboWorkflow*. Corresponding unit test is shown in Figure 4(b). “HasObjectives” of the *IfcSboWorkflow* entity is shown in Figure 3, which represents a set of *IfcObjectiveFunction* instances are assigned to one *IfcSboWorkflow* instance. In the unit test, the process of adding a module group to *IfcSboWorkflow* results in a ‘False’, which indicates an incorrect state of the IFC test model.

4 A case study of LLM agent-enhanced SBO

To illustrate ‘why’ and ‘how’ in addition to ‘what’ of IFC incremental updates, an energy consumption optimization scenario is selected as a representative design-change case study. The design optimization of a modular integrated construction (MiC) project for a university student hostel located in Hong Kong is selected as a case. The developed LLM Agent for efficient and interpretable SBO is presented in the published work of Zhou and Xue (2025).

4.1 Case settings

In this case, the optimization objective was to minimize the energy use intensity (EUI), defined as the total annual energy consumption divided by the gross floor area ($kWh/m^2 \cdot yr$). As shown in Figure 5, the project features a symmetrical layout with fixed modules and movable modules. The optimization process focuses on three types of movable modules which vary in length, namely M_A, M_B, and M_C. Thus, module layout, window size and material properties are involved as design parameters shown in Table 3.

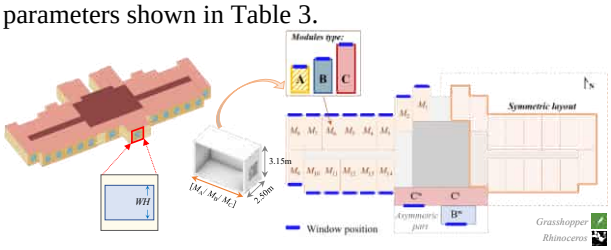

Figure 5. MiC case layout and schematic of module types (adopted from Zhou & Xue (2025))

4.2 Results

4.2.1 Schemas and sample changes

The implementation of the *IfcSboExtension* model using *IfcDoc* is presented in Figure 6 as an EXPRESS-G

diagram. Black rectangles represent rooted entities, whereas grey rectangles denote non-rooted entities. Entity's attributes – comprising own and inherited attributes - are separated by an ellipsis and categorized as either explicit or derived attributes (in black font) or inverse attributes (in light grey font). Relationships between the extended entities are connected through inverse attributes. For example, an *IfcOptimization-Iteration* is referenced by an *IfcSboWorkflow* through its inverse attributes '*HasIterations'*.

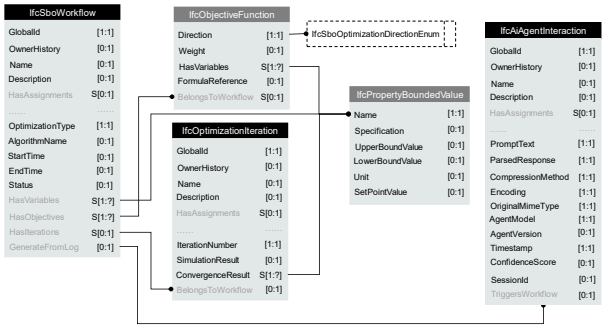

Figure 6. EXPRESS-G representation of *IfcSboExtension* model

The embedded LLM Agent-enhanced SBO semantics is illustrated in Figure 7. *IfcSboWorkflow* is assigned to a module through *IfcRelAssignsToGroup*, and *IfcAiAgentInteraction* is assigned to *IfcSboWorkflow* through *IfcRelAssignsToControl*. To illustrate the change of parameters during SBO iterations, parameters listed in Table 3 are selected. For instance, when an iteration increases the north window area from 4.33 m² to 4.49 m², embedded convergence semantics allow the owner to immediately identify this change as the primary driver for reducing Energy Use Intensity. This transparent exposure of the 'why' (energy optimization) and 'how' (sensitivity analysis) enables the owner to grasp the technical rationale instantly, facilitating an informed approval decision.

4.2.2 Sensitivity analysis

The text-based IFC-SPF file exhibits acute sensitivity to: (1) excessive line lengths, (2) special characters such as unescaped Unicode or JSON brackets, and (3) exponential file growth. Specifically, the extended *IfcAiAgentInteraction* records prompt and structured responses, which may comprise multi-megabyte strings, that can significantly decrease data exchange efficiency.

In this study, two mitigation strategies were evaluated: (1) compressing the structured response using the Gzip algorithm and encoding the compressed result as Base64 strings; and (2) storing LLM Agent prompts and structured responses in external files referenced via *IfcURIReference*. Gzip and Base64 are open standards for data compression and encoding, respectively. Metadata describing the compression and encoding algorithms are embedded in *IfcAiAgentInteraction* to ensure self-descriptiveness. URIs for external files should conform to standard URI schemes (e.g., HTTP and HTTPS), and the corresponding MIME type should be explicitly specified.

The evaluation was performed over 30 iterations of LLM Agent-enhanced SBO, with results presented in Table 4. The result indicates that the 'Gzip + Base64' strategy increased the IFC file size by a maximum of 2.47% and an average of 1.91%. The *IfcURIReference* strategy effectively eliminates the impact of LLM Agent responses on IFC file size.

Table 3. Design parameters for MiC parametric design

Design parameters	Parameter type	Unit	Parameter domain intervals	Precision
MiC Module Type	Categorial	-	$[M_A, M_B, M_C]$	-
Window-to-Wall Ratio (WWR_N, WWR_S)	Continuous	-	$0.10 \leq WWR_N, WWR_S \leq 0.60$	0.01
Window Height (WH_N, WH_S)	Discrete	M	$1.0 \leq WH_N, WH_S \leq 2.5$	0.1
Window U-value (U_w)	Continuous	$W/(m^2 \cdot k)$	$0.50 \leq U_w \leq 5.78$	0.01
Window Solar Heat Gain Coefficient (g)	Continuous	-	$0.100 \leq g \leq 0.775$	0.001
Window Visible Transmittance (τ_v)	Continuous	-	$0.300 \leq \tau_v \leq 0.881$	0.001

4.2.3 User acceptance and comments

The extended *IfcSboExtension* model was implemented on a real MiC project for a university student hostel located in Hong Kong. Stakeholders of the MiC project gave positive comments. For example, the owner of the project claimed that "The LLM Agent platform using extended IFC has transformed our design optimization. The black box SBO is interpretable, traceable and exchangeable through open BIM. This enables non-professional stakeholders to understand the design intentions and make decisions. Technical users emphasized that "Through the adoption of open BIM, we

can work smoothly between different software and disciplines with an open standard, which helps us streamline and automate many manual processes in LLM Agent and SBO. This has greatly increased our productivity by eliminating misunderstanding of design changes that happened in the black box SBO process.

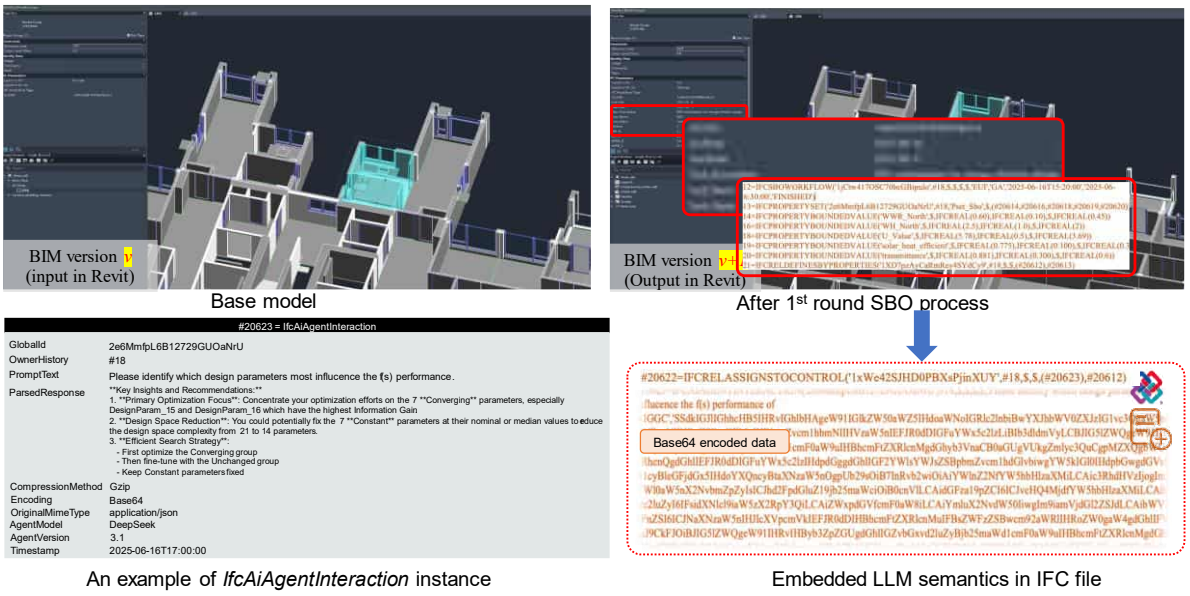

Figure 7. Embedded LLM Agent-enhanced SBO semantics in IFC

Table 4. File size comparison of two strategies

Strategy	Original	Gzip & Base64		External Ref.	
	(KB)	(KB)	Δ (%)	(KB)	Δ (%)
Minimal	1939	1946	+0.36	1940	+0.05
Maximum	1939	1987	+2.48	1941	+0.10
Average	1939	1976	+1.91	1941	+0.10

5 Discussion and Conclusion

The snapshot-based exchange paradigm of IFC introduces inefficiencies in data transmission, version control, and change impact analysis for making decisions in the collaborative, multi-disciplinary environment. To address these limitations, a modular version of IFC 5 is under development to support incremental IFC updates.

Simulation-based optimization (SBO) for energy-efficient building design exemplifies a typical design-change process which remains disconnected from open BIM-supported collaboration. The gap stems from IFC's poor capability of representing information generated by SBO. To bridge the gap and illustrate the full provenance of such design changes, including the 'why', 'how', and 'what' in incremental IFC updates, this study proposes a novel IFC schema extension for the LLM Agent-enhanced SBO.

The contributions of this study are twofold:

(1) An *IfcSboExtension* model was proposed and verified to enhance the IFC's capacity to represent the LLM Agent-enhanced SBO process.

(2) The feasibility and practical value of the proposed extension were validated through a MiC case study.

The case study yields two key findings:

(1) All information generated by the LLM Agent-enhanced SBO is embedded within the extended IFC entities, involving three rooted IFC entities: *IfcSboWorkflow*, *IfcAiAgentInteraction*, and *IfcOptimizationIteration*; and two non-rooted IFC entities: *IfcObjectiveFunction* and *IfcSboOptimizationDirectionEnum*.

(2) The changes of design parameters throughout the LLM Agent-enhanced SBO process can be captured as incremental IFC updates.

Nevertheless, several limitations remain that require further investigation:

(1) The extended *IfcAiAgentInteraction* faces a trade-off between semantic integrity and storage efficiency. If LLM Agent prompts and responses are fully encoded as structured data within *IfcAiAgentInteraction*, individual lines in the IFC file may exceed parser limits, resulting in increased file size and reduced exchange efficiency. Conversely, compressing the data (e.g., via Gzip) or referencing external files avoids file bloat, but incurs semantic opacity, requires stakeholders to employ additional tools to interpret the compressed string or external files.

(2) Semantic changes of the extended IFC entities

are not supported by the mainstream commercial BIM platforms (e.g., *Revit*) or open-source IFC parsing tools (e.g., *IfcOpenshell*). This limitation arises because the proposed IFC extension has not yet been submitted to buildingSMART for formal standardization – a necessary step for broader adoption.

Abstract –

Leakage detection in subway tunnel linings remain critical yet challenging tasks. Conventional deep learning models typically require tens of thousands of training samples that are scarce in engineering practice. Large Vision Models (LVMs) possess impressive general-purpose capabilities but fall short when applied to specialized downstream tasks. To address this gap, this study proposes a tailored framework to fine-tune LVMs for leakage segmentation. Built upon Segment Anything Model 2 (SAM2), this framework comprises four dedicated components to address the complex visual characteristics of subway tunnels: (i) a tunable module for enhancing leakage edge delineation; (ii) embedding generators for projecting visual features into a leakage-adapted representation space; (iii) adaptors for learning leakage-specific representations; and (iv) a fully fine-tuned decoder for pixel-level segmentation. These components collectively activate SAM2's rich prior knowledge, facilitating high-accuracy leakage segmentation. Experiments demonstrate that the proposed method improves untuned SAM2's accuracy by 3 to 4 times. Remarkably, it achieves performance comparable to DeepLabV3+ (a state-of-the-art deep learning model trained on 2000 samples) using only 50 samples.

1 Introduction

With the rapid expansion of subway networks, water leakage remains a critical threat to operational safety [1-2]. Current manual detection is labor-intensive and subjective, creating a pressing need for efficient, high-precision, and fully automated solutions.

To overcome the limitations of traditional inspection methods, researchers have increasingly explored deep learning-based computer vision techniques for tunnel leakage detection. In recent years, convolutional neural networks (CNNs) have demonstrated remarkable advantages in automated leakage detection. For instance, Chen et al. [3] developed Leakage-YOLO, an enhanced version of YOLOv8, while Xue et al. [4] modified the Faster R-CNN model to further improve detection accuracy. However, these object detection methods cannot achieve pixel-level segmentation. To address this, Xue et al. [5] employed a Cascade Mask R-CNN framework to achieve segmentation of tunnel leakage. Zhao et al. [6] integrated ResNet-101 with Mask R-CNN for classification and segmentation of leakage images, while Feng et al. [7] enhanced the encoder structure of U-net and U-net++ to develop a U-shape model. These deep learning-based approaches have demonstrated promising results on specific datasets. However, these models require large annotated datasets (often comprising tens of thousands of images) for multiple rounds of training and validation [6]. Acquiring and labeling such large-scale datasets is labor-intensive and time-consuming, a difficulty compounded by the intrinsic scarcity of seepage data in engineering practice [8].

In recent years, Vision Transformers (ViTs) and Large Vision Models (LVMs) have attracted significant attention and have been widely adopted across a broad spectrum of visual domains [9-10]. Notably, one representative model, the Segment Anything Model (SAM) demonstrates strong zero-shot segmentation capability across diverse objects such as humans, vehicles, and animals [11]. Extending this potential to tunnel inspection, Wei et al. [12] extracted the encoder module of SAM and integrated it with an enhanced U²-Net to construct the DeU²-Net model for leakage segmentation. Nevertheless, as their method remains built upon traditional backbone architectures, it still requires extensive training data.

An emerging approach that has attracted increasing attention is the fine-tuning of LVMs with domain-specific knowledge, enabling these models to exhibit data-efficient learning behavior. However, tunnel leakage typically appears as a surface-attached, weak-edged, and low-contrast pattern on concrete, which can easily be mistaken for background noise and thus overlooked. Moreover, subway tunnels often exhibit complex visual conditions, including low illumination, texture interference, and strong visual clutter, making reliable segmentation even more difficult. Existing frameworks largely rely on uniform architectural fine-tuning strategies [13]. Fine-tuning an LVM for leakage segmentation, specifically considering the distinctive visual and structural characteristics of leakage patterns, remains largely unexplored.

To address this gap, we propose a specialized fine-tuning framework for tunnel leakage segmentation. Built on SAM2, this data-efficient learning strategy leverages pre-trained priors instead of complex training paradigm, ensuring high accuracy through a simpler, more robust training process practical for infrastructure maintenance. A Leakage Information Enhancement Module first amplifies leakage boundaries and suppresses background noise in the frequency domain. The Embedding Generator then projects general encoder features into a leakage-adapted latent space, enriching the model's semantic understanding of leakage patterns. These enhanced and projected features are integrated by Adaptors, which inject task-specific prompts into the SAM2 encoder to guide attention toward leakage-relevant regions. Finally, a fully fine-tuned Mask Decoder performs pixel-level segmentation, producing high-precision leakage masks with sharp boundaries and coherent spatial consistency.

2 Methodology

2.1 The Original SAM2 Architecture

SAM2 is a large vision foundation model specifically developed for image semantic segmentation [14]. Building upon the powerful segmentation capabilities of its predecessor SAM, SAM2 further enhances segmentation accuracy, boundary delineation, and computational efficiency. The model is based on the Vision Transformer (ViT) architecture and is specifically designed for Promptable Visual Segmentation, a segmentation paradigm that performs target segmentation through prompts such as points, boxes, or masks. As illustrated in Figure. 1 [14], Image Encoder, Prompt Encoder, and Mask Decoder constitute the core structure of SAM2.

Although the original SAM2 model possesses strong prior knowledge and demonstrates excellent generalization capacity, preliminary experiments (further discussed in Section 3.4) reveal several limitations when it is directly applied to tunnel leakage segmentation: (i) Dependency on user prompts. SAM2 requires user-provided prompts for each image, rendering it impractical for large-scale, automated workflows. (ii) Low leakage segmentation accuracy. Due to the lack of domain-specific training, SAM2 struggles with complex tunnel backgrounds, often misidentifying structural features (Figure. 1), while overlooking actual leakage regions.

2.2 The Proposed Framework

2.2.1 Framework overview

To address the suboptimal performance of SAM2 in tunnel environments, a fine-tuning framework is proposed (Figure 2) based on a parameter-efficient fine-tuning (PEFT) strategy. To minimize computational overhead, the heavy Image and Prompt Encoders are frozen; consequently, only 3.94 M parameters (representing approximately 1.76% of the 224.51 M total parameters) are updated. These trainable parameters comprise the fully fine-tuned Mask Decoder and three modules: the Leakage Information Enhancement Module, the Embedding Generator, and the Adaptors. This configuration ensures a lightweight architecture that maintains inference speeds and memory usage nearly identical to the original SAM2 while enabling effective domain knowledge learning.

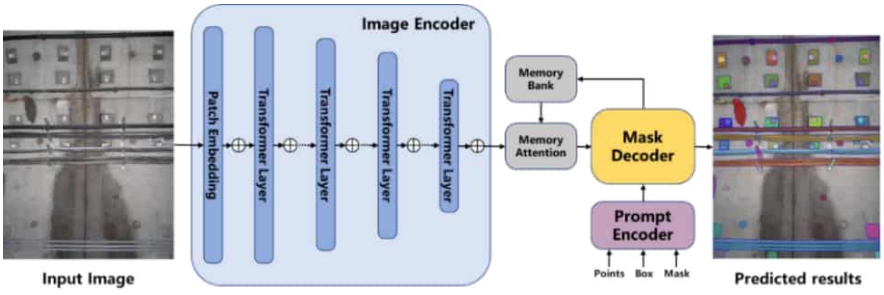

Figure 1. Architecture of the SAM2 large model and segmentation results on tunnel leakage.

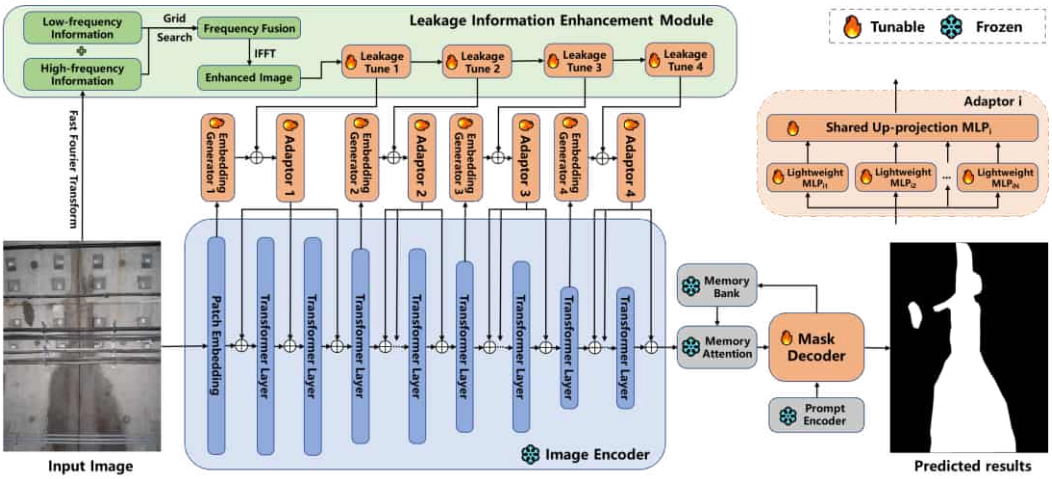

Figure 2. Architecture of the proposed fine-tuning framework.

2.2.2 Leakage Information Enhancement Module

The leakage recognition task in shield tunnels exhibits distinct challenges: (i) leakage boundaries are often blurred and gradual, lacking clear structural features; (ii) the tunnel background contains strong visual noise, including pipelines, bolts, grouting holes, and segment joints, all of which have sharp edges. Targeting these issues, an information enhancement module is designed.

The raw image I (of size $H\times W$) is first transformed into the frequency domain using the Fast Fourier Transform (FFT): z=FFT(I). The low-frequency components are shifted to the spectrum center (H/2, W/2), with frequency increasing radially outward. Two binary masks are constructed to extract different frequency bands:

(i) High-frequency mask $M_{\mathrm{h}}(\tau)$ for extracting rapidly varying edge and texture information:

$$M_{\mathrm{h}}^{i,j}(i,j,\tau)=\begin{cases}0, & \dfrac{4\,|(i-H/2)(j-W/2)|}{HW}<\tau\\ 1, & \text{otherwise}\end{cases} \tag{1}$$

(ii) Low-frequency mask $M_{\mathrm{l}}(\tau)$ for capturing slowly varying structural information and overall brightness:

$$M_{\mathrm{l}}^{i,j}(i,j,\tau)=\begin{cases}0, & \dfrac{HW-4\,|(i-H/2)(j-W/2)|}{HW}<\tau\\ 1, & \text{otherwise}\end{cases} \tag{2}$$

The corresponding high- and low-frequency components are then obtained as:

$$z_{\mathrm{h}}=zM_{\mathrm{h}}(\tau) \tag{3}$$

$$z_{\mathrm{l}}=zM_{\mathrm{l}}(\tau) \tag{4}$$

where the high-frequency component z_{h} captures sharp pixel variations, i.e., edges and texture details, including the boundaries of leakage, pipelines, and bolt holes. The low-frequency component z_{l} represents slowly varying regions, such as the main leakage body and background concrete surface. To highlight leakage characteristics while suppressing interference from irrelevant features, this module performs weighted fusion of the two components:

$$z_{\mathrm{e}}=\alpha z_{\mathrm{h}}+\beta z_{\mathrm{l}} \tag{5}$$

where α and β are learnable hyperparameters. After task-specific fine-tuning, the learned weights yield two key effects: (i) Leakage edges becomes clearer, while isolated non-target structures are attenuated; (ii) The gradient information of the main leakage region is retained, whereas smooth concrete backgrounds are weakened.

Finally, the enhanced image is reconstructed via the inverse FFT (IFFT): I_e=IFFT(z_e), and subsequently passed through four trainable Overlapping Patch Embedding layers, referred to as Leakage Tune modules. These modules are specifically designed to process enhanced leakage features corresponding to the four resolution stages of the SAM2 Image Encoder. This process generates multi-scale enhanced features F_{E1}, …, F_{E4}, which are then fed into the subsequent Adaptor modules for further feature learning.

2.2.3 Embedding Generator

Embedding Generators are further introduced to enhance the model's auto-prompting capability for leakage detection. Each Embedding Generator serves as an auxiliary input source for the Adaptor modules. Following the four-resolution stages of the SAM2 Image Encoder, four trainable Embedding Generator modules are constructed accordingly: When the raw image I enters the Image Encoder, it first passes through the Patch Embedding layer for patch extraction and embedding, resulting in the initial embedded feature I_p. Subsequently, Embedding Generator 1 projects this feature into a task-adaptive feature space:

$$F_{G1}=L_{EG1}(I_p) \tag{6}$$

The remaining three Embedding Generators follow a

similar process; however, their inputs are taken from the first Transformer layer of each corresponding resolution stage (see Figure 2). $L_{EGi}(.)$ (i = 1, 2, 3, 4) denotes a learnable linear transformation layer. By fine-tuning its internal weight matrices and bias terms, the generic visual features produced by the pretrained Encoder are reprojected into the leakage-specific task space. After projection, the resulting features F_{G1}, …, F_{G4}, are obtained sequentially and serve as additional inputs to the subsequent Adaptor modules.

2.2.4 Adaptor

Adaptors are further introduced to fuse the previously obtained leakage-enhanced features F_{Ei} and embedding features F_{Gi} (i=1, 2, 3, 4), guiding task-specific knowledge into the original SAM2 network based on the concept of prompt injection. This allows fine-grained adaptation and enhancement for downstream tasks without compromising the ability of the original model [15].

Four adaptors are constructed, corresponding to the four resolution stages of the Image Encoder (see Figure 2). For each Adaptor, F_{Ei} and F_{Gi} (i=1, 2, 3, 4) are fused to form the input embeddings F_{Ini}, which is subsequently processed multiple times within the internal structure of Adaptor. As shown in Figure 2, each Adaptor adopts a lightweight two-stage multilayer perceptron (MLP) architecture.

F_{Ini} first enters the initial linear layer of the first stage MLP_{i1}, passes through a *GELU* activation function, and is then fed into the shared projection layer MLP_i, producing the output prompt vector:

$$P_{i,1} = MLP_i(GELU(MLP_{i,1}(F_{INi}))) \tag{7}$$

Subsequently, F_{Ini} is sequentially processed by MLP_{i2}, …., MLP_{iN}. By fine-tuning the linear weight matrices and bias terms of the MLP layers, the model generates a set of leakage task-specific prompt embeddings $\{P_{i,1}, ..., P_{i,N}\}$, which are injected layer by layer into the outputs of the corresponding network layers in the i-th stage of the Image Encoder.

2.2.5 Fully fine-tuned Mask Decoder

The Mask Decoder is fully fine-tuned due to its pivotal role in mask generation and its parameter efficiency. Specifically, the Mask Decoder receives the embedding features through the previous framework, and processes them via a combination of multi-layer Transformers, upsampling modules, and Hypernetwork structures to produce multi-scale candidate masks along with their corresponding confidence scores. During fine-tuning, manually annotated leakage regions are used as supervision signals, and the model parameters are updated. Through the synergistic enhancement of the preceding modules, the model ultimately generates leakage masks with sharp boundaries, coherent structures, and high semantic consistency.

3 Experiment

3.1 Datasets

An extensive dataset was provided by Xue et al. [5], comprising 4755 images of shield tunnel leakages collected from Shanghai Metro tunnels. After verifying the one-to-one correspondence between images and labels and removing 196 invalid samples, we obtained a final set of 3359 annotated images for model training and 1000 annotated images to evaluate model performance. Representative examples from this dataset are shown in Figure 3.

3.2 Evaluation Metrics

To quantitatively evaluate the performance of the proposed method, two commonly used segmentation metrics are employed : Intersection over Union (*IoU*), Dice coefficient (*Dice*). The definitions of these metrics are as follows:

$$IoU = \frac{1}{N}\sum^{N}\frac{Int}{Uni} \tag{8}$$

$$Dice = \frac{1}{N}\sum^{N}\frac{2\times Int}{Int+Uni} \tag{9}$$

where, N denotes the total number of testing samples, *Int* and *Uni* refer to the intersection and union between ground truth mask and predicted mask generated by the model, respectively .

Figure 3. Representative samples from the used dataset, adapted from [5].

3.3 Experimental Settings

Among the four official SAM2 checkpoints, we adopted hiera-large as the backbone to fully leverage its strong prior knowledge and superior pretrained performance. During fine-tuning process, a joint loss function combining Binary Cross-Entropy (BCE) and *IoU* loss was employed to optimize the network. The batch size and number of training epochs were set to 2 and 40, respectively. To fine-tune the hyperparameters α, β, both defined within [0,1], a systematic grid search method was introduced. Candidate values for α and β were evaluated at intervals of 0.25. The grid-search results are presented in Figure 4, which identifies α=0.25 and β=0.75 as the optimal hyperparameter combination across all evaluation metrics; these values were therefore adopted for the final model configuration.

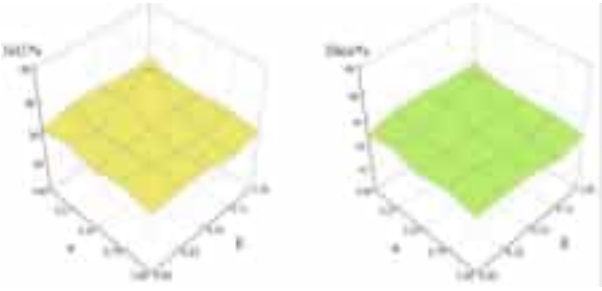

Figure 4. Grid search results for α and β.

3.4 Experimental Results

The validation set, i.e., the remaining 1,000 annotated images [5], was used to evaluate the performance of the fine-tuned model. For comparison, the original SAM2 model was also tested on the same dataset. Because SAM2 requires a manual prompt as an additional input, we simulated this process by randomly selecting one point from the ground-truth mask of each image as the prompt, which actually overestimates the original SAM2 model performance. The results are shown in Table 1.

The fine-tuned model substantially outperforms the original SAM2, achieving improvements by a factor of approximately 3–4. Specifically, the fine-tuned model attains an IoU of 87.01% and a Dice (F1-score) of 92.90%, with Precision and Recall reaching 92.34% and 93.89%, respectively. Representative segmentation results for the two models are shown in Figure 5.

Table 1. Performance comparison on the annotated validation dataset

Model	IoU(%)	Dice(%)
Proposed Framework	**87.01**	**92.90**
Original SAM2	21.49	30.75
UNet	83.07	90.75
SegFormer	85.88	92.42
Mask R-CNN	83.05	90.74
DeepLabV3+	85.96	92.45

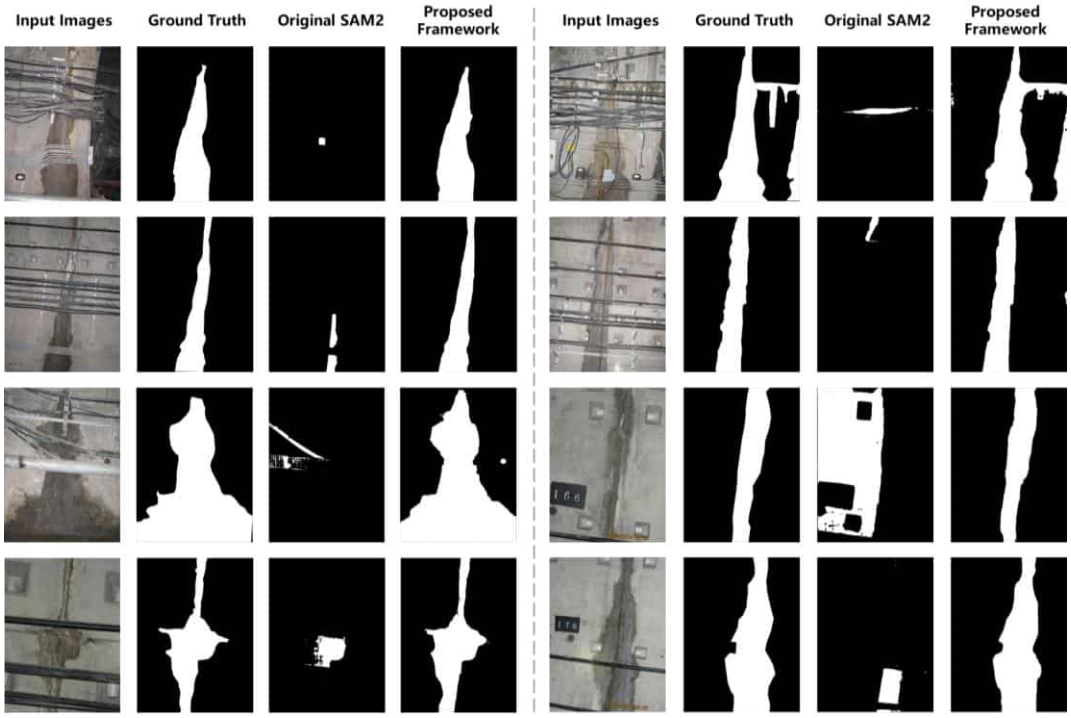

Figure 5. Representative leakage segmentation results on the annotated validation dataset.

4 Discussion

4.1 Comparison with the State-of-the-Art Model

The proposed approach is evaluated against state-of-the-art conventional deep learning models widely utilized for tunnel leakage segmentation. As summarized in Table 1, the framework is compared with several mainstream architectures, including UNet, SegFormer, Mask R-CNN, and DeepLabV3+, all of which are surpassed by the proposed method in terms of accuracy. Notably, DeepLabV3+ emerges as the strongest baseline and is therefore selected for a more rigorous comparative analysis under data-scarce conditions.

Consequently, DeepLabV3+ with an Xception backbone serves as the primary benchmark for evaluating model performance across increasingly constrained data regimes. To systematically investigate data efficiency and model robustness, experiments are conducted across eight training subsets , ranging from 3,000 images down to 10 randomly sampled images.

Table 2. Performance comparison between the proposed framework and DeepLabV3+

Training Set Size	Proposed Framework		DeepLabV3	
	IoU(%)	Dice(%)	IoU(%)	Dice(%)
3359	**87.01**	92.90	**85.96**	92.45
3000	**86.73**	92.72	**80.64**	88.28
2000	**85.37**	91.90	**71.31**	80.48
1000	**83.90**	90.85	**36.68**	47.05
500	**83.66**	90.73	**20.87**	30.44
100	**73.64**	83.71	**1.370**	2.540
50	**69.72**	80.95	**1.170**	2.140
20	**47.46**	63.15	**0.600**	1.160
10	**2.450**	4.780	**2.020**	3.740

The experimental results are summarized in Table 2, and the corresponding trend of IoU performance with respect to training set size is illustrated in Figure 6. The results show that when the training set contains only 10 images, both the fine-tuned SAM2 and DeepLabV3+ perform extremely poorly. Notably, the performance of the fine-tuned SAM2 improves steadily as the training set size increases. When the training set reaches 50 images, the IoU of the large model approaches 70%, which represents a reasonably competitive performance for applications with moderate segmentation requirements. In contrast, DeepLabV3+ shows almost no improvement at this scale, achieving an IoU of only 1.17%, suggesting that it requires substantially more data to learn effectively.

When the training set size reaches 500 images, the fine-tuned SAM2 achieves metrics exceeding 80% across all evaluation criteria, with Dice surpassing 90%, which corresponds to a high-accuracy segmentation performance commonly reported across applied imaging domains. As the dataset size increases further, the accuracy of the fine-tuned large model continues to improve, although the performance gains become less pronounced. Interestingly, DeepLabV3+ requires approximately 2000 training images to achieve a performance comparable to that of the fine-tuned large model trained with 50 images. This finding highlights the strong data-efficient learning capability of the proposed framework. When both models are trained with 3000 images, their performances become broadly similar; however, DeepLabV3+ still exhibits slightly lower overall accuracy (Figure6).

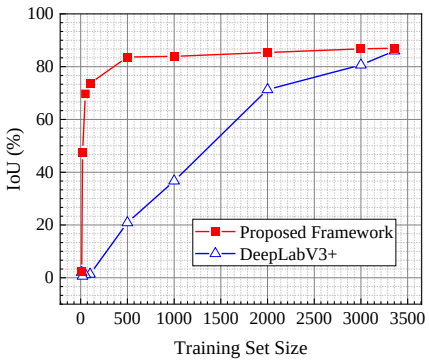

Figure 6. IoU performance versus training set size for the proposed framework and DeepLabV3+.

In summary, conventional deep learning models require large quantities of annotated images to achieve accurate shield-tunnel seepage segmentation. In contrast, although a large vision model initially lacks domain-specific knowledge, it exhibits a fundamentally different learning behavior. Once provided with even a small amount of task-specific supervision, the large model can rapidly activate its latent knowledge and extensive pretrained representations, enabling it to perform the previously unfamiliar task effectively. Importantly, the amount of data required for such fine-tuning is significantly smaller than that demanded by conventional deep learning approaches.

This property is particularly valuable for engineering applications, where annotated data are often scarce or difficult to obtain. For example, tunnel leakage images are typically controlled by transportation authorities or research institutions, resulting in inherently limited datasets. In such scenarios, the ability to fine-tune a large model is transformative, making effective machine learning workflows feasible even under limited data conditions. To further demonstrate this advantage, an engineering case study will be presented in the following subsection.

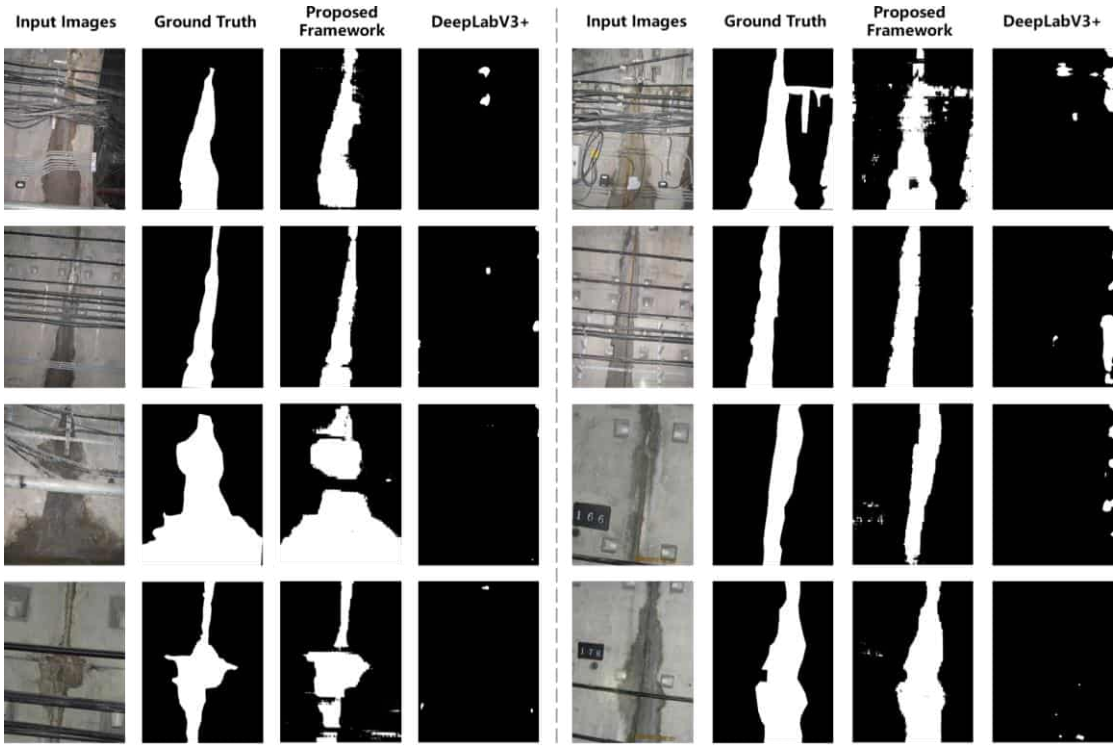

Figure 7. Representative leakage segmentation results on the annotated validation dataset using 50 training samples.

4.2 Ablation Study

In the proposed framework, the Leakage Information Enhancement Module and the Embedding Generator are architecturally coupled, as they generate the synergistic inputs (F_{Ei} and F_{Gi}) required by the Adaptors. These Adaptors serve as the central mechanism for injecting task-specific knowledge into the frozen SAM2 backbone through a prompt-injection strategy. Due to this functional interdependence, the Adaptors are consistently activated in our experimental configurations whenever either the Leakage Information Enhancement Module or the Embedding Generator is enabled to ensure the effective transmission of domain knowledge through the injection chain. To further investigate how this specialized fine-tuning transforms a general large model into a high-precision domain-specific one, four experimental configurations were designed to isolate the contribution of these key components. All configurations were trained on the same dataset and evaluated on the validation set, with the quantitative results summarized in Table 3.

It can be observed in Table 3 that fine-tuning only the Mask Decoder yields a remarkable improvement, increasing IoU from 21.49% to 78.47%. This substantial gain arises from the fact that, fine-tuned Mask Decoder refines the model's understanding of specific leakage cues, allowing it to distinguish weak-edged, low-contrast patterns from the generic objects emphasized in SAM2's pretraining. Nevertheless, the model still exhibits limitations in accuracy, falling short of the requirements for high-precision engineering applications.

Table 3. Results of the ablation study

Fine-tuning configurations	IoU(%)	Dice(%)
Original SAM2	21.49	30.75
Only Mask Decoder	78.47	87.51
Embedding Generator + Mask Decoder	85.89	92.17
Leakage Information Enhancement Module + Mask Decoder	85.61	92.01
Complete Framework	**87.01**	**92.90**

After introducing the Embedding Generator, the performance is further improved, achieving 85.89% IoU. The improvement arises from domain adaptation performed by the Adapter, together with the more effective prompt guidance provided by the Embedding Generator.

Similarly, adding the Leakage Information Enhancement Module produces gains comparable to those achieved with the Embedding Generator, attaining 85.61% IoU. Notably, the Leakage Information Enhancement Module strengthens the high-frequency boundary components of leakage regions in the frequency domain while suppressing background interference.

Finally, the full configuration achieves the optimal performance of 87.01% IoU.

5 Conclusion

This study adapts Segment Anything Model 2 into a specialized tunnel leakage segmentation model through a parameter-efficient fine-tuning framework. The main conclusions are as follows:

(i) The proposed framework overcomes SAM2's original lack of domain knowledge, transforming it into a high-precision tool for tunnel leakage detection.

(ii) The model exhibits remarkable data-efficient capability, where only 50 annotated samples achieve segmentation accuracy comparable to state-of-the-art model trained on 2,000 samples.

(iii) The framework's superiority stems from leveraging SAM2's pretrained priors through the synergy of the Mask Decoder and the proposed Leakage Information Enhancement Module, Embedding Generator, and Adaptors, which collectively enhance boundary delineation and generalization.

Preliminary tests on a Nanjing Metro dataset achieved 83.12% IoU through direct validation without retraining, demonstrating robust generalization. Future research will utilize multi-scale ablations and multi-city studies to further validate cross-domain adaptability and probe theoretical limits.

Abstract -

Conventional rebar quality inspection in construction relies heavily on manual measurements, which are time-consuming, error-prone, and impractical for dense reinforcement layouts. 3D Gaussian Splatting (3DGS) has recently emerged as a promising technique for vision-based automated rebar inspection, enabling dense 3D reconstruction under complex reinforcement configurations. Despite this potential, most existing approaches lack systematic parameter optimization and are primarily validated under laboratory conditions, which limits their applicability and reliability on real-world construction sites. This study proposes a structured experimental design to identify optimal parameters for a 3DGS-based automated rebar inspection pipeline, thereby reducing the need for trial-and-error during on-site deployment. A key contribution of this work is the identification of an optimal parameter configuration, comprising 10–20k training steps, a maximum splat count of 1M, 1920p downsampling, and UHD recording resolution. These parameters are subsequently validated on real-world U-girder reinforcement cages captured under constrained site conditions. Among the five field datasets, three demonstrate reconstruction and detection performance consistent with simulated predictions. Field validation further confirms that elevated camera viewpoints significantly improve reconstruction completeness and rebar detectability. Overall, the proposed virtual testbed enables efficient pre-deployment optimization, reducing calibration effort and enhancing the robustness of 3DGS-based rebar inspection in real-world construction environments.

1 Introduction

In the construction industry, conventional quality assessment of reinforcement remains heavily reliant on manual inspection methods, which are both time-consuming and inconsistent, and introduce errors [1]. On-site engineers typically measure rebar spacing, alignment, and layout using tapes and gauges, which requires direct physical access to dense reinforcement cages. Such practices not only compromise inspection efficiency but may also disturb the reinforcement arrangement, affecting construction quality [2]. With increasing project complexity and workforce shortages, the conventional inspection method is becoming more challenging [3]. In this context, digital and automated vision-based rebar inspection systems have emerged as a more effective solution to overcome the limitations of conventional assessment, offering the potential to standardize assessments, reduce rework, and enable continuous monitoring of structural compliance.

An automated rebar inspection pipeline typically consists of two sequential key processes: (i) data acquisition and (ii) computational processing for quality assessment [1]. Data acquisition aims to capture geometric information of reinforcement cages. It has been implemented using various sensing modalities, such as terrestrial or mobile laser scanners (TLS/MLS), RGB-D cameras, or monocular RGB cameras [4]. TLS and MLS systems directly generate dense, accurate point clouds and have demonstrated high precision in rebar spacing measurements, particularly under laboratory conditions [2, 3]. However, these systems are costly, require skilled operators, and involve significant setup time, which limits their scalability for routine on-site deployment. RGB-D cameras offer a lower-cost alternative and can directly provide depth information, but their effective range and robustness remain constrained in cluttered or large-scale construction environments [5]. Consequently, monocular RGB cameras have attracted growing attention due to their low cost, ease of deployment, and flexibility in real construction settings.

Unlike TLS/MLS and RGB-D sensors, monocular RGB cameras do not directly produce 3D geometry; therefore, they require an additional 3D reconstruction or preprocessing step to recover spatial information. Traditionally, this reconstruction has been achieved using photogrammetry or multi-view stereo (MVS) techniques [6]. While MVS is computationally efficient and widely adopted, it often struggles to reliably reconstruct dense

and repetitive geometries, such as closely spaced rebar cages, especially under occlusions and complex viewing conditions. These limitations significantly restrict the applicability of MVS-based pipelines in real-world rebar inspection scenarios.

Recently, 3-Dimensional Gaussian Splatting (3DGS) has emerged as a state-of-the-art technique for high-fidelity 3D reconstruction in visually complex scenes [7]. Compared to traditional MVS, 3DGS has demonstrated superior performance in handling repetitive patterns and complex occlusions. Recent studies have explored 3DGS-based rebar detection pipelines, typically developed and validated within a virtual reality (VR) environment, and have reported substantially improved geometric detail and reconstruction accuracy compared to MVS-based approaches [8]. However, the literature in this domain is nascent, is primarily focused on establishing a proof-of-concept experimental testbed, and does not systematically investigate the influence of 3DGS reconstruction parameter selection. Despite the demonstrated potential of 3DGS for reconstructing dense reinforcement geometries, its performance is susceptible to a range of reconstruction-level parameters [7, 9]. These parameters include the number of training steps, the maximum splat count, the image downsampling factor, and the selection of the best frames (training views). In addition, 3DGS performance is strongly influenced by field-level data acquisition parameters, such as the camera's trajectory, illumination levels, and recording resolution, which jointly affect view coverage and geometric quality [10]. However, existing studies employing 3DGS largely adopt fixed or empirically chosen parameter settings, without systematically examining their influence on reconstruction accuracy. This lack of parameter-level understanding represents a critical barrier to the reliable deployment of 3DGS-based rebar detection pipeline in real construction environments, where extensive trial-and-error optimization is impractical. Thus, there is a clear need for a structured experimental investigation that enables systematic parameter optimization prior to on-site deployment, thereby minimizing the effort required to tune and calibrate under real construction conditions.

Also, despite notable progress, the majority of existing automated rebar inspection studies are still evaluated primarily in laboratory or VR conditions. Among the reviewed literature, Yuan et al. (2023) present one of the few studies that conduct in-situ rebar inspection on a single-layer structural element, primarily focusing on relatively larger rebar spacing [2]. However, the study does not systematically account for variability in capture strategy, site constraints, or site conditions. In contrast, Kim et al. (2024) investigate multiple data collection scenarios to improve the generalizability of their approach [3]. However, their methodology is primarily validated in VR environments using synthetic datasets with single-layer rebar cages, and the framework lacks comprehensive validation on real-world data. More importantly, complex reinforcement geometries, such as multi-layered rebar cages in U-girders or I-girders, are underrepresented in existing field-based evaluations.

To address this research gap, this study builds upon a previously developed VR-based rebar inspection workflow featuring large-scale U-griders [8]. The study introduces a structured experimental design aimed at identifying optimal 3DGS reconstruction parameters (training steps, maximum splat count, image downsampling, and best frame selection). In parallel, key field-level data acquisition parameters (camera path, illumination, and recording resolution) are examined in the VR-based workflow to assess their impact on reconstruction quality. The resulting optimal data acquisition and reconstruction parameters are then field-validated on real on-site U-girders, where 3DGS-based rebar spacing measurements are compared with manual ground truth. The study makes significant contributions towards establishing systematic validation frameworks that bridge virtual (synthetic) or laboratory-based evaluations with real-world field validations.

2 Methodology

The methodology of this study builds upon the author's previous work on a 3DGS-based rebar detection pipeline. It extends it into a systematic framework for evaluating real-world scenarios and parameters to identify their optimal values.

2.1 3DGS-based Rebar Detection Pipeline

The developed pipeline follows a multi-step process. In the first stage, a synthetic environment is generated using the *Unity* engine, with a rebar cage designed in *Rhino* and a camera configuration to replicate realistic video capture conditions closely. The resulting environment is rendered as a video sequence and processed using *RealityCapture*. The synthetic video data are then processed using the 3DGS tool *Jawset PostShot* to generate splat cloud representations of the scene. These splat clouds are subsequently refined and denoised using *CloudCompare* to enhance data quality and remove outliers. Eventually, the cleaned point cloud is served as input to a custom analytical dashboard developed. Within this dashboard, K-means clustering is applied to segment the rebar into distinct layers, followed by a histogram-based projection method to identify individual rebar elements. Overall, this pipeline achieves a spacing error of less than 3% even for complex rebar configurations, such as U-girder (see

Figure 1). This end-to-end pipeline enables controlled experimentation while maintaining relevance to real-world conditions.

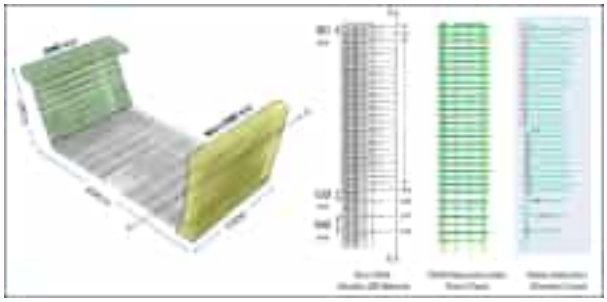

Figure 1. Overall process of rebar detection of non-OHE U-girder rebar cage.

2.2 Study Design and Evaluation Framework

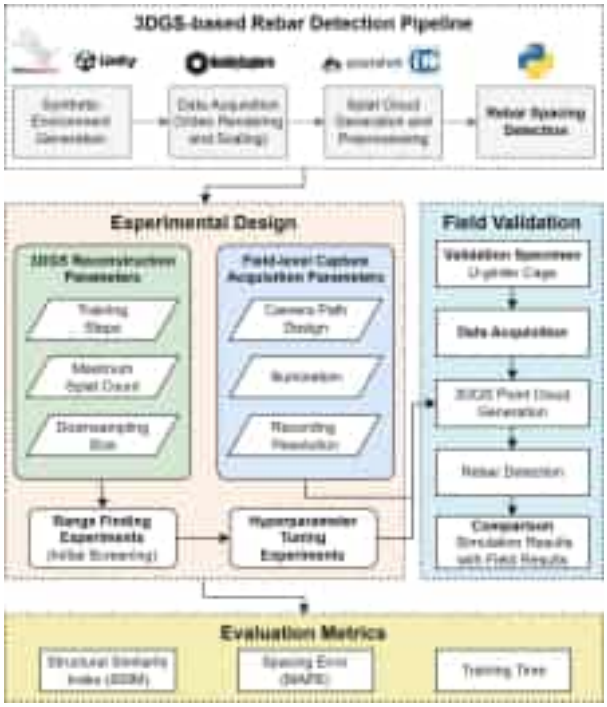

Figure 2. Schematic of the methodology of experimental design and field validation of the rebar detection pipeline.

The overall study design adopted in this research is illustrated in Figure 2. The study is structured into two main components: (i) controlled experiments conducted using synthetic data to investigate the influence of reconstruction and acquisition parameters, and (ii) field-level validation using real-world data captured from a representative U-girder specimen. To ensure consistent evaluation across all experiments and validation stages, a fixed region of interest within the U-girder rebar cage was selected as the reference layout (see Figure 1). The selected region corresponds to the non-OHE wall segment, which contains 28 closely spaced vertical rebars. This region was intentionally chosen for its high geometric complexity; the rebars are densely packed, partially occluded, and intersect with transverse reinforcement members, making both 3D reconstruction and rebar detection significantly more challenging than in single-layer rebar cage configurations.

3 Experimental Design

This section explains the experimental variables used to evaluate the 3DGS-based rebar inspection pipeline. The experiments were designed to separate reconstruction parameters from field-level acquisition parameters, enabling a systematic study of their individual and combined effects on inspection accuracy.

3.1 3DGS Reconstruction Parameters

The quality of 3DGS reconstruction is influenced by three key training parameters, namely training steps, maximum splat count, and downsampling size [7, 11]. These parameters were selected for systematic experimentation and varied individually using a one-factor-at-a-time approach, while all other conditions were kept constant. Specifically, during each experiment, a fixed orbital camera path, constant illumination (bright daylight), consistent recording resolution and identical preprocessing and reconstruction settings (other than the parameter under study) were maintained. **Training steps** control the duration of 3DGS optimization; increasing steps improves refinement of Gaussian position, shape, and colour up to a limit, beyond which gains are minimal and computation cost increases [11]. Hence, a range of training steps was tested to balance accuracy and efficiency. The **Maximum splat count** controls the number of Gaussian splats representing the scene. Higher values improve geometric detail for thin elements such as rebars but increase memory and training time; beyond a certain density, gains are marginal. Therefore, multiple splat limits were tested to identify a stable upper bound. Finally, the **Downsampling size** defines the resolution of input images during training. Higher resolutions preserve texture and edge detail but increase computational cost, so multiple levels were evaluated to determine the optimal setting. Range-finding experiments were conducted to establish suitable parameter bounds for subsequent hyperparameter tuning.

3.2 Field-level Data Acquisition Parameters

While 3DGS reconstruction parameters control the fidelity of the generated output, the overall rebar detection pipeline performance is also affected by field-level data-acquisition conditions. To investigate this effect,

a series of systematic experiments was conducted. These experiments were carefully designed to identify optimal conditions for achieving efficient and reliable reconstruction and detection performance. Among the capture parameters, camera path design, illumination, and recording resolution were selected due to their direct impact on image quality, coverage, and reconstruction [9, 10, 11].

3.2.1 Camera Path Design

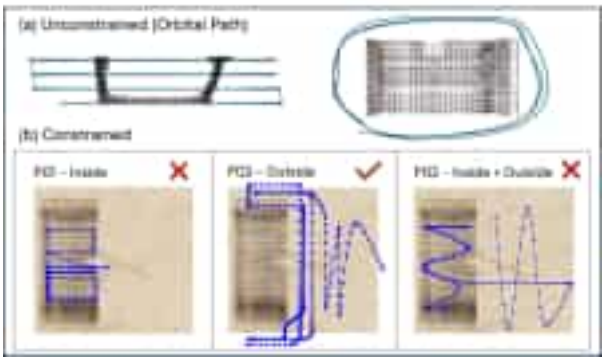

Figure 3. (a) Camera path design for unconstrained (orbital) and constrained scenarios (P01 to P03).

Camera path design determines how the camera moves around the rebar cage during data capture, directly influencing viewpoint diversity for reconstruction [10]. This experiment considers two practical site-based scenarios: unconstrained and constrained rebar cages. The unconstrained scenario represents cases where the rebar cage is fully accessible, allowing the camera to move and rotate freely around the structure. For this case, an orbital camera path was employed, in which the camera follows a closed-loop trajectory providing full 360° coverage of the cage at multiple fixed elevations. The constrained scenario reflects real construction conditions, where accessibility is limited, such as when rebar cages are embedded within U-girders or adjacent to formwork. To simulate these conditions, controlled camera paths were defined. Three configurations were evaluated: P01, where scanning is performed only from within the cage; P02, where scanning is performed only from outside the cage; and P03, which combines both inside and outside scanning. These paths were designed to assess the impact of accessibility constraints and camera placement on reconstruction performance.

3.2.2 Illumination

Illumination varies naturally throughout the day as the sun moves across the sky, resulting in fluctuations in on-site lighting conditions. For this reason, two illumination conditions were evaluated using experiments. First is a Bright daylight condition, representing typical outdoor precast yard environments, simulated at approximately 100,000 lux. Second is Low-light conditions, representing shaded or late-day site conditions, simulated at approximately 10,000 lux (see Figure 4a) [9].

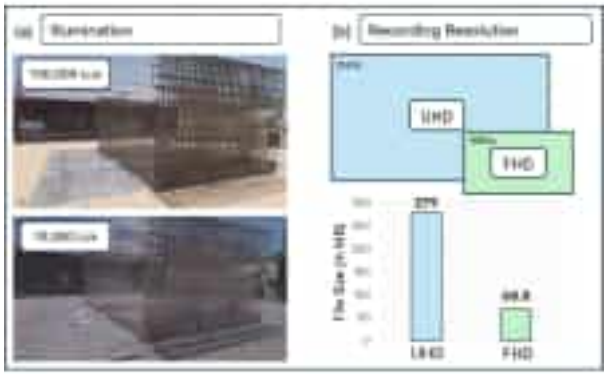

Figure 4. (a) Experimental variations for illumination, and (b) Recording resolution along with file size comparison.

3.2.3 Recording Resolution

The recording resolution of the raw video determines the finest pixel detail available before downsampling. Higher resolution offers more texture for feature matching, but at the expense of larger file sizes and longer processing times. The two most common recording resolutions were evaluated: FHD (1080p) and UHD (2160p) [12].

3.3 Evaluation Criteria

For evaluation purposes, an experiment was considered valid only if the rebar detection pipeline successfully detected all 28 rebars. Spacing errors were computed exclusively for these valid rebars using the Rhino model as ground truth. Three quantitative metrics were used consistently across all experiments to evaluate reconstruction quality, inspection accuracy, and computational feasibility. The first criterion is the Structural Similarity Index (SSIM). It captures similarity in structure, contrast, and luminance, and serves as an indicator of reconstruction stability rather than inspection accuracy. SSIM values were directly taken from *Jawset PostShot* after 3DGS reconstruction. The second criterion is Mean Absolute Percentage Error (MAPE), which measures the percentage deviation between detected rebar spacing values and the known ground-truth spacing obtained from the reference model, calculated using Equation (1).

$$\text{MAPE} = \frac{100}{n} \sum_{i=1}^{n} \frac{\left| e_i^T - e_i^P \right|}{e_i^T} \tag{1}$$

where n is the total number of spacings analysed in a trial. e_i^P denotes the spacing estimated by the

workflow for the i-th bar pair, while e_i^T represents the corresponding ground-truth spacing obtained from manual calliper measurements (field data) or directly from the 3D model (synthetic data). The third evaluation criterion is training time, which represents the total duration required to complete the 3DGS reconstruction for a given configuration. This metric was recorded to evaluate the practical feasibility of the workflow and to balance accuracy gains against computational cost.

4 Results and Discussion

4.1 3DGS Reconstruction Parameters Results

This subsection discusses the influence of 3DGS generation parameters on reconstruction quality and spacing accuracy. The experiments were performed in two stages: range-finding and detailed hyperparameter tuning.

4.1.1 Range Finding Experiments

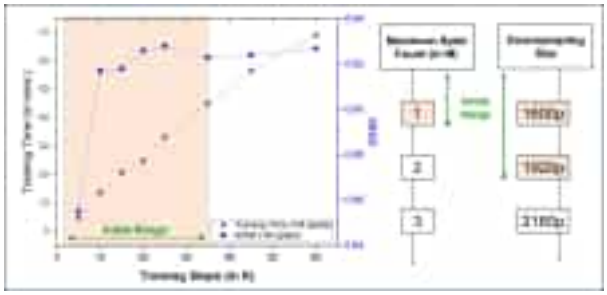

Figure 5. Training time and SSIM trends versus training steps, with highlighted initial range for maximum splat count and downsampling size.

Initially, a set of range-finding experiments was conducted to identify practical operating bounds for key 3DGS reconstruction parameters. A total of 19 experiments were performed using a fixed orbital camera path. Training steps varied from 5k to 60k, maximum splat count was set to 1M, 2M, and 3M, and input resolution was downsampled to 1600p, 1920p, and 2160p. Figure 5 illustrates the effect of training steps on SSIM and training time for a representative configuration (1M splats). While additional experiments with higher splat counts (2M and 3M) were conducted, they resulted in only marginal improvements in SSIM and no consistent reduction in MAPE. Therefore, these results are summarized here rather than explicitly plotted for clarity. Similarly, increasing the input resolution beyond 1920p results in higher training time, with negligible improvement in MAPE and only minor gains in SSIM, indicating diminishing returns beyond these thresholds.

4.1.2 Hyperparameter Tuning Experiments

Following the range-finding experiment, a structured hyperparameter tuning study was conducted to identify performance-efficient parameters for 3DGS reconstruction. A total of 60 experimental trials were conducted systematically by varying the reconstruction parameters listed in Table 1. The experimental results show a consistent trend across all resolutions. SSIM increases rapidly up to 20k training steps and plateaus thereafter for all resolutions (see Figure 6a). However, after reconstruction, the rebar detection pipeline with an 800p downsampling size failed to achieve complete rebar detection and was discarded (marked in red *). In addition, training with fewer than 10k training steps for resolutions 1600p and 1920p also failed. Thus, those samples were also discarded. The remaining samples demonstrated the best performance, achieving 100% rebar detection. Figure 6b compares the downsampling sizes of 1600p and 1920p, and for 1920p, the spacing error drops below 1% between 10k and 20k training steps.

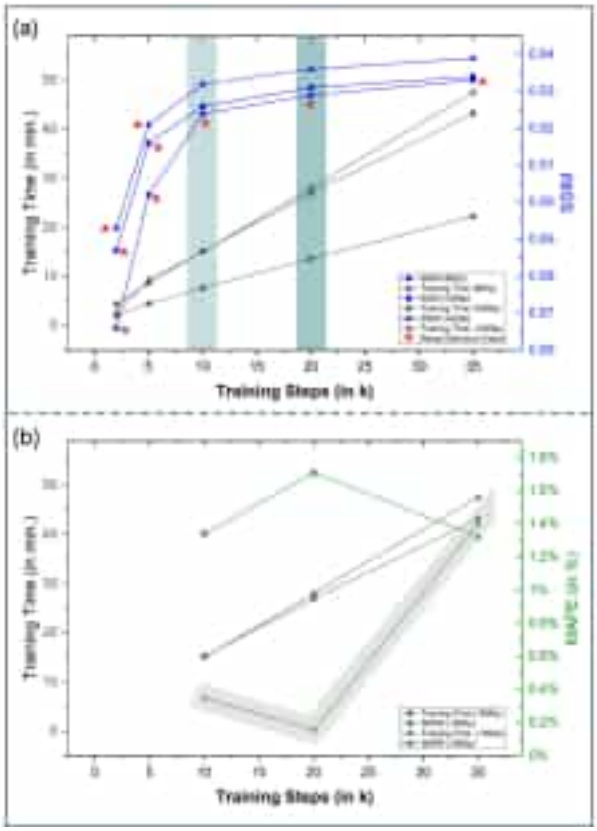

Figure 6. Training time versus training steps with SSIM, and (b) MAPE across different resolutions.

The maximum splat count strongly influenced detection reliability. Configurations with 0.1M and 0.2M splats frequently missed rebars, even at higher training steps. 0.5M splats improved detection but remained inconsistent,

whereas 1M splats consistently achieved 100% rebar detection across valid configurations. Increasing splats beyond this value did not yield further accuracy gains. Overall, based on these observations, the hyperparameter tuning phase identified 10k -20k training steps, 1M maximum splats, and 1920p downsampling as the most optimal and computationally efficient configuration. These values were fixed for all subsequent site-level parameter experiments.

Table 1. Hyperparameter variations and total number of experiments

Hyperparameters	Variation	#
Training steps	2k / 5k / 10k / 20k / 35k	5
Maximum splats	0.1M / 0.2M / 0.5M / 1.0M	4
Downsampling size	800p / 1600p / 1920p	3
	Total Experiment	**60**

4.2 Field-Level Parameters Results

A total of 24 field-level experimental trials were conducted to evaluate the influence of capture conditions on reconstruction quality (SSIM) and spacing accuracy (MAPE). The experiments systematically varied camera trajectory, illumination level, and recording resolution, with reconstructions evaluated at training steps of 10k and 20k. Under controlled acquisition conditions, the orbital camera path consistently achieved 100% rebar detection and exhibited minimal spacing error. For constraint scenarios, only path P02 enabled complete rebar detection across all trials. Therefore, subsequent analysis for constraint scenarios is limited to the P02 path.

Under bright daylight conditions, the orbital camera path consistently achieved low spacing error, with MAPE values remaining below approximately 2% across most configurations (Figure 7a). In contrast, the P02 path exhibited slightly higher, yet stable, error levels (4%), indicating reduced sensitivity to training duration and resolution. A rebar detection failure was observed for the orbital trajectory at 20k training steps using FHD input, highlighting the limitations of lower-resolution capture even under favourable illumination.

Moderate daylight conditions resulted in substantially different behaviour (Figure 7b). While controlled-path MAPE remained relatively constant (2-3%), orbital-path reconstructions showed pronounced error inflation for FHD recordings, with MAPE exceeding 12% at both 10k and 20k training steps. This degradation was mitigated primarily by UHD capture, which consistently reduced spacing error to below 4%, thereby increasing robustness to illumination-related feature loss. Across both lighting conditions, recording resolution emerged as the dominant site-level factor. UHD recordings consistently outperformed FHD recordings in all scenarios, maintaining less than 4% MAPE across all experimental trials. Overall, the experimental results indicate that site-level parameters can significantly impact rebar inspection performance, even when reconstruction parameters are optimized. Another point is that increasing the training steps from 10k to 20k roughly doubled the training time but produced only a limited improvement in accuracy, indicating that recording resolution is more critical than deeper hyperparameter optimization for 3DGS reconstruction.

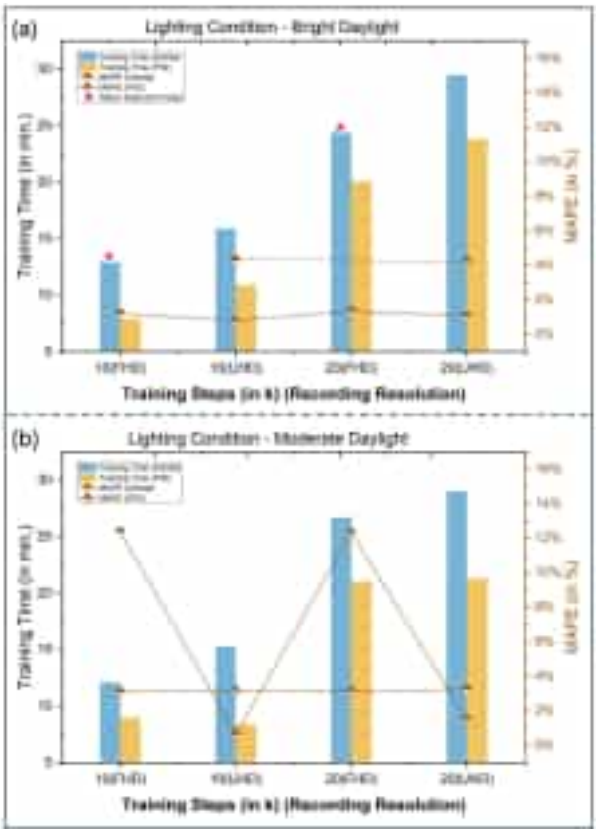

Figure 7. Training time and MAPE comparison for orbital and P02 camera path under (a) bright daylight. and (b) moderate daylight.

5 Site Validation

Site validation was conducted to verify whether the simulation-optimized parameters perform reliably under real-world precast yard conditions. A production U-girder reinforcement cage was evaluated under bright daylight, consistent with the simulated illumination setting.

5.1 Data Collection

For field validation, the capture strategies were intentionally designed to replicate the simulated strategies, including recording resolution, camera parameters, and

Table 2. Comparison across site validation, contrasting field data with its corresponding simulated data.

Trial	Recording Resolution	Training Steps (k)	Version	Training Time	SSIM	Detected Rebars (/28)	Detection Accuracy	MAPE (%)
1	FHD	10	S01	07:52	0.84	19	67.86%	–
			F01	10:25	0.65	27	96.43%	–
2	FHD	20	S02	20:03	0.87	23	82.14%	–
			F02	21:43	0.79	17	60.71%	–
3	UHD	10	S03	10:52	0.91	28	100.00%	4.31%
			F03	12:38	0.77	12	42.86%	–
4	UHD	20	S04	23:48	0.93	28	100.00%	4.23%
			F04	23:25	0.86	19	67.86%	–
			F04*	24:37	0.84	28	100.00%	15.03%

Note: S – Simulated, F – Field, F04* is data captured partially from the elevated ramp (shown in Figure 8b).

camera path. All recordings were captured from a smartphone device camera with fixed parameters across trials, matched to the simulation settings to ensure consistency with the underlying assumptions. Based on the experimental observations, both FHD and UHD recording resolutions, along with training steps of 10k and 20k, were selected, and the P02 camera path was fixed for data collection. All recordings were processed using the same multi-step rebar detection pipeline used in simulation. Evaluation was restricted to the same 28 rebars on the non-OHE wall to maintain consistency (See Figure 8a).

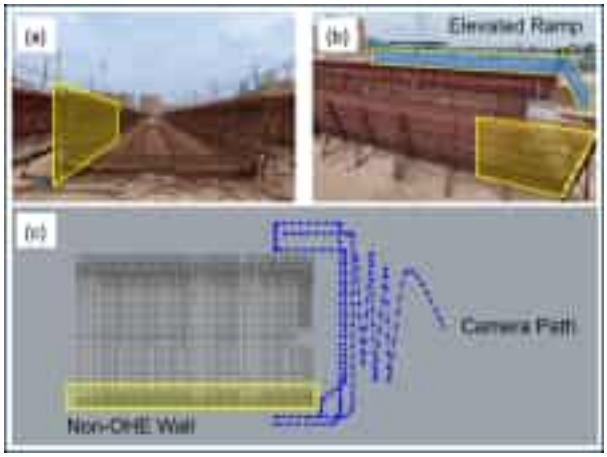

Figure 8. (a) U-girder reinforcement cage, (b) back-end isometric view highlighting elevated ramps, (c) schematic of the camera path used for site validation.

5.2 Field Validation Results

A total of five field samples were collected and processed using the rebar detection pipeline. The key parameters and their corresponding results are summarized in Table 2. Among the five samples, F01 and F02, captured in FHD resolution, failed to detect the rebars, identifying only 27 and 17 rebars, respectively. These results exactly match their corresponding simulated trials (S01 and S02), thereby classifying them as true negative cases. Although both cases resulted in incomplete detection, variations in detection accuracy between simulation and field trials indicate the influence of real-world factors, such as noise, illumination variability, and partial occlusions, that are not fully represented in the synthetic setup. Similarly, samples F03 and F04, which were captured in UHD, also failed to detect the rebars, detecting only 12 and 19 rebars, respectively. However, their replicated simulation cases (S03 and S04) were successful, classifying F03 and F04 as false positive cases.

In contrast to the four field trials that initially failed to achieve complete rebar detection, sample F04* was collected. The only variation in this case was that the capture was performed from a slightly elevated side view using an elevated ramp, as illustrated in Figure 8(b). In this sample, the rebar detection pipeline successfully detected all 28 rebars, with a MAPE of 15.03% in spacing estimation. Since the corresponding simulated case S04 also succeeded, this sample is considered a successful validation case and is treated as a true positive for outcome consistency, despite differences in capture geometry.

Figure 9. Confusion matrix summarizing agreement between simulation and field outcomes.

Figure 9 presents the confusion matrix derived from all evaluated samples. The key observations from the field trials indicate that under constrained scenarios, high-elevation capture is a decisive factor. Specifically, the introduction of a top-down perspective through elevated acquisition in F04* enabled complete

rebar detection, confirming that at least one elevated camera pass is essential for successful reconstruction in dense reinforcement layouts, consistent with the role of viewpoint diversity in camera path design (Section 3.2.1). Additionally, spacing errors in the successful field sample (F04*) were higher than those observed in simulation (approximately 15%), reflecting the impact of real-world noise, material variability, and uncontrolled occlusions. Finally, the consistent failure of F01 and F02 in both field and simulation confirms that the simulation framework accurately identified capture geometries unsuitable for reliable reconstruction.

6 Conclusion

Existing studies on automated rebar spacing detection are largely limited to controlled environments or simple geometries, with limited focus on complex configurations, such as U-girders, and on real-world feasibility. This study addresses this gap by investigating a 3DGS-based inspection pipeline previously developed by the authors using a structured, simulation-driven experimental design [8]. The experimental results established practical limits for key 3DGS reconstruction parameters (10-20k training steps, 1M splat count, and downsampling size 1920p) beyond which accuracy gains diminish while computational cost increases. Further experiments demonstrated that site-level capture conditions, particularly the camera path design and UHD recording resolution, were critical. While orbital trajectories performed best under unconstrained conditions, constrained scenarios required carefully designed paths, with outside-only scanning (P02) being the most reliable.

Field validation of metro U-girders demonstrated general correspondence between simulated predictions and real-world performance, particularly in identifying both successful and failed inspection scenarios. However, variations observed between simulation and field results, including differences within failure cases and the influence of elevated camera viewpoints, indicate that these relationships are not yet fully characterized. In particular, while elevated camera viewpoints were observed to improve reconstruction completeness in constrained scenarios, this factor was not systematically explored within the synthetic virtual environment and therefore requires further investigation. Similarly, differences in detection accuracy between simulation and field trials highlight the impact of real-world conditions, such as noise, occlusions, and illumination variability, that are not fully captured in the synthetic environment. Overall, while the proposed framework demonstrates promising practical applicability, further validation across diverse capture conditions, elevated viewpoints, and site scenarios is required to strengthen generalizability.

Abstract –
The modular construction industry requires early and tightly coupled reasoning across spatial layout, structural systems, module interfaces, and building services under fabrication, transportation, and assembly constraints. With recent advances in generative artificial intelligence (AI) and the emergence of large language models (LLMs), there is growing interest in leveraging these technologies to support design reasoning through natural language interaction. However, existing studies lack domain-specific methodologies that systematically translate modular design reasoning into effective prompts for generative AI systems. This study addresses this gap by introducing a reasoning-oriented taxonomy of modular construction design tasks and a structured prompt engineering framework tailored to modular design contexts. The proposed framework formalizes prompt construction through standardized blocks and demonstrates its application using representative prompts grounded in a modular residential case study. The proposed framework provides a methodological foundation for reasoning-aware human–AI interaction in early-stage modular construction design.

Modular Construction; Prompt Engineering; Large Language Models; Design Reasoning; BIM

1 Introduction

Modular construction has gained increasing attention as an alternative to conventional on-site construction due to its potential to improve productivity, quality control, and construction safety by shifting substantial portions of the building process from site environments to controlled factory settings [1], [2]. Prior research consistently indicates that off-site and modular construction can reduce schedule uncertainty, enhance manufacturing precision, and mitigate safety risks associated with labor-intensive site activities, particularly in residential and mid-rise building projects [3], [4]. Despite these advantages, modular construction introduces a distinct set of design and coordination challenges that differ fundamentally from traditional cast-in-situ construction. Modular projects require early and tightly coupled reasoning across spatial layout, structural systems, module interfaces, and building services to ensure manufacturability, transportability, and on-site assembly feasibility [1], [5]. Errors or inconsistencies introduced during the early design stages are difficult and costly to correct once production has commenced, highlighting the importance of structured, front-loaded design decision-making [6]. Building Information Modeling (BIM) has been widely adopted to support modular and off-site construction by enabling the integrated representation of geometry, components, and construction information across disciplines [2], [7]. However, prior BIM-based approaches largely rely on manual modelling, rule-based automation, or discipline-specific scripts, which remain time-consuming and require significant expert input [8], [9], [10]. As a result, BIM tools alone provide limited support for the reasoning-intensive nature of early modular design, where designers must iteratively explore layout configurations, assess structural logic, and anticipate inter-module and service coordination constraints.

Recent advances in generative artificial intelligence (AI), particularly large language models (LLMs), have demonstrated strong capabilities in interpreting natural language instructions, supporting design reasoning, and generating structured responses across complex problem domains [11], [12]. In parallel

domains, LLM performance has been shown to depend strongly on prompt formulation, with structured prompt engineering strategies significantly improving reasoning quality, consistency, and controllability [13], [14].

Within the construction and BIM context, emerging studies have begun exploring the use of LLMs for tasks such as automated compliance checking, design interpretation, and limited forms of reasoning support [11], [15]. However, current LLM research in the AEC and BIM space is still reported largely as isolated, task-level prototypes, such as BIM information search assistants, schedule or sequence generation, and chatbot-style query systems, rather than as reusable prompting methodologies that generalize across design reasoning tasks [16]. Moreover, recent AEC reviews explicitly note that outcomes are highly prompt-dependent, yet the prompt practices documented across studies vary widely (e.g., template-based, few-shot, role-based, chain-of-thought, iterative prompting), indicating limited consolidation into a consistent and transferable prompting approach for design reasoning [16], [17], [18], [19]. As a result, there is limited guidance on how to systematically translate reasoning-intensive modular design problems, such as the coupling of layout, structure, interfaces, and MEP systems under fabrication and transport constraints, into robust prompt structures that can be reused across modular design stages.

To address this gap, this study proposes a structured prompt engineering approach tailored to modular construction design. The research contributes (1) a task taxonomy that categorizes modular design activities based on their dominant reasoning requirements, (2) a structured prompt engineering framework that formalizes how modular design tasks can be expressed as prompts, and (3) representative prompt examples grounded in a realistic modular residential design scenario. Rather than evaluating model performance, the focus of this work is on clarifying the relationship between modular design reasoning and prompt structure, thereby providing a foundational framework for future generative AI applications in modular construction design.

2 Literature Review

Prior research on modular and off-site construction has primarily emphasized process optimization, production efficiency, and lifecycle performance. Reviews of prefabricated and modular construction management consistently highlight that modular projects require earlier design finalization and stronger cross-disciplinary coordination than conventional construction, due to the interdependence between manufacturing, transportation, and on-site assembly decisions [3], [4]. These studies emphasize that design decisions related to layout, structural systems, and service integration must be resolved up front to avoid costly rework once factory production begins, underscoring the reasoning-intensive nature of early modular design stages. Moreover, BIM has been widely adopted for providing integrated digital representations of building geometry, components, and construction information. Prior studies demonstrate that BIM facilitates coordination across design and construction disciplines in modular and off-site projects, enabling improved visualization, clash detection, and constructability analysis [2], [20]. Recent advancements in AI within construction engineering have introduced data-driven and learning-based approaches for design support, optimization, and automation. These applications commonly employ knowledge-based and machine-learning techniques for planning, monitoring, and decision support. These approaches often rely on predefined rules or structured project data (e.g., BIM/event logs), and several methods still face constraints such as limited adaptability and knowledge acquisition bottlenecks [21], [22]. These limitations are particularly pronounced in conceptual design contexts, where problem definitions are incomplete and reasoning requirements evolve dynamically.

More recently, generative AI and LLMs have demonstrated strong capabilities in interpreting natural language, generating structured outputs, and supporting reasoning-oriented tasks across engineering domains. Studies in engineering design report that LLMs can assist with concept generation, explanation, and design reasoning, particularly when problems are expressed in well-structured textual forms [23]. Within the construction and BIM domain, early investigations have applied LLMs to automated compliance checking and information retrieval tasks, showing that natural language interfaces can improve accessibility to BIM data and rule interpretation [15], [24]. However, these applications primarily focus on downstream validation or query tasks rather than upstream design reasoning.

Parallel research in prompt engineering has shown that LLM performance is highly sensitive to how tasks are framed. Studies indicate that structured prompt formulations, including explicit context definition, constraint specification, and reasoning objectives, significantly improve model reliability, interpretability, and reasoning depth [14], [25]. Design tasks differ from conventional NLP benchmarks in that they require spatial reasoning, constraint satisfaction, and multi-objective trade-off exploration. However, prompt engineering research remains largely domain-agnostic, offering limited guidance on how domain-specific reasoning tasks, such as those in modular construction design, should be translated into effective prompts. This limitation is critical for modular construction design, where early-stage decisions must simultaneously satisfy

manufacturability, transportation, and assembly constraints. Within modular construction research, computational design studies increasingly recognize the need for integrated reasoning across layout, structure, and services.

Taken together, the literature reveals a clear gap at the intersection of modular construction design, BIM-based workflows, and generative AI. While BIM provides an integrated data environment and LLMs offer powerful natural language reasoning capabilities, there is limited research on how modular design tasks can be systematically translated into structured, reasoning-oriented prompts that align with both domain constraints and principles of prompt engineering. This gap motivates the development of a domain-specific prompt engineering framework that explicitly connects modular design task characteristics with structured prompt formulations, enabling more effective use of generative AI during early modular design stages.

3 Research Methodology

This study adopts a design-oriented methodological approach to develop a structured prompt engineering framework grounded in modular construction design reasoning. The methodology systematically organizes modular design tasks and links design reasoning requirements to prompt formulation for generative AI systems. Figure 1 presents an overview of the research methodology.

The methodology consists of four sequential steps. First, modular design reasoning was analyzed using insights from modular and off-site construction literature and the representative case, identifying key design reasoning characteristics that distinguish modular construction from conventional building design, particularly in early design stages. These reasoning characteristics highlight the need for early coordination across spatial layout, structural systems, module interfaces, and building services under fabrication and transportation constraints. Second, building on the reasoning characteristics identified in Step 1 and the analysis of a representative modular residential scenario, modular construction design activities were decomposed and organized into a reasoning-oriented task taxonomy. For example, in the representative modular residential scenario (Section 6), the need to maintain vertical alignment of wet areas across stacked units, such as bathrooms and kitchens, was identified in Step 1 as a key reasoning constraint and formalized in Step 2 under layout and MEP coordination tasks. The taxonomy emphasizes core reasoning dimensions, such as spatial layout logic, structural continuity, module connection consistency, and building service coordination, rather than software tools or implementation-specific modelling techniques.

Third, the task taxonomy developed in Step 2 was used as a conceptual bridge to structure prompt formulation, drawing on established prompt engineering concepts such as context specification, explicit task definition, constraint articulation, and expected output structuring. This step resulted in a structured prompt engineering framework linking modular design task characteristics with prompt components and reasoning objectives. Finally, a representative modular residential case study was used to illustrate the application of the proposed taxonomy and structured prompt engineering framework. This step demonstrates how modular design tasks are translated into reasoning-oriented prompts, clarifying the coherence and applicability of the proposed approach, as detailed in Sections 4–6 corresponding to the task taxonomy, structured prompt framework, and case study components of the methodology (Figure 1).

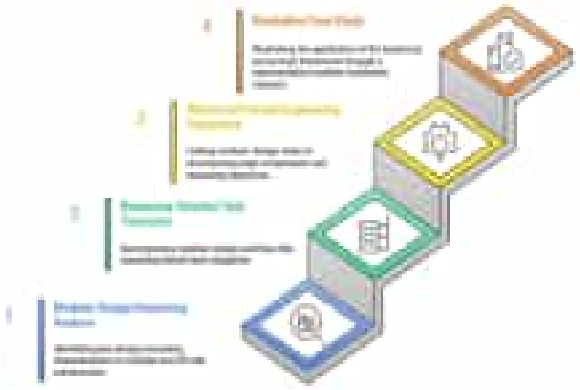

Figure 1. Research workflow for developing the prompt engineering framework.

4 Modular Construction Design Task Taxonomy

Modular construction design consists of a set of interconnected tasks that differ significantly from traditional on-site building design. This distinction stems from the production-oriented nature of modular construction, which requires off-site fabrication, transportation, and on-site assembly. Consequently, coordinated reasoning is needed for spatial layout, structural systems, inter-module connections, and building services, including zoning rooms within transport-constrained module envelopes, maintaining load-path continuity across stacked modules, aligning module interfaces for vertical stacking, and preserving vertical continuity of building services. As a result, design effort is shifted toward early-stage reasoning and decision-making rather than downstream detailing. Given this level of interdependence, the effective use of

generative AI in modular construction relies on understanding the types of design tasks and associated reasoning processes needed. In response to this need, this study presents a taxonomy of modular construction design tasks that organize these activities based on their primary reasoning requirements. The taxonomy is derived from a realistic modular residential design using a design decomposition approach, in which design decisions, constraints, and coordination requirements were identified and iteratively grouped according to their dominant reasoning characteristics. Task categorization was guided by the primary reasoning required to resolve each requirement, including spatial layout, structural continuity, module interface coordination, and building service integration. This approach ensures conceptual consistency across task categories and supports direct mapping between design reasoning and prompt formulation. To emphasize reasoning over implementation details, the taxonomy organizes modular design into reasoning-driven categories rather than software-specific modelling processes. Accordingly, Figure 2 presents the proposed modular construction design task taxonomy, derived through design decomposition of the case scenario, illustrating how design decisions, constraints, and coordination requirements are grouped based on their dominant reasoning characteristics and serving as the foundation for the prompt engineering framework introduced in the following section.

Figure 2. Reasoning-oriented task taxonomy derived from modular design decomposition.

Layout design tasks address spatial zoning, circulation organization, room adjacency logic, and compliance with transport envelopes and minimum dimensional requirements. In contrast, structural design tasks focus on framing logic, load-path continuity, and structural consistency across stacked modules, particularly under conditions of transport, lifting, and in-service use (e.g., maintaining vertical load transfer across module boundaries). Building upon these considerations, module connection tasks involve reasoning about vertical stacking alignment, horizontal joining strategies, continuity of load transfer surfaces, and fire or acoustic separation across module interfaces (e.g., alignment tolerances at vertical module interfaces). In parallel, MEP coordination tasks address service zoning, plumbing stack alignment, clash awareness, and continuity of building services across modules (e.g., preserving vertical service continuity across stacked units).

5 Structured Prompt Engineering Framework

Modular construction tasks differ in scope and complexity; therefore, their effective use of generative AI systems relies on how these tasks are converted into prompts. Unstructured prompts often lead to unclear or incomplete reasoning, particularly under modular fabrication and transportation constraints. To tackle this issue, this study proposes a structured prompt engineering framework specifically for modular construction design tasks. Figure 3 illustrates the proposed framework, showing how modular design tasks are translated into structured prompts through standardized prompt blocks and instantiated as different prompt types depending on the intended reasoning objective. The framework standardizes how prompts are created by breaking each prompt into a set of functional blocks that guide AI reasoning and minimize ambiguity. It is intentionally not tied to any specific tool and aims to support design reasoning across various generative AI systems, including general-purpose LLMs and BIM-integrated design assistants.

Each prompt is composed of five core elements. A Context Block defines the modular design scenario, including building type, modular system characteristics, and high-level constraints. A Task Definition Block explicitly states the intended action, such as generating, analyzing, checking, or revising a design aspect. A Constraints Block specifies relevant dimensional, structural, code-related, or modular limitations that must be respected. An Expected Output Block defines the desired response format, such as structured text, stepwise reasoning, or descriptive lists. Finally, a Validation and Guardrails Block requests explicit checks for known failure points or critical conditions, discouraging unsupported assumptions or hallucinated design elements. The five core blocks serve as a reference structure rather than a rigid template, allowing prompt configurations to be adapted, simplified, or extended in accordance with task complexity and specific reasoning requirements.

Using this structure, modular design tasks can be systematically linked to different prompt types, such as directive prompts for generation, analytical prompts for explanation, diagnostic prompts for checking consistency, and corrective prompts for refinement. Each prompt type emphasizes a different reasoning objective while retaining the same underlying block structure.

Reusable prompt templates are created by filling in the structured blocks with task-specific information and constraints, allowing for consistent prompt development across various modular design scenarios and supporting iterative prompt reuse as design objectives evolve.

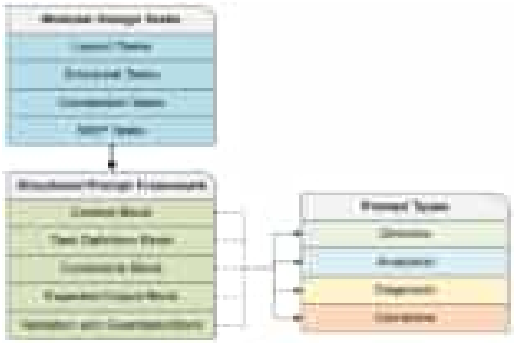

Figure 3. Structured prompt engineering framework for modular construction design tasks

6 Modular Case Study and Prompt Instantiation

This section presents a representative modular residential case study that demonstrates how the proposed task taxonomy and prompt engineering framework can be applied in practice. The purpose of the case study is not to validate the performance of automated modelling or generate construction-ready outputs, but rather to provide a realistic design context for prompt formulation and reasoning-based interaction with generative AI systems.

6.1 Scenario Definition

The demonstration scenario is based on a low-rise residential building composed of vertically stacked modular units, representative of common volumetric modular construction practices. The building configuration consists of two primary above-grade levels organized around a central circulation core, with repeated and aligned spatial layouts across floors. A sectional axonometric view of the case study is shown in Figure 4, illustrating the stacked modular arrangement, floor separation, and overall spatial organization. The internal program reflects a typical residential layout, including living, dining, and kitchen spaces on the lower level, and bedroom and bathroom spaces on the upper level. Wet areas and service zones are vertically aligned, reflecting common modular strategies that support service continuity and inter-module coordination. The scenario is constrained by module dimensions and the need for vertical alignment of structural and service elements across stacked units. Structural and MEP systems are represented at a conceptual level to highlight coordination logic, interface relationships, and service alignment, without implying finalized engineering specifications.

Figure 4. Modular residential case illustrating design stages aligned with task categories and prompt types

6.2 Example Prompts Based on Modular Design Tasks

Using the modular residential scenario illustrated in Figure 4, a set of representative prompts was created to demonstrate how the modular design task taxonomy (Section 4) can be operationalized using the structured prompt engineering framework introduced in Section 5. The examples presented in this section are designed to show how different modular design tasks can be translated into clear, reasoning-oriented prompts suitable for generative AI systems.

Although the representative prompts are expressed at an abstract level, they are implicitly grounded in the modular residential scenario described in Section 5.1, including vertically stacked units, aligned wet areas, centralized circulation, and transport-constrained module dimensions. These scenario characteristics inform the intent and constraints of each prompt without requiring explicit numerical parameterization.

Each example prompt follows a consistent structure, including a clearly defined context, an explicit task specification, relevant modular constraints, and an articulated expected output and validation intent. This structure enables a direct mapping between the modular design task categories (layout, structural, module connection, and MEP coordination) and the corresponding prompt types (directive, analytical, diagnostic, and corrective) defined in the proposed framework. In this mapping, the task category specifies the design aspect under consideration (e.g., layout or structure), the prompt type defines the intended reasoning action (e.g., generation or diagnosis), and the structured prompt blocks provide the mechanism for expressing this intent in a consistent and explicit form.

Table 1 summarizes the representative prompts used in this study, illustrating how each modular design task category is paired with an appropriate prompt type and

expressed as a concise, reasoning-oriented instruction. The examples in Table 1 demonstrate how abstract modular design tasks can be systematically translated into clear and reusable prompts suitable for generative AI systems, while maintaining alignment with the reasoning-driven taxonomy presented earlier.

Table 1. Representative prompts mapped to modular design task categories and prompt types (presented as concise, illustrative instructions)

Task Category	Prompt Type	Representative Prompt
Layout	Directive	Generate a spatial layout for a transport-constrained modular unit that minimizes corridor length while preserving privacy and maintaining vertical alignment of wet areas and service zones.
Structural	Analytical	Explain how load-path continuity can be maintained across vertically stacked modular units, including across module interfaces.
Connection	Diagnostic	Identify potential alignment issues at vertical module interfaces in a stacked modular configuration.
MEP	Diagnostic	Check whether the layout supports vertical continuity of plumbing and mechanical services across modules.

To further illustrate the added value of the proposed task taxonomy and structured prompt engineering framework, the following expanded example demonstrates how a modular design task can be systematically translated into an explicit, reusable prompt structure, rather than relying on ad hoc or user-specific prompt formulations, using a directive layout design task based on the modular residential scenario in Figure 4. For clarity, the representative prompts in Table 1 are intentionally expressed in concise form, whereas the expanded example below demonstrates how a single prompt can be fully instantiated using the same block structure defined in Section 4, without loss of generality across other prompt types.

Context Block: Consider a low-rise residential building composed of vertically stacked modular units with aligned floor layouts, centralized circulation, and vertically continuous wet areas, representative of the modular configuration shown in Figure 3.

Task Definition Block: Generate a conceptual spatial layout for a single modular unit that supports the overall building configuration and preserves the stated stacking and service-alignment logic across levels.

Constraints Block: The layout must respect transport-constrained module dimensions, preserve privacy between primary living and sleeping spaces, and maintain vertical alignment of wet areas and service zones across stacked units.

Expected Output Block: Provide a stepwise explanation of the proposed layout strategy, describing room zoning, circulation organization, and service alignment logic.

Validation and Guardrails Block: Verify that the proposed layout maintains vertical service continuity of wet areas and service zones, avoids introducing structural claims not supported by the stated scenario, and does not introduce spaces that violate modular transport or stacking constraints.

6.3 Implications of Structured Prompting for Modular Design Tasks

The examples presented in Section 6.2, grounded in the modular residential scenario illustrated in Figure 4 and summarized in Table 1, demonstrate how modular design tasks can be systematically translated into structured prompts, providing a common and repeatable way to express design reasoning that does not depend solely on individual user experience or personal prompt-writing skills by decomposing each task into explicit context, task intent, constraints, expected outputs, and validation objectives, the proposed framework transforms implicit design reasoning into more transparent, communicable, and reusable representation for interaction with generative AI systems.

From a modular design perspective, this structured prompting approach supports clearer separation between different types of design reasoning. Layout tasks emphasize spatial organization and adjacency logic, structural tasks focus on continuity and alignment across stacked modules, connection tasks highlight interface consistency, and MEP coordination tasks address service zoning and vertical continuity. The framework offers a consistent vocabulary and structure for expressing modular design intent, rather than relying on ad hoc or experience-driven prompt formulations.

More broadly, the framework contributes a task-driven method for prompt formulation in modular construction design. Rather than treating prompts as isolated or tool-specific inputs, the proposed approach frames them as reusable design artifacts that encode

domain knowledge and reasoning expectations. This supports knowledge transfer across designers, projects, and design stages, and offers a conceptual foundation for future integration with BIM-based workflows, design assistants, and decision-support tools, without requiring immediate automation or performance benchmarking. In a BIM-integrated context, the proposed framework can act as an intermediate reasoning layer between structured BIM data and generative AI systems. Inputs may be extracted from model properties, schedules, or IFC-based representations (e.g., space lists, module grids, dimensional envelopes, and coordination zones) and translated into prompt context and constraints. The resulting outputs represent structured reasoning responses, such as layout recommendations or coordination checks, which can be mapped back to BIM actions including model revision, alignment validation, and issue identification.

7 Conclusion

This study addressed a critical gap at the intersection of modular construction design, BIM-based workflows, and generative AI by proposing a domain-specific prompt engineering framework grounded in modular design reasoning. Modular construction demands early and integrated decision-making across layout, structure, module connections, and building services, yet existing AI and BIM-based approaches provide limited guidance on how such reasoning-intensive tasks should be translated into effective prompts for generative AI systems.

To respond to this challenge, the study first developed a reasoning-oriented taxonomy of modular construction design tasks, derived from a production-oriented residential modular scenario. By organizing modular design activities according to their primary reasoning requirements rather than implementation tools or modelling techniques, the taxonomy establishes a conceptual bridge between modular design logic and prompt formulation. Building on this foundation, a structured prompt engineering framework was introduced, defining a consistent set of prompt blocks and linking modular design tasks to distinct prompt types aligned with different reasoning objectives.

The Framework was illustrated through a representative modular residential case study and a set of example prompts, including a fully instantiated prompt demonstrating how contextual information, constraints, and validation objectives can be explicitly encoded. These examples illustrate how structured prompting can represent modular design reasoning as clear, reusable instructions suitable for interaction with generative AI systems, without requiring construction-ready outputs or performance benchmarking. The primary contribution of this work lies in its methodological framing rather than technical evaluation. By explicitly connecting modular design reasoning with structured prompt engineering principles, the proposed approach supports more transparent and controllable human–AI collaboration during early-stage modular design. Future research may extend this framework by applying it to additional building typologies, integrating it with BIM-based design assistants, or empirically evaluating its impact on design quality, efficiency, and user trust in generative AI–supported modular construction workflows. While the proposed framework provides a structured approach to prompt formulation, its impact on reasoning quality and performance has not been quantitatively evaluated in this study and remains an important direction for future research.

Abstract –

Autonomous mobile robots deployed in building environments require comprehensive spatial semantics for navigation and operation. However, while current Industry Foundation Classes (IFC) standards provide both geometric and semantic information, they lack robot-operational attributes. This paper presents a Point-of-Interest (POI) framework that enriches IFC building models with robot-oriented behavioural intelligence through function-based mapping rules. The proposed semantic enrichment methodology utilizes IfcOpenShell to augment standard IFC entities with custom property sets that encode POI definitions, thereby enabling the integration of building geometry and robot semantics within Unity-based virtual reality simulation environment. The framework is validated through various scenarios, including doorway accessibility assessment, multi-robot coordination, and wall-following tasks, demonstrating its effectiveness and applicability. The approach establishes a foundation for proactive robot-compatible building design and supports the development of automated accessibility evaluation tools.

1 Introduction

The deployment of autonomous mobile robots in building environments has become increasingly prevalent [1]. For robots to navigate effectively, they require comprehensive spatial understanding. Robots must identify navigable pathways, detect and avoid obstacles, recognize transition points between spaces, locate service stations for charging and maintenance, and coordinate movements with other robots and human occupants [2]. These operational requirements necessitate rich semantic information about the built environment that encodes not merely what spaces and objects are, but how they function in relation to robotic navigation and task execution [3].

Navigation environment modeling for autonomous systems is conventionally categorized into three types based on spatial representation: metric-based models (grid or voxel discretization), topology-based models (graph structures with nodes and edges), and network models that combine geometry with topology [4–6]. Metric-based approaches tessellate space into cells with pathfinding algorithms such as A* and Dijkstra applied for shortest path analysis, but suffer from computational overhead and storage requirements [7]. Topology-based models provide compact graph structures but lack the geometric precision necessary for operational robot guidance [4]. Network models integrate geometric coordinates with topological connectivity through representations including Visibility Graphs, Voronoi Diagrams, and Medial Axis Transforms, yet these geometry-derived methods face scalability challenges in complex building environments and struggle with irregular floor layouts [8].

Building Information Modeling (BIM) has emerged as the dominant framework for digitally representing building assets throughout their entire lifecycle, from initial design conception through construction execution to long-term operational management [9,10]. The Industry Foundation Classes (IFC) standard, maintained by BuildingSMART International, provides the foundational data schema for BIM interoperability, defining standardized representations for building elements, spatial structures, material properties, and functional relationships[11]. The prior studies have used

IFC data to construct navigation models, such as voxel-based maps, which are generated using IFC geometry [6], and a graph-based network for building-level connectivity is developed using IFC semantics [12].

However, current IFC specifications, while comprehensive for human-centric building design and construction management, exhibit fundamental limitations when applied to robot navigation and operation contexts. IFC schemas define building elements: walls, doors, floors, and spaces, primarily through properties relevant to architectural design, structural engineering, and building code compliance. Attributes such as wall thickness, door fire ratings, floor load capacities, and room occupancy classifications serve architectural and engineering purposes effectively, yet these properties do not directly address robotic operational requirements. Critical robot-navigation parameters remain largely absent from standard IFC property definitions. Consequently, existing BIM-driven navigation studies cannot directly support robot deployment planning, as the authoritative building information models do not contain the behavioral and operational attributes necessary to inform robot path planning, obstacle avoidance, and service execution algorithms.

Addressing this gap requires a systematic approach to the semantic enrichment of building information models with robot-oriented spatial intelligence [13]. Recent research has introduced Point-of-Interest (POI) frameworks as a mechanism for redefining building elements from robotic behavioral perspectives. Unlike geographic POIs that mark locations of human interest, such as landmarks or commercial establishments, robot-oriented POIs represent spatial elements that directly influence autonomous navigation decisions and task execution. A door, for instance, functions not merely as a physical barrier with dimensional properties, but as a transition element that governs spatial accessibility under specific clearance and passage constraints. A wall serves simultaneously as an obstacle requiring avoidance and as a reference boundary for path guidance. By assigning such behavioral roles to building elements, POI frameworks transform static architectural representations into semantically rich spatial models that encode how robots should perceive, interpret, and interact with their operational environments.

This paper presents a comprehensive framework for semantic POI-based robot navigation that leverages IFC through systematic semantic enrichment. By embedding POI behavioral roles as native IFC metadata, the framework enables a semantics-first approach where building elements carry robot-operational intelligence within the authoritative BIM model, directly informing navigation algorithms without requiring separate POI annotation systems or geometry-derived topology extraction. Virtual Reality simulation in Unity validates that POI-enriched IFC models provide actionable navigation guidance through sensor-based accessibility testing and iterative design refinement before physical construction.

2 Method

The proposed framework integrates BIM-based building representation, semantic POI enrichment, VR simulation, and robot navigation through a systematic methodology comprising four components. Figure 1 illustrates the overall system architecture and data flow. Each component maintains interoperability with standard BIM workflows while introducing robot-specific semantic intelligence necessary for autonomous navigation.

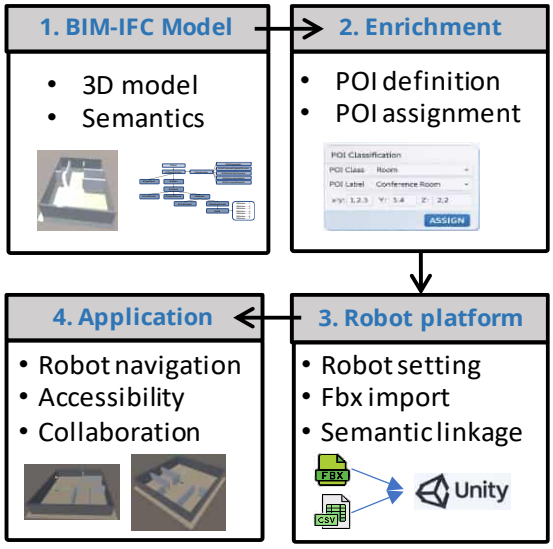

Figure 1. Proposed **F**ramework

2.1 BIM-IFC Building Model Development

Building information is represented as an IFC 4.3 file following standard BIM authoring practices, with building elements organized according to IFC hierarchical structure: IfcWall for boundary elements, IfcDoor for transition openings, IfcSpace for spatial zones (rooms, corridors), and IfcSlab for floor surfaces. IfcOpenShell, an open-source Python library for IFC file manipulation, is employed to parse the IFC model and extract both geometric and semantic information. Rather than developing custom IFC parsers, IfcOpenShell provides robust support for different IFC schema versions and enables straightforward extraction of element attributes through Python dot notation (e.g., IfcDoor.OverallWidth returns door width). The library's geometry processing capabilities convert implicit IFC

geometric representations (swept geometry, boundary representations, compound solids) into explicit mesh data comprising vertices, edges, and faces with absolute coordinate placement, eliminating the complexity of handling relative IFC placement hierarchies.

For each IFC element, the extraction process captures: (1) Global Unique Identifiers (GUIDs) for element tracking, (2) geometric parameters including mesh vertices, faces, edges, and spatial coordinates, (3) semantic attributes and element classifications, and (4) spatial hierarchies. This structured dataset serves as the foundation for subsequent POI semantic enrichment, with element GUIDs providing persistent links between IFC entities and their robot-operational metadata.

2.2 Semantic Enrichment with POI Classifications

2.2.1 Formal Mapping Rules

The semantic enrichment process employs a function-based classification framework that systematically assigns POI roles to IFC entities based on their spatial and functional characteristics. This approach ensures framework generalizability across the complete IFC schema, with mapping rules applicable to related IFC entities possessing the relevant functional properties. Five core mapping rules govern POI assignment based on entity function: spatial boundary provision, space connection, spatial containment, fixed object presence, and runtime constraint detection. Table 1 presents the formal mapping rules with representative example entities illustrating rule application across structural, functional, and object-based POI categories.

Table 1: Formal POI mapping rules

Rules	Functional Condition	POI Assignment	Examples
R1	Provides spatial boundary	Structural POI (A-1, A-3)	IfcWall, IfcColumn, IfcCurtainWall, IfcRailing, IfcBeam
R2	Connects two spatial zones	Structural POI (A-2, B-2 if clearance <threshold)	IfcDoor, IfcWindow, IfcRamp, IfcStair, IfcOpening
R3	Defines a spatial container	Functional POI (A-3, C-1, B-1)	IfcSpace (any predefined type or name)
R4	Fixed object or equipment	Object-based POI (A-1)	IfcFurniture, IfcEquipment, IfcDistribution element
R5	Runtime constraint detected	Dynamic role addition (B-2, C-2)	Any element with active sensor feedback

2.2.2 POI Role Taxonomy

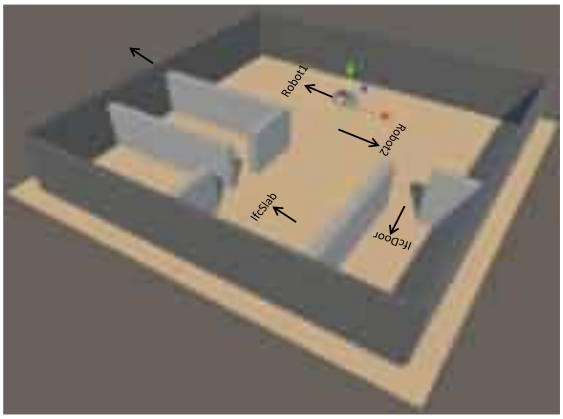
This research demonstrates framework feasibility through three core POI categories essential for autonomous navigation: A-Mobility, B-Safety, and C-Coordination. Table 2 defines the complete role taxonomy for these categories, specifying seven operational roles that govern robot behavioral responses to building elements during navigation.

Table 2 POI role taxonomy

Category	Code	Role Name	Robot Behaviour
A-Mobility	A-1	Avoidance	Maintain clearance
A-Mobility	A-2	Transition	Verify clearance, control passage speed
A-Mobility	A-3	Path Guidance	Use as a trajectory reference
B-Safety	B-1	Hazard Zone	Proceed with caution
B-Safety	B-2	Narrow/Congested	Reduce speed
C-Coordination	C-1	Multi-Robot Zone	Apply the coordination protocol
C-Coordination	C-2	Robot-Robot Interaction	Maintain separation, adjust speed

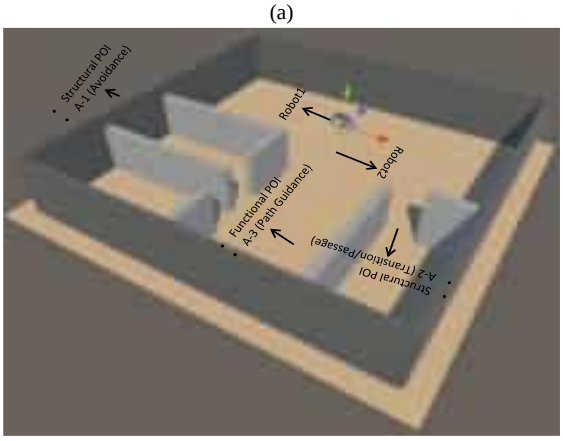
2.2.3 IFC Property Set Extensions

Three custom property sets are programmatically attached to IFC entities using IfcOpenShell property manipulation capabilities, extending standard IFC entities with robot-operational metadata while maintaining full backward compatibility with BIM authoring and viewing software. Pset_POI_Classification (attached to all relevant entities) defines POI_Category {Structural, Functional, Object-based}, POI_Type {Boundary Element, Transition Element, Space Type}, POI_PrimaryRoles [array of assigned role codes], and POI_ConditionalRoles [runtime-assignable roles based on sensor feedback]. Pset_RobotAccessibility (attached to IfcDoor, IfcSpace) specifies MinClearanceWidth (meters),



MinClearanceHeight (meters), AccessibilityStatus {FULL_ACCESS, RESTRICTED, BLOCKED, PENDING_VALIDATION}, ValidationMethod {SENSOR_BASED, GEOMETRIC_ANALYSIS, MANUAL}, and LastValidated (timestamp). Pset_RobotCoordination (attached to IfcSpace) establishes MaxSimultaneousRobots (integer), MinInterRobotSeparation (meters), CoordinationProtocol {YIELD, PRIORITY_PASS, SPEED_REDUCTION}, and AppliesTo {ALL_ROBOTS, SPECIFIC_TYPES}.

Following semantic enrichment, building data is exported in dual complementary formats: (1) geometric representations as FBX format preserving 3D mesh geometry, hierarchical structure, and material assignments for Unity import, and (2) semantic data as CSV tabular format containing element GUIDs, POI classifications, behavioural role codes, and property set values for runtime mapping within the VR simulation environment. This dual-export strategy ensures that both geometric fidelity and semantic richness are transferred to the VR platform while maintaining clear data provenance linking virtual building elements to their authoritative IFC representations.



To validate the formal mapping framework, this research applies the enrichment methodology to a representative subset of IFC entity types covering structural elements, opening elements, and spatial zones essential for indoor robot navigation. Table 3 presents POI role assignments for the demonstration entities, illustrating systematic application of the formal mapping rules defined in Table 1. The framework is not limited to these six entities; rather, the function-based mapping rules (R1–R5) generalize to any IFC-compliant building model. Additional entity types, such as IfcColumn, IfcRamp, IfcStair, IfcFurniture, and IfcEquipment, can be enriched through identical rule application based on their functional characteristics. Also, Figure 2 presents an example of a visual POI assigned role to IFC classes.

Table 3 POI role assignments for demonstration

IFC Entity	Function	POI Category	Roles
IfcWall (exterior)	Building boundary	Structural POI	A-1, A-3
IfcWall (corridor)	Navigation boundary	Structural POI	A-1, A-3
IfcDoor	Space transition	Structural POI	A-2; cond. B-2
IfcSpace (corridor)	Shared navigation	Functional POI	A-3, C-1
IfcSpace (room)	Task destination	Functional POI	Destination
IfcSlab (floor)	Surface reference	Structural POI	A-3

2.3 POI-Driven Navigation Logic

The POI-enriched IFC data informs robot navigation through a systematic decision process that queries semantic properties at runtime and translates POI role assignments into behavioural responses. Algorithm 1 presents the navigation logic executed when robot sensors detect building elements within operational range. The algorithm demonstrates how POI semantic enrichment enables context-aware navigation decisions: sensor detections are matched to IFC entities via GUIDs, POI roles determine behavioural responses, and conditional roles are dynamically activated based on runtime spatial assessments.

Algorithm 1: POI-Driven Navigation Decision

Input: Robot position P, Sensor readings S, POI database D

Output: Navigation action A

```
Begin
    FOR each element E detected by sensors S:
        GUID = GetElementIdentifier(E)
        POI = QueryDatabase(D, GUID)
        roles = POI.PrimaryRoles UNION POI.ConditionalRoles
        IF A-1 (Avoidance) IN roles THEN
            MaintainClearance(E, minimum_distance)
        END IF
        IF A-2 (Transition) IN roles THEN
            clearance = POI.Pset_RobotAccessibility.MinClearanceWidth
            IF SensorClearance(E) < clearance THEN
                AddConditionalRole (E, B-2)
                SetAccessibilityStatus(E, RESTRICTED)
            ELSE
                SetAccessibilityStatus(E, FULL_ACCESS)
            END IF
        END IF
        IF C-1 (Multi-Robot Zone) IN roles THEN
            separation = POI.Pset_RobotCoordination.MinInterRobotSeparation
            IF DetectRobot(S) AND RobotDistance() < separation THEN
                AddConditionalRole (E, C-2)
                ExecuteProtocol(SPEED_REDUCTION)
            END IF
        END IF
        IF A-3 (Path Guidance) IN roles THEN
            UseAsTrajectoryReference(E)
        END IF
    END FOR
    RETURN ComputeNavigationAction(roles)
        End
```

2.4 Robot Navigation Platform in Unity VR

The robot navigation platform is implemented using Unity 6, a real-time 3D development engine providing physics simulation, sensor emulation, and interactive visualization capabilities. The FBX geometric model is imported into Unity, reconstructing the building environment with accurate spatial relationships and dimensional properties. Each imported building element is configured with physics components, including colliders for collision detection and rigid body properties where dynamic interactions are required. The CSV semantic data file is parsed within Unity using a custom POI Manager script that establishes mappings between Unity GameObjects (identified by name) and their associated IFC entities (identified by GUID). Each building element GameObject receives a POI Component attachment encoding its POI category, type, behavioural roles, and robot-navigation parameters extracted from the CSV data, enabling runtime queries by robot navigation algorithms to determine appropriate behavioural responses.

Two robot platforms are instantiated as autonomous agents within the Unity environment, each equipped with physics-based locomotion systems (mass: 5 kg, movement speed: 5.0 m/s, rotation speed: 100°/s), five-directional sensor arrays, and rotating brush mechanisms (500°/s). The sensor configuration projects rays at angular offsets of 0° (forward-center), ±30° (forward-angled), and ±90° (lateral) with 5.0m detection range, providing real-time visual feedback through color-coded visualization: Robot1 displays green (clear) and red (obstacle detected) sensor rays, while Robot2 displays green and blue rays for multi-robot visual distinction during simultaneous operation. Independent control schemes enable concurrent operation: Robot1 via arrow keys and Robot2 via WASD keys, with graphical interface buttons providing brush activation toggles. A dual-camera system (top-down and perspective views) switchable via keyboard input enables comprehensive observation of navigation scenarios from multiple vantage points. Figure 3 presents the Unity platform interface and robot physics configuration.

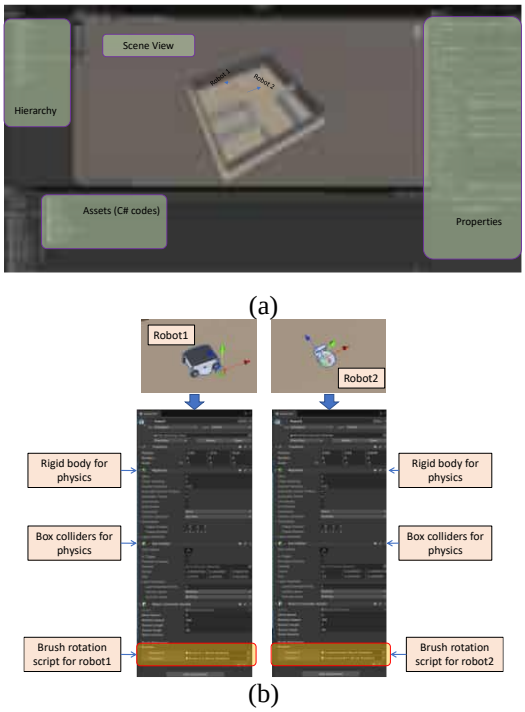

Figure 3. (a) Interface of the platform, and (b) example of physics properties assignment into the robot.

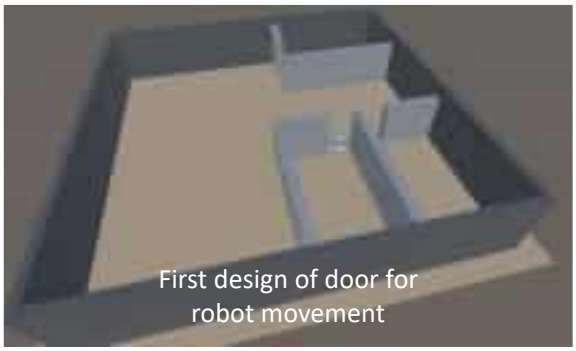
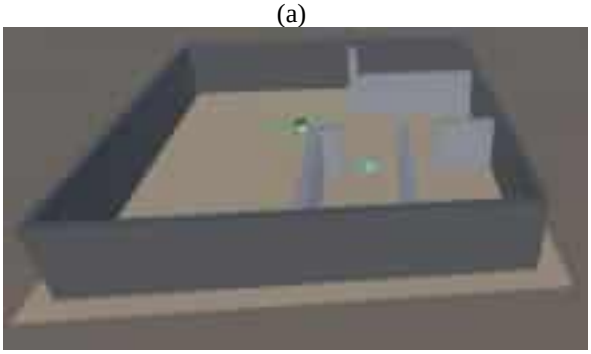
3 Validation Scenarios



The POI-enriched framework is validated through

three sensor-based navigation scenarios demonstrating how semantic building information directly informs robot behavioural responses.

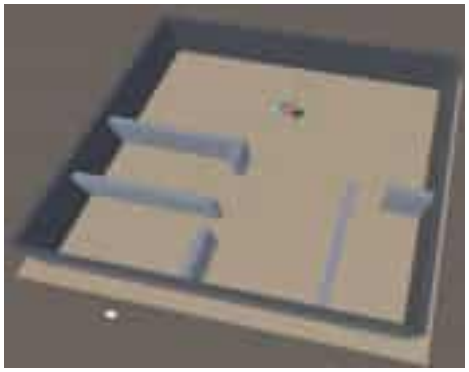


3.1 POI-Driven Doorway Accessibility Validation

The interior doorway connecting the central corridor to Room 2 is initially designed at 0.80m width, meeting standard architectural requirements for human passage but not validated for robot clearance constraints. The doorway's IFC entity (IfcDoor) is enriched with Pset_POI_Classification, assigning Structural POI category, Transition Element type, and A-2 (Transition/Passage) primary role, while Pset_RobotAccessibility specifies MinClearanceWidth = 0.90m as the robot platform's minimum safe passage requirement. As Robot2 approaches the doorway from the corridor at 5.0 m/s navigation speed, the five-directional sensor array evaluates spatial clearances against POI-defined constraints. The forward-center sensor (0°) maintains green status throughout approach, detecting unobstructed passage through the doorway centerline. However, both forward-angled sensors (+30° and −30°) transition to blue at 1.8m approach distance, detecting door frame edges within their angular projection cones at ranges below the 5.0m detection threshold. This sensor pattern indicates that while direct centerline passage is geometrically feasible, approach trajectories at ±30° encounter insufficient clearance margins. The simultaneous blue status of angled sensors triggers conditional POI role addition: the doorway classification updates from A-2 (Transition/Passage) to A-2 + B-2 (Transition with Narrow/Congested constraint), and Pset_RobotAccessibility.AccessibilityStatus property is set to restricted.

Based on sensor feedback indicating inadequate clearance at angled approach vectors, the building geometry is iteratively refined within the BIM authoring environment. The doorway width is increased from 0.80m to 1.20m (50% expansion), the IFC model is re-exported, and POI enrichment is reapplied with updated dimensional properties automatically reflected in Pset_RobotAccessibility parameters. Robot2's subsequent approach to the modified doorway produces distinctly different sensor responses: all forward sensors (0°, ±30°) now maintain GREEN status throughout the approach, indicating that door frame edges remain outside the ±30° detection cones even at proximity. The POI conditional role reverts to standard A-2 (Transition/Passage), and AccessibilityStatus updates to FULL_ACCESS. Figure 4 presents comparative sensor visualizations showing before-modification (BLUE angled sensors) and after-modification (GREEN angled sensors) states.

(a)



(b)

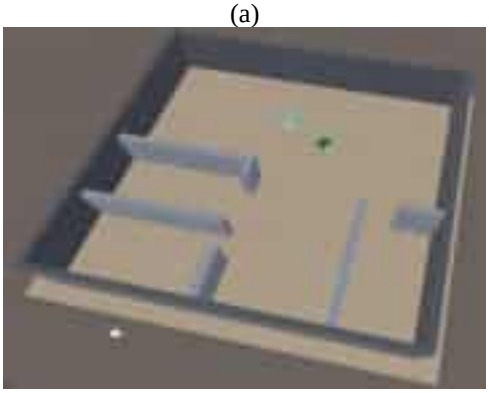


Figure 4. Doorway Validation Comparison

3.2 Multi-Robot Safe Separation Validation

Multi-robot coordination capabilities are validated through scenarios where both Robot1 and Robot2 navigate shared corridor spaces classified as Functional POI with C-1 (Multi-Robot Zone) role assignments. The central corridor IfcSpace entity is enriched with Pset_RobotCoordination specifying MaxSimultaneousRobots, MinInterRobotSeparation of 2.0m between them, and CoordinationProtocol set to SPEED_REDUCTION. As the two robots approach each other from opposite corridor ends, their sensor arrays continuously monitor inter-robot distances. When the separation distance decreases below the 2.0m threshold defined in the POI metadata, both robots trigger C-2 (Robot-Robot Interaction) conditional role activation and execute coordinated speed reduction from 5.0 m/s to 2.5 m/s (50% reduction), maintaining safe operational spacing while allowing continued navigation through the shared zone. Visual sensor feedback differentiates robot detection through color coding: Robot1 displays red rays when detecting Robot2, while Robot2 displays blue rays, enabling clear visualization of proximity detection and coordination protocol execution. This validation demonstrates how the Pset_RobotCoordination property sets embedded in IfcSpace entities directly govern multi-agent behavioural responses without requiring external coordination systems.

Figure 5. Multi-robot safe separation validation

3.3 Corridor Navigation Using Wall-Following Behaviour

Robot1 navigates along the central corridor by maintaining alignment parallel to the left wall boundary, classified as a Structural POI with A-3 (Path Guidance) role. The lateral sensor (+90°) continuously monitors the wall at 0.5m standoff distance, providing trajectory reference for corridor navigation. The wall POI classification enables the robot to use the corridor boundary as a navigation reference point, maintaining centered trajectory while moving toward the target room. This scenario validates how POI-enriched building elements provide spatial guidance for autonomous navigation beyond simple obstacle avoidance.

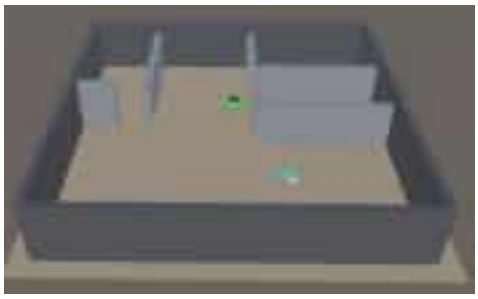

Figure 6. Corridor Navigation Using Wall-Following Behaviour

4 Discussion and limitations

The integration of POI classifications into IFC building models extends BIM utility beyond architectural documentation into autonomous robot operations. Traditional IFC entities provide geometric and material specifications adequate for construction management, yet lack behavioural semantics necessary for robot navigation algorithms to make context-aware decisions. The POI enrichment methodology transforms passive building descriptions into active navigation frameworks by augmenting standard IFC property sets with robot-operational intelligence accessible at runtime.

POI semantic enrichment operates at three levels: classification (Structural, Functional, Object-based categories organize elements by navigation role), behavioural (role codes encode specific responses such as deceleration near narrow passages or coordination in shared corridors), and validation (POI-defined thresholds provide quantitative criteria for automated accessibility assessment). The doorway validation scenario demonstrates proactive design optimization absent from conventional BIM workflows, rather than discovering accessibility constraints post-construction, the POI-driven simulation identified insufficient clearances during design, enabling cost-effective geometric modifications validated through iterative virtual testing.

The current implementation exhibits four primary limitations. First, the validation environment represents simplified geometry that does not capture real-world facility complexity, including furniture clutter, irregular layouts, and environmental variability. Second, validation relies exclusively on virtual Unity simulation rather than physical robot deployments in real buildings. Third, manual semantic enrichment becomes labour-intensive for large-scale projects; automated POI assignment algorithms would significantly improve scalability. Fourth, the POI role taxonomy has been validated only for a subset of role codes through demonstration scenarios, with comprehensive empirical validation across all role groups remaining necessary for full framework validation.

5 Conclusion

This research presents a framework for semantic POI-driven robot navigation through systematic IFC building model enrichment. By augmenting standard BIM entities with robot-oriented POI classifications and behavioural role assignments via three custom property sets (Pset_POI_Classification, Pset_RobotAccessibility, Pset_RobotCoordination), the framework transforms conventional architectural models into semantically rich spatial representations that directly support autonomous navigation while maintaining full compatibility with

existing BIM workflows. Unity VR-based validation confirms that POI-enriched building models provide actionable guidance for robot systems, with the doorway accessibility case study demonstrating sensor-based validation that identified and corrected spatial constraints during virtual design iteration before physical construction.

The framework's contribution extends beyond technical implementation to establish conceptual foundations for robot-compatible building design. By formalizing robot-operational requirements as standardized IFC metadata, the research provides a pathway toward automated accessibility assessment tools and building standards that explicitly accommodate autonomous robotic systems alongside human occupants. Future research directions include validation in complex real-world environments, integration with physical robot platforms, development of automated POI assignment algorithms, and engagement with BuildingSMART International to establish formal POI classification standards within the IFC specification.

Process-Aware Reward Modeling for Automated Construction Planning

Akarsth Kumar Singh and Shang-Hsien Hsieh

Department of Civil Engineering, National Taiwan University, Taiwan

Abstract –
Construction planning remains error-prone because existing automated approaches primarily assess final schedules and lack mechanisms to evaluate intermediate planning decisions. As a result, early-stage errors in task decomposition, sequencing, or duration estimation can propagate unnoticed across planning stages. This study proposes a process-aware framework for automated construction planning that embeds planning-time supervision through a construction-specialized Process Reward Model (PRM). The framework integrates sequential multi-stage plan generation with rubric-based Small Language Model (SLM)-as-a-Judge evaluation to generate step-level quality signals, which are used to train the PRM to predict the quality of partial planning states. Experiments on real-world building construction data show that the PRM achieves 78% agreement with human-verified evaluations while reducing evaluation cost by approximately 50× and inference time by more than 5× compared to SLM-as-a-Judge assessment. The results indicate that process-level reward modeling provides scalable and efficient quality assurance for structured planning elements such as work breakdown consistency and resource feasibility, while serving as a pre-screening mechanism for complex dependency reasoning.

Keywords –
Automated Construction Planning, Process Reward Model, SLM-as-a-Judge, Process-Level Evaluation, Large Language Model

1 Introduction

Construction projects worldwide continue to experience significant delays and cost overruns, largely due to inadequate planning and scheduling, limited resource availability, and inefficient decision-making processes [1][2]. Developing a reliable construction schedule requires identifying activities from extensive contract documents and transforming them into structured planning elements. This process is typically performed manually, making it time-consuming, inconsistent, and susceptible to human error [3][4]. Although conventional project management software supports schedule generation, it provides little capability to assess planning quality during the progressive decomposition of complex construction scopes into executable work packages.

Recent advances in construction informatics have explored the use of large language models (LLM) and natural language processing (NLP) for activity extraction from textual documents [3][5], knowledge graphs for adaptive work packaging and reasoning [6], and machine learning techniques for schedule enhancement and optimization [7]. While these approaches improve automation and efficiency, they primarily focus on extracting information or validating final schedules. They do not explicitly assess intermediate planning decisions, including task decomposition, dependency formulation, and duration estimation.

In parallel, process reward models (PRMs) have recently shown strong potential in improving reasoning performance in domains such as mathematics [8], financial analysis [9], and question-answering systems [10]. Unlike conventional reward mechanisms that evaluate only final outputs, PRMs assess the quality of intermediate reasoning steps. Domain-specific PRMs, such as Fin-PRM, further demonstrate that embedding expert knowledge and procedural constraints leads to substantial performance gains [9]. Despite this progress, no PRM framework has been developed for construction planning, a domain characterized by sequential, interdependent decisions that must satisfy constructability rules, resource constraints, and contractual requirements.

This gap is particularly critical because construction planning errors tend to propagate across multiple stages, including work breakdown structure development, task sequencing, duration estimation, and resource allocation. General-purpose language models lack the domain knowledge required to reliably evaluate intermediate planning states against industry practices and project-specific constraints [11][12]. As a result, automated planning systems remain vulnerable to infeasible or low-quality schedules.

To address this limitation, this study proposes a process-aware framework for automated construction planning that integrates sequential plan generation, domain-calibrated LLM-as-a-Judge evaluation, and Process Reward Model (PRM) training. Construction planning is decomposed into four stages—work breakdown structure generation, task relationship identification, duration estimation, and resource allocation—evaluated using construction-specific rubrics to produce step-level quality signals that guide generation. Validation on real-world building projects shows that the approach (i) provides construction-specialized process-level supervision for planning, (ii) enables planning-time quality assurance rather than post-hoc validation, and (iii) supports transferable planning knowledge across similar projects. The study further introduces a hybrid evaluation framework in which the PRM performs planning-time screening of structured planning logic, while complex dependency reasoning is selectively validated using higher-fidelity evaluators.

2 Related Work

2.1 Automated Construction Planning

Construction planning remains largely dependent on manual expert judgment and semi-structured representations [4]. A three-decade review showed that although automated methods for scope definition, WBS generation, and sequencing exist, most projects still rely on manual workflows due to inflexible knowledge representations, dependence on manually maintained templates, limited learning from historical data, and weak integration between planning and optimization [7]. Earlier rule-based and optimization approaches, including genetic algorithms, require predefined task networks, limiting generalizability [13]. BIM-based 4D planning remains labor-intensive to maintain [14], while knowledge graph approaches improve semantic work packaging but rely on explicitly constructed graphs and do not infer implicit constructability logic from documents [6].

2.2 Large Language Models in Construction

NLP and LLMs have been applied to construction documents with high accuracy in activity and procedural information extraction [3][5][18], but these methods focus on retrieval rather than complete schedule generation. Learning-based approaches have modeled task dependencies and improved scheduling performance [7][12]. Multi-LLM pipelines with SLM-as-a-judge evaluation have also been proposed [11]; however, supervision is limited to synthetic WBS and construction description generation and post-hoc evaluation of final outputs, leaving intermediate planning stages unsupervised.

2.3 Process Reward Models

PRMs evaluate intermediate reasoning steps rather than only final outputs and have demonstrated notable performance gains in structured domains. Trajectory-aware PRMs improve mathematical reasoning by incorporating step-level supervision [8], while domain-specialized models such as Fin-PRM enhance financial reasoning through procedural and factual verification [9]. Generative PRMs further strengthen step-wise evaluation using chain-of-thought verification with limited supervision [16][10].Despite these advances, existing PRMs assume well-defined correctness criteria and structured reasoning spaces. Construction planning, by contrast, involves constraint satisfaction across constructability logic, resource feasibility, document alignment, and industry standards, which cannot be directly addressed using current PRM formulations.

2.4 LLM-as-a-Judge Evaluation

LLM-as-a-judge approaches enable rubric-based, domain-specific evaluation beyond generic accuracy metrics and correlate strongly with expert judgment when customized criteria are applied [17]. In construction contexts, rubric-guided evaluation has been used to assess planning completeness, hierarchical consistency, and task relationship correctness, including SLM-as-a-judge assessment [11][18]. However, these approaches operate post-hoc, requiring additional inference passes after plan generation, introducing computational overhead and preventing real-time feedback. In contrast, the proposed framework embeds a construction-specialized PRM directly within the planning loop, enabling planning-time guidance of intermediate decisions and mitigating error propagation across planning stages.

2.5 Research Gap

Despite advances in LLM-based planning, construction planning lacks a process-level supervision framework that validates intermediate decisions during generation. Existing approaches emphasize final-output evaluation, allowing decomposition and sequencing errors to propagate unchecked. Current PRMs are limited to domains with explicit correctness criteria, restricting their applicability to construction planning. This study addresses this gap by introducing a construction-specialized process reward modeling framework that incorporates explicit evaluation of intermediate planning decisions and integrates quality guidance throughout the reasoning process.

3 Methodology

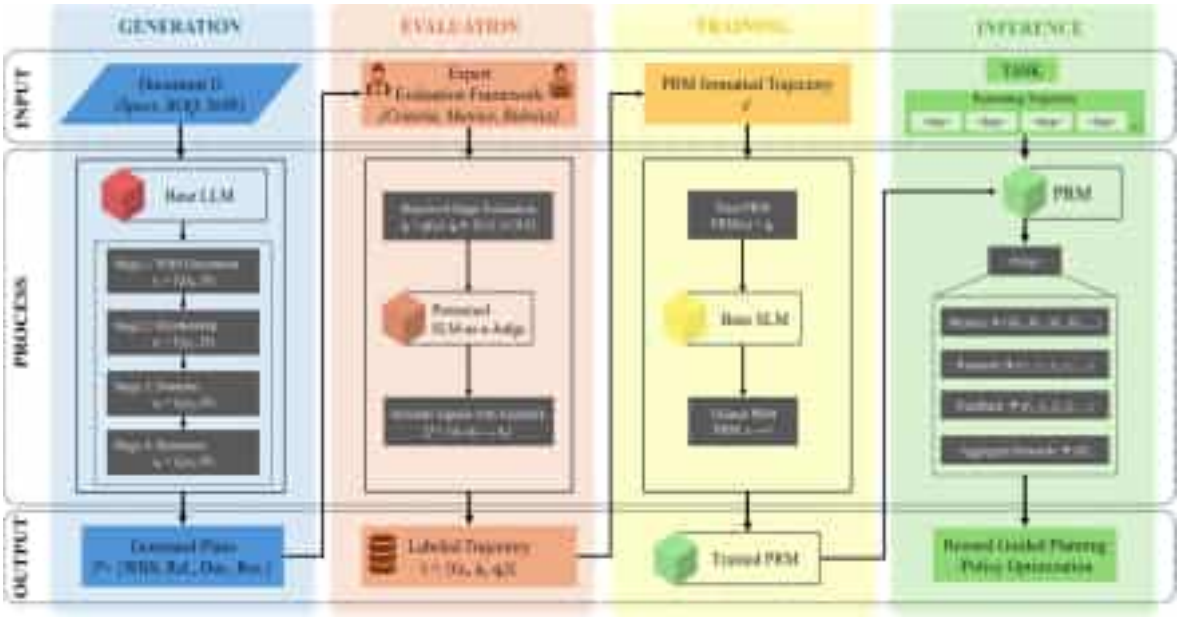

Figure 1. Overview of Methodology

This study proposes, as shown in Fig. 1, a process-aware framework for automated construction planning that integrates sequential plan generation, intermediate quality evaluation, and learning-based guidance. The framework operates in three stages: (1) sequential construction planning generation, (2) intermediate evaluation using a large language model acting as a judge, and (3) PRM training. Construction inputs are represented as the document set D defined in Eq. (1), while the generated construction plan P is defined in Eq. (2). Stage-level quality signals produced during planning are denoted by Q in Eq. (3). The PRM is formulated as a mapping from partial planning states to predicted quality rewards, as shown in Eq. (4).

$$D = \{\text{specifications,BOQ,scope}\} \quad (1)$$

$$P = \{WBS, Relationship, Duration, Resources\} \quad (2)$$

$$Q = \{q_1, q_2, \dots, q_n\} \quad (3)$$

$$\text{PRM}: s \rightarrow r \quad (4)$$

3.1 Sequential Construction Planning

Construction planning is formulated as a sequence of interdependent decision stages reflecting standard project workflows. Rather than generating a complete schedule in a single step, the framework incrementally transforms a partial planning state s_t into a refined state s_{t+1} using a stage-specific planning operator, as expressed in Eq. (5).

$$s_{t+1} = f_t(s_t, D) \quad (5)$$

This sequential formulation exposes intermediate planning states and enables targeted evaluation and correction across work breakdown formulation, task relationship reasoning, duration estimation, and resource allocation stages.

3.2 Intermediate Evaluation via SLM-as-a-Judge

Intermediate planning states are evaluated using a domain-calibrated LLM acting as a judge. For each planning stage t, the evaluator assigns quality signals using two instruments: binary scores $q_t \in \{0,1\}$ for structural validation checks (e.g., schema compliance, field presence), and 5-point Likert scores $q_t \in \{1,...,5\}$ for reasoning dimensions admitting partial credit. The stage-level signal is the mean across all applicable metrics within a step, with Likert scores linearly rescaled to [0,1], yielding a normalized composite reward $q_t \in [0,1]$ as defined in Eq. (6).

$$q_t = \text{g}(s_t), \text{q}_\text{t} \in \{0,1\} \text{ or } [0,5] \quad (6)$$

Each scale point is anchored to a domain-specific behavioral descriptor; for example, for Sequence Logic Explained: 1 = no sequencing rationale provided; 5 = explicit constructability justification for every task link (e.g., formwork must precede concrete pour as it defines the structural mould). In addition to the scalar quality signal, the evaluator generates structured textual feedback identifying logical inconsistencies, feasibility issues, and misalignment with the source construction context/documents; this feedback is used for analysis and interpretation but does not constitute the reward signal.

3.3 Process Reward Model Learning

Outputs from the evaluation stage are aggregated into labeled planning trajectories, where each trajectory captures the partial planning state, the corresponding planning action, and the assigned quality signal, as formalized in Eq. (7).

$$\tau = \{(s_t, a_t, q_t)\}_{t=1}^{T} \quad (7)$$

The PRM is trained to approximate the evaluation function by predicting the quality signal associated with a given partial planning state, as shown in Eq. (8).

$$\mathrm{PRM}(s_t) \approx q_t \quad (8)$$

During planning, the PRM guides decision-making by scoring candidate actions and selecting the action expected to yield the highest-quality planning outcome, as expressed in Eq. (9).

$$a_t^* = \arg\max_{a \in A_t} \mathrm{PRM}(s_t \oplus a) \quad (9)$$

Critically, this selection mechanism relies on ordinal ranking rather than precise cardinal scoring. The PRM is not required to predict absolute quality values, but only to consistently rank candidate actions such that an action a_1 leading to a higher-quality planning state is preferred over a_2. This distinction between relative comparison and absolute evaluation is central to the effectiveness of PRM-guided construction planning. Unlike SLM-as-a-Judge evaluation, which is applied after plan generation, the PRM is queried during the planning process to score candidate actions and guide selection toward higher-quality intermediate states. This guidance mechanism enables early suppression of low-quality planning paths and improves robustness and interpretability.

4 Experimental Setup

4.1 Dataset Construction

The experimental dataset is derived from a real-world high-rise residential building project comprising a reinforced concrete (RCC) framed structure of 22 floors above ground, with more than 2,500 scheduled activities spanning structural works, all internal and external architectural finishing, and full mechanical, electrical, plumbing, and fire protection (MEPF) systems. The majority of these activities represent repetitions of the same work types across different floors and locations. To avoid redundancy and prevent overfitting the PRM on structurally identical samples, 243 unique activity types were selected, capturing the minimum sufficient set of distinct planning scenarios across all domains. Selected activities were manually reviewed for completeness, clarity, and representativeness, producing a high-quality seed dataset for generation and evaluation.

4.2 Sequential Planning Generation

For each activity, synthetic Bill of Quantities (BOQ) detailed descriptions were generated following the procedure established in prior work [11]. These BOQ descriptions serve as the primary input documents for the multi-stage planning generation process.

At each planning stage, the system generates step-wise reasoning traces structured as ⟨Thought, Analysis, Decision⟩ triplets, followed by a stage-specific structured output that conforms to a predefined schema. This explicit reasoning decomposition exposes intermediate decision-making processes and enables targeted evaluation of planning logic at each stage. The complete generation workflow is formalized in Algorithm 1.

Algorithm 1: Multi-Stage BOQ Processing with Structured Reasoning
Input: Project data D, BOQ items B, prompt set Π, environment E
Output: Structured representations per BOQ item

1: **Initialize** LLM model and client using E
2: **Load** BOQ items B and project context Cproj from P

3: **for** each b ∈ B do ▷ Item level
4: Cb ← ComposeContext(b, C_{proj})
5: x ← ⊥ ▷ Initial state
6: **for** each stage s∈⟨WBS, REL, DUR, RES⟩ **do** ▷ Stage level
7: T ← GenerateReasoning (s, b, x, Cb) ▷ Thought
8: A ← Derive Intermediate (T, s, Cb) ▷ Analysis
9: x ← Select Structured Output (A, s) ▷ Decision
10: Store (b, s, x)
11: **end** for
12: **end** for

4.3 Step-Wise Evaluation with SLM-as-a-Judge

Each intermediate reasoning step produced during planning is evaluated using a rubric-based assessment framework calibrated for construction planning tasks. The evaluation combines binary validation metrics (0 or 1) with fine-grained Likert-scale scores (0–5). The framework quantifies reasoning quality across four dimensions applied in Algorithm 2 (lines 8–10 per reasoning step; lines 12–14 for structured output validation): (1) constructability logic via Likert metrics such as Sequence Logic Explained and Lag Time Justification; (2) domain knowledge correctness via binary checks verifying that task names, relationship types (FS/SS/FF/SF), and resource selections conform to industry norms; (3) hierarchical consistency via metrics such as L1–L7 Reasoning Shown and 100% Rule

Verified; and (4) document alignment via traceability checks linking extracted activities and quantities to the input BOQ.

Evaluation is conducted at three levels: (1) step-level assessment of individual ⟨Thought, Analysis, Decision⟩ triplets, (2) validation of stage-specific structured outputs against schema constraints, and (3) cross-stage consistency verification. For each evaluation instance, the judge model returns both a numerical score and explanatory feedback identifying specific strengths or deficiencies in the reasoning trace. The complete evaluation procedure is formalized in Algorithm 2.

Algorithm 2: Multi-Stage Reasoning Evaluation with SLM-as-a-Judge

Input: Stage outputs S, BOQ data B, metrics M, stage config Q, judge J
Output: Quality scores R per stage per sample

Load metrics M and quality config Q
for each stage σ ∈ ⟨WBS, REL, DUR, RES⟩ do
  Load stage outputs Sσ and BOQ data Bσ
  for each sample si ∈ S σ **do**
    Ci ← BuildContext (B σ , σ)
    for each reasoning step rj ∈ si **do**
      Tj ← Merge (rj.thought, rj.analysis, rj.decision)
      for each metric mk ∈ M[σ][rj] **do**
      R[σ][si][rj][mk] ← J.Evaluate (mk, Q[σ][rj], Ci, Tj)
      end for
    end for
    for each validation metric mv ∈ M[σ][val] do
      R[σ][si][val][mv] ← J.Evaluate(mv, Q[σ][val], Ci, si.output)
    end for
    PersistResults(R[σ][si])
  end for
end for
return R

The resulting evaluation dataset consists of labeled planning trajectories with dense, step-wise reward signals. These data support supervised training of PRM that estimate intermediate planning quality and guide future generations toward higher-quality, logically consistent, and feasible construction plans.

4.4 PRM Model Training

The labeled planning trajectories generated by the SLM-as-a-Judge evaluation are used to train the PRM. Each trajectory consists of partial planning states, corresponding ⟨Thought, Analysis, Decision⟩ reasoning steps, and judge-assigned quality scores. The PRM is trained to predict quality signals from partial planning states by minimizing the error between predicted rewards and judge-provided scores. Inputs to the model include the construction context and BOQ descriptions, the planning stage identifier, the accumulated planning state, and the current reasoning step. The model outputs scalar reward predictions aligned with the evaluation scale, using binary values (0 or 1) for validation metrics and discrete scores (0–5) for Likert-scale assessments.

Table 1. PRM training configuration

Item	Value
Model	Qwen2.5-1.5B-Instruct
Adaptation	LoRA (r=16, α=16, dropout=0)
Seq. length	2048
Optimizer	AdamW (lr=2e-4)
Batch / Epochs	2 / 3
Loss	MSE

The PRM is fine-tuned using parameter-efficient adaptation. Key training hyperparameters, including LoRA configuration, learning rate, batch size, and optimization settings, are summarized in Table 1. This setup enables efficient training while preserving the base model's general reasoning capabilities.

5 Results

5.1 Evaluation Setup

The PRM was evaluated against SLM-as-a-Judge reference scores across 251 matched samples spanning four construction planning stages: work breakdown structure generation, task relationship identification, duration estimation, and resource allocation. The SLM-as-a-Judge framework was used to generate reference scores, which were subsequently verified by the authors to ensure consistency and reliability. This combined automated and manual validation establishes a robust ground truth for PRM performance evaluation.

5.2 Overall Performance

Table 2 reports the overall agreement between PRM predictions and the manually verified SLM-as-a-Judge scores. The PRM achieved 78% accuracy with near-zero mean bias (−0.05), indicating it reliably captures relative quality differences between planning candidates without systematic over- or under-estimation. The moderate correlation ($r = 0.515$) confirms the model ranks alternatives consistently with human judgment.

For reward-guided generation (Eq. 9), this ranking

capability is more critical than absolute scoring accuracy: the PRM need only identify that candidate A is superior to candidate B, not assigning objectively correct scores to either.

Table 2. Overall performance metrics

Metric	Value
Samples (n)	251
Accuracy	78%
Pearson correlation (r)	0.515
MAE	0.887
RMSE	1.159
Within ±1.0	65.7%
Mean bias	−0.05

The minimal bias demonstrates the PRM fulfills this comparative function, enabling effective guidance away from low-quality planning paths during iterative generation.

5.3 Stage-wise Performance Analysis

Figure 2 presents a radar comparison of PRM and SLM-as-a-Judge scores across the four planning stages. The PRM shows strongest agreement for WBS generation and resource allocation, with correlations exceeding 0.5 in both stages. In WBS generation, the model performs reliably on scope interpretation and hierarchical structuring, indicating effective evaluation of structured decomposition tasks. Similarly, strong agreement in resource allocation reflects consistent assessment of labor crew composition and equipment selection.

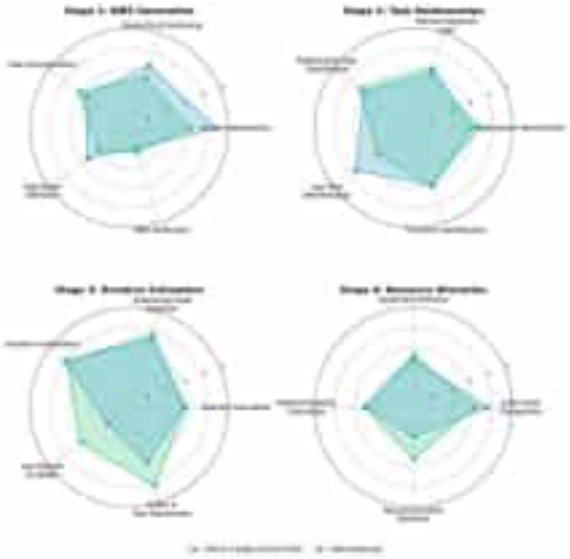

Figure 2. Stage-wise comparison of PRM and SLM-as-a-Judge evaluation scores.

In contrast, task relationship evaluation exhibits the weakest agreement, with near-zero correlation, highlighting challenges in assessing complex task relationship logic, predecessor–successor reasoning, and sequencing rationale. This stage requires multi-step causal reasoning and implicit constructability knowledge, which remains difficult for the current PRM formulation. Duration estimation shows moderate correlation, with the PRM exhibiting conservative scoring tendencies relative to the SLM baseline, particularly for buffer and risk-related considerations.

5.4 Cost–Accuracy and Cost–Time Trade-Offs

The accuracy–cost relationship between PRM and SLM-as-a-Judge is shown in Figure 3. While SLM-as-a-Judge achieves perfect agreement with the verified ground truth, it incurs substantially higher per-sample cost. In contrast, the PRM achieves 78% accuracy at a cost of approximately $0.003 per sample, representing an approximate 50× cost reduction. Cost estimates are based on online GPU pricing for an RTX 3090 (24 GB VRAM, 128 GB RAM) configuration.

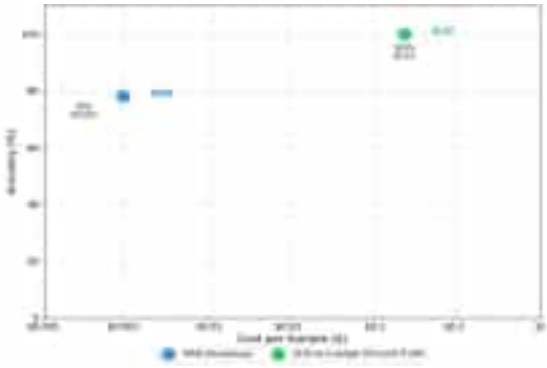

Figure 3. Accuracy–cost trade-off between PRM and SLM-as-a-Judge evaluation

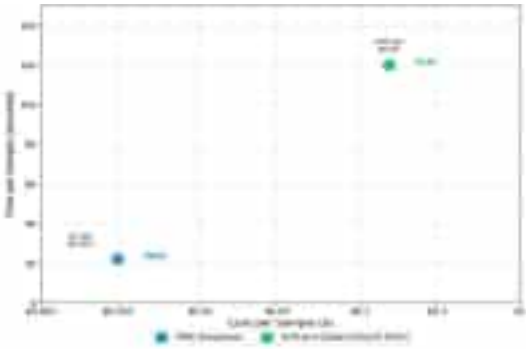

Figure 4. Cost–time efficiency comparison of PRM and SLM-as-a-Judge evaluation

Computational efficiency is compared in Figure 4. PRM inference requires approximately 22 seconds per sample, compared to 120 seconds for SLM-as-a-Judge, resulting in a 5.5× speed-up and an order-of-magnitude reduction in total evaluation cost under the same hardware assumptions. These results demonstrate the practical advantages of PRM for scalable construction planning assessment.

6 Discussion

The results indicate a deployment-aware performance profile rather than a fundamental limitation of the proposed approach. The Process Reward Model (PRM) demonstrates strong agreement for hierarchical planning tasks, including work breakdown structure generation and resource allocation, while exhibiting substantially weaker performance for task relationship evaluation. This divergence reflects differences in underlying reasoning requirements across planning stages.

Task relationship evaluation exposes a fundamental representational boundary of text-based PRMs. While linguistic representations support local and hierarchical reasoning, they do not explicitly encode the global network structure required to enforce precedence, concurrency, and constructability constraints across an activity graph. Multiple dependency configurations may appear locally plausible in text, but only a subset satisfies global feasibility. The near-zero correlation therefore reflects inconsistent scoring of locally valid but globally distinct dependency configurations due to missing structural information, rather than random model behavior.

This stage-wise performance profile motivates a tiered evaluation strategy in which the PRM is deployed as a first-stage screening and guidance mechanism rather than a final certification authority. The PRM's strength lies in comparative ranking of planning candidates based on hierarchical consistency and feasibility, enabling early filtering of low-quality plans. More complex dependency reasoning, which requires explicit topological constraints, can then be addressed using higher-fidelity evaluation methods capable of enforcing global network logic. In this role, the PRM enables focused application of detailed validation within large-scale automated planning pipelines.

Critically, within the iterative planning process of Algorithm 1, absolute correctness of intermediate evaluations is less important than relative improvement across candidate actions. The PRM guides selection by estimating which candidate is likely to yield a higher-quality planning state, rather than certifying global schedule correctness. Even when exact agreement on task relationships is limited, the PRM fulfills its role by consistently identifying inferior candidates and steering generation away from infeasible reasoning paths. This reliance on ordinal ranking rather than precise cardinal scoring, together with minimal systematic bias, explains why the PRM remains effective as a reward-guided planning signal despite imperfect dependency grading.

The PRM further supports this role by requiring substantially fewer computational resources and enabling significantly faster inference than SLM-as-a-Judge evaluation under identical hardware assumptions. This efficiency allows quality assessment to be embedded directly into the planning loop, supporting early suppression of low-quality reasoning paths and iterative refinement of candidate plans.

These findings directly inform future research directions. Improving task relationship evaluation will require incorporating graph-structured representations of task networks and explicit constructability constraints into the PRM input space. Additional opportunities include integrating PRM-based guidance with rule-based schedulability validators and applying active learning strategies to expand supervision in regions where PRM and high-fidelity evaluations diverge. Together, these directions point toward hybrid evaluation architectures that combine linguistic reasoning, structured representations, and deterministic constraints for robust automated construction planning.

7 Conclusion

This study introduces a process-aware framework for automated construction planning that embeds construction-specialized supervision through a Process Reward Model. The primary contribution lies in enabling planning-time quality assessment across intermediate planning stages, including work breakdown structure generation, task relationship formulation, duration estimation, and resource allocation, thereby supporting early identification and correction of planning errors before they propagate.

The framework's key contribution is the explicit alignment of evaluation strategy with representational requirements of different planning tasks. By recognizing that hierarchical decomposition and topological sequencing demand different forms of supervision, the proposed approach positions the PRM as an effective first-stage screening mechanism within a tiered evaluation architecture, while reserving dependency validation for methods capable of enforcing global network constraints.

Beyond immediate performance outcomes, this work clarifies both the strengths and boundaries of text-based intermediate supervision in construction planning and demonstrates how these boundaries can inform system design. Future work will focus on developing graph-augmented PRM architectures, expanding evaluation

across diverse construction domains, incorporating active learning strategies, and integrating learned rewards with deterministic schedulability validation in hybrid planning frameworks and extending the framework to support multi-domain schedule integration and project-level duration computation. Collectively, these directions advance the practical realization of reliable, domain-aware, AI-assisted construction planning systems.

Abstract

Building construction projects are socio-technical production systems in which variance, uncertainty and unpredictable events are the norm. Such systems need short-cycle Plan–Do–Check–Act (PDCA) loops to detect anomalies in production flow as early as possible so that remedial actions can be evaluated and well-informed decisions made. This is the goal of Digital Twin Construction (DTC). We define practical DTC as a minimal coherent system that captures a project's current status, compares the status to design and planning intent, analyses variance, predicts the outcomes of possible interventions, and thus informs specific managerial decisions at the required cadence. We introduce a 'thinking backward' decision-centric design approach for DTC systems that traces requirements from a target decision and its PDCA cycle through knowledge and information needs to data acquisition and enabling technologies. The approach characterizes managerial decisions by autonomy, fidelity, and scope, and proposes five degrees of implementation as system capability configurations for incremental development. This contributes an actionable basis for specifying and incrementally implementing DTC systems that deliver decision value early while maintaining a clear pathway toward more advanced implementations.

Digital Twin Construction; Automation; Lean Construction; Decision-centric System Design; Plan-Do-Check-Act; Knowledge-Information-Data

1 Introduction

Building construction projects are socio-technical production systems where variance, uncertainty, and unpredictable events are the norm [1]. Production rates fluctuate, defects trigger rework, and small human errors can compound into major delays, while design changes, technical constraints, and supply-chain disruptions add further uncertainty. Managing such conditions requires short-cycle PDCA loops [2] to detect deviations early and support timely corrective decisions while recovery remains possible.

DTC [3] addresses this need. It is a data-centric mode of construction management that combines digital-twin information systems with lean construction thinking to close production control loops and support PDCA during the construction phase. DTC workflow continuously compares project intent with updated project status and feeds the resulting evaluations to people or algorithms that intervene on site and verify outcomes in the next cycle.

State-of-the-art research shows progress toward realizing DTC workflows, including interoperable information management layers, increasingly automated progress monitoring. Case studies have demonstrated closure of intent to status to intent feedback loops in live projects [4,5]. These efforts reveal that the key challenge in implementing DTC systems is not the availability of sensing, analytics, or cloud infrastructure, but the design problem of turning these components into coherent decision support pipelines that reliably improve planning and control outcomes. Whereas successful case studies begin from a clearly bounded use case and demonstrate measurable benefits, many other initiatives struggle to translate technological capability into repeatable closed-loop decision making.

A common pattern in both research and practice is a predominantly technology-driven starting point: teams begin from available technologies and only later ask what decisions the system should improve, so that digitalization often fails to deliver full decision value.

We propose a decision-centric perspective for designing practical DTC systems that support incremental adoption without sacrificing coherence. This is a "thinking backward" approach [6] that traces requirements from a target decision and its PDCA cycle back through knowledge and information needs to data acquisition and enabling technologies. It characterizes production planning and control decisions along three dimensions, autonomy, fidelity, and scope, and presents degrees of DTC implementation as coherent system configurations that help teams set realistic targets, avoid overengineering, and plan a stepwise pathway toward stronger closed-loop control.

2 State-of-the-Art in Digital Twin Construction

Sacks et al. [3] introduced DTC as a data-centric mode of construction management that combines digital-twin information systems with lean construction thinking to close production control loops and support PDCA cycles during the construction phase. In the DTC workflow, design and planning intent is formalized as project intent information (the as-designed product and as-planned process). Project intent is continuously compared with project status information (the as-built product and as-performed process), which is derived from raw data from site and supply-chain monitoring that is interpreted using data-fusion functions. Subsequently, the comparisons yield conformance evaluations that inform project status knowledge suitable for proposing possible corrective interventions. In parallel, simulations and analytics produce new project intent knowledge that supports performance prediction and the evaluation of decision alternatives, while bidirectional feedback connects these digital representations back to both planning/design updates and real-time production control on site. Archiving digital building twins that capture all this information enables learning across projects.

Practical DTC systems require a system architecture with explicit data layers and interfaces that integrate sensing, management, and analytics into a decision support pipeline. A common approach uses Semantic Web technologies to link heterogeneous product, process, and status data through open standards. Schlenger et al. [7] addressed the limited guidance on data management layers for DTC by proposing a plug-in-based reference architecture that couples multiple RDF graphs with specialized databases and introduces a Digital Twin Construction Ontology to compare planning information with monitored status, validated on the ConSLAM dataset. Complementing this platform view, Zheng et al. [8] proposed the DiCon-DT framework for construction workflow monitoring, where an ontology network integrates diverse data into a semantic DT data lake and supports simulation and contextual interpretation.

Among the technical building blocks of DTC systems, automated progress monitoring has been developed rapidly. Recent studies demonstrate that imagery and video can support inference of construction progress [9]. For geometry centric assessment, point cloud pipelines continue to improve scan to BIM alignment and association for element level completion inference [10]. Complementary nonvisual sensing provides additional evidence streams that can help connect captured evidence to coordination and compliance actions in management workflows [11].

Beyond monitoring, researchers have connected digital twin status synchronization with simulation and optimization to enable decision models to update assumptions and explore alternatives using current constraints. Work in this area typically targets two horizons: production planning that supports system configuration and medium-term plans, and production control that adjusts daily logistics and execution in near real time. For example, Yeung et al. [12] integrated an ontology based digital twin with parametric agent based simulation to support adaptive production system design, enabling real time data ingestion, status model instantiation, and scenario analysis. Jiang et al. [13] proposed a digital twin-enabled real time synchronization system for just-in-time precast on site assembly that uses real time resource status and construction progress to support planning, scheduling, and execution coordination and dynamic adjustment.

Large scale research and innovation initiatives have also sought to integrate the DTC building blocks into end-to-end prototypes and to validate them beyond isolated case studies. Under the EU Horizon 2020 Digital Building Twins call, a coordinated cluster of projects moved construction phase digital twin concepts toward cloud prototypes that combine data integration with decision support services. BIM2TWIN aligned closely with the DTC system concept by specifying a Digital Building Twin platform based on semantic-linked data from multiple sensor streams into a real time project status model along with data from BIM and project management data, and exposes it through APIs and dashboards for an extensible set of construction management applications. ASHVIN and COGITO complement this platform logic with toolboxes and vertical services for monitoring, planning, and governed workflows, including quality and health and safety functions and traceability mechanisms such as smart contracts. BIMprove focused on real time tracking and field interfaces such as AR and VR to keep BIM and digital twin views synchronized during execution.

Beyond component-level advances, recent full-workflow demonstrators illustrate how DTC concepts translate into closed-loop production control in live projects. Valinejadshoubi et al. [4] implemented a closed-loop production control workflow for a cement silo project by integrating BIM, IoT sensing, and GIS to enable near-real-time progress monitoring, planned versus actual comparisons, and deviation-triggered management actions. Their system coupled a BIM model with an ArcGIS-based digital twin environment and a cloud database, and it streamed formwork sensing data to support timely conformance checking and corrective intervention. They reported a 28% reduction in execution time and a 15% reduction in construction wastage, which they attributed to faster information updates and tighter coordination enabled by the integrated platform.

Martinez et al. [5] presented a mechanized tunnelling demonstrator in which the digital twin closed an intent-

to-status-to-intent loop for bracketry drilling design and installation. The team consolidated TBM and segment-manufacturing data into an as-built tunnel lining model and then used the updated status model to define no-drill zones, perform clash detection, and support bracketry design and execution. Automating this consolidation reduced the per-ring modelling effort from 15 to 20 minutes to about 1 minute of manual quality checks, cutting cycle time by more than 90%. The authors also noted persistent barriers such as imperfect interoperability across proprietary software and hardware systems and the lack of standardized BIM-IFC representations of tunnel geometry and information.

3 Decision-Centric System Design

The state-of-the-art review shows rapid progress toward realizing DTC workflows, including interoperable information management layers, increasingly automated progress monitoring, and end-to-end demonstrators that close intent to status to intent feedback loops in live projects. These efforts also reveal that the hardest part of DTC system implementation is often not the availability of sensing, analytics, or cloud infrastructure, but the design problem of turning these ingredients into a coherent decision support pipeline that reliably improves planning and control outcomes. Whereas successful case studies begin from a clearly bounded use case and demonstrate measurable benefits, many other initiatives struggle to translate technological capability into repeatable closed loop decision making.

A common pattern in both research and practice is a predominantly technology-driven starting point. Teams adopt tools such as cameras, LiDAR sensors, or monitoring services first and only later ask what decisions they improve and how they strengthen a closed-loop PDCA cycle. This opportunistic mindset is understandable. In research, it is often easier to trial novel sensing, algorithms, or system architectures than to define and validate end value across heterogeneous stakeholders. In commercial settings, technology vendors naturally lead with their product propositions and attempt to persuade project teams to adopt their products. As a result, many DTC implementations start from available technologies and then work forward toward decisions and learning loops.

We propose to flip this logic and take a decision-centred approach to DTC system design. DTC is framed as a management paradigm whose core purpose is to support and improve decisions through systematic learning, rather than as an umbrella label for digitalization technologies. The starting point is therefore the set of managerial decisions that are intended to be made within a closed loop PDCA cycle.

Two broad horizons are especially relevant in construction. Production control decisions govern near term execution, including daily coordination, constraint removal, sequencing, workface logistics, and the allocation of crews, equipment, and materials. Production planning decisions shape the production system itself, including adaptive production system design and the periodic reconfiguration of plans, control policies, and resource strategies in response to evolving constraints and performance. In both horizons, the central question is not what the digital twin can technically compute, but what decisions must be made, who makes them, how often they must be revisited, and what learning is expected from repeated cycles.

From an explicit target decision, the system designer can work down through levels of knowledge, information and data. At the knowledge level, a designer asks what knowledge about project intent and project status is needed to make and improve the decision over time, including what must be understood about conformance, deviations, causes, and consequences. At the information level, they ask what information must be synthesized to support those knowledge claims. For example, which state variables, constraints, progress states, resource states, and performance indicators must be explicitly represented. At the data level, they ask what combinations of raw observations can be used to derive that information. Multiple data sets can often support the same information requirements, and direct measurement is not always feasible. In such cases, indirect measurements, partial measurements, or complementary measurements from different tools may be combined through interpretation and data fusion to reconstruct the information of interest. Only once these requirements have been defined explicitly does it become rational to select monitoring solutions, data management strategies, and system architectures that implement a pipeline from data to information and then to knowledge that supports the decision defined at the outset.

This sequence helps avoid over engineering and over complication, because it focuses attention on the minimal sufficient evidence and transformations needed for the decision, rather than on maximizing the volume of captured data or assembling an attractive architecture that lacks a clear operational purpose.

A practical consequence of starting from decisions is that the use case must be characterized in a way that sets realistic expectations for the required system capability and complexity. As illustrated in Figure 1, production planning or control decisions can be described using three parameters with values arrayed along three axes: *autonomy*, *fidelity*, and *scope*. The autonomy axis describes the prospective agency of the human planner in the decision process, ranging from *human decide*, through *human decide with machine advice*, to *machine decide with human supervision*, and ultimately to

machine decide, while recognizing that responsibility, risk, and centralized versus distributed authority create intermediate nuances. The fidelity axis describes how close the information must be to reality for the decision to be valid. Fidelity can be specified through required *precision* or *resolution*, required *accuracy*, *acceptable latency* and *update frequency*. The scope axis describes the breadth and interdependence of the decision within the production system, including whether it is *localized or global*, whether it is a *single decision or a coupled set of decisions*, and whether it creates dependencies and cascading effects across other decisions and system states. Together, these axes help determine whether a simple single component solution is sufficient or whether the use case demands multiple modules, rich data fusion, and/or sophisticated predictive or prescriptive analytics.

We can apply this decision-centric approach to the silo case study [4] reviewed in the previous section. In slip-form construction, the team can first isolate the near-term production-control decisions that plausibly benefit from short-cycle PDCA. The silo workflow supports four such decisions: 1) whether to adjust formwork alignment to maintain verticality and rotation, 2) whether to intervene when curing conditions drift toward risk, 3) whether to change pouring rate and near-term resource allocation to maintain planned progress, and 4) what materials or embedded components to pull to the site next as progress advances. As a group, these decisions remain in the *human decide* autonomy class. They stay within a small and localized scope centred on the silo production-control loop. The use case demands high fidelity, with minute-level temporal resolution and high accuracy, and an hourly update frequency that matches the production-control cadence.

With the decision set fixed, the designer can then trace down the knowledge, information, and data pyramid to elicit system requirements. Figure 2 summarises this trace as a dependency map. At the knowledge level, the four decisions require knowledge of structural alignment relative to intent, curing condition status relative to thresholds, progress versus plan, geometric conformance for embedded elements, and material pull needs for the next work segment. At the information level, these knowledge requirements translate into a minimal set of information products that the system must maintain, including real-time construction parameters, trend histories that expose drift, visual status indicators on the model, progress metrics, alerts that flag excursions, and an as-built versus as-designed overlay that supports conformance assessment. At the data level, the same trace identifies a minimal viable data set and its sources, including distance and inclination sensing for geometry and stability, temperature sensing for curing conditions, BIM intent geometry as the reference for planned states, timestamps to support trend and auditability, and site spatial context where needed for situational framing.

Figure 1. Orthogonal axes characterizing a DTC system use case

This worked example shows how the thinking-backwards approach helps convert a case description into an explicit requirement specification for a practical DTC system. By linking a target decision and its cadence to concrete knowledge, information products, and data sources, the approach guides purposeful technology selection and, equally, prepares the production team to use the resulting information routinely to check conformance and act within the decision window.

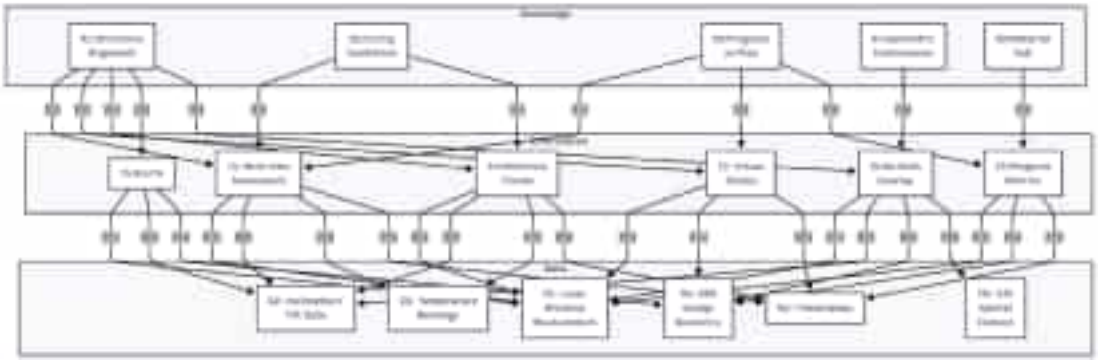

Figure 2. Derivation of required knowledge, information, and data for use cases in Valinejadshoubi et al. [20]

4 Degrees of DTC System Implementation

Building on the decision-centric framing, a key practical question is, "Given a target decision, its requirement for autonomy, fidelity, scope, knowledge, information, and data, what degree of DTC implementation is realistic, and what capabilities must be in place for the PDCA loop to run systematically?" The supportive and autonomous visions of DTC provide useful long-term reference points, but they can also appear overly ambitious when viewed against the realities of construction variability, fragmented responsibilities, and the cost of instrumentation and integration. At the same time, meaningful DTC is not an all-or-nothing proposition. Projects can achieve measurable improvement with partial digitization and partial automation, provided that the system delivers decision support that is traceable to the use case and enables learning across repeated cycles.

This section therefore proposes five degrees of DTC implementation (Figure 3) that describe coherent capability bundles, rather than a checklist of isolated technical features. The degrees presented in Figure 3 are not intended as a strictly linear maturity ladder. Organizations can adopt different degrees for different decisions, and a single project can exhibit mixed degrees across planning horizons and work packages. What changes across degrees is primarily the extent to which the system implements the knowledge-information-data chain for the target decision, and the extent to which monitoring, interpretation, and feedback become structured, repeatable, and timely. Higher degrees typically correspond to higher attainable autonomy, higher fidelity of the intent and status representations, and broader scope of the decision support.

The first degree is **unassisted**. Here, the PDCA loop exists in the traditional sense described in lean construction and production control practice, but it is largely manual and relies on managerial judgement. The only structured digital representation of intent is usually a schedule and associated planning artifacts, while project status awareness is formed through site walks, phone calls, ad hoc updates, and meetings. Teams check progress against the plan and revise near-term commitments, but the evidence base is fragmented and informal, so the loop's effectiveness depends on the availability, memory, and interpretation capacity of the management team.

The second degree is the **digital model**. Relative to the unassisted case, teams deploy monitoring technologies and generate richer project status data, for example through photogrammetry and computer vision, scanning, tagging, or other capture methods that observe both inputs and outputs of the production system. These observations can indicate where labour and materials have been deployed and what intermediate or final products have been installed in specific work zones. The key characteristic is that the data typically flows into the human planner's situational awareness model rather than into a structured digital interpretation pipeline. Project intent information still resides primarily in the schedule, BIM, and planning documents, and the comparison of intent and status remains a human task. This degree is therefore best described as data-augmented rather than systematically data-driven. Richer, more frequent, and potentially more objective observations support decisions, but they do not yet consistently produce consolidated project status information and actionable knowledge.

The third degree is **digital shadow**. This degree retains monitoring of inputs and outputs, but it differs from the digital model in that the system integrates multiple data sources and performs explicit interpretation and data fusion to generate consolidated project status information. Different sensing modalities provide partial views of the production system, and their combination makes it possible to reconstruct a more complete picture across resources, processes, and products. For example, beacons can provide evidence of labour presence and

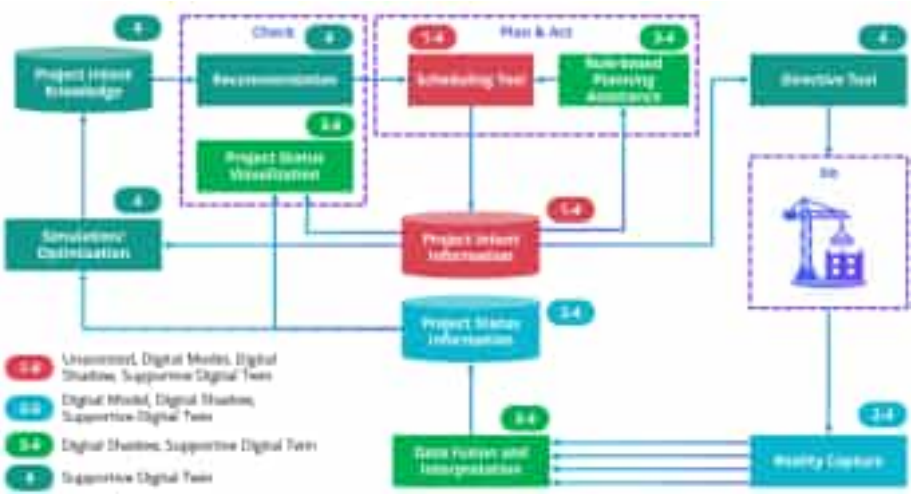

Figure 3. Degrees of DTC system implementation

movement, RFID can indicate material location and consumption, image-based methods can capture visible installation progress, and aerial or terrestrial scanning can characterize geometry for exterior or structural elements. The system uses these complementary observations to support consistent conformance evaluation, not only identifying deviations between intent and status but also helping explain why deviations occur, such as delays driven by missing inputs, rework, or disrupted workflows. Importantly, the feedback loop is increasingly explicit. Updated project intent information, including revised plans and constraints, is recorded and used as input for subsequent evaluations, enabling rule-based planning assistance and systematic iteration across PDCA cycles.

The fourth degree is the **supportive digital twin**. At this degree, the system extends beyond consolidated status to generate project intent knowledge through simulation, analytics, and optimization. The digital shadow foundation provides the evidence base for current state estimation, while predictive and prescriptive modules explore what-if scenarios, estimate consequences, and propose decision alternatives. This corresponds to predictive situational awareness, where the system supports not only understanding what happened and why, but also anticipating what will happen next and evaluating the likely impact of alternative actions. The system remains supportive because the human planner retains decision authority. It provides recommendations, explanations, and visualizations that help the planner decide whether and how to act, and the resulting plan updates are fed back into digital representations to support continuous improvement.

The fifth degree is the **autonomous digital twin**, which can be described as a digital agent governing decision selection. Here, the fused project status information and the project intent information feed an autonomous decision algorithm that evaluates alternatives and selects an action, which is then written back into the project intent representation and issued as directives, policies, or control inputs for execution. In the ideal form, the planner no longer participates in the loop. However, in practice, construction conditions, risk, and capital intensity will motivate a supervised autonomy arrangement in which human planners oversee, approve, or override algorithmic decisions. This makes explainability, traceability, and logging critical, both for operational assurance and for long-term learning through a digital repository of intent, status, and decision histories that can improve future models and algorithms.

Across these degrees, the central point remains consistent with the preceding section: the PDCA loop is not binary. Lower degrees can still run PDCA cycles, but with higher reliance on intuition and informal evidence. Higher degrees make the loop more systematic by formalizing what must be known, what must be inferred, how intent and status are compared, and how actions are selected and recorded. This typology therefore provides a practical bridge from a decision-centric system design approach to implementable system targets.

In relation to existing digital twin maturity models, these degrees align broadly with established capability progressions in the literature, particularly the transition from digital model and digital shadow toward predictive or prescriptive and autonomous twins described in models such as [14] and [15]. The similarity lies in the increasing formalization of data integration, interpretation, and feedback, and in the resulting shift from status visibility toward prediction, decision support, and eventually decision automation. The novelty of the proposed degrees is that they recast this progression for construction planning and control around the implementation of a target PDCA loop rather than around digital twin technological maturity. This shift is reflected first in the inclusion of an explicit unassisted degree, which recognizes that PDCA already exists in practice before a formal digital twin is introduced and therefore starts the framework from the real managerial baseline rather than from the first digital artifact. It is reflected again in the definition of the higher degrees, which are distinguished not simply by more advanced technology but by how systematically the knowledge-information-data chain is implemented to support a specific managerial decision.

5 Discussion

DTC initiatives frequently begin with a technology-first mindset, where teams adopt sensing and analytics tools and then attempt to fit management decisions around whatever data those tools produce. This approach often results in fragmented architectures and unclear value, because it optimizes technical capability rather than strengthening a specific PDCA loop. The framework proposed in this paper reverses that sequence. It starts from a decision that must be improved, and it treats system components as means to close that decision loop reliably.

The autonomy, fidelity, and scope characterization helps developers translate decisions into implementable requirements. Autonomy clarifies who decides and what the system is allowed to do, fidelity clarifies how accurate and timely the information must be, and scope clarifies how far the decision's effects propagate across planning and control. Framed this way, a project team can state what the system must deliver before selecting technologies, which reduces over-engineering and helps align organisational responsibilities, data ownership, and update frequency with the actual decision context.

Once requirements are clear, the knowledge–

information–data decomposition provides a practical route from decision needs to system design. It derives the minimal data capture and processing pipeline from what the decision maker must know about project intent and project status, rather than collecting data opportunistically. This logic supports lean implementation, including the use of partial measurements, proxies, and staged sensing deployments, provided they satisfy the fidelity requirements of the targeted PDCA loop.

Finally, the degrees of DTC implementation position DTC as incremental progress rather than a yes or no achievement. They enable teams to diagnose what a system can currently support and to prioritize the next feasible capability that materially strengthens the decision loop, without assuming that full automation or comprehensive sensing is necessary. The remainder of this discussion illustrates this practicality by applying the framework to three real-world demonstrators.

Table 1 details the proposed characterization with respect to three case studies and shows, first, how each implementation starts from a clearly bounded managerial decision and, second, how the system architecture is designed to deliver the specific status information needed to act on that decision.

Valinejadshoubi et al. [4] targeted concreting crew task assignment. While decisions remained human-centric (human decide), the use case demanded high fidelity with minute-level resolution. Consequently, the system required automated fusion of formwork sensing data to trigger threshold-based recommendations, placing it at the Digital Shadow level (Degree 3).

Similarly, the mechanized tunnelling system [5] supported bracketry design. It operated at a lower temporal cadence (daily) but required precise spatial data fusion. By consolidating TBM and manufacturing data into an as-built model to identify no-drill zones, it provided machine advice, also qualifying as a Digital Shadow.

As part of the EU BIM2TWIN research project, the authors implemented a DTC system for adaptive production system design rather than short-cycle production control [12]. The system integrated an ontology-based digital twin with agent-based simulation to ingest current project status, instantiate the status model, and evaluate alternative production configurations under changing project conditions. Relative to the first two case studies, it added predictive recommendation and supported updating the baseline production plan, but it did not rely on automated reality capture and only partially automated conformance evaluation. It therefore sits between Degree 3 and Degree 4, showing that the proposed degrees are better understood as practical capability regions along a spectrum than as rigid thresholds that a project must fully satisfy before it becomes useful.

Table 1. Classification of use case and degree of DTC implementation for three case studies

Study		**Valinejadshoubi et al. [4]**	**Martinez et al. [5]**	**Yeung et al. [12]**
Use Case		Concreting crew task assignment, conformance checking	Define no-drill zones, perform clash detection, and support bracketry design and execution	Adaptive production system design through adjusting resource, location, and work package parameters
Autonomy		Human decide	Human decide with machine advice	Human decide with machine advice
Fidelity	**Temporal Resolution**	Minute	Day	Day
	Update Frequency	Hourly	Daily	Weekly
	Accuracy	High	High	Medium
Scope		Small	Medium	Medium
Reality Capture		Yes, automated	Yes, automated	No
Data Fusion and Interpretation		Yes, automated	Yes, automated	Yes, automated
Conformance Evaluation		Yes, automated	Yes, automated	Yes, semi-automated
Simulation/Optimization		No	No	Yes, agent-based simulation
Recommendation		Yes, remedial action if monitored concrete condition below preset threshold	Yes, no drill zones per segment	Yes, alternative production system configurations
Report & Visualization		Yes, sensor data visualization and concrete pouring progress	Yes, 3D as-built IFC model with production information per segment	Yes, schedule, progress, and simulation results of alternative plans in visual dashboard
Rule-based Assistance		No	No	No
Directive Tool		No	No	Yes, update new baseline production plan to digital twin repository
Degree of DTC Implementation		3 - Digital Shadow	3 - Digital Shadow	Between 3 – Digital Shadow and 4 – Supportive Digital Twin

Taken together, the case studies show that practical DTC implementation is already feasible with existing technologies when the system is designed around a bounded managerial decision and its associated PDCA loop. The reported outcomes show that meaningful operational value can be achieved without an all-encompassing or highly autonomous twin, provided that the implementation delivers the specific status information, interpretation, and decision support required for that use case with sufficient reliability and cycle time. At the same time, the framework is most readily applied when the target decision and its PDCA loop can be defined clearly. In more highly coupled project settings, applying it may require decomposing interdependent decisions into smaller linked loops before coherent system requirements can be specified. Seen this way, the proposed degrees are not targets to be pursued for their own sake, but a framework for characterizing which capabilities have been implemented, which remain absent, and which additional capabilities are justified by the expected decision value, thus reframing DTC from an idealized end state to a practical system design problem of aligning scope, automation, and decision support with concrete managerial needs.

6 Conclusion

Short-cycle PDCA is needed to manage variance and uncertainty during construction production, yet DTC systems are often conceived based on available technologies and idealized end states rather than being based on the decisions they must support. This paper proposed a decision-centric design perspective and the notion of practical DTC as the minimal system capability required to improve a specific PDCA decision at its required cadence.

The paper introduced three decision axes, derived design principles that trace requirements from the target decision through information and knowledge needs to data acquisition and defined five degrees of DTC implementation to guide staged development. Applied to three real-world case studies, the framework separated the managerial use cases from the particular technologies and architectures used to implement them and clarified that PDCA improvement is achievable at multiple degrees of digitalization and automation. Together, these contributions provide a pragmatic basis for specifying and incrementally implementing DTC systems that prioritize decision value over technology completeness.

Abstract –

This study develops an automated disaster response report generation system that integrates large language models (LLMs), web scraping, and computer vision techniques. The system automatically retrieves data from 16 heterogeneous and distributed sources and, by combining Retrieval-Augmented Generation (RAG) with Chain-of-Thought (CoT) prompting, produces first drafts of disaster response reports that conform to the official reporting framework. Empirical results show that the system achieves a System Usability Scale (SUS) score of 85.8 and reduces report preparation time by approximately 73% for typhoon events and 64% for heavy-rain events. Expert evaluations indicate that the generated content attains acceptable levels of completeness, accuracy, and readability. To further validate content reliability, TLM trustworthiness scores of 0.89 and 0.95 confirm high factual reliability, while RAGAS Faithfulness scores of 0.99 (RAG–CoT) versus 0.43 (vanilla LLM) demonstrate the contribution of the proposed framework. These findings confirm the feasibility and practical potential of the proposed system for automated report generation in professional disaster management contexts.

Disaster Response, Large Language Models (LLMs), Retrieval-Augmented Generation (RAG), Chain-of-Thought (CoT), Credibility Evaluation

1 Introduction

In recent years, extreme weather events have become increasingly frequent worldwide, and the associated economic and social impacts of natural disasters continue to escalate. In Taiwan, weather-related disasters cause average annual economic losses of approximately NT$15 billion (about US$490 million). According to statistics from the Water Resources Agency (WRA), the number of disaster response operations has increased markedly, from about 40–50 per year between 2015 and 2020 to 60–90 per year after 2020. The growing frequency of response operations has substantially increased the workload of frontline personnel. In particular, the preparation of post-disaster response reports—which must be completed within 30 days and serve as critical records for institutional learning—has become one of the most labor-intensive components of disaster response work.

At present, disaster response reports are still written largely by hand through a complex and time-consuming process. Taking the 2024 Typhoon Gaemi response report as an example, the preparation of this report required integrating 16 distinct data sources, compiling 11 tables, and producing 26 figures, resulting in a document of 163 pages. The entire process consumed approximately three full working days. Moreover, the sections describing meteorological evolution require substantial domain expertise; new staff members often need several months of training before independently drafting such reports, and during peak flood seasons, report writing must be conducted concurrently with ongoing emergency operations, further intensifying the burden on already-limited personnel.

In response to these challenges, this study proposes an automated disaster response report generation system that integrates LLMs, web scraping, and computer vision. The system primarily targets typhoon events and large-scale heavy-rain events, and seeks to improve report-writing efficiency through automated data acquisition, chart generation, and draft text generation. Furthermore, the system adopts a RAG–CoT framework and incorporates TLM-based evaluation to achieve the following objectives:

1. Reduce workload and improve efficiency by automating the labor-intensive processes of data collection and initial report drafting.
2. Integrate scattered heterogeneous data into standardized reporting templates, thereby lowering the technical threshold and facilitating the rapid onboarding of new staff.
3. Validate generative performance and content reliability through a hybrid evaluation framework combining expert assessment, TLM credibility scoring, and RAGAS faithfulness metrics.

2 Related Work

This section reviews literature relevant to the proposed system. First, it introduces the structure and

data integration challenges of disaster response reports in Taiwan. Second, it examines the automated report generation technologies adopted in this study, including web scraping, computer vision, and LLMs, and discusses hallucination issues and corresponding mitigation strategies. Finally, it surveys the current applications of LLMs in disaster response, which form the theoretical foundation of this research.

2.1 Disaster Response Report Standards and Architecture

Disaster response reports are key documents in the post-disaster recovery and mitigation cycle. In Taiwan, the Water Resources Administration of the Ministry of Economic Affairs has formulated structured writing standards for disaster response reports, requiring them to systematically present the background of the incident, meteorological and hydrological evolution, response operations, and the actual impact of disasters. These reports cover three core modules: event background and meteorological developments, hydrological status and disaster impact, and response operations and notification records.

However, producing such standardized disaster response reports relies heavily on cross-system data integration. In practice, the information required for the reports is distributed across multiple independent information systems that differ substantially in technical architecture, data formats, and access mechanisms. This study identifies 16 distinct data sources dispersed across 6 web platforms (Table 1), making cross-system integration a highly complex technical challenge. These data sources are maintained by various government agencies and include HTML tables, JSON data, image files (JPG/PNG), and unstructured text. Issues such as missing data and inconsistent time stamps are common. Under tight response timelines, specialists must repeatedly access multiple systems to retrieve and reconcile data, highlighting both the cumbersome nature of existing workflows and the urgent need for automation.

Table 1 Classification of data sources

Category	Primary Source Platforms and Formats
Water Conservancy Monitoring	Alert Issuance Log, Disaster Emergency Response System (TXT, HTML, JSON, DOCX)
Meteorological Information	Weather Analysis and Taiwan Climate Hybrid monitor system (WATCH), Typhoon Database (TXT, JPG, PNG)
External Warning	Public Open Data Platform (TXT)
Marine Conditions	Safe Ocean (XLSX)

2.2 Report Automation and LLMs-Based Technology

In the field of disaster management, automation has been widely adopted to handle multi-source heterogeneous data and real-time requirements. With respect to data collection, web scraping combined with API access has been used to automatically aggregate disaster-related information from government open data portals, alert platforms, and news or social media streams, thereby improving situational awareness[1, 2]. However, most of these studies focus on real-time monitoring dashboards rather than on the long-term event histories and multi-chapter structures required for formal reporting.

For data visualization and chart understanding, prior work has shown that directly summarizing charts using end-to-end language models can easily lead to numerical hallucinations[3]. A more reliable approach is to first recover intermediate structured data (e.g., tables or statistical matrices) from chart images and then apply data-to-text generation, which improves the consistency between textual descriptions and the underlying quantitative data[4]. This suggests that, in the context of formal disaster reports, converting meteorological and hydrological maps into machine-readable structured indicators is an important prerequisite for trustworthy text generation.

LLMs have been widely applied in text summarization, question answering, and automated report generation. Nevertheless, in high-risk professional domains such as disaster response, content accuracy and hallucinations remain major concerns[5, 6]. To address these issues, recent research has proposed strategies such as RAG and CoT[5]. RAG dynamically retrieves verifiable external information during generation, grounding model outputs in authoritative documents and reducing hallucination rates. CoT prompting encourages models to perform step-by-step reasoning, decomposing complex tasks into a sequence of intermediate reasoning steps, thereby improving the structure and interpretability of responses. Empirical studies have shown that combining RAG and CoT can enhance the reliability of generated professional texts while maintaining overall performance.

In the disaster response domain, automated reporting pipelines and disaster information systems have been developed to support situation awareness and documentation, while recent studies survey broader AI applications across multiple phases of disaster management, from early warning to post-event analysis. Recent interdisciplinary reviews indicate that AI and

LLM applications in disaster management span multiple phases—from detection and situation analysis to decision support and post-event documentation—with social media analysis and decision recommendation representing the most mature application areas[7]. For instance, DisasterResponseGPT integrates response guidelines and expert knowledge into prompts to accelerate the formulation of response plans[8]. Beyond individual LLM applications, knowledge graph-enhanced systems have been developed to provide evidence-based recommendations in emergency decision-making scenarios[9], and multi-agent AI frameworks have been proposed to integrate sensing, analysis, and communication functions into unified disaster management architectures [10]. Other studies employ LLMs to aggregate disaster-related texts and integrate multi-source information[11, 12]. However, existing approaches rarely integrate visual information, structured operational data, and standardized governmental reporting formats, and few quantitatively assess content credibility. This study addresses these gaps by proposing a RAG-CoT framework that automatically generates structured, traceable first drafts of Taiwan's water-related disaster response reports with quantitative credibility evaluation..

3 Methodology

This section describes the architecture and implementation of the proposed disaster response report generation system. The core design principle is human–AI collaboration: automated components handle highly repetitive data-integration tasks, while LLMs assist with drafting narrative sections, allowing domain experts to concentrate on high-value judgment and decision-making. The system supports the automatic generation of six sections of a complete disaster response report: Event Overview, Meteorological Situation, Hydrological Information, Emergency Response Team Operations, Disaster Impacts, and Conclusion and Annexes. Among these, the first three sections are highly narrative and require the integration of a large volume of meteorological and hydrological information; consequently, they are the primary focus of the LLMs-based generation strategies in this study.

3.1 System Architecture

The overall system architecture is shown in **Error! Reference source not found.**. It consists of six main modules: Data Collection, Data Acquisition, Data Visualization, Data Analysis, Text Generation, and Report Integration. Through the user interface, report compilers specify the event name and the time ranges for rainfall and water-level data. The Data Collection and Data Acquisition modules then automatically retrieve the raw data required for each chapter from multiple platforms. These data are passed to the Data Visualization and Data Analysis modules, which generate the figures and analytical results required in the report. The Text Generation module uses the structured datasets and analytical outputs to produce draft text for the corresponding sections. Finally, the Report Integration module assembles all generated texts, tables, and figures into a pre-defined Word template, thereby producing a first draft of the disaster response report for the selected event.

3.2 Clarification of Data Sources and Processing Pipelines

To ensure that the automated system can effectively support real-world reporting requirements, the content of the disaster response report was first analyzed and categorized according to information type and generation risk. The report includes both highly descriptive narrative texts and quantitative content—tables and figures—for which numerical accuracy is critical. Relying on a single generation strategy for all content would likely yield uneven quality and factual errors. Accordingly, this study adopts a diverted generation design, in which different sections are handled by different technical pipelines depending on their semantic and numerical requirements. The narrative sections—Event Overview, Meteorological Situation, and Hydrological Information—must synthesize a large number of weather bulletins, observational records, and response logs into coherent textual descriptions. For these sections, the system leverages LLMs with integrated RAG and CoT prompting. Automatically collected and pre-processed meteorological and hydrological data are converted into reference documents that serve as contextual inputs for the LLMs, which in turn generates draft paragraphs aligned with official reporting style and structure. In contrast, sections such as the charts in Hydrological Information, Emergency Response Team Operations, Disaster Impacts, Conclusion, and Annexes are primarily composed of numerical data, statistical tables, and visualizations. The key objectives for these sections are numerical correctness and consistent formatting rather than free-form narrative. For them, the system relies on automated data processing and visualization pipelines to perform data cleaning, computation, and figure/table generation. In practice, the pipeline consists of three steps: heterogeneous inputs from the 16 data sources are first converted into a unified, event-based schema with basic cleaning (e.g., missing-value handling and time alignment). The cleaned data are then aggregated into chapter-specific statistical indicators, which the visualization module uses to automatically generate standardized charts and tables and insert them into the predefined Word report template. This approach yields standardized charts and tables that conform to reporting specifications and ensures the reliability of the

quantitative content.

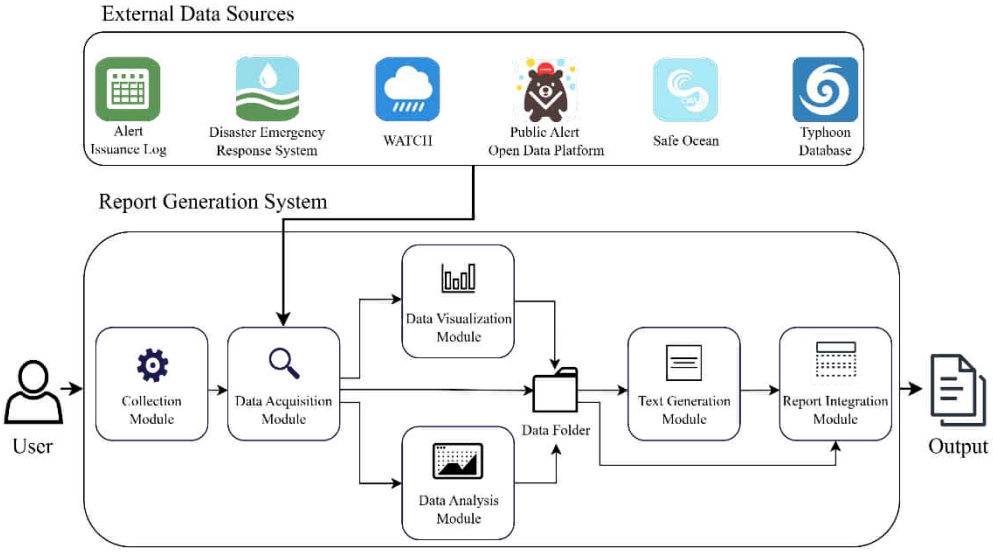

Figure 1 System architecture of the disaster response report generation system

3.3 RAG and CoT Implementation

To improve text generation quality and reduce hallucination risks, the system integrates RAG and CoT strategies, as illustrated in Figure 2. The multi-level prompting mechanism is designed to generate descriptive paragraphs for the Event Overview, Meteorological Situation, and Hydrological Information sections. For the RAG component, long-duration typhoon events can accumulate a large volume of textual data that exceeds the input length limits of current LLMs. To address this, the system first segments multi-day weather bulletins and related texts into smaller chunks, then encodes them into vectors using an embedding model and stores them in a FAISS vector database. During generation, the system performs similarity search based on the current prompt and retrieves the most relevant text fragments, which are supplied as contextual evidence to the LLMs. For the CoT component, prompts explicitly specify the reasoning steps required to construct each paragraph, decomposing complex generation tasks into sequential sub-tasks. Few-shot exemplars are included to demonstrate the desired writing style and paragraph structure of disaster response reports. For example, in the "Typhoon Development History" subsection, the prompt guides the model to chronologically summarize the typhoon track, key time points (e.g., warning issuance, landfall, departure, and cancellation), and to integrate rainfall and wind information at each stage, thereby producing narratives with clear timelines and causal relationships. In addition, hard constraints are embedded in the prompts to restrict the model to using only information retrieved by the RAG component, thereby discouraging unsupported speculation. Through the joint use of RAG and CoT, the system generates interpretable and well-grounded draft texts based on multi-source data, which are then subject to expert review and refinement.

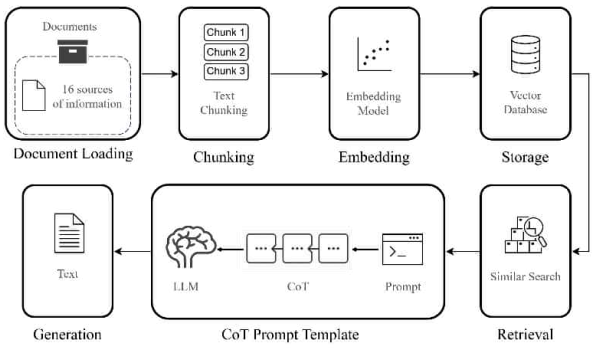

Figure 2 RAG - CoT architecture diagram

4 Validation

The system was evaluated across three stages: (1) system usability assessment, (2) expert evaluation of content quality and production efficiency, and (3) TLM credibility assessment. Test participants were personnel responsible for drafting disaster response reports at the Water Resources Administration of the Ministry of Economic Affairs of Taiwan.

4.1 Validation Methodology

Stage 1 – System usability.

The first stage examined whether the system effectively integrates dispersed data and reduces the

difficulty of report writing. Participants were asked to complete predefined tasks using the system without assistance. Their task completion time and operational difficulties were recorded. After the tasks, participants completed the SUS questionnaire and participated in semi-structured interviews to supplement the quantitative results. Six users with experience in disaster response report writing were recruited: two were classified as novice and four as experienced based on their years of practice, allowing the study to capture the perspectives of different user groups.

Stage 2 – Expert assessment of content quality and efficiency.

In the second stage, experts evaluated both the quality and efficiency of system-generated reports. One typhoon event and one heavy-rain event were selected as test cases, and experts with more than ten years of disaster response experience were invited to participate. For content quality, the experts rated each automatically generated paragraph on three dimensions—completeness, correctness, and readability—and compared the results with manually written versions to determine whether the generated content covered the necessary information and remained readable. All ratings used a five-point Likert scale. For production efficiency, experts recorded (i) the time required for the system to generate the first draft, (ii) the time needed to revise the drafts, and (iii) the time required to write the reports entirely by hand. The overall system-assisted production time was defined as the sum of generation and editing times and was compared with purely manual writing to calculate the percentage of time saved.

Stage 3 – Credibility assessment using TLM.

The third stage aimed to objectively and reproducibly evaluate the credibility of the system-generated texts, with particular attention to hallucination risks. Even when RAG is employed, LLMs may still produce misleading or incorrect statements; thus, an automated reliability check is necessary[13]. This study adopts the TLM proposed by Cleanlab[14] to evaluate the generated paragraphs in the Event Overview and Meteorological Situation and Hydrological Information sections. TLM quantifies the trustworthiness of responses based on the relationship among the user query, retrieved context, and generated output. The evaluation includes an overall trustworthiness score and four sub-indicators: context sufficiency, response groundedness, response helpfulness, and query ease. These metrics allow us to assess whether the generated content is sufficiently supported by retrieved evidence and internally consistent when synthesizing multi-source data, and the results also guide further system optimization. In addition, RAGAS is employed as a complementary evaluation tool to compare the RAG–CoT-enhanced configuration with a vanilla LLM using the same underlying model, quantifying differences in Faithfulness and Answer Relevancy and thereby demonstrating the contribution of the RAG–CoT architecture to overall content quality.

4.2 Sample Selection

To ensure representative samples for the Stage-3 TLM evaluation, disaster events that occurred in 2024 were screened using predefined criteria. Typhoon events were required to trigger at least a Level-1 response by the Ministry of Economic Affairs and to cause multiple flooding incidents across counties and cities. Large-scale heavy-rain events were required to trigger at least a Level-2 response or to result in 10 or more flooding locations. Based on these criteria, eight events were selected—four typhoon events and four heavy-rain events—as summarized in Table 2.

Table 2 List of selected typhoon and heavy-rain events

Event Name	Cumulative Rainfall (mm)	Screening Criteria
Typhoon GAEMI	1,944	Level 1 response: 3,308 floods in 15 counties and cities
Typhoon KRATHON	1,725	Level 1 response: 604 floods in 8 counties and cities
Typhoon KONG-REY	1,184	Level 1 response: 109 floods in 9 counties and cities
Typhoon USAGI	492	Level 1 response: 9 flooding in 3 counties and cities
0602 Heavy-Rain	223	Level 2 response: 12 floods in 5 counties and cities
0710 Heavy-Rain	135	Level 3 response: 55 flooding in 1 county and city
0806 Heavy-Rain	191	Level 3 response: 16 flooding in 2 counties and cities
0921 Heavy-Rain	436	Level 2 response: 83 floods in 6 counties and cities

4.3 Result

The SUS was used to evaluate overall system usability. According to Bangor et al. (2009), an average SUS score of 68 is generally considered the benchmark for acceptable usability[15, 16]. The proposed system achieved an average SUS score of 85.8 (Figure 3), which falls into the Excellent range, indicating a high level of usability in terms of both operation and user experience.

Further analysis revealed clear differences between novice and experienced users. Experienced staff scored the system between 92.5 and 100, reflecting strong recognition of its benefits for data integration and report preparation. Novice users, by contrast, assigned scores between 57.5 and 65, slightly below the benchmark. This suggests that users who have previously written large-scale disaster reports are more capable of perceiving the practical advantages of the system for multi-source data integration and draft generation, whereas novices tend to focus on interface intuitiveness and may have limited understanding of the complex disaster-response scenarios the system is designed to support. Nevertheless, during follow-up interviews, novice users generally agreed that the automatically generated Event Overview, Meteorological Situation, and Hydrological Information sections helped them quickly grasp the report structure and served as useful templates for writing.

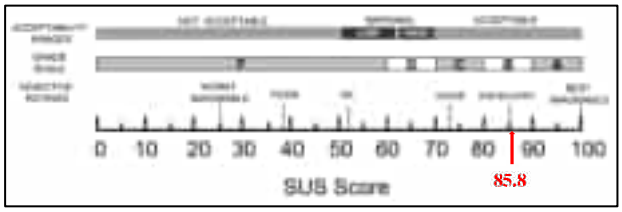

Figure 3 System Usability Scale score

Table 3 summarizes the expert evaluation results. For the specific content checklist, all chapters generated by the system obtained average scores of at least 3 out of 5, indicating that the model was able to cover the key information required in disaster response reports. For the overall quality dimensions—completeness, correctness, and readability—average scores were all at or above 4, suggesting that the generated content met the basic quality requirements of formal response reports. Experts noted that a small number of paragraphs could benefit from more precise wording and tighter narrative focus, but overall, only minor manual editing was needed before practical use. In terms of production efficiency, manually writing a typhoon event report required approximately 36 hours. With system assistance (automatic draft plus expert editing), the total time was reduced to about 9.60 hours, corresponding to a 73% reduction. For heavy-rain event reports, manual writing required about 2 hours, whereas the system-assisted process required approximately 0.73 hours, saving around 64% of the time. These results demonstrate that the proposed system can substantially improve report-writing efficiency for disaster events of varying scales.

TLM was employed to assess the credibility of the Event Overview and Meteorological Situation and Hydrological Information sections generated by the system. Scores range from 0 to 1; following Cleanlab's guidelines, values below 0.7 are considered low confidence, while values above 0.9 are regarded as high confidence. As shown in Table 4, the Event Overview and Meteorological Situation section achieved an average trustworthiness score of 0.89, close to the high-confidence range, whereas the Hydrological Information section achieved an average of 0.95, which clearly falls within the high-confidence range. These results indicate that the generated content is well supported by factual evidence and is overall reliable. Regarding the sub-indicators, average scores for context sufficiency, response groundedness, and response helpfulness all exceeded 0.9. In particular, response groundedness and response helpfulness both averaged 0.99, implying that the generated responses were highly dependent on retrieved evidence and exhibited virtually no hallucinations.

Table 3 Expert evaluation result table

Evaluation Dimension	Indicator	Evaluation Result
Completeness	Key Information Coverage	Average Score ≧ 3
Quality	Overall Quality Score	Average Score ≧ 4
Efficiency (Typhoon)	Report Generation Time	36 h → 9.60 h (73% Time Saved)
Efficiency (Heavy-Rain)	Report Generation Time	2 h → 0.73 h (64% Time Saved)

Slight differences were observed between disaster types: compared with typhoon events—where data continuity and publicly available information are more complete—heavy-rain events obtained a lower Query Ease score because the corresponding hydrological generation tasks must integrate heterogeneous evidence sources (textual alerts, numerical daily maximum rainfall data, and JSON-formatted rainfall-map analysis results) and follow prompts that require the model to infer daily weather patterns and affected areas during the response period, making these queries inherently more complex for the TLM to evaluate. Even so, both the Hydrological Information and Event Overview and Meteorological Situation sections remained at high credibility levels.

Overall, the TLM results demonstrate that the proposed system can consistently generate highly trustworthy and practically useful textual content in complex multi-source data settings.

Beyond assessing trustworthiness with TLM, this study further examined whether incorporating the proposed RAG–CoT framework improves the quality of LLM-generated reports. As shown in Table 5, both configurations achieved very similar Answer Relevancy scores (~0.82), indicating that the vanilla LLM is capable of generating topically relevant content. However, the large difference in Faithfulness (0.99 vs. 0.43) shows that vanilla LLM outputs frequently contain fabricated or unsupported statements, which is a critical risk in professional disaster reporting where factual accuracy is required. These results demonstrate that adopting the proposed RAG–CoT framework improves the factual grounding of automatically generated reports in this professional domain.

Table 4 Credibility assessment result table

Indicators/Chapters	Event Overview and Meteorological Situation	Hydrological Information
Trustworthiness	0.89	0.95
Context Sufficiency	0.98	0.93
Response Groundedness	0.99	0.99
Response Helpfulness	0.99	0.99
Query Ease	0.96	0.80

Table 5 vanilla LLM vs. RAG-CoT

Indicators/Configuration	Vanilla LLM	RAG–CoT	Improvement
Faithfulness	0.43	0.99	+ 0.56
Answer Relevancy	0.81	0.82	+ 0.01

5 Discussion

The disaster response report generation system developed in this study integrates web scraping, geospatial data analysis, and LLM-based text generation to automatically produce draft content for the Event Overview, Meteorological Situation, and Hydrological Information sections. Expert evaluations confirm that the generated content meets the basic quality requirements of formal disaster response reports, while the system reduces report preparation time by approximately 73% for typhoon events and 64% for heavy-rain events. Based on the 96 heavy-rain and 4 typhoon response events recorded in Taiwan in 2024, purely manual drafting would require an estimated 108 working days, whereas the proposed system reduces this workload to 17 working days, substantially easing the operational burden on response units during periods of intensive disaster activity. In addition, the SUS score of 85.8 (Excellent) indicates that the system achieves strong usability in practical settings.

Despite these promising results, several limitations remain. First, the system currently depends heavily on the availability and stability of external data sources and website structures; when source platforms change their interfaces or data formats, the scraping and parsing components must be updated accordingly. When critical data cannot be retrieved or are insufficient to generate a given section, the system automatically inserts a placeholder (e.g., “to be completed by responders”) into the draft report to clearly indicate that manual completion is required. Second, although the generated texts are generally factually correct, final review and refinement by domain experts are still required to ensure that the tone, wording preferences, and points of emphasis align with the conventions of specific agencies and with politically or socially sensitive issues. Third, in the case of small, localized heavy-rain events, the limited availability of official data can lead to insufficient context, causing the model to produce overly brief descriptions or explicit indications of missing data, which may reduce the perceived completeness and credibility of the final report.

In this study, the report structure is decomposed by analyzing each chapter’s content into three categories—narrative text, visual maps and charts, and numerical tables—and assigning each category to an appropriate technical module (LLM with RAG–CoT prompting for narrative sections, computer vision for map-derived indicators, and automated data processing and visualization pipelines for quantitative content). The same design principle can be applied in other regions or hazard types by re-analyzing the local report template,

classifying its required content into these three categories, and then adapting the data sources, computer-vision routines, and RAG document collections and prompt templates to local monitoring systems and reporting standards, while reusing the core RAG–CoT and report-integration architecture.

Future work will focus on three directions: developing an interactive query interface so that responders can use natural language to explore historical events and analogous cases, integrating historical reports and impact data to provide simple, context-aware response recommendations, and introducing AI agents and the Model Context Protocol (MCP) to enhance the system's ability to self-check, self-repair, and scale in real-world operational environments.

6 Conclusion

To address the practical need for responders to handle both real-time operations and formal report writing under high event frequency, this study proposes an automated disaster response report generation system that integrates LLMs, web scraping, and geospatial data analysis. The results show that, when coupled with a structured data-integration mechanism and interpretable generation strategies, LLMs can reliably support the production of first drafts of disaster response reports with acceptable credibility and practical utility. Overall, these findings confirm the practical feasibility of applying LLMs to governmental disaster-prevention documentation and public-sector reporting tasks, offering a modular and reusable framework adaptable to other professional domains.

Abstract -

Modular construction (MC) has attracted increasing attention as a promising strategy for carbon emission reduction in the context of global low-carbon transitions. However, accurate estimation and continuous tracking of lifecycle carbon emissions in MC projects remain limited, as existing studies predominantly focus on individual stages and provide fragmented evidence. To address this gap, this study proposes a lifecycle-oriented carbon tracking approach for MC based on the integration of Building Information Modeling (BIM) and the Internet of Things (IoT). By combining BIM-based object representations with multi-source IoT-enabled sensing mechanisms, the proposed approach establishes a unified mechanism for carbon accounting and data integration at the module level, enabling consistent representation of carbon emissions within a unified framework. The approach is demonstrated through two real-world modular integrated construction (MiC) projects in Hong Kong, validated separately for the construction and operational stages. The results show that the approach supports continuous, time-resolved characterization of carbon emissions and effectively captures their dynamic patterns under different application contexts. Overall, this study provides a systematic methodological framework for lifecycle-oriented carbon tracking in modular construction, contributing to more data-driven carbon assessment practices.

Keywords -

Modular Construction, Lifecycle Carbon Monitoring, BIM, IoT

1 Introduction

The building sector contributes a substantial share of global energy-related carbon emissions, making it a key target for decarbonization strategies [1]. MC has been increasingly adopted to improve productivity and reduce environmental impacts, particularly in high-density cities such as Hong Kong [2]. However, existing studies have struggled to systematically characterize the carbon emission profile of MC at the lifecycle scale. This limitation is largely attributable to the lack of methods capable of supporting continuous lifecycle carbon data acquisition and tracking.

Existing MC carbon studies still rely predominantly on material-driven estimation approaches. Although BIM and IoT have been introduced to support carbon data acquisition and management, their applications are typically confined to individual stages or isolated systems. As a result, a lifecycle-wide data integration mechanism and unified accounting pathway have yet to be established, limiting further systematic analysis of carbon emission characteristics.

From the perspective of embodied carbon (EC), MC exhibits highly discrete and process-oriented characteristics. Conventional cast-in-situ construction is dominated by on-site activities, with carbon emissions largely localized in both spatial and temporal dimensions. Although prefabricated construction relocates part of component production to factories, substantial wet works remain on-site, and EC emissions are still primarily material-driven. MC adopts modules as highly integrated, standardized, and traceable construction units, resulting in EC emissions being distributed across multiple construction stages, including factory manufacturing, transportation, and on-site assembly. Due to highly dispersed production processes and a module-based object hierarchy, carbon emission data in MC are difficult to continuously acquire and consistently represent across construction stages, which weakens the applicability of traditional material-based estimation approaches at both module and building scales.

For operational carbon (OC), MC exhibits stronger early-stage coupling with EC. Module envelope design, connection configurations, and integrated building services are typically finalized during the manufacturing stage, thereby exerting persistent influences on building energy performance and operational carbon during long-term operation. However, existing OC studies in MC predominantly rely on design-stage energy simulations for independent estimation, which cannot capture dynamic variations during actual operation and lack effective linkage with construction-stage data, limiting deeper understanding of operational carbon behaviours.

To address these gaps, this study proposes a lifecycle-oriented BIM–IoT-based carbon tracking approach for MC. The proposed approach supports continuous carbon data acquisition and integration across lifecycle stages and enables unified carbon accounting across different stages, providing a systematic methodological framework for data-driven carbon assessment in modular construction. The remainder of this paper is organized as follows.

Section 2 reviews related literature, Section 3 introduces the proposed methodology, Section 4 presents the case studies and results, and Section 5 concludes the paper.

2 Literature review

In recent years, increasing research attention has been directed toward the use of digital technologies to address the complexities of lifecycle carbon assessment in MC [3]. Due to the fragmented nature of production processes and the hierarchical organization of building objects in MC, effective carbon assessment requires consistent object-level representation across different stages, and the capability to continuously capture time-resolved data from construction processes and building operation. In this context, BIM and IoT have emerged as key technological foundations for carbon data integration and analysis in modular construction.

BIM provides structured building semantics and supports automated quantity take-off, enabling multi-level representation of carbon emissions from components to modules and buildings [4]. It also facilitates identification of dominant material- and process-related emission sources [5]. However, existing BIM-based approaches largely rely on static databases and ex post accounting mechanisms, which limits their ability to capture temporal dynamics of carbon emissions [6].

Meanwhile, IoT technologies enable distributed sensing and real-time data acquisition, allowing process-level information across construction and operation stages to be continuously recorded, which is particularly critical for fragmented production processes in MC [7, 8]. Nevertheless, recent review studies indicate that IoT-based carbon management in the construction sector still faces challenges related to limited interoperability, fragmented system deployment, and lack of standardized integration frameworks, which constrain scalability and applicability for cross-stage carbon tracking [9].

Building on the above studies, recent research has explored BIM–IoT integration to establish links between digital building models and physical process data [10]. Existing studies indicate that such approaches can support process-level tracking of embodied carbon at component and module scales and can also be applied to operational energy monitoring and data acquisition [11]. However, compared with existing BIM–IoT-based studies that primarily focus on embodied carbon tracking during the construction stage, most applications remain focused on specific processes, individual lifecycle stages, or localized use cases, and a unified framework that enables lifecycle-wide data integration and consistent carbon accounting has yet to be established [12, 13].

In summary, although BIM and IoT provide important capabilities for carbon data acquisition in modular construction, systematic methods that support lifecycle-wide data integration and unified carbon accounting across stages remain insufficient. To address this gap, this study proposes a BIM-IoT-based carbon tracking framework for modular construction to support continuous lifecycle carbon data acquisition and integrated carbon accounting.

3 Methodology

3.1 Research design

This study proposes a BIM–IoT-integrated framework for carbon tracking in modular construction, in which modules are defined as the primary analytical unit and buildings as the aggregation level. The overall research framework of the proposed BIM–IoT-integrated approach is illustrated in Figure 1. By linking module-level BIM semantics with process- and operation-level data acquired through IoT, the framework enables consistent module-scale attribution of carbon emissions across lifecycle stages, providing a basis for the integrated analysis of embodied and operational carbon.

3.2 Data acquisition and preprocessing

This study employs a data acquisition strategy targeting lifecycle stages of modular buildings to support the quantitative analysis of carbon emissions during both construction and operation. In accordance with EN 15978 [14], and considering the research scope and data availability, the system boundary includes construction-related stages A1–A5, representing embodied carbon (EC), and the use stage B6, representing operational carbon (OC). Other lifecycle stages, including maintenance and replacement (B2–B5), end-of-life processes (C1–C4), and benefits beyond the system boundary (D), are excluded. The corresponding carbon emission sources, data types, and acquisition approaches are summarised in Table 1. For construction-related stages (A1–A5), data acquisition is organised around process-level activities, focusing on energy use associated with module production, transportation, and installation. In contrast, for the operational stage (B6), data acquisition is structured by end-use energy consumption, capturing subsystem-level demand such as HVAC, lighting, and plug loads.

The proposed method integrates three categories of input data: BIM semantic data, IoT-derived sensing data, and carbon emission factors. BIM semantic data define a structured hierarchy linking components, modules, and buildings, enabling consistent carbon attribution across lifecycle stages. IoT-derived data capture time-resolved activity states and energy-use patterns associated with module production, transportation, installation, and building operation. Carbon emission factors are obtained from established life cycle assessment databases, including Ecoin-

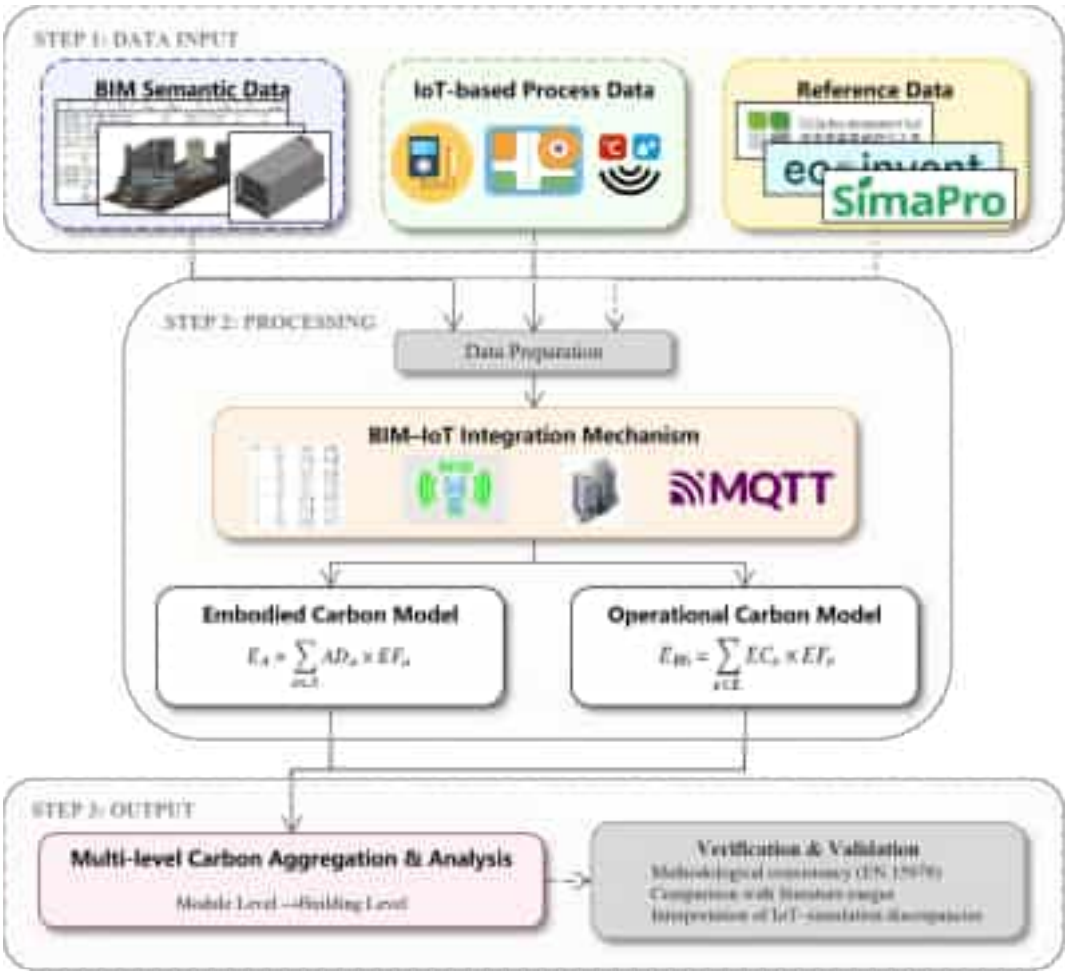

Figure 1. Research design of the proposed BIM-IoT integrated framework.

vent [15], SimaPro-integrated databases [16], ICE [17], and the CIC Carbon Assessment Toolkit [18].

Prior to integration, heterogeneous data from different lifecycle stages are preprocessed to improve temporal consistency and data reliability. This includes addressing differences in sampling frequency and temporal resolution, handling missing or incomplete data, and aligning time-resolved IoT data with BIM-defined modular objects and corresponding emission factors. These steps provide a reliable basis for subsequent module-level carbon quantification and lifecycle-scale analysis.

3.3 BIM–IoT integration mechanism

The integration of BIM and IoT introduces challenges related to object consistency and temporal alignment, as data collected from different lifecycle stages exhibit heterogeneity in structure, temporal resolution, and activity semantics. Without a unified reference framework, such data cannot be reliably linked to modular objects, thereby limiting the traceability of carbon emission quantification.

To address this issue, a module-oriented BIM–IoT integration mechanism is established, in which the module serves as the unified unit of analysis across lifecycle stages. Each module is assigned a unique identifier (Module ID) and linked to its corresponding BIM object, ensuring consistent identity representation within the defined system boundary. A one-to-one mapping between Module IDs and RFID tags enables physical identification of modules and supports the association of activity-related data during construction processes.

During module manufacturing, transportation, and onsite installation, RFID-based identification events are captured at key process nodes to link operational states and energy consumption data to individual modules. In this way, each construction activity can be directly associated with specific modules, allowing energy use to be traced back to corresponding processes. This activity-oriented integration approach establishes a clear connection between construction activities, energy consumption, and modu-

Table 1. Carbon emission sources and IoT sensors

Stage	Carbon Source Category	Representative Activities	Data Type	IoT Sensors
A1–A3	Material production; Module manufacturing	Raw material processing; Module manufacturing; Module decoration	Energy consumption; Equipment status	Smart meters; Accelerometers; Vibration sensors; etc.
A4	Module transportation	Off-site transportation	Travel distance; Transport status	GPS sensors
A5	On-site installation	Module lifting; Equipment operation	Energy consumption; Equipment status	Smart meters; Accelerometers; Vibration sensors; etc.
B6	HVAC systems	AC on/off switching; Temperature adjustment	Operating duration; Temp. & humidity	Environmental sensors; Current sensors
	Plug loads	Appliance usage; Device charging	Active power; Device status	Smart plugs; Smart switch
	Lighting	Light on/off switching; Active fixture count	Illuminance level; Operating status	Illuminance sensors; Smart switches
	Domestic water use	Water consumption; Usage patterns	Water volume; Flow rate	Smart water meters
	Gas consumption	Cooking; Hot water supply	Gas volume; Operating status	Smart gas meters

lar components, thereby enabling traceable module-level carbon quantification.

To ensure the temporal consistency and effective integration of multi-source IoT data, a publish–subscribe communication mechanism is adopted, with MQTT facilitating asynchronous data acquisition from distributed sensors. By linking module identifiers with activity types and corresponding data topics, heterogeneous operational data collected at different temporal resolutions can be systematically organized at the module level. This supports cross-stage data alignment and provides a coherent basis for subsequent carbon quantification.

3.4 Carbon emission accounting model

Based on the BIM–IoT data integration mechanism, carbon-related data generated at different lifecycle stages are consistently attributed at the module level. Within the defined system boundary, this study quantifies embodied carbon during the construction stages (A1–A5) and operational carbon during the use stage (B6) of modular buildings. All emissions are expressed in carbon dioxide equivalent (CO_2e), including major greenhouse gases such as CO_2, CH_4, and N_2O. Greenhouse gas emissions are converted into CO_2e using 100-year global warming potential factors (GWP100) from the IPCC Fifth Assessment Report (AR5) [19]. This choice ensures consistency with established LCA databases and prior studies commonly used in construction-related carbon assessment. Although updated characterization factors are provided in IPCC AR6 (2021), the differences are generally limited for the emission sources considered in this study and do not affect the methodological framework or comparative analysis.

For the construction stages (A1–A5), EC is quantified based on activity-related energy consumption captured through the IoT sensing system. Energy use associated with construction-related activities is converted into carbon emissions using corresponding emission factors, following an activity-based accounting logic. The general calculation form is expressed as:

$$E_A = \sum_{a \in A} AD_a \times EF_a \tag{1}$$

Where E_A denotes the total embodied carbon emissions of a module during the construction stages (A1–A5); AD_a represents the activity data associated with activity a, such as energy consumption, equipment operating time, or transportation distance; and EF_a refers to the emission factor corresponding to the activity and associated energy type.

For the operational stage (B6), OC covers emissions induced by energy use during normal building operation. Based on time-resolved energy consumption data collected by the IoT system, operational activities such as HVAC operation, lighting usage, and plug-load equipment operation are identified and aggregated over their operating periods. Operational carbon emissions are calculated as:

$$E_{B6} = \sum_{e \in E} EC_e \times EF_e \quad (2)$$

Where E_{B6} represents the operational carbon emissions associated with energy use during the use stage (B6); EC_e denotes the consumption of energy type e; and EF_e is the emission factor corresponding to the specific energy type.

After module-level quantification, carbon emissions are further aggregated across different object levels using the hierarchical structure defined in BIM. At the component level, emissions can be disaggregated based on component–module relationships, while at the building level, module-level emissions are aggregated to derive overall carbon indicators. This hierarchical aggregation ensures consistency across object levels and supports lifecycle-scale carbon analysis.

3.5 Verification and validation

The reliability of the proposed lifecycle carbon assessment approach is examined through methodological consistency checks and comparative interpretation of results. Rather than aiming to establish absolute accuracy, the evaluation focuses on whether the framework produces reasonable and interpretable carbon estimates under real operating conditions.

Methodological consistency is ensured by adopting the lifecycle stage definitions of EN 15978 [14] and applying a unified activity-based accounting logic across construction and operational stages. This provides a coherent basis for cross-stage comparison and aggregation of carbon emissions.

The plausibility of the results is assessed through two complementary perspectives. First, the magnitude of estimated carbon emissions is compared with ranges reported in existing modular construction studies, providing a reference for overall emission levels. Second, IoT-based monitoring results are interpreted in relation to simulation outputs, not as a direct validation benchmark, but as a means of examining deviations between assumed and actual conditions. In particular, discrepancies in temporal patterns are analysed to identify behaviour-driven variations, such as occupant-induced fluctuations in energy use, which are not captured by schedule-based simulations.

Given the absence of fully observed lifecycle carbon data, these comparisons remain indirect and do not constitute validation against ground truth. Instead, they provide supporting evidence on the interpretability and practical relevance of the proposed approach. This limitation reflects the inherent challenges of lifecycle carbon assessment under real-world conditions.

4 Case study

4.1 Embodied carbon emissions in the construction stage

Case I is a MiC student dormitory project in Kowloon Tong, Hong Kong, selected to evaluate the proposed BIM–IoT method for monitoring construction-stage embodied carbon (A1–A5). The project is a 15-storey steel-structured dormitory consisting of 867 prefabricated modules, with a gross floor area of approximately 50,200 m^2. A cast-in-situ portion of the project contributes about 33,042.82 tCO_2e during construction. As these emissions cannot be reliably attributed at the module level, they are excluded from the analysis. It should be noted that this exclusion represents a substantial portion of the total construction-stage emissions and therefore constitutes an important limitation of the module-level analysis. Within this scope, on-site emissions are limited to crane operations for module lifting, while other equipment energy use without consistent module-level attribution is omitted, in accordance with the defined module-based accounting boundary.

Figure 2 illustrates the composition of module-level embodied carbon emissions. Material-related emissions dominate across all module types, accounting for approximately 94.3% of the total, while contributions from production equipment, transportation, and on-site lifting remain relatively small. As summarised in Table 2, embodied carbon per module ranges from approximately 11.0 to 11.9 tCO_2e across different module types. This consistency, together with the dominant contribution of material-related emissions observed in Figure 2, indicates that, in a highly standardised MiC system, module-level embodied carbon is primarily governed by shared material compositions and uniform production arrangements, with limited influence from functional or spatial differences. These patterns are consistent with previous studies on modular construction [20, 21, 22]. Overall, Case I demonstrates that the BIM-IoT-based monitoring approach enables attributable and interpretable embodied carbon analysis during construction, particularly in scenarios where conventional inventory-based methods cannot provide traceable module-level attribution.

4.2 Operational carbon emissions in the operational stage

Case II investigates a MiC student dormitory project in Wong Chuk Hang, Hong Kong, to evaluate the proposed BIM–IoT-based approach for operational-stage carbon monitoring (B6). The project has been in operation since September 2023 and comprises two 17-storey MiC residential towers with 952 prefabricated modules. This case serves as an operational-stage validation of the proposed framework, complementing the construction-stage

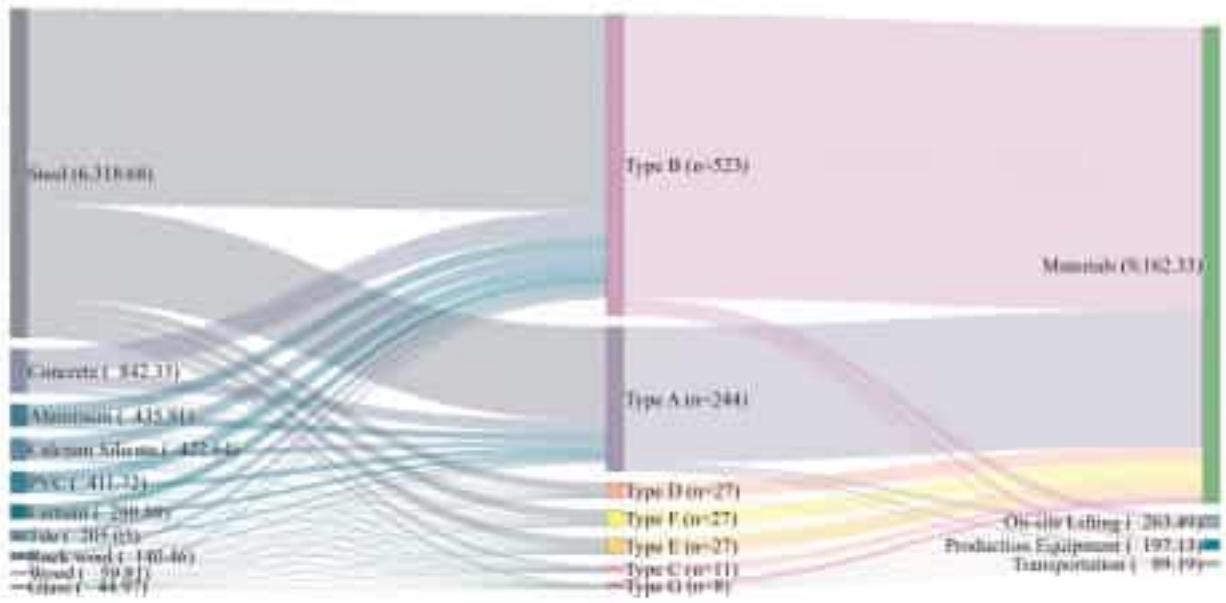

Figure 2. Carbon flow of module-related embodied carbon (tCO_2e)

Table 2. Carbon emission inventory of MiC modules by stage and type (kg CO_2e)

Module Type	Quantity	Production Equipment	Material	Transport	On-site Lifting	Total per Module	Total Emission by Type
Type A	244	230.04	10,744.96	104.17	306.32	11,385.49	2,778,060.18
Type B	523	224.73	10,431.34	101.12	300.62	11,057.81	5,783,235.75
Type C	11	220.51	10,430.61	98.52	300.08	11,049.72	121,546.93
Type D	27	228.89	10,638.78	104.91	309.77	11,282.36	304,623.65
Type E	27	237.47	10,959.92	110.92	318.42	11,626.72	313,921.57
Type F	27	246.20	11,250.80	117.02	327.64	11,941.67	322,425.02
Type G	8	224.73	10,412.25	101.37	302.11	11,040.46	88,323.72

analysis in Case I. Given the standardised layout and function of dormitory rooms, room-level energy use is primarily electricity-based. Multi-source IoT data, including HVAC energy consumption, plug loads, and lighting electricity use, were collected at the module level (room level) over a one-month period. These data provide time-resolved carbon emission profiles across different end-use categories and are compared with EnergyPlus simulation results.

Figure 3 presents the comparison between IoT-based monitoring and simulation at both total and end-use levels, based on a representative room selected from the monitored dataset. At the aggregate level, monitored carbon emissions exhibit pronounced temporal variability and noticeable deviations from simulation results. At the end-use level, lighting emissions show intermittent peaks associated with occupant-driven usage, plug-load emissions display irregular fluctuations not captured by simulation, and HVAC-related emissions deviate from simulated trends due to differences between assumed control conditions and actual indoor operation.

Overall, while simulation captures general trends, it fails to represent short-term variability and peak emissions observed in monitoring data. These results highlight the strong dependence of operational carbon emissions on occupant behaviour and demonstrate the advantage of the BIM–IoT-based approach in capturing dynamic, time-resolved carbon characteristics in modular residential buildings.

A combined view of Case I and Case II shows that the proposed BIM–IoT-based approach enables detailed module-level carbon analysis across both construction (A1–A5) and operational (B6) stages. Together, these results further indicate the broad applicability and versatility of the proposed framework across different lifecycle stages.

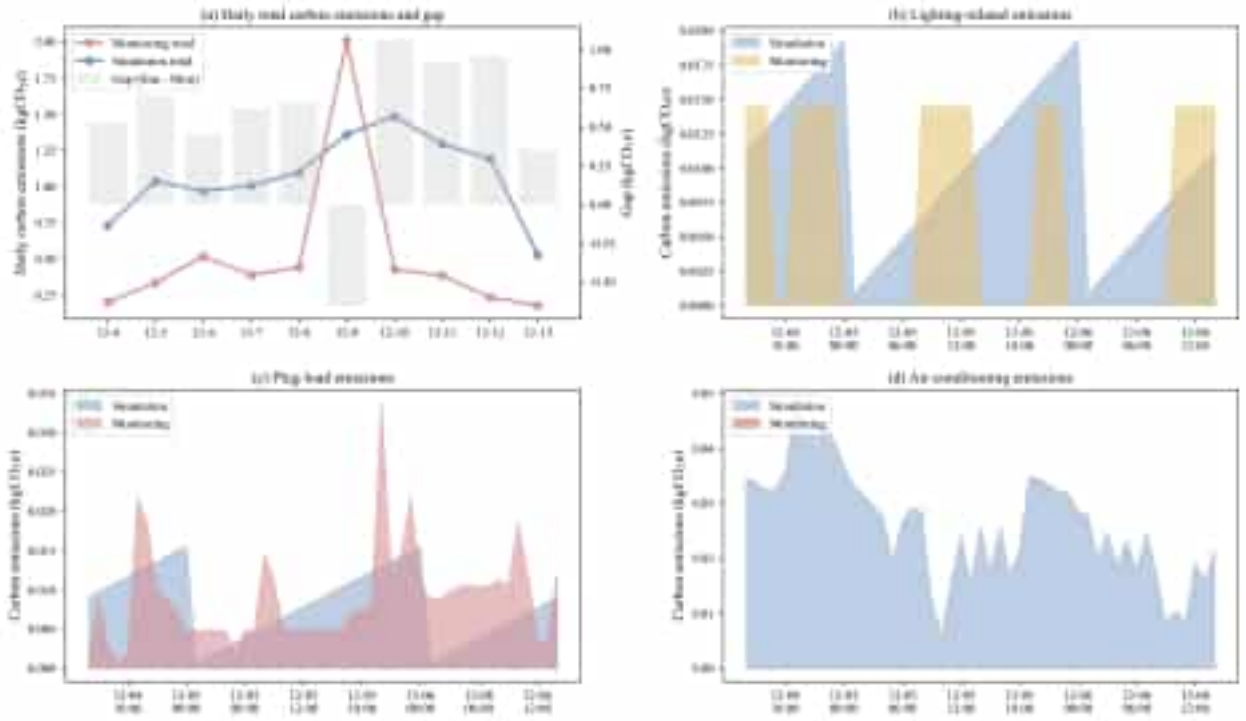

Figure 3. Operational carbon tracking using BIM–IoT integration at total and end-use levels.

5 Conclusion and discussion

Accurate and continuous lifecycle carbon monitoring in MC remains challenging, primarily due to fragmented production processes, heterogeneous data sources, and the lack of reliable mechanisms. To address these challenges, this study proposes a BIM–IoT-integrated approach in which modules serve as the fundamental analytical unit for carbon accounting, enabling consistent lifecycle carbon tracking at the module scale.

The results show that the approach supports consistent module-level representation of carbon emissions across both construction (A1–A5) and operational (B6) stages. By integrating BIM-based structural information with time-resolved IoT data, it enables attributable and traceable carbon analysis, providing clearer insights into carbon emission dynamics across activities and processes.

The findings also reveal key differences between simulation-based and measurement-based estimation of operational carbon. While simulation captures general trends, it overlooks short-term variability and peak emissions driven by occupant behaviour and operating conditions, potentially introducing systematic bias at finer temporal and spatial scales, particularly in highly standardised modular buildings.

Despite these contributions, several limitations should be acknowledged. The lifecycle scope is confined to stages A1–A5 and B6, excluding other stages, such as maintenance, and end-of-life processes, due to data constraints. Emissions from cast-in-situ components are also excluded as they cannot be reliably attributed at the module level, limiting completeness. In addition, embodied and operational carbon are demonstrated using separate projects rather than a single integrated case, due to the difficulty of obtaining continuous lifecycle data. Data uncertainty is also insufficiently addressed, including sensor noise, missing data, and their propagation in carbon accounting.

Future work will focus on implementing the framework within a single project to enable continuous data collection across construction and operational phases, extending coverage to additional lifecycle stages (e.g., maintenance and end-of-life) as data become available, and incorporating uncertainty-aware data processing and validation methods. These efforts are expected to enhance the robustness and practical applicability of data-driven lifecycle carbon management in MC.

Abstract –

Construction productivity has remained stagnant for decades, underscoring the need for productivity improvement methods. Crew Balance Charts (CBCs) are an effective tool for analysing crew dynamics and identifying opportunities for productivity improvement. However, manual preparation of CBCs is time-consuming and limits scalability. This paper proposes a Computer Vision-based Crew Balance Chart (CV-CBC) framework for automated CBC generation using construction site videos. The framework comprises: Activity Definition, Data Preparation, Activity recognition model development, Inference pipeline, and CBC generation and Validation. The activity-level outputs are further aggregated into Crew-Based Work Sampling (CBWS) metrics for high-level labour monitoring. The framework is implemented and evaluated on masonry activity, with validation performed through per-second comparison between the automatically generated CBC and the manually prepared CBC. Results show that the activity recognition model achieves a macro-F1 score of 0.54 on the validation set across four activity classes, while the CBC achieves an accuracy of 60%. Activity predictions are aggregated into Value-Adding (VA), Non-Value-Adding (NVA), and Non-Value-Adding, but Necessary (NVAN) categories, enabling the calculation of CBWS metrics. The study introduces automated CBC generation and highlights its potential for scalable crew-level analysis in construction, while performance improvements remain an area for future work.

1 Introduction

The construction industry is one of the largest sectors of the global economy, accounting for nearly 7% of global gross output, and is projected to reach USD 22 trillion by 2040 [1]. Despite this scale and anticipated growth, construction productivity has remained largely stagnant for decades. Between 2000 and 2022, global construction productivity increased by approximately 10%, whereas manufacturing productivity rose by roughly 90%, and the overall economy by 50% [1]. This highlights the need to improve productivity to meet future demands amid persistent labour shortages.

Labour accounts for approximately 30–50% of project costs, yet is often utilised at only 40–60% of its potential due to coordination inefficiencies [3]. Improving labour productivity is challenging due to the nature of construction work. Construction projects are temporary and executed in dynamic environments. Consequently, performance depends on interdependent and sequential activities, rather than isolated tasks [2][3]. At the operational level, work is predominantly executed by crews whose productivity is largely dependent on coordination, task sequencing and interaction among the crew members [3]. These underscore the need for crew-level analysis to quantify productivity losses and identify opportunities for improvement.

Lean Construction emphasises maximising value by eliminating waste, which requires systematic waste identification [4][5]. Crew Balance Charts (CBCs) and Crew-Based Work Sampling (CBWS) are established lean tools for analysing crew-level productivity. CBCs capture the temporal distribution of work among the crew across work cycles, highlighting crew interdependencies, exposing forced idleness, and work imbalance. By making such inefficiencies visible, CBCs facilitate the identification of opportunities for productivity improvement [6][7]. In contrast, CBWS quantifies waste by aggregating each worker's activities into Value-Adding (VA), Non-Value-Adding (NVA), and Non-Value-Adding but Necessary (NVAN) categories and can be applied beyond cyclic activities. While CBCs enable productivity improvements, CBWS enables effective labour monitoring.

Traditionally, CBCs are prepared through manual observation of crews across work cycles, requiring continuous observation of crew members across multiple

cycles. Task durations are recorded manually using stopwatches or time-lapse video and then translated into a graphical representation. The process is illustrated in Figure 1. While effective for identifying inefficiencies and supporting improvement decisions, this manual process is labour-intensive and limits the number of cycles that can be analysed [8]. To enable scalability and repeatability, this manual process needs to be automated. Similarly, CBWS requires repeated manual observations, making it time-consuming and challenging to scale.

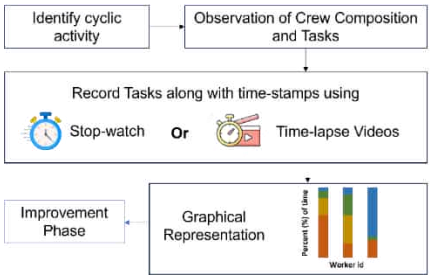

Figure 1 Traditional Crew Balance Chart Process

Prior studies have explored automating activity recognition using wearable sensors such as accelerometers [9]. While these capture detailed motion information, the hardware required for large-scale deployment is intensive and can be uncomfortable for workers. In contrast, recent advances in Computer Vision (CV) enable automated interpretation of construction site videos in a non-intrusive way by detecting, tracking and recognising worker activities [10]. This makes computer vision suitable for capturing crew interactions in labour-intensive construction activities.

Despite the potential of CV for automating construction site observation, existing applications remain fragmented and largely isolated. These approaches rarely translate the outputs into structured analytical tools such as CBC. Consequently, there is no integrated framework that uses computer vision to support crew-level analysis.

Accordingly, this study focuses primarily on CBC as the analytical tool, with CBWS concepts used only to aggregate recognised activities for high-level labour monitoring. Therefore, the objectives of this paper are to:

1. Investigate the feasibility of using CV to automate the CBC generation from construction site videos.
2. Develop an integrated framework, referred to as CV-CBC, that integrates worker detection, worker tracking, and activity recognition to convert video-based observations into CBC.
3. Evaluate the framework on real-world data and identify key technical limitations.

The remainder of this paper is organised as follows. Section 2 reviews related work on computer vision applications in construction productivity. Section 3 presents the proposed CV-CBC framework and its components. Section 4 describes the implementation and validation of CV-CBC framework using masonry activity. Section 5 presents the key results, Section 6 discusses ethical considerations, and Section 7 concludes by outlining future research directions.

2 Related Work

Computer vision applications in construction have largely focused on safety monitoring, while studies on productivity analysis remain limited [11]. The papers that address productivity are also focused on equipment rather than workers. Workers pose various challenges, as their movements are less well-defined and structured than those of equipment operations. Nonetheless, researchers have attempted to model the workers' actions, and a summary of these studies is presented below.

2.1 Equipment-Centric Activity Analysis

Several studies have focused on recognising equipment activities due to their structured, predictable motion patterns. Roberts and Golparvar-Fard proposed an end-to-end pipeline for detecting, tracking, and recognising excavator activities. However, the authors noted that extending such approaches to workers is challenging due to the complexity of human motion [12].

The multi-stage process can lead to error accumulation across modules, which affects the overall performance of the system. Ghelmani et al. developed a single-stage spatio-temporal activity recognition framework for excavator actions. This improved the performance compared to a multi-stage pipeline, highlighting the advantages of single-stage architectures [13]. Nevertheless, the study is limited to excavators and does not consider workers' activity recognition.

2.2 Worker-Centric Activity Analysis

Worker-centric analysis is slightly more challenging than equipment-centric analysis. Toledo et al. used YOLOv5 to detect worker postures and classify them into productive and contributory works, enabling the generation of CBC [6]. While promising, the approach was limited to single-worker scenarios and did not incorporate tracking or temporal modelling. Roberts et al. developed a 2D pose-estimation-based approach for CBC automation that achieved good accuracy but was limited to a single-worker scenario. As a result, the approach does not capture interaction among multiple workers, limiting its applicability for crew-level analysis [14].

Kim et al. proposed a generalised vision-based framework for construction productivity analysis, aiming to improve scalability. The framework addresses both

equipment and labour productivity analysis. However, it relies heavily on the synthetic and web-crawled images, rather than video data. In addition, limited emphasis is placed on fine-grained worker activity recognition, which is essential to developing CBC [15].

In summary, existing studies have explored vision-based productivity analysis. Despite these advances, current methods have largely focused on equipment, are limited to single-worker analysis and mostly rely on static images rather than continuous video data. To address these limitations, an integrated CV-CBC framework is developed to enable CBC generation.

3 Computer Vision-based Crew Balance Chart (CV-CBC) Framework

Based on previous studies, automated generation of CBCs requires three major CV techniques: object detection, tracking and activity recognition. Object detection enables the localisation of workers, object tracking maintains worker identity over time, and activity recognition classifies the activities performed by the worker [12] [10]. These techniques form the CV pipeline for generating CBC from site videos. The proposed CV-CBC framework comprises five components: Activity Definition, Data Preparation, Activity Recognition model development, Inference Pipeline, and CBC Generation and Validation. The detailed framework is illustrated in Figure 2 and each component is discussed in the following subsections.

3.1 Activity Definition

The first step is to identify the main activity for CBC analysis. CBC analysis is effective when applied to cyclic, labour-intensive, repetitive, and coordination-intensive work. Small improvements in cyclic activities can yield significant productivity gains over time. The selected activity should also be critical to the project in terms of time and cost.

In this study, the term *"main activity"* refers to the overall construction operation selected for CBC analysis. In contrast, *"activity"* refers to the specific actions carried out by workers within the main activity. Once the main activity is selected, it is further broken down into a set of activities that represent the work performed by the individual workers. This breakdown is carried out by observing on-site operations and understanding the crew composition. The objective is to identify all activities that may occur during one complete work cycle. Activities are classified into Value-Adding (VA), Non-Value-Adding (NVA), and Non-Value-Adding but Necessary (NVAN) categories to enable CBWS. To reduce ambiguity, activities are defined to be distinguishable based on visual cues, with visually similar activities grouped into broader categories.

3.2 Data Preparation

This stage converts the site videos into a structured dataset that enables model training in the subsequent stage. It includes Data Collection and Annotation, Clips Generation, Data Augmentation and Dataset Split.

Data Collection: Video data are collected from construction sites using standard camera-based methods. The primary requirement is that workers are clearly visible for a sufficient time to capture their activities. To improve robustness, videos are collected across different work cycles, camera viewpoints and site conditions.

Data Annotation: The videos are manually annotated using standard tools. For each visible worker, a bounding box (bbox) is drawn, and an activity label is assigned based on a pre-defined activity breakdown. A new bbox will be drawn each time the worker changes the activity. The bounding boxes are updated over time in response to the worker's movement. During annotation, the worker is preferably kept near the centre of the bbox, with a small margin, to capture more spatial context. The annotations are exported in a structured format, such as CVAT 1.1, which enables clip generation in the subsequent step.

Clips Generation: Using the annotations, videos are processed to extract worker-level tracks, which are then trimmed into shorter clips for training and validation.

Data Augmentation: It is used to improve the diversity of the dataset and the activity recognition model robustness. Both spatial (horizontal flipping) and photometric (brightness, contrast) augmentation techniques are applied. Data augmentation also helps eliminate the imbalance among activity classes.

Dataset Split: The dataset is split into training, validation, and test sets using a video-level splitting strategy to prevent data leakage and ensure fair evaluation. All clips that belong to the same video are assigned to a single subset.

3.3 Activity Recognition Model Development

This stage involves developing an activity recognition model to classify video clips into pre-defined activity classes, which requires learning both spatial and temporal information. Model development includes model selection, training and evaluation. Model hyperparameters are tuned using validation data to improve performance. Model selection is based on macro F1-score, where F1-score is defined as the harmonic mean of precision and recall, and the macro F1-score is computed by averaging the F1-scores across all classes giving equal importance to each class. This metric provides a balanced assessment of model performance. The output of this stage is a trained activity recognition model that is used in the subsequent inference pipeline.

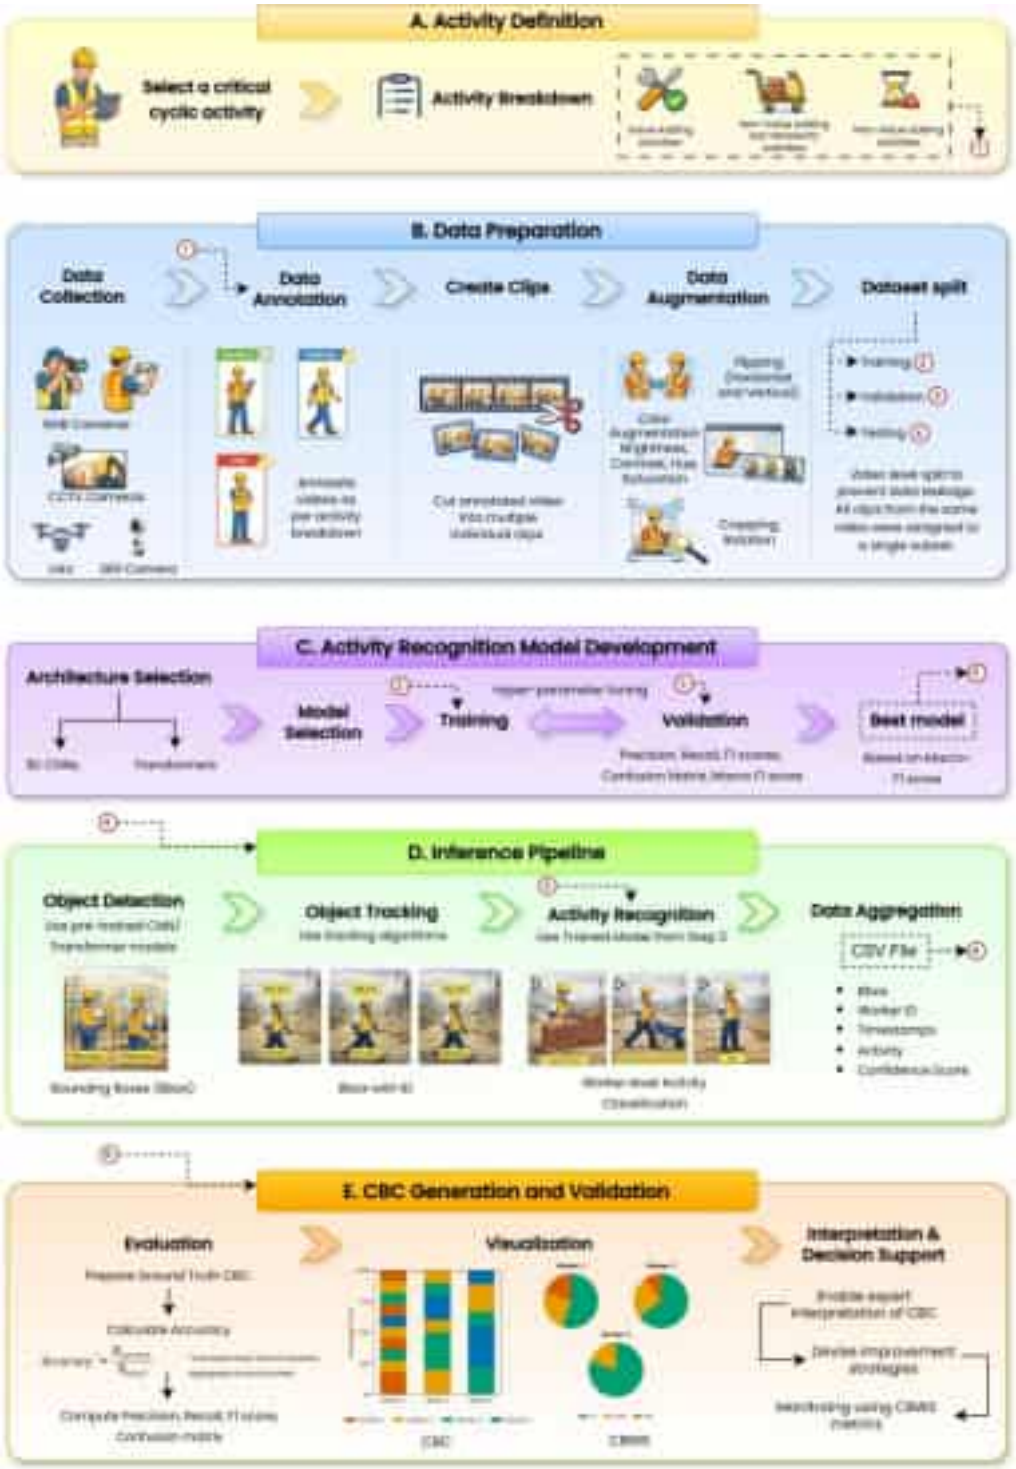

Figure 2 Computer Vision-based Crew Balance Chart Framework

3.4 Inference Pipeline

This stage represents the operational stage of the proposed CV-CBC framework. During inference, workers are detected in each frame, tracked across time with unique IDs, and converted into worker-level clips. The trained activity recognition model is used to predict the activity classes. These predictions are stored in a Comma-Separated Values (CSV) format along with temporal information. This serves as an input for CBC generation in the next stage.

3.5 CBC Generation and Validation

The final stage of the framework converts worker-level activity predictions from the inference pipeline into a CBC and evaluates its accuracy. Predicted activities are temporally organised into continuous timelines for each worker and aligned along a common time axis to generate the CBC. The accuracy is computed by comparing predicted activities with manually annotated ground truth labels at a per-second temporal resolution, aggregated across all workers, as shown in Equation (1)

$$Accuracy = \frac{N_{Correct}}{N_{Total}} \quad (1)$$

where N_{correct} and N_{total} denote the total number of correctly predicted and total activity predictions, respectively, aggregated across all workers.

Performance is evaluated using standard metrics, including accuracy, F1-score, precision, recall, and confusion matrices. Similarly, CBWS metrics are calculated by aggregating recognised activities into the Value-Adding (VA), Non-Value-Adding (NVA), and Non-Value-Adding but Necessary (NVAN) categories, enabling high-level crew monitoring.

4 Implementing CV-CBC Framework

4.1 Activity Definition

This section presents the implementation of the proposed CV-CBC framework using masonry as the main activity. Masonry was selected because it is a labour-intensive, repetitive process that requires close crew coordination, making it prone to work imbalance and enforced idleness. These characteristics make masonry well-suited for CBC analysis. Based on on-site observations of the masonry work, the main activity was broken down into a set of worker-level activities that occur during execution. These activities were defined to represent distinct and meaningful work states observed repeatedly across work cycles. The selected activities and their descriptions are summarised in Table 1.

Table 1 Description of selected activities

Activity	Category	Description
Applying Mortar	VA	Applying mortar between blocks and preparing bed
Idle	NVA	No productive or supporting work
Laying Blocks	VA	Placing and positioning masonry blocks
Shifting Materials	NVAN	Transporting/ Repositioning materials or tools

4.2 Dataset Preparation

Video data were collected from multiple construction sites under normal working conditions using a static camera. Most of the videos were not recorded specifically for computer vision analysis, but rather captured for manual observation. A total of seven videos were collected, with crew sizes ranging between three and four workers. The videos were annotated using the Computer Vision Annotation Tool (CVAT), and the XML files were exported in CVAT 1.1 format, which enabled clip generation. Worker-level clips were generated, each with a fixed duration of 8 seconds. Data Augmentation was applied using horizontal mirroring, brightness, and contrast adjustments. The details of the clips, class-wise, are presented in Table 2.

Table 2 Details of Clips

Class	Clips (No.)	Duration (min.)
Applying Mortar	305	42.62
Idle	357	47.75
Laying Blocks	263	35.15
Shifting Materials	318	40.81

The dataset was split using the following strategy: one video was reserved for validation, one for inference, and the remaining for training.

4.3 Model Training

A transformer-based architecture was selected for activity recognition, as transformer models are well-suited for learning spatio-temporal information from videos. In this experiment, the VideoMAE-Small model pre-trained on the Kinetics-400 dataset was used.

The small variant was chosen to mitigate overfitting given the limited dataset size. Each 8-second clip was uniformly sampled and resized to 224 × 224 pixels to match the pre-training input configuration. The proposed model was then fine-tuned on the annotated videos using supervised learning. A partial fine-tuning strategy was employed by unfreezing 6 of the 12 backbone layers, enabling greater adaptation to construction while preserving common spatial and temporal characteristics learned during pre-training. The trained model achieved a macro F1-score of 0.54, indicating balanced recognition performance across activity classes. During training, class-wise F1-scores were 0.44 for Applying Mortar, 0.56 for Idle, 0.49 for Laying Blocks, and 0.66 for Shifting Materials.

To validate the model choice, a 3D CNN-based I3D model was also evaluated, achieving a macro F1-score of 0.43, with class-wise scores ranging from 0.36 to 0.48. In comparison, VideoMAE achieved a higher macro F1-score of 0.54 and was therefore selected for subsequent experiments.

4.4 Inference Pipeline

During inference, the test set was used to generate the CBC using an end-to-end pipeline. The pipeline comprises object detection, object tracking, activity recognition and post-processing. The test video is 164 seconds long; a segment was trimmed to include only activity classes on which the model is trained, enabling fair evaluation. The crew size is three, and the work cycle is defined as the construction of one masonry course.

4.4.1 Object Detection

The YOLO11x object detection model, pre-trained on the COCO dataset, was used to identify workers in each video frame. In cluttered construction site environments, detection sensitivity and localisation accuracy were balanced using an Intersection-over-Union (IoU) threshold of 0.5 and a confidence threshold of 0.3. Frame-wise bounding boxes generated by the detector were used as inputs for tracking. High detection performance is achieved with a precision of 98.8% and a recall of 98.6%, indicating reliable worker localization.

4.4.2 Object Tracking

The BoT-SORT multi-object tracking algorithm with re-identification (ReID) enabled was used to track detected workers across frames. This was made to assign distinct worker IDs consistently. Only tracked IDs with a minimum continuous duration of 30 frames were retained for further analysis to eliminate workers not relevant to the work cycle. A total of two ID switches were observed across all workers, with Multi-Object Tracking Accuracy of (MOTA) of 97.4%. For better visualisation, tracking IDs were grouped for subsequent analysis.

4.4.3 Activity Recognition

For each tracked worker, bounding box–based crops were used to generate worker-centric clips. Activity recognition was performed using the trained VideoMAE model with an input resolution of 224 × 224 pixels. A 2-second sliding window, consisting of 16 frames, was applied with a stride of 1 second, enabling per-second activity predictions. For overlapping windows, the activity with the highest confidence was selected.

4.4.4 Post-processing

Before CBC generation, worker-level activity timelines were stabilised using post-processing rules. Idle predictions were filtered using a temporal persistence rule, assigning the idle label only if it persisted for more than two seconds and exceeded a confidence threshold of 0.75. This reduces false idle predictions caused by short pauses or low-motion intervals that occur during continuous productive work (such as laying blocks). The worker-level activity timelines were then combined to generate a CBC.

4.5 CBC Generation and Validation

Activity recognition performance was assessed using class-wise F1-score. The model shows limited generalisation compared to training performance. Laying Blocks achieved the highest F1-score (0.62), followed by Shifting Materials (0.38), while Applying Mortar and Idle recorded lower F1-scores of 0.18 and 0.09, respectively. The confusion matrix in Figure 3 shows that Applying Mortar and Laying Blocks are the most frequently misclassified activities, with many Applying Mortar instances incorrectly predicted as Laying Blocks. This confusion arises because both activities exhibit similar motion cues, such as bending and hand actions with a trowel or masonry blocks, making it difficult to distinguish between them.

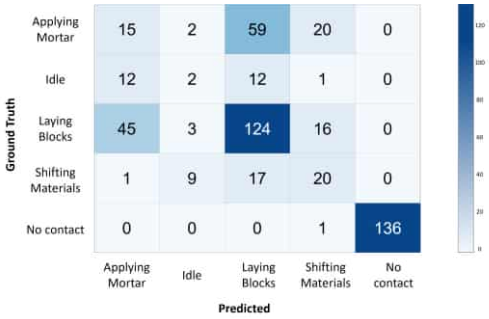

Figure 3 Confusion Matrix

The automated CBC is produced by aggregating worker timelines, whereas the manual CBC was prepared using the traditional process. To ensure ground truth reliability, inter-annotator agreement (IAA) was evaluated on the test set with two annotators and Cohen's κ, achieving 93.30% agreement ($\kappa \approx 0.90$), indicating almost perfect agreement. When the worker is out of the frame, it is termed "No Contact". Figure 4 illustrates the manually created Crew Balance Chart with automated CBCs generated by the CV-CBC framework.

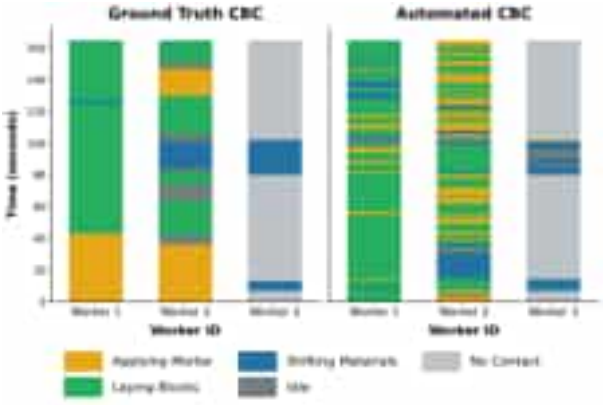

Figure 4 Ground truth CBC and Automated CBC

CBC accuracy was computed by comparing predicted and ground-truth activity labels at a per-second, per-worker resolution (Equation 1). The automated CBC achieved an accuracy of 60.0 % (297 accurate predictions out of 495 total) including No-Contact periods and 45% excluding them. This metric reflects the framework's ability to reconstruct the temporal structure of activities.

CBWS metrics were derived by aggregating activity predictions into VA, NVAN and NVA categories. For each worker, VA, NVAN and NVA time proportions were computed from ground truth and predicted activities and compared using absolute percentage deviation, as reported in Table 3. Workers 1 and 2 primarily engage in value-adding tasks, whereas Worker 3 is involved only in NVA and NVAN. This distribution is consistent with typical mason–helper role patterns and demonstrates the potential for identifying worker-level contributions to support high-level labour monitoring.

Table 3 CBWS comparison between ground truth and predictions

Worker	Category	Ground Truth (%)	Predicted (%)	Absolute Error (%)
1	VA	98.79	90.91	7.88
	NVAN	1.21	7.27	6.06
	NVA	0.00	1.82	1.82
2	VA	73.33	81.21	7.88
	NVAN	10.30	15.76	5.46
	NVA	16.36	3.03	13.33
3	VA	0.00	3.45	3.45
	NVAN	100.00	68.97	31.03
	NVA	0.00	27.59	27.59

5 Discussion

This study demonstrates that the proposed CV-CBC framework can automatically extract activity-level information to generate CBC. The activity recognition model achieved a validation macro F1 score of 0.54, while the automated CBC achieved an accuracy of 60%, comparable to prior work. Toledo et al. reported a 58% CBC accuracy under site conditions using a fixed camera, with contributory work not detected (0%) due to occlusions and viewpoint limitations [6]. The literature does not define strict deployment thresholds; however, prior studies suggest that accuracy levels around 78–85% are sufficient for practical use [14][15]. Accordingly, the results should be interpreted as a proof of concept.

The reported CBC accuracy of 60% includes no-contact periods, which inflates performance as it is easier to detect the absence of a worker; excluding them reduces accuracy to 45%, which better reflects the activity recognition performance. Given the high performance of detection and tracking stages, the overall pipeline performance is primarily constrained by activity recognition, which limits the CBC accuracy. Most errors arise from activity misclassifications, while detection and tracking contribute comparatively less. Although only two ID switches were observed, identity consistency remains critical for CBC generation, as even minor track fragmentation can affect worker-level timelines, suggesting the potential for post-processing strategies to maintain consistent identities.

These results should be interpreted in the context of the dataset. The dataset is small, and the framework is validated only on masonry activity, limiting generalizability. Extending to other activities or larger datasets may introduce class imbalance (e.g., overrepresented idle class), requiring resampling or augmentation. Due to the data constraints, the study was not extended to other activities.

At the activity level, significant confusion was observed between laying blocks and applying mortar because of their similar motion patterns. Table 3 shows that the mean absolute error for VA activities is within 8%, indicating higher reliability in detecting productive work. In contrast, NVA and NVAN activities exhibit higher error rates. The distinction between these two categories is subjective, as even human observers may classify the same activity differently during manual CBC generation. Higher error rates observed for Worker 3 can be attributed to the worker's limited presence in the video, which amplifies relative errors.

The generated CBCs reveal enforced idleness and work imbalance, supporting productivity improvement strategies during meetings. Extending activity level outputs to CBWS further enables high-level monitoring of worker contributions within a crew. Such monitoring enables supervisors to identify any sustained deviations from the expected value-adding work, allowing earlier intervention compared to post-hoc productivity reporting. Overall, the framework enables automation of Lean tools such as CBC and CBWS, supporting scalable crew-level productivity monitoring and continuous improvement.

6 Ethical Considerations

The video data used in this study were collected for manual observation of construction activities. To preserve worker anonymity, no images or visual data are presented in the manuscript. The analysis is limited to activity-level information, and no individual worker identities are used or reported.

The framework is aligned with Lean Construction Principles, where the activity classifications are intended for waste identification and process improvement. Periods labeled as "Idle" or "Non-Value-Adding" should be interpreted as indicators of workflow constraints (e.g., work front unavailability) and not as worker inefficiency.

A tolerance for short durations of idle activity should be accounted for allowing the natural rhythm of the worker. The framework is not intended for individual-level performance monitoring or punitive use, but for identifying recurring process-level inefficiencies, and outputs should be interpreted at the crew level.

7 Conclusions

This paper proposes a Computer Vision–based Crew Balance Chart (CV-CBC) framework for automatically generating CBCs from construction site videos by integrating worker detection, tracking, and activity recognition. The framework was implemented on the masonry activity and validated through per-second comparison with manually prepared CBCs. The results show that the activity recognition model achieves a macro F1-score of 0.54, while the automated CBC attains an accuracy of 60%. Analysis indicates that the primary source of error arises from confusion between temporally similar activities, Laying Blocks and Applying Mortar, which share similar motion cues. Despite these results, the study has several limitations. The dataset is relatively small and was not originally captured for computer vision–based analysis. Furthermore, the evaluation is restricted to a single construction activity, which limits the extent to which the results can be generalised. Moreover, the inclusion of No-Contact periods can inflate overall CBC accuracy, highlighting the need for more representative CBC-level evaluation metrics.

Future work will focus on implementing the framework on larger, more diverse datasets and on multiple construction activities. Incorporating vision–language models to capture richer spatial context, such as identifying the tools and materials workers handle, could enable zero-shot activity recognition. Given their strong ability to learn temporal information, video transformers can be ensembled with vision-language or keypoint-based models to improve robustness and better distinguish visually similar activities. Overall, the proposed framework highlights how computer vision can support crew-level productivity monitoring and productivity improvement.

Abstract -

The Last Planner System® (LPS®) and Building Information Modeling (BIM) hold strong potential to improve construction productivity, yet their integration at the data-processing level remains limited. Information embedded in BIM models is often insufficiently structured and therefore not directly exploitable for LPS® implementation. This study proposes an approach that integrates LPS® with BIM while leveraging multiple sources of operational project data to automate phase planning. The work focuses on the mechanical, electrical, and plumbing (MEP) domain, which is particularly complex and has been less explored in prior research.

A digital tool was developed to automatically generate time–location schedules by combining tender-phase estimates, execution-phase BIM models, client-defined milestones, and expert knowledge of MEP work sequencing. System requirements were defined through a literature review and surveys with MEP professionals. Installation operations were standardized, and the solution was implemented as a three-tier web application supporting automated data extraction, processing, and visualization for project planning, using tools such as Dynamo Revit, MySQL, Java, and Angular.

Validation on a real project demonstrated clear benefits: the time required for initial planning is reduced by up to one week compared with traditional methods. In addition, automated schedule generation and updates yield a financial gain of 0.91% of project revenue - equivalent to nearly 30% of the planned profit margin - highlighting both the practical value and the economic relevance of the proposed approach.

Keywords -

LPS®, BIM, Lean construction, MEP, Construction Management

1 Introduction

Detailed production planning and control has been consistently emphasized in the Lean Construction (LC) literature as fundamental to overcoming the shortcomings of high-level project plans developed during the preconstruction stage (master plans). Such plans typically provide sufficient detail and time horizons for owner-contractor coordination, but are inadequate for guiding day-to-day construction activities and ensuring reliable project delivery [1, 2]. To address this limitation, LC advocates progressively translating project objectives into executable tasks closer to the point of delivery. The Last Planner System® (LPS®) operationalizes this principle by introducing phase planning as an intermediate level that bridges long-term strategies and short-term commitments, and by incorporating lookahead planning to identify and remove upcoming constraints. Combined, these components enhance planning reliability, stabilize workflow, and improve the predictability of project delivery [3, 4, 5].

Recent research shows that integrating LC and BIM, particularly through BIM-LPS® co-application, further extends these benefits, as BIM supports the rational use of resources (e.g., materials, crews, and equipment) in alignment with the schedule and facilitates improved information flow [6]. This synergy has motivated the development of so-called Lean IT-tools, which are designed to support one or more aspects of the LPS® while providing links to BIM models. Examples include LEWIS [7], which integrates 2D/3D plans, production data, and 4D visualization; KanBIM [8, 9], which enables short-term planning and monitoring with clear task-maturity visualization; and VisiLean [10], which supports multiple planning levels and resolutions, such as phase, lookahead, and weekly planning. VisiLean also provides a mobile interface allowing workers to access task information, update status, and synchronize progress with the BIM model in real time.

Despite these advances, BIM-based production management systems still lack data-level integration between BIM and LPS® [11, 12]. In practice, BIM information is not systematically structured for direct use in LPS®, and object–task links are often created manually during workshops, making the process slow and inefficient. These links also fail to enrich task attributes such as quantities or costs, leaving much of BIM's potential underused. This aligns with findings by Schimanski et al. [13, 14], who note that seamless BIM-LPS® integration requires advanced capabilities such as automatic task generation, cost estimation, and flexible data exchange. Reflecting this need, recent work shows that automating planning and control within LPS® supports 10 of the 11 Lean Construction principles [15].

Parallel to these observations, automated BIM-based

scheduling has been widely explored in structural engineering [16]. Early studies, such as De Vries and Harink [17], generated preliminary schedules using component relationships from 3D CAD models and duration estimates. Kataoka [18] expanded this direction by producing multiple schedule scenarios from early design models and construction knowledge templates. More recently, Wang and Lin [19] enhanced BIM with work-package information to address resource-constrained scheduling problems. Yet despite these contributions, a core scientific challenge persists: integrating heterogeneous datasets (e.g., estimates, BIM models, contracts, tenders, and task-sequencing knowledge) into a coherent automated planning process.

Field evidence gathered in this research reinforces this gap. While practitioners show strong proficiency in 3D modelling, a clear need remains to advance toward 4D BIM integration [20]. Tender-stage BIM models are often inconsistent (e.g., oversized vertical ducts or duplicated network elements) and frequently lack standardized codification (Omniclass, Uniclass), making them unreliable for workload estimation or schedule development [21, 22, 23]. As a result, professionals manually consolidate fragmented data (quantity take-offs, estimates, contracts) and create schedules in tools like MS Project or Primavera, relying more on personal expertise than on automated, data-driven methods. This process is time-consuming—about 0.91% of project revenue, a significant cost given a 3% profit margin [23]—and highlights the need for automation in MEP planning, where BIM-based scheduling remains underdeveloped [16].

2 Research objectives and methodology

In response to these gaps, this research aims to advance BIM-LPS® data integration by automating the generation of LPS® phase schedules. It focuses on MEP schedule automation, an area less explored than structural works due to its complexity and interdisciplinary nature [16]. The study moves beyond conventional BIM use by integrating multi-source, multi-phase data, combining project estimation information with execution-phase BIM outputs to detect discrepancies between tender assumptions and execution realities. This enhances decision-making and strengthens alignment between tendering and execution teams. Accordingly, the research investigates how integrating such operational data enables automated LPS® phase schedule generation in the complex context of MEP works, thereby laying the foundation for an optimized approach to managing building information, termed Lean BIM Management.

To ensure both practical relevance and theoretical contribution, the study follows a Constructive Research Approach (CRA). CRA develops innovative artifacts that address real-world problems while informing theory. It relies on abductive reasoning and close collaboration with practitioners [24]. Guided by the CRA framework (Figure 1), the research identifies the BIM–LPS® integration challenge through literature review, and an assessment of MEP scheduling practices and need within the industrial partner, Equans (Section 1: Introduction). Empirical insights were gathered through a survey of 100 professionals and semi-structured interviews with five project managers. The proposed automated planning solution was then designed (Section 3), implemented, and validated through a case study and qualitative feedback (Section 4), from which its theoretical contributions were derived (Section 5).

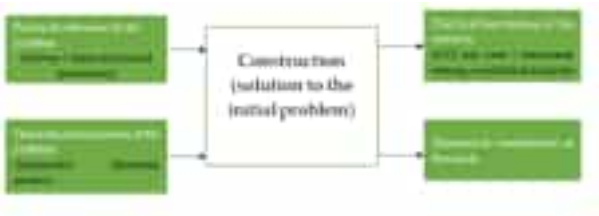

Figure 1. CRA framework and methods used

3 Design and development of the automatic scheduling solution

The system was developed from functional and operational requirements, as detailed in [20, 23], and implemented as a 3-tier web-based scheduling solution. Figure 2 presents the overall framework of the developed artefact. While the framework can guide automated planning in other MEP enterprises, consistent data requirements and algorithms notwithstanding, variations in input sources' structure and availability require careful analysis and adaptation to each organizational context.

3.1 Data sources

The first pillar outlines the primary data sources, including project cost estimates and the execution-phase BIM model, which provide material quantities at the tendering and execution stages, respectively. Cost estimate data are obtained from two sources: quantity takeoff sheets prepared by cost estimators and the final bidding document (client contract) generated using QuickDevis. An initial analysis of both sources reveals key limitations. The QuickDevis file lacks contextual information, such as the location of materials and their associated systems. Instead, it is organized into custom sections based on the client's global price decomposition structure (DPGF), which often results in the grouping of equipment and their associated installation durations without detailed breakdowns. Conversely, the quantity takeoff sheets provide

valuable contextual and technical information, including material quantities, locations (building and floor), MEP system assignments, and technical specifications (e.g., diameter, flow rate, pressure). However, they do not include installation durations. Although incomplete, this structured technical data could nonetheless serve as a basis for deriving installation times by matching each article to the corresponding cost database item, using material classification codes and technical characteristics. In case of ambiguity, item codes were assigned in consultation with superintendents. For example, a 315 mm flexible duct may correspond to GNF 0315 (aluminium), GNF I-315 (insulated aluminium), or GNF G-0315 (semi-rigid, non-insulated), with installation times of 0.2 h/m for the first two and 1 h/m for the third, illustrating the impact of incomplete specifications on planning.

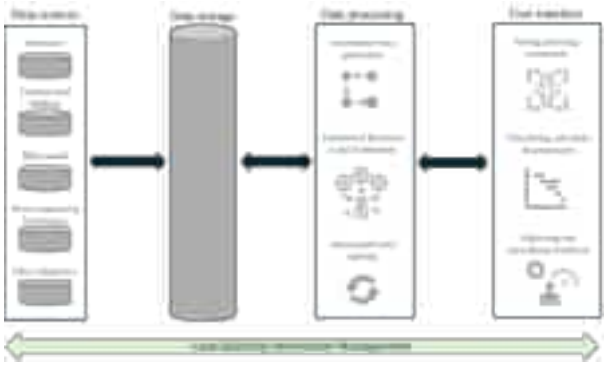

Figure 2. Architecture of the automated planning solution

A similar challenge arose when working with execution-phase BIM models, which often lack sufficient detail, including installation durations and technical specifications needed for direct cost database coding. To address this, a custom Dynamo–Python workflow was developed to link BIM materials to cost database categories, with item codes assigned in consultation with superintendents to resolve inconsistencies and ensure accurate mapping.

Beyond material quantities and durations, the contractual schedule provides the system with project milestones, organized by building level and, where relevant, by specific zones. Finally, the automated scheduling system required formalization of material installation sequences and time allocations, which were captured through expert workshops, converting informal know-how into structured planning knowledge. Previous work by the authors detailed the bill of process for the stainless black steel distribution pipe category (“TAD”) [20].

3.2 Data integration and database architecture

The second pillar consists of a MySQL database, whose conceptual model is illustrated in Figure 3. The database is structured around several entities (yellow blocks) interconnected by associations (blue blocks). For clarity, these entities and associations are grouped into four categories, each corresponding to a distinct data typology and visually delineated by dashed rectangles, within which the previously described data sources are stored. In terms of data integration, BIM quantity take-offs were automatically imported via a Dynamo script, whereas all other data were manually uploaded in Open Document Format.

3.3 Data processing algorithms and workflow

The third pillar is a backend server that represents the central and “intelligent” component of our automatic scheduling system. It handles data processing and employs advanced algorithms to transform scheduling input data into accurate and reliable time-location schedules. Developed using the Java programming language, this layer interfaces with both the database and the user interface, as shown in Figure 4. The data transformation process includes task instantiation by building, level, system type, and superfamily, followed by computation of durations, start, and end dates for the tendering and design phases. Execution dates account for working hours, level availability, and prerequisite tasks. Tasks are first transformed into a graph and topologically sorted using a depth-first search algorithm (DFS) to respect predecessor-successor relationships. The mathematical model described in [20] then computes task durations and dates while estimating required daily manpower.

3.4 User interface

The final layer is the user interface, implemented using the Angular framework, enabling intuitive interaction with the automatic planning tool. Results for the Rennes Surgical and Interventional Center case study are presented in the next section.

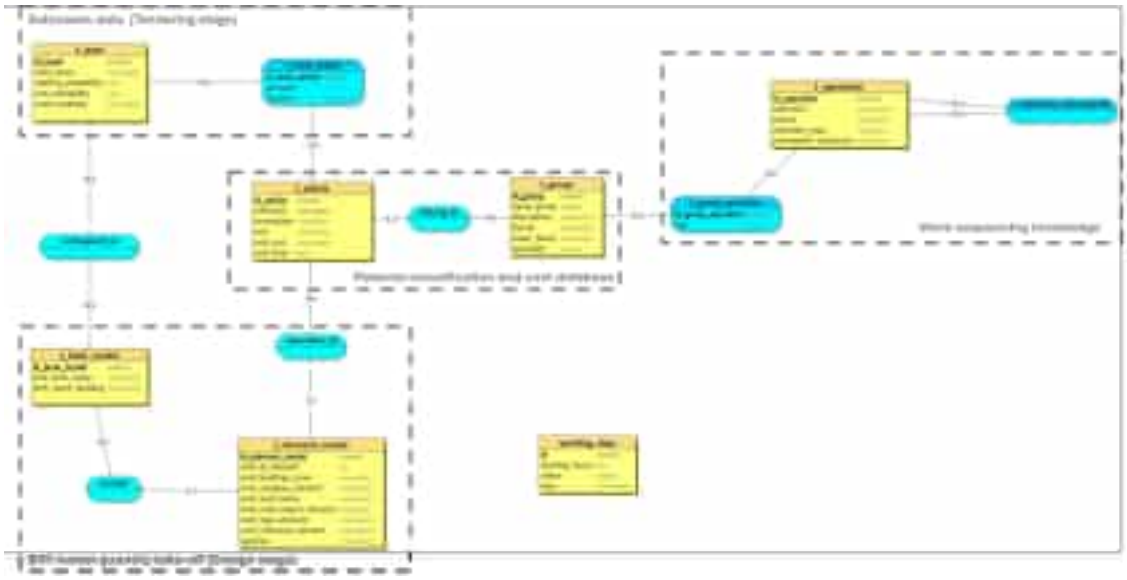

Figure 3. The conceptual model of the scheduling database

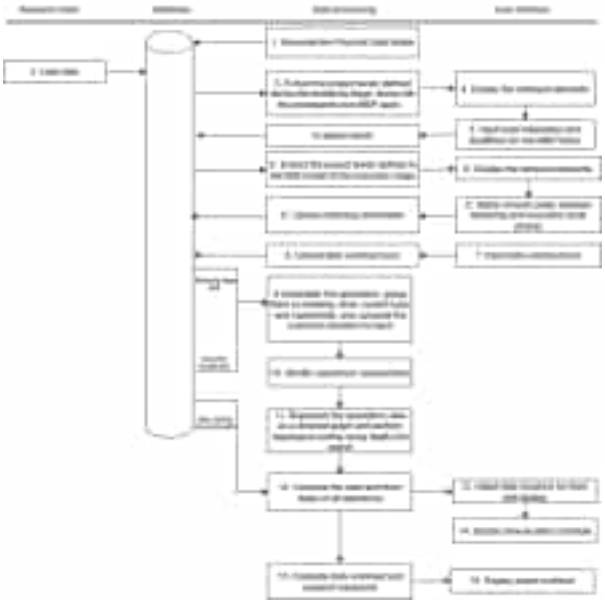

Figure 4. Algorithmic Workflow of the Automated Scheduling System

4 Case study

To assess the practical functionality of the solution in accordance with CRA guidelines, the proposed system was evaluated through a case study with Equans, using operational MEP data of the €20.8 M Surgical and Interventional Center in Rennes. The project involves the construction of a technical platform dedicated to surgery, interventional radiology, and intensive care, consolidating all surgical blocks and interventional radiology rooms of the Rennes University Hospital Center (CHU) in northwestern France. Figure 5 presents a 3D view of the project's BIM model. The evaluation comprised two phases: demonstration of core functionalities and validation of results through expert review.

Figure 5. Capture of the case study project 3D BIM model, featuring the properties of a circular flexible duct instance "GNF-G-0315"

4.1 Demonstration of the solution functionalities

The user interface offers functions for inputting scheduling constraints such as level availability dates, preliminary milestones from other disciplines affecting MEP activities, and working days and hours. Based on these inputs, the system automatically generates a time-location schedule, first using cost estimation data and subsequently updated with execution-phase BIM data. Results are visualized through a multi-level GANTT diagram (Figure 6), with cost-based schedules shown in green and BIM-based updates in orange. The "Start PRJ," "End PRJ," and "Du-

ration PRJ" columns show task dates and durations from costing data, while the "EXE Start," "EXE End," and "EXE Duration" columns report the corresponding values from the execution stage using the 3D BIM model. Unlike conventional LPS® representations, tasks are not displayed in a time-distance diagram, preserving detailed MEP sequencing and preventing overlaps.

Figure 6. Detailed overview of the tasks required to install hot water system terminals on the ground floor

Figure 7. Detailed task information. (a) General information tab. (b) Predecessors tab. (c) Resources tab. (d) Notes tab.

The interface further provides detailed task views through four windows (Figure 7):

- **General**: contains information on task duration, start, and end dates.
- **Dependencies**: lists all predecessors of the selected task.
- **Resources**: lists the equipment linked to this task derived from the quantity surveying data, along with their quantities. These correspond to the items checked in the list.
- **Notes**: lists the equipment linked to this task derived from the BIM model, including their quantities and properties.

Lastly, the system computes daily workload and provides estimates of the required human resources.

4.2 Expert validation results

To validate alignment with user requirements identified in semi-structured interviews, a workshop was conducted with six senior project managers ($\geq$ 20 years of experience, projects exceeding €15 M). The session presented the application's features and gathered feedback on functionality, gaps, and potential improvements. Figure 8 summarizes functional coverage and participant feedback.

A post-workshop questionnaire evaluated the solution's utility and reliability through seven key questions addressing problem relevance, current applicability, usefulness for construction planning, result accuracy, computation time, functional coverage, and willingness to test the solution on a pilot site.

Participants recognized the solution's relevance; however, two-thirds expressed concerns regarding calculation accuracy, potentially due to past negative experiences with automation, a preference for manual processes, or resistance to change. Eighty-three percent found processing times reasonable, and 67% indicated willingness to test the tool on live projects.

5 Discussion and analysis

Although planning automation is not a new issue, this study offers several significant contributions.

First, it addresses the automation of MEP work scheduling, an area that has received considerably less attention than structural works [16]. The relative neglect of MEP disciplines can be explained by their inherent complexity, as they involve highly interconnected systems installed in confined spaces and require coordination among multiple subcontractors. These challenges, combined with the dynamic and uncertain nature of construction projects, make the planning and control of MEP works particularly critical.

Second, the proposed solution capitalizes on operational data from multiple sources beyond the BIM model alone. This distinguishes it from previous research efforts, which often rely exclusively on BIM data [17, 18, 19]. However, the study also highlights key challenges encountered in construction projects, notably data incompleteness and heterogeneity. Data incompleteness stems from the lack of exhaustive equipment descriptions in both costing sheets and BIM models, which hinders accurate identification of corresponding equipment codes in cost databases. To improve the reliability and efficiency of the proposed au-

Figure 8. Coverage of User-Specified Functionalities and Project Manager Feedback (green: functionality fully developed, yellow: partially developed, orange: not developed, purple: new functionality identified)

tomated scheduling system, it is therefore essential to enhance the level of detail in these data sources. At present, this limitation restricts the full deployment of required functionalities and constrains the scalability of the solution. Consequently, rigorous data capture, codification, and preservation from the early project phases are required to fully realize the potential of the proposed planning approach. In addition, the adoption of standardized classification systems such as Omniclass or Uniclass could help reduce semantic incompatibilities between data produced by different actors and project phases.

Third, the research formalizes MEP planning know-how through expert workshops. However, the manual and explicit modeling of each material's operations and dependencies proves to be costly and labor-intensive, which may limit scalability when extending the system to new material categories. A promising direction for future work is the automated acquisition of planning knowledge from existing project records, such as historical schedules, BIM-based process data, technical specifications, and execution reports. Recent studies have demonstrated the potential of sequential machine learning to learn dynamic work templates from past schedules, of pattern-recognition methods to identify recurring process logic in BIM-based schedules, and of natural language processing techniques to extract structured knowledge from construction documents. Taken together, these advances suggest that part of the sequencing knowledge currently captured through expert elicitation could in the future be inferred automatically from accumulated project data, thus reducing setup cost and improving transferability across new material families [16, 25].

Fourth, the proposed automated scheduling application streamlines the project planning process by rapidly and effectively processing complex datasets. When input data are complete, the solution can save an average of one week of manual work per project manager, thereby freeing time for higher-value activities such as decision-making and problem-solving. Beyond these time savings, the economic impact is equally significant: automation generates a gain of approximately 0.91% of project revenue, corresponding to nearly 30% of the targeted profit margin (3%). These estimates were developed collaboratively with domain experts using average project data, reinforcing both their credibility and practical relevance. To further enhance its contribution, the application should be extended to the remaining phases of the LPS®, including lookahead planning, weekly work planning, and progress monitoring. The latter could itself be automated using advanced techniques such as unmanned aerial vehicles (UAVs) or real-time location systems (RTLS) for data capture, as well as 3D digital imaging and computer vision algorithms for progress measurement [26, 27].

Finally, this work aligns with broader objectives related to ensuring data continuity throughout the construction project lifecycle, thereby paving the way for more efficient building information management. A significant avenue for future research lies in expanding the automated planning tool to involve additional project stakeholders, including actors in design, procurement, manufacturing, logistics, and commissioning. This evolution entails harnessing large volumes of data from diverse operational sources, which requires the implementation of data warehouses (Figure 9). Such data warehouses are supplied with information generated by multiple operational soft-

ware systems across project stages, enabling reporting, data mining, and strategic decision-support analyses [28]. This approach introduces a new perspective on lean building information management, referred to as *Lean BIM Management*, and contributes to the emergence of a new era in Lean Construction characterized by intelligence and interconnection between machines, humans, and materials - an evolution described as the *Smart Lean era* by Demir [29].

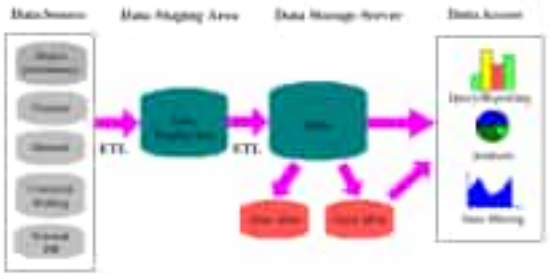

Figure 9. Architecture of a construction-project data warehouse [28]

6 Conclusion

This study aimed to enhance the integration between the Last Planner System® (LPS®) and Building Information Modeling (BIM) at the data-processing level. The main contribution of this work is the development of a web-based application that automatically generates time–location schedules for MEP trades by leveraging multiple data sources, namely cost-estimation data and BIM model information.

Following a Constructive Research Approach, the paper first identifies the planning problem and reviews its theoretical background, before detailing the architecture, input data, and user interface panels of the proposed automated scheduling solution. Real project data from the Rennes Surgical and Interventional Center case study are then used to demonstrate the practical functioning of the system. In addition, an analytical evaluation conducted through focus groups highlights the utility and relevance of the developed application, despite some initial and largely unfounded skepticism regarding the accuracy of automated planning calculations.

Finally, the study discusses the theoretical implications of the proposed artefact, laying the foundation for an effective approach to building information management, referred to as *Lean BIM Management*. Building on this foundation, the paradigm opens avenues for future developments through the integration of data from multiple construction stakeholders into centralized data warehouses. Such integration would ensure data continuity across the entire project lifecycle- from design and procurement to manufacturing, logistics, construction and commissioning- thereby significantly enhancing project management practices and data utilization within the construction industry. This progression ultimately supports the emergence of a Smart Lean Construction era, characterized by greater intelligence and stronger interconnections among data, actors, and processes.

AI-based Dynamic Quiz System: Disaster Knowledge King

Chen-Hao Tseng[1] and James Yichu Chen[1]

[1] National Taiwan University of Science and Technology, Taiwan
chtseng@9999gmail.com, yie@mail.ntust.edu.tw

Abstract

Amidst escalating global climatic threats, effectively disseminating disaster preparedness knowledge to the public remains a critical challenge. This study introduces Disaster Knowledge King (DKK), an automated, dynamic quiz system designed to modernize disaster risk reduction (DRR) education. While traditional educational games suffer from static, "dead" databases that require manual updates, DKK leverages Large Language Models (LLMs) and Retrieval-Augmented Generation (RAG) to facilitate real-time content creation.

The system features a fully automated pipeline that scrapes global news from sources like AP and Reuters, filters for recency, and utilizes the Gemini API to generate multiple-choice questions. By grounding responses in professional Ready.gov guidelines via RAG, DKK provides users with both situational awareness and actionable response strategies, and system is implemented as a LINE Bot to ensure high accessibility. While the DKK reduces the production cost to approximately $0.002 per question set, its G-Eval and UAT scores significantly exceed the median threshold. This study indicates that integrating AI-driven automation with gamified social media interfaces offers a scalable and efficient pathway for enhancing public disaster literacy.

Keywords

LLMs, RAG, automation, DRR, disaster literacy, education, LINE Bot, multiple choice questions.

1 Introduction

1.1 Background

For decades, humanity has confronted the escalating threat of anthropogenic global warming, characterized by an increase in extreme climatic events and natural disasters. While disaster management experts over the world have developed sophisticated mitigation strategies and response frameworks, a persistent challenge remains: the effective spread of “disaster preparedness knowledge” and “environmental literacy” to the general public.

The 2022 debut of OpenAI’s ChatGPT precipitated a revolutionary transformation in both professional productivity and daily life, signalling a new era of AI-augmented workflows. Consequently, the application of Large Language Models (LLMs) has expanded across diverse sectors, fostering unprecedented levels of innovation and generation. Within this context, experts have begun leveraging these models to enhance disaster education through the pedagogical adaptation of complex materials, the design of immersive practice scenarios, and the high-level analysis of learner performance.

1.2 Motivation

The classic mobile game “Knowledge King” is a landmark educational title that has achieved widespread popularity in Taiwan. The game utilizes a vast database of multiple-choice questions across diverse fields, challenging users’ knowledge in a competitive "contest mode." By presenting information in a thrilling and engaging format, Knowledge King has successfully demonstrated how gamification can enhance general knowledge. This study argues that “an educational tool modeled after Knowledge King is an ideal method for disseminating “disaster preparedness knowledge” and “environmental literacy” to the general public.”

However, this study identifies a critical limitation within the current Knowledge King model: the static nature of its database. Because the question pool is "dead," it requires labor-intensive and time-consuming manual updates to renew. This prevents the content from real-time information, so it’s a drawback that must be addressed.

1.3 Objective

This study aims to develop a dynamic quiz system titled "Disaster Knowledge King" (DKK). Designed as an advanced iteration of the Knowledge King framework, DKK focuses specifically on disaster prevention education. The system provides multiple-choice questions based on real-time disaster information, accompanied by comprehensive explanations and recommended response strategies. The most significant innovation of DKK is its ability to maintain a contemporary database; unlike traditional static systems, DKK utilizes Large Language Models to automate the

generation of questions. By leveraging the successful engagement strategies of its predecessor, DKK serves as a highly efficient educational tool for spreading “disaster preparedness knowledge” and “environmental literacy”.

2 Literature Review

As extreme weather and associated disasters are the biggest contemporary global concern, “disaster risk reduction (DRR)” is imperative that many papers have valued its integration into education and explored the better methods to practice it. Research argues that DRR in education is a psycho-social concept that the successful integration of DRR requires a transition in instructional design toward localized and participatory approaches, emphasizing individual specialized action and active engagement within local communities and environments[1]. Nahid Aghaei [2] et al. also focus on the DRR education strategy for raising knowledge, and the critical point is to transfer accessible information with high quality, especially through the community involvement to share knowledge.

However, the main challenge remains the deficiency in conceptual understanding regarding DRR, directly contributing to resource scarcity and the stagnation of social development in this area. As it is difficult to enhance public disaster literacy through traditional methods, utilizing social networks or media offers a viable and potential channel[1, 2].

Because of resource scarcity, utilizing Artificial Intelligence to assist material production is a promising method. Biancini et al.[3] have introduced a methodology for generating multiple choices question by LLMs. By providing the context and specific prompts, GPT-3.5 could be proficient in generating MCQs, which is evaluated through the non-parametric Friedman test. This study illustrates the viability of LLMs to produce MCQs and provides valuable insights for the future.

Additional research either demonstrates the capacity of LLMs to generate complex questions—specifically those involving analysis and synthesis—which highlights this model’s suitability for educational curricula. GPT-4 has exhibited the greatest versatility in constructing tasks of different formats and at multiple cognitive levels in alignment with Bloom's Taxonomy.[4] Concurrently, Shahab Sheikhalishahi et al. [5] compared the performance of ChatGPT-4o, ChatGPT-5, and Gemini 2.5 Flash on Persian internal medicine subspecialty board questions; the results reveal the superior performance of Gemini 2.5 in text-based clinical reasoning. Among existing LLMs, Gemini appears to possess the most robust textual understanding and Inference abilities.

Based on the concept above, content of DDK education should customize for diverse communities and environments, so the response strategies would be highly varied that LLMs can leverage Retrieval-Augmented Generation (RAG) to produce more ideal and accurate responses. Yunfan Gao et al.[6] thoroughly introduce RAG which effectively integrates parametric knowledge of LLMs with non-parametric external data sources, thereby mitigating hallucinations and inaccuracies; this establishes it as one of the essential frameworks for deploying large language models. The fundamental components of RAG are ”Indexing”, “Retrieve” and “Generation”, while indexing further consisted of data indexing, chunking and embedding. As a method combining retrieval and generation, RAG can offers multiple avenues for future research.

While early retrieval models rely on sparse representation (e.g., BM25 or TF-IDF), they frequently struggle with the vocabulary mismatch problem and complex semantic queries. Alternatively, by using pre-trained transformers to generate dense vector embeddings, these models can identify deeper conceptual connections between queries and documents. Consequently, dense retrieval offers a more robust framework for capturing context and improving overall retrieval precision[7].

The application of AI has emerged as a significant trend in disaster prevention, particularly within DRR education. There have been several examples, for instance, Ömer Cem Karacaoğlu et al.[8] explore AI-driven strategies in disaster education to determine their feasibility in fostering innovative and proactive preparedness. The research reveals that “Text classification guides students by identifying the topics covered in the educational material and helps focused learning. Question-answer applications enhance the learning experience by automatically extracting answers from texts.”

In addition to AI, DRR education can be integrated with others technology, such as chatbot, for the purpose of innovative pedagogies to enhance learning efficacy. Okan Yetişensoy [9] explores the effectiveness of AI-assisted chatbots in disaster education by comparing chatbot-integrated instruction against conventional pedagogical methods. The result reveals a significant positive impact on cognitive learning outcomes, with the experimental group demonstrating superior knowledge retention compared to the control group. Furthermore, semi-structured interviews suggested that learners favored the chatbot approach, citing its student-centered design and engaging pedagogical features as key drivers for more effective education. The research also suggests that “technology combining XR and chatbots would be helpful in enabling students to experience disaster situations firsthand and enhance the skills necessary for dealing with disasters.”

Squire’s research suggests that the immersive nature of computer and video games provides a comprehensive

framework for learning that surpasses traditional pedagogies in global reach and effectiveness[10]. Fletcher's research highlights the superiority of interactive tools, noting that students retain 75% of information through simultaneous seeing, hearing, and interacting, compared to just 40% of visual data and 20% via auditory instruction[11]. Therefore, gamification might be a suitable pedagogy for DRR education.

3 Methodology

This study constructs the Disaster Knowledge King (DKK), which is organized into three subordinate sections: the Generation System, the Database, and the Answer System, with several detailed modules under each section. The specific system architecture is illustrated in Figure 1. Specifically, this study develops a variety of functions into corresponding modules and then integrates associated modules into a primary section. Consequently, each section executes its respective tasks independently, allowing the DKK to stream results from all sections to form a complete, dynamic quiz system.

In the Generation System, the server executes a procedure at each interval to generate a series of intact question sets. First, the News Module collects real-time news sources concerning disaster events occurring globally. Second, the Filter Module ensures the news is fresh and removes expired question sets from the database. Third, the AI Manufacture Module utilizes a Large Language Model (LLM) to generate the question set, subsequently employing the RAG method with specific disaster response documentation to recommend response strategies. Lastly, the Packaging Module organizes the LLM output into a specific format and uploads it to the Database..

In the Database, this section consists of the "DB Calling Module" and the "Cloud DB". Its primary function is the storage of all question sets; it also serves as the connection between the Generative and Answer systems while transferring the DKK's essential properties: disaster preparedness knowledge and environmental literacy.

In the Answer System, this study adopts the LINE Bot as the operational medium for the DKK, substituting traditional application software with a near-ubiquitous social media interface. Upon user initiation, the Question Module retrieves and renders a question from the database. Subsequently, the Options Module presents four processed alternatives to the user. Following the user's input, the Answer Module displays the correct answer, an explanation, and the response method, using specific colour to indicate whether the user's response was correct.

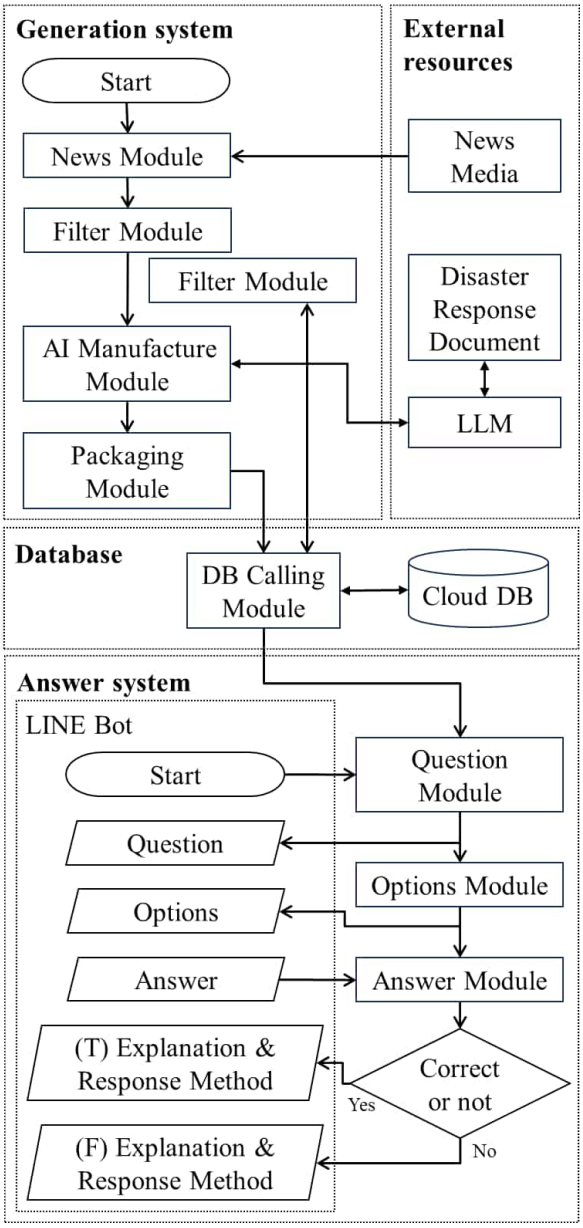

Figure 1 Disaster Knowledge King Disaster Knowledge system architecture diagram

4 Implementation

Diverse APIs and LLMs are integrated into DKK's framework, with key research outcomes focusing on prompt engineering, production pipeline design, and dynamic disaster prevention methodologies, and the whole system development is based on Python.

4.1 Generation system

The Generation system serves as the fundamental driver of overall operations. The system is comprised of

four distinct modules to establish a production pipeline: the News Integration Module, the Filter Module, the AI Manufacture Module and the Packaging Module.

4.1.1 News Module

To acquire global disaster information, the system integrates three primary news sources—the Associated Press, Reuters, and Channel News Asia—selected for their credibility and extensive regional coverage. The news integration workflow proceeds in three stages: first, defining extraction parameters (keywords, media outlets, and volume); second, utilizing the NewsAPI.org service to retrieve headlines, publication times, and URLs; and third, employing the BeautifulSoup library to scrape full web content from those URLs.

Once ingested, the News Module categorizes the data into specific disaster types, including “avalanche, earthquake, fire, explosion, extreme heat, drought, flood, hazardous materials, hurricane, typhoon, debris flow, pandemic, severe weather, thunderstorms, lightning strike, tornado, tsunami, volcano, wildfire, and snowstorm.”, and standardizes publication dates into a unified format (YYYY-MM-DD HH:MM:SS) for database consistency.

Finally, the module encapsulates this data into a structured schema—comprising news content, date, disaster type, and URL—before transmitting it to the Filter Module for processing.

4.1.2 Filter Module

The core characteristic of the DKK’s questions is their "dynamism," signifying that all information must maintain a high degree of real-time relevance and freshness. Consequently, the system must strictly manage the temporal validity of both newly imported news data and existing items within the database.

In the first step, the Filter Module receives data packets from the News Module. It compares the "publication date" of each entry against a pre-defined "update threshold" set in the system parameters, thereby filtering out data that exceeds the permissible latency.

In the second step, the system executes a stale data purging operation. Utilizing a data deletion function, the Filter Module applies a specific retention rule: "any data record with a publication date older than N days (N being the retention period defined by system parameters) shall be removed." If the deletion of records results in a specific disaster category containing zero items, the module invokes the table dropping function to remove the empty category table. This process ensures the structural integrity and operational stability of the Generation system.

In the final step, the Filter Module encapsulates all qualified data into a standardized format—"news content, publication date, disaster type, and news URL—and transmits it to the AI Manufacture Generation Module to serve as the foundational material for subsequent question generation.

4.1.3 AI Manufacture Module

The core of the DKK generation system is the AI Manufacture Module, which integrates the Gemini API, Retrieval-Augmented Generation (RAG), and structured data schemas to produce "news-dissemination-oriented" educational content. Gemini was selected as the primary LLM for its superior semantic parsing and reasoning capabilities. To ensure structural reliability, the module utilizes pydantic and google-genai libraries to enforce a predefined schema, guaranteeing that every output includes a high-quality question, four options, and a detailed explanation.

Prompt engineering serves as the study’s central research focus, guided by two principles: "multi-layered iterative development" and "contextual supplementation." The former breaks down complex tasks into high-success sub-tasks through iteration, while the latter applies directional constraints to ensure strict adherence to the desired content. Together, these principles enable the system to achieve superior and stable generation quality.

A distinctive feature of the DKK is the "response method" included in every explanation to meet Disaster Risk Reduction (DRR) goals. To ensure these methods are accurate, the research employs RAG by grounding the Gemini API in professional Ready.gov guidelines. This workflow involves converting guidelines to Markdown, indexing them via the google-genai SDK, and generating grounded responses. Ultimately, prompt engineering remains most vital, as it dictates the overall educational effectiveness of the module.

The following are the prompts used for each of the five production steps in AI Manufacture Module:

prompt1: f'You are now a global disaster intelligence expert. Please organize the article from link {news[“news_URL”]} into four key points, focusing on the damages caused.'

prompt2: 'Based on these four key points, create a multiple-choice question with four options(A, B, C, D), designed so that people can use reasoning to arrive at the answer and understand what happened. Please also provide the correct answer.'

prompt3: 'Then provide an explanation for the answer in under 70 words, and ensure that the text does not contain the words \'option\' or \'A, B, C, D\'." '

prompt4 : Next, based on the knowledge and content in "fileSearchStores", please tell everyone how to respond if they are personally involved in the case of this article, within 70 words.

prompt5: ‘Based on the content above, return the “Question”, “Option_A”, “Option_B”, “Option_C”,

"Option_D", "Correct_Answer", "Explanation", and "Response_Method". Do not change anything, especially the question and the options.'

4.1.4 Packaging Module

The Packaging Module processes source response from Gemini, which is received as a Python dictionary, by assigning a unique item ID, labeling options, and merging the "Explanation" and "Response Method" into a single string separated by a "&&&" delimiter. This concatenation strategy ensures the dataset can fit into the pre-defined database schema while allowing both data points to be stored in one block for future scalability.

To generate the unique ID, the module queries the database to identify existing entries and randomly selects a new value from a range of 1 to k, where k is an adjustable parameter tailored to table capacity. The finalized data is encapsulated into a standardized "questions dataset" having a schema: ('ID', 'Question', 'Option A', 'Option B', 'Option C', 'Option D', 'Correct Answer', 'Explanation & Response Method', 'Publication Date', 'News Title', 'News_URL').

Finally, the DB Calling Module uploads this dataset to the target database via a data-appending function to complete the run.

4.2 Answer system

This study adopts a chatbot as the primary vehicle for the answering system, with LINE selected as the implementation platform. Given its high penetration rate and convenience, the LINE platform allows users to access and engage with educational resources through a low technical barrier and at zero cost.

4.2.1 LINE Bot

The LINE Bot facilitates user interaction through message templates and Rich Menus. The LINE Bot's internal logic serves as the central controller for the entire answering system, as Figure 2 shows. Its development involved chatbot account creation, Vercel project establishment, API configuration, and UI design.

At the core of the system is the "Central Processor," a module built on the official LINE SDK. This processor governs the DKK-robot's operational modes and integrates database workflows to provide real-time question generation and feedback. The Central Processor operates via a five-step workflow: "initializing the Flask framework", "connecting to the LINE Messaging API", "monitoring webhook data", "parsing incoming information" and "executing module results".

Depending on the parsed input, the Central Processor triggers one of three functional modules—Question, Options, or Answer—each performing data operations via a DB Calling Module connected to a cloud database. To ensure a professional user experience, the interface was crafted using the LINE Bot Designer and Flex Message Simulator. The resulting JSON layouts are embedded directly into the bot's logic, providing users with an intuitive and clear educational interface.

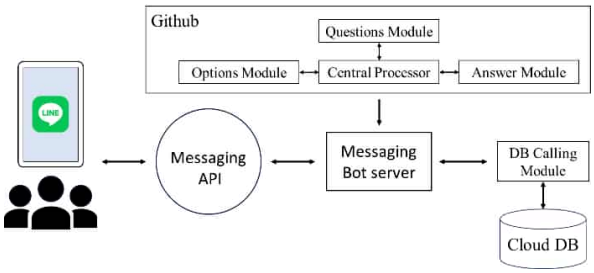

Figure 2 architecture framework of LINE Bot

4.2.2 Question Module

When receiving a response 'Disaster', the Central Processor invokes the Question Module to initiate the question generation process. The Question Module randomly fetches a record from the cloud database and deconstructs it into an 'information packet,' which is then returned to the Central Processor for subsequent process. Throughout its operation, the Question Module interacts with the database via the DB Calling module, utilizing several functions for connection configuration, table deletion, data deletion and data fetching.

The operational workflow of the Question Module designed in this study is as follows:

1. Data availability verification: The module first confirms the existence of question datasets within the database. If nothing is found, an error notification is transmitted to the Central Processor.

2. Random selection: If question dataset is available, the module retrieves all item IDs in database and utilizes the Python random library to select a single ID randomly.

3. Data extraction: Based on the selected ID, the module fetches the complete question dataset, including ID, Question, Option A, Option B, Option C, Option D, Correct Answer, Explanation & Response Method, Publication Date, News Title, News_URL.

4 .Message formatting: The module generates a text message formatted as 'disaster-[ID]: Question'.

5. Information packet encapsulation: The text message, question data are integrated into an information packet, which is then returned to the Central Processor.

Finally, once receiving this packet, the Central Processor triggers the Options Module, passing the information packet as an execution parameter. Notably, test message will be display later along with options.

4.2.3 Options Module

Immediately following the Item Module, the Options Module is activated to process the 'option content' within the item dataset. This module features two critical design

priorities: First, to mitigate potential spatial bias in LLM-generated outputs, an Option Shuffling Mechanism re-randomizes the choice sequence. Second, since the LINE Bot interface is inherently stateless and the complete interaction workflow (Category Selection → Item Generation → Answering → Feedback) requires three distinct exchanges, a cloud-based session memory mechanism was developed. This ensures that the context of the user's answering process is accurately tracked and retrieved. The operational workflow is as follows:

1. Extraction and shuffling: The module retrieves the four original options and applies a randomization algorithm to re-map the correct answer to a new position.

2. Session Management: To support concurrent multi-user access, a unique 8-digit Temporary ID is dynamically generated (e.g., 10125002), encoding the session status, category, and item number.

3. Data Persistence: A temporary dataset, including the shuffled options, metadata, and a start-time timestamp, is uploaded to the database's 'Memory' table.

4. UI Generation: The module constructs a Carousel Flex Message where each card serves as an interactive option containing the description and a postback trigger.

The Temporary ID serves as a primary key within the database's Memory table to uniquely identify each transient answering record. The 8-digit ID follows a specific encoding rule: 10,000,000 + (Category Code * 100,000) + (Item Number * 100) + Session ID.

In the end, Central Processor will display the question and options after receiving the Carousel Flex Message.

4.2.4 Answer Module

When receiving the user's response (containing a newline delimiter \n), the Central Processor invokes the Answer Module. The module retrieves the corresponding session record from the database's Memory table to compare the user's input with the correct answer. Given the high information density of the feedback, Flex Messages are adopted to provide a structured, customizable, and visually clear template for the user.

The operational workflow of the Answer Module is as follows:

1. Message parsing: The incoming string is deconstructed by using the \n and - delimiters to extract the item category, the Temporary ID, and the user's selected option.

2. Temporal validation: The module utilizes the datetime library to compare the current system time against the session timestamp. If the response exceeds the predefined time limit, an error message is returned.

3. Memory purging: To maintain database efficiency and minimize storage overhead, the module invokes a deletion function to remove the temporary record from the 'Memory' table once it is processed.

4. Conditional formatting: The system performs a logic check between the user's answer and the correct entry. The Flex Message adopts a green color scheme for correct answers and a red scheme for incorrect ones.

5. Flex message construction: The feedback's Flex Message is assembled into three distinct layers: upper block displaying the correct answer; middle block containing the explanation explanation; and lower block showing the publication date and the source URL.

6. Response method: After separating the response method from Explanation_Plue_Response_Method, the module displays it in another Flex Message template, which synchronize the pattern with feedback's template.

7. Final Dispatch: The finalized Flex Message of feedback and response method are returned to the Central Processor and transmitted to the user.

This structured interface allows users to quickly grasp the correct knowledge and background information, with the option to access the original news manuscript via the embedded hyperlink for deeper learning.

4.3 Database

To support the high-frequency and real-time data access requirements of the DKK, this study establishes a database. The database also serves as the connection for information transition between the independently operated Generation System and the Answering System. To ensure constant availability, the database is deployed on the Google Cloud.

4.3.1 Cloud DB (google sheet)

To mitigate the high operational costs of maintaining a MySQL instance on GCP, this study constructs an alternative storing framework by leveraging Google sheet, which is free under 15 GB. The database consists of only one single table 'disaster,' which contains 200 data slots (a capacity set by the DKK's Parameter Control Panel). Each data slot is in a uniform schema: 'ID', 'Question', 'Option A', 'Option B', 'Option C', 'Option D', 'Correct Answer', 'Explanation & Response Method', 'Publication 'Date', 'News Title' and 'Source URL.'

4.3.2 DB Calling Module

This study utilizes the distinct data source by leveraging specialized SDK "gspread". This library provides Python-based programmatic access, enabling this study to develop the DB Calling Module. This module is integrated into both the Generation system and Answering systems to serve as the primary interface for database interaction.

The DB Calling Module comprises seven functional functions: Connection Setting, Table Creating, Table Dropping, Table showing, Data Appending, Data Dropping and Data fetching. By adopting this modular architecture, functional components across the dual systems can execute database operations simply by

invoking the relevant function, regardless of the underlying data source.

5 Result

After registering a LINE account, users can scan the QR-Code (Figure 3) , click the “Add friend” block, then initial interaction with the DKK-robot which displays the comprehensive result.

Figure 3 QR-Code of DKK-robot

5.1 DKK Operation

The Generation System features fully automated, production capabilities. By utilizing a scheduled server task, the system initiates its operational pipeline daily at 13:00 (GMT+8), consistently performing news scraping, data filtering, item generation, and packaging.

Regarding economic efficiency, the DKK system operates with zero human labor costs. Infrastructure expenses include $1.67 per day for GCP MySQL and $0 for Google Sheets. With the Gemini-2.5-flash-lite model priced at $0.40 per million tokens and an average consumption of 5,000 tokens per item, the production cost per question is approximately $0.002.

5.2 DKK’s question set & AI generation

All question sets in DKK’s are made by AI, and generation at every steps are evaluated by G-Eval, a widely recognized benchmark in the NLP community. G-Eval is an open-source framework using LLM-as-a-judge with chain-of-thoughts (CoT) to evaluate LLM outputs,

"This study recorded 26 data points collected between March 20 and March 28, 2026. Based on the official default evaluation criteria shown in Figure 4, DKK’s average G-Eval scores for the first four production stages were 0.949, 0.950, 0.904, and 0.865, respectively, significantly exceeding the quality threshold (0.5). These results confirm the LLM integrated within DKK exhibits excellent robustness.

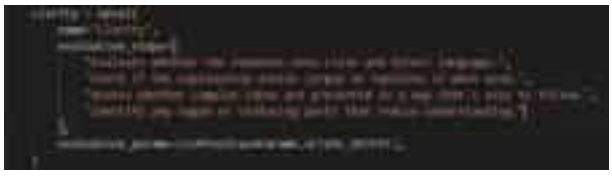

Figure 4 Official default evaluation criteria

"Table 1 presents an example of the DKK’s AI Manufacture Module generation, and it is based on the Source new: https://reurl.cc/ZldgVV

Table 1 Question set of DKK

Dataset Items	Content
Question	Considering the damages caused by the Wang Fuk Court fire, which of the following statements best summarizes the multifaceted nature of the disaster's impact?
Option A	The fire primarily caused minor property damage and a few injuries, with the main impact being a temporary disruption to local services.
Option B	The primary damages were limited to the immediate structure of the building, with minimal loss of life and no significant long-term economic consequences.
Option C	The fire resulted in a catastrophic loss of life, extensive structural destruction of multiple buildings, substantial financial strain on victims and the community, and profound psychological trauma.
Option D	The damages were solely economic, with significant insurance payouts compensating for the loss of personal belongings and the structural rebuilding efforts.
Correct Answer	C
Explanation	The correct choice encompasses the widespread fatalities, the severe destruction across multiple residential blocks, the considerable financial aid required for victims and rebuilding, and the lasting psychological impact on survivors. The other choices significantly underestimate the scale and breadth of the devastation
Response Method	In the event of a home fire, victims should immediately prioritize escape. If there's smoke, stay low and crawl to an exit. Before opening a door, feel it for heat; if hot, use an alternate escape route. Close doors behind you to slow the fire's spread. Once safely outside, call emergency services. If unable to escape, close the door, seal gaps, and signal for help from a window.

5.3 Users interface

Figure 5 illustrates the interface of the DKK-robot. By simply clicking the button “START” and “Select”, user is able to engage in the DRR educational gameplay.

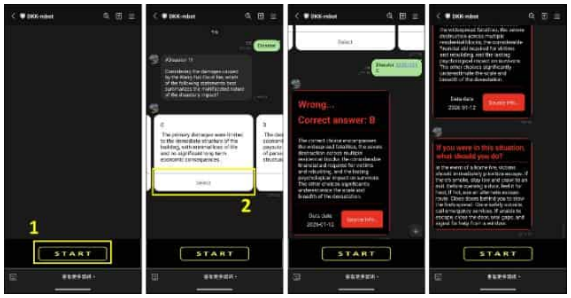

Figure 5 DKK-robot operation process

5.4 User acceptance testing (UAT)

This study utilized five customized questions to preliminarily evaluate user experience, each graded from 0 (disagree) to 5 (agree). 20 students and staff members from NTUST participated in the usability testing of DKK.

As illustrated in Table 2, the average UAT scores indicate that while system's usability is excellent, the tutorial content was rated as relatively moderate.

Table 2 UAT questions and scores

Questions	score
I find the operating process of this system very simple.	4.526
I believe most people can easily access and use this system.	4.579
I think the user interface of this system is clear and straightforward.	3.895
Compared traditional lectures, this system is more engaging for my learning.	3.684
The information presented by this system is fresh and interesting, and the knowledge I learned is very practical.	3.737

6 Future work

First, developing others more popular social media to be the interface of the DKK-robot, e.g. WhatsApp.

Second, while this paper prioritizes the execution framework, further research into prompt engineering is essential to refine the DKK questions' quality.

Third, various applications can be integrated into DKK, e.g. site safety induction for workers.

7 Conclusion

By integrating the LLMs with RAG, Chatbot, and automation, this study has "successfully developed a groundbreaking Disaster Risk Reduction education method". DKK is an advanced evolution of the classic mobile game Knowledge King, distinguished by its automatically and dynamically updating question database. Through a engaging gameplay process, users can effectively learn disaster-related news and practical knowledge from real cases.

While the average cost per question set in DKK is only $0.002, all G-Eval and UAT scores significantly exceed the median threshold. This study proposes a viable framework of DKK, so further research and development are needed to improve its practicality.

Abstract

Construction projects frequently face disputes caused by unclear documentation, conflicting design versions, and accountability gaps among stakeholders. While Building Information Modeling (BIM) enhances collaboration, it currently lacks the immutable audit trails necessary for legal evidence. This paper explores the integration of blockchain technology with BIM to create transparent, tamper-proof systems for dispute administration. This study proposes a Blockchain-Enabled BIM Dispute Resolution (B-BIM-DR) architecture using Hyperledger Fabric. The framework maps contractual dispute clauses to smart contract logic and defines a three-stage data flow Pre-construction, Construction, and Closeout compliant with ISO 19650 information management standards. Two illustrative scenarios, analyzing dispute contexts from the Dubai Creek Tower and Hong Kong International Airport, are utilized to verify the logical consistency of the framework. The proposed architecture demonstrates how automating the "Initial Decision Maker" and "Mediation" phases via smart contracts provides a legally robust mechanism for data-driven conflict management, theoretically reducing the time required for evidence assembly and arbitration.

Keywords –

Keywords: Blockchain, BIM, Dispute Resolution, Smart Contracts, Transparency

1 Introduction

The construction industry is undergoing rapid digital transformation, with Building Information Modeling (BIM) emerging as a central technology for collaboration, visualization, and project coordination. BIM enhances data integration across disciplines, enabling improved design accuracy and real-time decision-making [1]. However, despite these technological benefits, construction disputes remain a persistent challenge, often stemming from unclear documentation, conflicting design versions, and accountability gaps among stakeholders [2]. Globally, construction disputes significantly erode project value. According to the Arcadis Global Construction Disputes Report [3], the average dispute costs approximately USD 42 million and lasts over a year, emphasizing the critical need for transparent and tamper-proof information management systems. While BIM facilitates information flow, it lacks the inherent mechanisms to ensure that project data are immutable, legally verifiable, and traceable across multiple stakeholders [4]. Blockchain Technology (BCT), a decentralized and immutable digital ledger, offers a potential solution to this critical trust deficit. When integrated with BIM (B-BIM), blockchain can record every transaction, design change, and approval as a time-stamped, tamper-proof entry [5], [1]. This integration can revolutionize how project records are managed and how disputes are prevented or resolved [6].

2 Literature Review

The integration of blockchain with BIM, often referred to as B-BIM, is gaining recognition as a transformative approach for achieving transparency, data integrity, and accountability in construction project management. Blockchain's core properties, decentralization, immutability, and distributed consensus, make it ideal for ensuring that data shared across project participants cannot be altered retroactively [7].

In addition to transparency and immutability, various researchers argue that blockchain can be viewed as a trust infrastructure between BIM based collaboration, thus replacing traditional central authorities with cryptographic consensus developed among distributed nodes. As an example, [8] show that specifically, multiparty transactions, accountability requirements, and information asymmetries inherent in construction projects are the areas where a distributed ledger architecture fits best and, therefore, blockchain is a

logical way to handle BIM-related data transfer through the building life cycle.

The latest systematic reviews expand the theoretical framework in the field of BIM-blockchain integration. [12] enter this conversation in the Journal of Construction Engineering and Management with an article in the form of a review that is an introduction to the field of mixed method, called When BIM Meets Blockchain, identifying the main themes of integrations, i.e., information management, payment and procurement, contract administration, and collaboration. According to their findings, BIM and blockchain interaction is not a simple tool convergence, but rather the essential restatement of responsibilities, approval procedures and records keeping, where the latter are encoded as tamper-free transactions pinned on model-based directories.

The view is further supported by [9], who investigate the idea of blockchain integration into the construction sector in a systematic survey of blockchain use and blockchain implementation barriers, discovering that BIM-inspired scenarios can be seen as a specific type, especially in the environment where trust, traceability, and coordination among many stakeholders are essential.

2.1 Early Conceptual and Review Studies on B-BIM

The conceptual and review studies of B-BIM will be presented in the very first chapter of the work. The possibilities of blockchain to enhance the reliability of data and the confidence of stakeholders in construction management were initially described in the early conceptual research by [8]. Later on, [10] conducted a review of its development.

Based on the previous works, [11] provide one of the first systematic reviews of available literature on the adaptation of Building Information Modelling (BIM) and blockchain technology in the conditions of project delivery. Their trajectory of analysis shows that there is a spectrum of application cases, such as smart contracts, supply chain traceability, and records of immutable models, with much conceptual potential, but with a significant lack of standardization and actual application. [12] elaborate on this discussion with the introduction of bibliometric techniques with the help of qualitative analysis, showing that the discourse has shifted, leaving the theoretical to the applications fields that include payments, procurement, and digital twins, but most of the studies are in the proof-of-concept phase.

[13] presented an extensive overview of the implementation of blockchain in the BIM processes and highlights that despite the current academic interest, the prevalent adoption of it in the industry is impeded by legal, organizational and technical concerns. All such initial conceptual and review works provide the theoretical basis of Building-Blockchain Integration Modelling (B-BIM). They thus highlight the need to create more action oriented, dispute resolution-oriented frameworks, including the one presented herein.

2.2 Empirical Applications: Traceability, Procurement, Claims and Payments

More recent empirical studies have given importance to the role of blockchain in terms of enhancing project traceability and automation. As an example, [14] created a document tracking system that uses a blockchain to automatically document any changes in the construction documents and thereby verify any claim. In China, Xiong'an New Area, [15] presented a fund management model, which utilizes blockchain. Their work showed that this model improves financial transparency and auditability. In a similar effort, [16] designed a Blockchain-BIM Automated Procurement System (BBAPS) that eliminates procurement bias by recording every transaction immutably.

The note of the present study is particularly relevant since a corresponding model is the Block-Based Automated Procurement System (BBAPS) proposed by [16] according to which Building Information Modelling (BIM) elements are used to designate procurement items and then utilize blockchain technology and smart contracts to independently assess and award contracts. Every single decision is stored in the blockchain and thus provides a clear and immutable history of purchase operations. The latter is an example of the potential of B-BIM to eliminate conflicts based on the perceived unfairness or vagueness of the awarding criteria.

At the same time, blockchain-based claims and dispute management tools have been developed by the Korea Society of Civil Engineers (KSCE). In the journal of civil engineering, [14] presented an automated construction documentation tracker and extraction based on blockchain with a specific focus on claim and dispute solutions. The system tracks the document transfers via email, creates engine blockchain transactions associated with every relevant event and supports the historical tracking and the authenticity verification. With this contribution, it is represented that blockchain can provide chronological, tamper-evident records that directly help in resolving disputes and legal complaints.

Empirical studies on the automation of payments further highlight the potential of blockchain in the field of BIM to reduce the amount of dispute. [7] presented payment schemes that depend upon smart-contracts to

activate payments upon certified progress measurements using BIM and reality-capture data. These processes reduce one of the most typical bases of building arguments consisting of delayed or contracted payments, by dispensing funds dependent on objectively verifiable computer manifestations.

2.3 Governance, Distributed Common Data Environments (CDEs) and City-Scale Applications

From a governance perspective, [17] proposed blockchain-based frameworks for City Information Modelling (CIM) to enhance data reliability in urban development. [18] further demonstrated blockchain's role in Hong Kong's infrastructure projects, identifying significant opportunities in automated payments and contract enforcement.

[19] suggested a decentralized CDE architecture, which incorporates blockchain and IPFS in the domain of Common Data Environments (CDE). The infrastructure is structured so that storing voluminous BIM files that are controlled by IPFS is separated into the storage of a transaction log on the blockchain, establishing a scalable infrastructure where every model revision and the metadata associated with it can be tracked without unnecessarily burdening the blockchain. Such a strategy is particularly relevant to Building-BIM (B-BIM) dispute resolution since it provides a powerful platform of maintaining the historical record on design modification and approvals on a large scale.

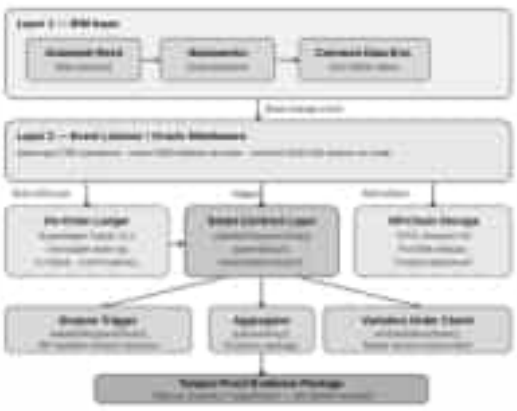

Figure 1. B-BIM-DR System Architecture

The diagram illustrates the three-layer structure: (1) As shown in Figure 1, BIM Input Layer (Autodesk Revit/Navisworks → CDE); (2) Event Listener/Oracle middleware routing large BIM artifacts to off-chain IPFS/S3 while committing SHA-256 hashes to the on-chain Hyperledger Fabric ledger; (3) Smart Contract Layer containing the Dispute Trigger Contract (*validateResponseTime()*), Evidence Aggregator Contract (*queryHistory()*), and Variation Order Verification Contract (*verifyVariationOrder()*), each operating on the immutable distributed ledger.

Besides that, [20] explore the concepts of using blockchain-based documentation systems and Common Data Environment (CDE) solutions to streamline design collaboration and contract administration. They claim that a distributed register can provide security as to the authenticity of the records of transactions carried out in the CDE operations. These architectures come in especially handy with large, multi-party projects, where ownership of data and the necessity to update information is often the source of controversy.

Blockchain-based City Information Modelling (CIM) frameworks at the municipal level can be used to show how these principles can be extended past the projects. According to [17], even a blockchain-based CIM can be used to create an immutable urban history, where approval of regulatory measures, maintenance work, and transfers of property are recorded safely. This type of structure provides a higher level of governance to project level B-BIM systems, especially where there is a dispute with government and long-life infrastructure ownership.

2.4 Dispute-Resolution–Oriented Frameworks and Remaining Gaps

With these developments, blockchain-based BIM is underdeveloped when it comes to resolving construction disputes. Most of the available research focuses on the technical viability, but there is no systematic approach of application. To improve the full potential of blockchain in solving construction disputes, [13] observes that the frameworks between technological capability and the legal and managerial practice do not exists.

Both [11] and [12] claimed that most of the studies on BIM-blockchain are based on the view that, instead of focusing on the dispute and claims workflows, the focus is on digital collaboration on the-large, payment systems, or integrating a supply-chain based solution, but not developing end-to-end workflows designed to serve this purpose. [9] also indicated that in most cases, validation of empirical validations is restricted and those based on piloting or lab-based, and with little information regarding the practical application of blockchain-authenticated records as a subset of arbitration, adjudication or negotiation.

In addition, works like [14], [16], and [19] provided strong backbone elements, which are document tracking underpinnings, automated procurement, and distributed common data ecosystems. However, these are usually provided to isolated functions rather than come up with a

comprehensive dispute-resolution framework. Therefore, it is observed that there still is a very discernible lack of Building-Information-Model-based (BBIM) systems that explicitly:

- Map BIM transaction, and document against legal contracts (marks of notices, instructions and variations).
- Contractual structure Blockchain records in compliance with traditional templates of contracts and dispute-resolution; and
- Prescribe transparent, reproducible workflow, which the project teams can replicate throughout the identification of a problem up to its solution.

Consequently, the academic discourse is narrowed down to the need of dispute-oriented, workflow-oriented B-BIM systems, situated beyond primitive technical prototyping. The Blockchain-Based BIM Dispute Resolution (B-BIMDR) paradigm developed in this project aims at filling this gap by incorporating the principles of BIM, blockchain, smart contracts, and common-data-environment into a consistent, logical approach to ensuring the transparent and impeccable prevention and resolution of disputes associated with actual construction scenarios.

3 Methodology

The proposed Blockchain-Enabled BIM Dispute Resolution (B-BIM-DR) framework is developed using a Design Science Research (DSR) methodology, operationalized through three interlocking DSR cycles: (1) the Relevance Cycle, which grounds the research in the construction industry's identified need for tamper-proof dispute evidence administration; (2) the Design Cycle, which iteratively specifies and refines the B-BIM-DR architecture artifact through conceptual design and logical evaluation; and (3) the Rigor Cycle, which ensures the design builds upon and contributes to the established knowledge base of BIM-blockchain integration [12][21]. This structured DSR approach ensures that the resulting artifact is both practically motivated and theoretically grounded. This section details the system's architectural design, its three-stage implementation model, the logical mapping of contractual rules to automated smart contract code, the technical network specification, and the conceptual validity boundaries of the framework.

3.1 Research Design and Framework Foundation

This study employs a conceptual framework development methodology, rigorously structured to align with the architectural specification protocols used by [21]. The conceptual approach is justified by the current state of the field, which recommends design specification following comprehensive reviews of BIM-Blockchain integration [12].

3.2 Framework Implementation Stages:

To ensure systematic management across the project duration, the B-BIM-DR architecture is structured into three discrete, chronologically linked stages, directly adapting the modular model proposed by [22]:

- **Stage 1:** Pre-construction (Rules Definition): The core contractual rules and project-specific Endorsement Policies are parameterized and translated into the initial smart contracts (chain code). This stage codifies the consensus mechanisms and establishes deterministic thresholds (e.g., RFI response deadlines) that will programmatically trigger potential breach events.
- **Stage 2:** Construction (Immutable Data Provenance): The B-BIM system operates as a secure logger for the Common Data Environment (CDE). Every critical transaction (RFI submission, Change Order, Model Version Update) is processed, hashed, and anchored to the ledger. This process ensures all digital artifacts adhere to the data transition states required by ISO 19650.
- **Stage 3:** Closeout and Dispute Resolution (Automated Adjudication): If a formal claim is initiated, the system automatically triggers the Evidence Aggregator Contract. This function instantaneously assembles the complete, timestamped, and tamper-proof evidentiary package from the ledger history, by passing the manual discovery process.

3.3 Architectural Components and Logic Mapping

The B-BIM-DR framework is built upon a hybrid on chain/off-chain data strategy to resolve the conflict between the large file size of BIM models and the scalability limitations of blockchain, while strictly adhering to legal admissibility standards.

3.3.1 Hybrid Data Flow Architecture (BIM Layer & Blockchain Layer)

The BIM layer (Input) leverages tools like Autodesk Revit and Navisworks as the data source. When information transitions within the CDE (Input), an Event Listener/Oracle intercepts the change. The Blockchain Layer (Processing and Immutability) then performs the following:

- Heavy BIM artifacts are sent to **Off-Chain Object**

Storage (e.g., IPFS/S3).

- The resulting **cryptographic hash (SHA-256)**, file Content ID, and minimal metadata (Timestamp, User ID) are committed to the **On-Chain Ledger**.

This system ensures that the hash acts as an immutable anchor, guaranteeing the file's integrity and authenticity [19].

3.3.2 Smart Contract Layer (Automation Logic)

The smart contract layer facilitates proactive dispute prevention by programmatically enforcing contractual clauses following the mapping methodology established by Faraji et al. [21]. This approach enables advanced automated functions similar to those demonstrated in automated procurement systems [16].The key functions within this layer include:

- Dispute Trigger Contract (*validateResponseTime()*): Automatically creates a formal dispute record if an RFI response exceeds a contractual deadline. The function accepts three inputs: *RFI_ID* (string), *IssueDate* (Unix timestamp), and *ContractualDeadline* (integer, days; default = 7 per FIDIC Red Book Clause 4.20) [25]. Processing logic: the function computes elapsed time by subtracting *IssueDate* from the current block timestamp. If elapsed time > *ContractualDeadline*, the function (1) writes a *BreachEvent* record to the ledger containing {*RFI_ID*, *IssueDate*, *BreachTimestamp*, *ContractorID*}; (2) sets the RFI status flag to '*DISPUTED*'; and (3) returns the *BreachTimestamp* as cryptographically immutable evidence. Given the assumed 5-second block time, breach events are anchored within one block interval, reducing evidentiary latency from days of manual discovery to seconds.
- Evidence Aggregator Contract (*queryHistory()*): Upon dispute initiation, the function accepts *DocumentHash* (SHA-256 string) as its sole input and returns an ordered array of all on-chain transactions linked to that hash. Each record includes: *BlockHeight*, Timestamp (Unix), *UserID*, *EventType* (e.g., RFI_SUBMITTED, BREACH_FLAGGED, MODEL_APPROVED), and the IPFS Content Identifier (CID) linking to the full off-chain BIM artifact. The resulting output constitutes a tamper-proof, court-admissible evidentiary package meeting BS 10008 authenticity requirement. With a 10 MB block size and 32-byte SHA-256 hash, the system can anchor approximately 327,680 document hashes per block, eliminating throughput bottlenecks on large projects [26].

Table 1 details the core Chain code modules designed to monitor and flag common construction challenges, establishing the necessary technical link to legal and information standards:

Table 1: Mapping Construction Challenges to Blockchain BIM Logic and Standards

Challenge	Contractual Role	Chaincode Function	Data Fields	Evidence Artifact	Legal/Evidence Standard
Late RFI Responses	Response required within 7 days (e.g., FIDIC Red Book).	validateResponseTime()	RFI_ID, IssueDate, RespondedID, Due_Date	Time-stamped 'Bench' Transaction Hash	ISO 19650-2 (Information Delivery Cycle)
Unverified Design Changes	Variations must be formally approved by the Project Engineer.	verify(VariationOrder)	ElementGUID, Status:APPROVED, SignerKey	Digitally Signed Block Header	BS 10008 (Evidential Integrity & Authenticity)
Tampered Audit Logs	Project records must remain unaltered for liability periods.	commitAnchorHash()	MerkleRoot, PreviousHash, Timestamp	Cryptographic Receipt (SHA-256)	BS 10008 (Electronic Identity & Integrity)

3.4 Technical Specification and Test Network Assumptions

To contextualize the B-BIM-DR framework, a permissioned blockchain environment simulating a Hyperledger Fabric deployment is assumed. The assumed network parameters and their logical implications are as follows. Platform: Hyperledger Fabric v2.x. Participants: four primary organizations (Owner, Engineer, Contractor, Subcontractor), each operating a peer node. Channels and Policies: a single Dispute Resolution Channel governed by a 2-of-4 endorsement policy, requiring signatures from at least two organizations before any transaction is committed. Performance Assumptions: 10MB maximum block size, 5-second block creation time. Chain code/SDK: Node.js SDK. These parameters support the following quantitative logical inferences.

- Evidentiary latency: breach events flagged by *validateResponseTime()* are anchored to the immutable ledger within 5 seconds (one block interval), compared to days or weeks of conventional manual discovery that is a reduction of at least four orders of magnitude.
- • Throughput capacity: a 10 MB block can anchor ~327,680 SHA-256 document hashes per block, confirming zero throughput bottleneck even on large, document-intensive projects such as the HKIA Expansion [23][26].
- Consensus integrity: a 2-of-4 endorsement policy ensures no single participant can unilaterally alter ledger state, satisfying the multi-party authentication requirements of BS 10008.

These inferences are grounded in the specified network parameters (platform: Hyperledger Fabric v2.x; block size: 10 MB; block time: 5 s; endorsement: 2-of-4;

SDK: Node.js) and are clearly labelled as assumed rather than measured, preserving scientific integrity.

3.5 Threats to Conceptual Validity

While the B-BIM-DR framework offers a detailed conceptual model, three specific threats to its conceptual validity are acknowledged. First, the Threat of Non-Empirical Data: the framework's efficacy is validated through illustrative scenarios rather than live deployments. Future work should pursue pilot implementations on actual projects to generate empirical performance data. Second, the Threat of Technical Simplification: the framework is intentionally scoped to objective, quantifiable contract clauses such as deadline-triggered RFI responses and model version endorsements. However, many construction contract clauses involve inherently subjective assessments, including judgements of "reasonable time", "fitness for purpose", or force majeure conditions, which cannot be encoded into deterministic smart contract logic without significant interpretive ambiguity. To address this, the B-BIM-DR framework adopts a hybrid governance model: clauses that are objectively quantifiable are enforced autonomously by the smart contract, while clauses requiring subjective interpretation are flagged by the contract and escalated to a designated human adjudicator within the Hyperledger Fabric channel, preserving legal oversight where automation is insufficient. Third, the Threat of Generalization: the framework is specified for a permissioned Hyperledger Fabric environment; adaptation to public blockchains or alternative DLT platforms would require re-evaluation of the endorsement policy model and confidentiality controls

4 Illustrative Scenarios and Conceptual Evaluation

4.1 Scenario 1: Dubai Creek Tower – Reactive Verification

The Dubai Creek Tower project, a complex, multi-billion dollar collaboration, frequently encountered high-stakes disputes related to the sequencing of design approval signoffs and resultant schedule delays. In a conventional CDE environment, proving accountability for these delays requires significant effort. The need for a robust blockchain solution for verifiable document tracking for claims is reinforced in literature.

1. Conventional Workflow Challenge

In a conventional CDE, when a contractor files a delay claim alleging a late RFI response, the legal process involves:

- **Manual Discovery:** Legal teams search through months of emails, server logs, and CDE audit trails (often weeks of effort).
- **Data Fragility:** Logs can be edited or lack cryptographic certainty. Establishing the exact moment the RFI was submitted and the exact moment the deadline was breached requires relying on human testimony or potentially inconclusive metadata.
- **Cost:** The preparation of evidence for arbitration typically costs tens of thousands of dollars and significantly extends the dispute resolution cycle.

2. Theoretical Application and Solution

The B-BIM-DR framework is conceptually applied to the RFI process. When the contractor submits an RFI, the Event Listener captures the action. The Blockchain Layer performs the following immutable transaction:

- **Transaction Data:** The transaction committed to Hyperledger Fabric includes the RFI document's hash (*H1*), the User ID, and the *IssueDate*.
- **Smart Contract Action:** The Dispute Trigger Contract (the function *validateResponseTime()* from Table 1) is activated. It creates a secondary ledger entry defining the immutable *Due_Date* (e.g., *IssueDate* + 7 days, as per the FIDIC Red Book standard).

3. Outcome: Post-Dispute Verification

- **Resolution:** When the dispute is formalized, the Evidence Aggregator Contract is triggered. Instead of launching a manual search, the contract instantaneously queries the ledger for all transactions linked to *H1*.
- **Admissibility:** The system provides an irrefutable package containing the initial RFI hash, the immutable *IssueDate*, and the automated "*Breach Event*" transaction timestamped after the *Due_Date*. Because every event is cryptographically anchored, the evidence satisfies the evidential integrity and authenticity requirements of BS 10008.
- **Impact:** This mechanism bypasses manual discovery, theoretically reducing the dispute resolution cycle from weeks to minutes [8]. The evidence is ready for adjudication, demonstrating the framework's superior reactive evidence verification capability.

4.2 Scenario 2: Hong Kong International Airport (HKIA) Expansion – Proactive Prevention

The $18 billion HKIA Expansion involves numerous

contractors and complex digital twin requirements, creating a chronic risk of "conflicting version" disputes where parties rely on outdated BIM models for execution and claims [23]. The goal is to enforce the Single Source of Truth (SSOT) proactively. The concept of using smart contracts for automated workflow validation is a key trend, including systems for automatic procurement [16].

1. Conventional Workflow Challenge

A contractor performs work based on an unverified or outdated BIM model (e.g., Model Version 5), then submits a payment claim.

- **Rework Risk:** When the engineer discovers the discrepancy against the official Model Version 6, the contractor is forced into costly rework, leading to a high-value Variation Order dispute.
- **Verification Time:** The verification process requires multiple stakeholders to manually compare model versions, which severely impacts the payment and project delivery schedules.

2. Theoretical Application and Solution

The B-BIM-DR framework operates as a unified, trust-based CDE. All model version updates must pass an Endorsement Policy (e.g., approval from the Design Manager and Project Engineer) before the new hash (*H6*) is anchored as *Status:PUBLISHED*.

- **Smart Contract Enforcement:** The system employs the Smart Contract Layer to enforce the ISO 19650 information delivery cycle. The contract includes the function *verifyVariationOrder()* (from Table 1), which is designed to prevent noncompliant transactions.
- **Proactive Veto:** When the contractor attempts to submit a claim referencing the outdated Model Version 5 (Hash *H5*), the smart contract automatically checks the ledger's state. It discovers that *H5* lacks the necessary *Status:PUBLISHED* endorsement.

3. Outcome: Risk Mitigation and Workflow Acceleration

- **Dispute** Prevention: Instead of allowing the claim to proceed to a dispute, the smart contract instantaneously rejects the transaction at the point of submission. The system informs the contractor that the reference hash is invalid for payment calculation. This action forces immediate compliance with the SSOT defined by the ledger.
- **Impact**: This demonstrates the system's shift from reactive dispute resolution to preventive governance. By programmatically enforcing the contractual requirement for the most current, verified data, the framework eliminates the opportunity for conflicting claims, resulting in a measurable acceleration of both verification and automated payment processes [18].

5 Discussion

The primary academic contribution is the detailed Conceptual Framework Specification (Section 4), particularly the Smart Contract Logic Mapping (Table 1). This mapping programmatically links contractual obligations to technical enforcement functions (e.g., *validateResponseTime()*), providing a rigorous model for digitalizing contract administration [21]. The resulting integration produces an unquestionable audit trail of time-stamped, unchangeable documentation of design modifications and milestone confirmations [1].

The conceptual evaluation via illustrative scenarios (Section 5) validated the framework's core utility: enabling a necessary shift from reactive, expensive evidence discovery to proactive governance. The framework was shown to enable near-instantaneous evidence verification in reactive scenarios (Dubai Creek Tower, supported by specialized claims tracking research, [24]. Furthermore, the integration of smart contract-based automated compliance procedures for claims and payment verification [16] was demonstrated to proactively avert disputes by enforcing the Single Source of Truth (HKIA Expansion, [23].

5.1 Compliance and Digital Governance Implications

The B-BIM-DR framework provides a critical mechanism for achieving compliance with international digital governance standards. By leveraging the ledger's immutable state, the system effectively maps the BIM workflow to the ISO 19650 information states: data only transitions from Work in Progress (WIP) to Shared/Published when its hash is immutably anchored and endorsed on the blockchain. Furthermore, blockchain features such as hashing, time-stamping, and non-repudiation ensure audit entries meet BS 10008 standards for integrity and authenticity, establishing B-BIM-DR as a trusted digital mechanism.

6 Conclusion

This study addresses data fragility and lack of transparency in construction dispute resolution by proposing the Blockchain-Enabled BIM Dispute Resolution (B-BIM-DR) framework. Using a Design Science Research approach, it introduces a three-stage architecture based on Hyperledger Fabric, with a hybrid on-chain/off-chain strategy that securely stores cryptographic hashes of BIM data to ensure tamper-proof evidence while maintaining scalability.

The framework's key contribution is mapping FIDIC

contract clauses into smart contract logic, demonstrated through scenarios of dispute verification and prevention. Results suggest significant efficiency gains, such as reducing breach detection time to seconds and supporting large-scale data handling. Limitations include its conceptual nature and focus on quantifiable clauses, with future work aimed at real-world testing and expanding contract coverage.

Abstract –

The construction industry faces persistent economic, social, and environmental challenges. Construction robotics and lean construction have emerged as potential solutions, yet their integration remains underexplored. This paper introduces the notion of Robot-Oriented Lean Construction (ROLC) – a toolkit that adapts lean principles to the characteristics of construction robots, emphasizing synergy between people, processes, and technology. Drawing on a case study of the research, development, and deployment of construction robots in Singapore, the paper demonstrates how lean methods such as Deming cycle, Last Planner System, 6S, Gemba Walk, and Total Productive Maintenance can guide the planning, development, deployment, and continuous improvement of construction robots. Findings with empirical evidence indicate that the toolkit enhances safety, efficiency, and collaboration, while reducing waste and highlighting respect for people. The paper concludes by outlining pathways for development, education, and standardization to advance the emerging research direction of ROLC.

Construction Robotics; Continuous Improvement; On-Site; Singapore; Toyota Production System

1 Introduction

The construction sector plays a crucial role in the global economy. Yet, it is constantly facing enormous economic, social, and environmental challenges. Economically, the sector shows slower productivity growth than any other industry, with low levels of digitization and lengthy planning and execution phases [1]. Socially, it faces a widespread shortage of skilled labor, worsened by hazardous working conditions and an aging population [2]. Environmentally, it is one of the most resource-intensive industries, making it central to efforts in combating climate change and achieving a circular economy [3]. These persistent challenges in the construction sector are largely caused by on-site production, the uniqueness of each project, and the high level of complexity involved [4]. As a result, the construction industry is in urgent need of innovative technologies and methods to tackle these challenges. Construction robotics and lean construction have emerged as promising potential solutions.

1.1 The Coming Ubiquity of Robots in the Construction Industry

Emerging in the late 1970s in Japan through the leading efforts of general contractors known as the "Big Five", construction robots began tackling major challenges in the industry by enhancing working conditions, safety, productivity, and quality [5]. Over the past decade, demand for construction robots has resurged, driven by government initiatives in regions like Hong Kong and Singapore that encourage the use of emerging technologies in the construction sector [6], [7]. Researchers have reported many advantages of robotic construction compared to manual work [8], [9]. However, there are still barriers to the full implementation of construction robots in the construction industry mainly due to fragmented nature of the industry, high initial investment, low level of standardization, resistance by workers and trade unions, lack of expertise, and lack of support from top management [10], [11].

1.2 The Evolution of Lean Construction

For the past fifty years, Western manufacturers have looked to Japanese manufacturing management practices as a benchmark, recognizing them as an innovative production paradigm widely known as lean manufacturing [4]. One of the most notable examples of lean manufacturing was Toyota Production System (TPS)

invented by T. Ohno who leveraged just-in-time and autonomation to eliminate waste and increase value for customers, while maintaining high quality [12].

Inspired by lean manufacturing, the construction industry expectedly adopted lean methods and formed the lean construction theory. It is generally believed that "lean construction" was coined by the International Group for Lean Construction (IGLC) in 1993 to describe the methods of planning and executing construction tasks that reduces waste in materials, time, and effort, while maximizing cost-efficiency [13]. Lean Construction Institute (LCI), an organization formed in 1997 by G. Ballard and G. Howell to develop and disseminate knowledge of lean construction, further refined its definition as "a culture of continuous improvement and collaboration among all project participants to maximize efficiency, minimize waste, and deliver exceptional project outcomes" [14]. Lean construction, ever since its advent, has continuously delivered a wide range of economic, social, and environmental benefits to the construction industry [15]. Over the years, many tools have been developed and successfully applied to lean construction including but not limited to Deming Cycle, 5S, Big Rooms, Daily Huddles, Kanban, Andon, Poka-Yoke, Heijunka, and Last Planner System [4], [16]. However, to continue advancing and benefiting the construction industry, lean construction must adapt to the transformations driven by Industry 4.0 while preserving its foundational focus on the synergy between people, processes, and technology [17].

1.3 The Crossroads

We are reaching a crossroads where two major emerging fields in construction, namely construction robotics and lean construction, need to synergize to further tackle the enduring challenges in the construction industry. Lean construction practices should consider the upcoming ubiquitous application of robotics in the construction industry [5]. In recent years, the Lean Construction 4.0 framework has emphasized integrating lean construction principles with advanced technologies like robotics [17]. Based on scientometric analysis, Cardenas et al. advocate for more synergies in the intersection of lean construction and construction robotics [18]. In a recent study, Hu et al. further reported that construction robots can potentially bring at least 17 lean related benefits to construction sites [7]. These studies indicate a strong potential for integrating lean construction with construction robotics.

As a highly developed city-state, Singapore has a strong economy and plays a unique role as a center of finance and innovation in Southeast Asia, bridging the East and West. The construction industry is one of its key sectors, employing over 450,000 workers [19]. Like many other countries, Singapore's construction sector faces many challenges such as stagnant productivity, construction waste, safety risks, labor shortages, and a heavy reliance on foreign workers [20], [21]. These issues were further intensified by the COVID-19 pandemic [19]. In response, Singaporean government agencies have introduced various incentives to foster both local and international innovation in the construction industry. This makes Singapore an ideal place for testing novel construction technologies including lean construction and construction robotics.

2 Methods

This paper aims to introduces the notion of Robot-Oriented Lean Construction (ROLC) and provide empirical evidence of how lean construction methods can be adapted to suit the characteristics of construction robots with a focus on the synergy between people, processes, and technology through a best-practice case study in Singapore. The study is primarily based on a case study of the planning, development, and deployment activities around construction robotics in the Construction Robotics Lab. Furthermore, a unique feature of this lab is its close link to several ongoing construction projects across Singapore, serving the ideal live testbed for the technologies developed in the lab environment or co-developed with partners. In this study, qualitative methods such as on-site observations, case study, and expert interviews are adopted. Specifically, various lean methods applied in the planning, development, and deployment of construction robots are shown in Figure 1.

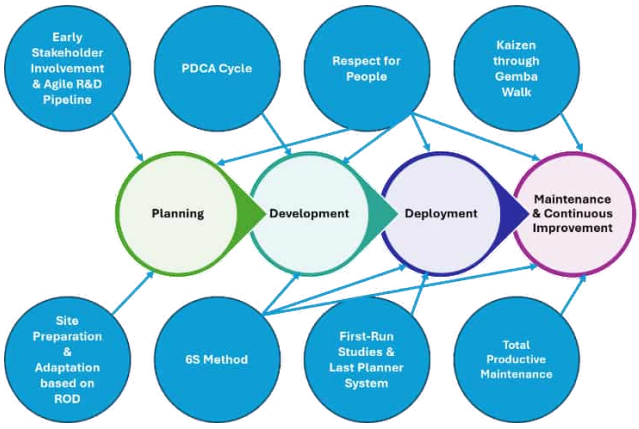

Figure 1. Non-exhaustive lean tools applied during construction projects' lifecycle

3 Results

The following sections will explain how these methods are applied in the case study in detail.

3.1 Planning

The lean methods applied in the planning phase of robots are reported as follows.

3.1.1 Early Stakeholder Involvement and Agile Research-Development-Deployment Pipeline

To begin the adoption process of robots on the construction sites, an agile research-development-deployment pipeline is adopted, involving all key stakeholders in the early stage (see Figure 2). The process begins with gathering requirements from the clients or general contractor affiliated departments, followed by assessing the availability of suitable technologies. If the target technology is already available and mature on the market, a market search is conducted, and collaboration with an external vendor is initiated to adapt the technology further to the site condition. If the technology is not available, R&D projects will be carried out in the Construction Robotics Lab to develop the technology (see Figure 3). In both cases, the developed or adapted technology is tested on affiliated construction sites. If the performance is found to be unsatisfactory, further improvements or iterations are made. Once the technology demonstrates satisfactory performance, it is deployed for use on real construction sites.

Figure 2. Research-develop-deploy pipeline for implementing construction robots

Figure 3. Construction Robotics Lab in Singapore

As shown in Figure 4, several construction robots including wall plastering robot, interior painting robot, floor grinding robot, mobile monitoring robot, and site inspection drone are deployed on the construction site of this case study. Methods such as Choosing by Advantages (CBA) workshops where key stakeholders quantitatively assess the advantages of all options by weighing the key criteria [22] are usually adopted to decide which technology to adopt for each task.

Figure 4. Examples of robotic solutions for various tasks tested for deployment on the real site

3.1.2 Site Preparation and Adaptation

The notion of Robot-Oriented Design (ROD) was first proposed by T. Bock, 1988, who emphasized that the final on-site construction operations shall already be considered at the design stage of building elements and construction methods in accordance with the characteristics of robots to improve their efficiency and usability [23]. This concept has also been applied to the site preparation process in this case study for better operation of robots. For example, a mobile monitoring robot is deployed on site to patrol in different rooms and spaces for site management. Barricades are modified so that the mobile robot's lidar sensor can detect which barricades are passable and which are not (see Figure 5). Also, slopes are added to the steps on the route of the robots to mitigate any height gaps.

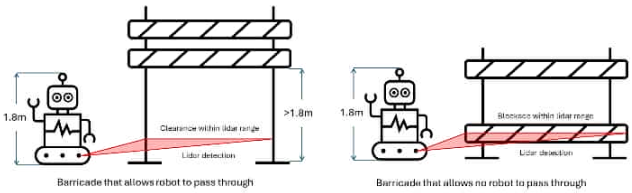

Figure 5. Example of site preparation and adaptation for implementing construction robots

Another common challenge for construction sites to adopt robots is network connectivity. Researchers have already discussed the strategy for deploying 5G infrastructure on construction sites [24]. However, connectivity may be limited in remote or underground locations where 4G/5G networks are unstable or unreachable. In such cases, it is necessary to assess network speed and signal strength in advance using tools

such as Opensignal. Based on the results, the site team may need to establish a wireless mesh network (WMN) to support the smooth operation of multiple robots.

3.1.3 Respect for People

As a key pillar of lean construction, respect for people is implemented throughout the construction phase to ensure smooth and harmonious collaboration between teams. For example, all signs on site including the ones on the robots are written in English, Chinese, Tamil, and Bengali, considering the demographic composition of the workers (see Figure 6).

Figure 6. Multilingual signage deployed on site

Furthermore, because Singapore is a multicultural "melting pot" where many ethnic groups coexist peacefully side by side including but not limited to Chinese, Malays, Indians, and other minority groups, the construction workers' faiths are also respected on the construction site. Figure 7 shows a Muslim prayer room and a Chinese shrine installed on the construction site for workers of different beliefs to practice their religions.

Figure 7. Prayer room and Chinese shrine on the construction site for workers of different faiths

3.2 Development

The lean methods applied in the development phase of robots are reported as follows.

3.2.1 PDCA Model for Developing Construction Robotic Applications

The development of construction robots typically involves various stakeholders from the construction sector, non-construction sectors, and investors. A domain-specific systematic design management approach helps integrate the needs and goals of different stakeholders and team members during the development process. Therefore, the construction robot development in this case study follows a procedure model derived from the Deming Cycle designed to provide comprehensive guidance on how to systematically conceptualize requirements and how to design, develop, implement, evaluate, manage, and refine the construction robots (see Figure 8).

Figure 8. Procedure model for developing construction robots (adapted from [25])

Specifically, its foundation follows the Deming cycle for continuous improvement (Layer ③), enabling the cyclic and iterative development process to begin at any stage and to be applied not only to new concepts but also to existing and even relatively mature construction robot designs. The central components of the procedure model are the four main process steps (Layer ②) located at its core, namely requirements engineering, development, implementation, and performance evaluation. Each of these steps consists of a defined set of activities, tasks, and specified requirements (Layer ④). The primary aim of the proposed process is the continuous advancement of the system architecture and progression of its Technology Readiness Levels (TRLs) (Layer ①). This development procedure model has been validated and proven feasible in multiple R&D projects. The procedure model's core principle allows it to evolve with each usage cycle. Furthermore, customized elements can be inserted into the model based on region, robot typology, and technology maturity [25].

3.2.2 6S Method Emphasizing Safety

Derived from 5S, 6S is workplace organization method which refers to "sort", "set in order", "shine", "standardize", "sustain", and "safety" [26]. In the lab, 6S is strictly implemented due to high risks of robots, where actions such as risk management implementation plan,

housekeeping, occupational health and safety (OHS) workshop are conducted periodically. On the construction site, 6S is also implemented with an emphasis on collaborating safely with robots on site. Workers must receive safety training and attend morning safety meetings. Moreover, incentives such as lucky draws for speaking up for safety and Why I Work Safe Cards are provided for workers on site to further strengthen their safety awareness (see Figure 9).

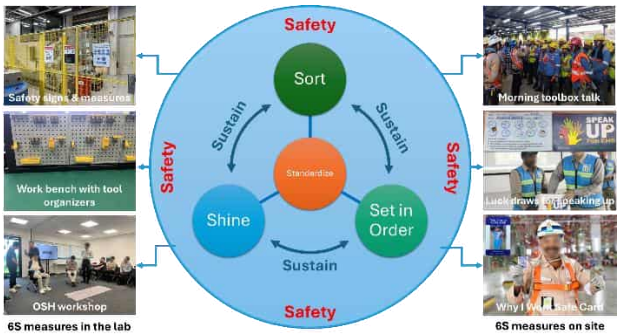

Figure 9. Use of 6S Method during R&D and deployment phases of construction robots

3.3 Deployment

The lean methods implemented in the deployment phase of robots are reported as follows.

3.3.1 First-Run Studies Before Robot Deployment

First-run study is a lean technique used to optimize a work process by conducting a controlled experiment to evaluate performance and uncover potential issues [27]. Because of high deployment cost, robotic technologies cannot be directly deployed before proven feasible by first-run studies.

For instance, the site team considered deploying a novel floor grinding robot. However, due to the robot provider's start-up nature, how different parameters of the robot settings will affect the task performance and quality was still unclear, especially for the concrete used on the construction site in Singapore (i.e., C40). With assistance from the R&D team, a first-run study was designed using a room of 2000 m^2 to evaluate the performance of the concrete grinding robot. As there are two main parameters in the robot's settings, namely robot moving speed (mm/s) and diamond grinding wheel's rotational speed (rpm), the first 500 m^2 was divided into 9 equal areas to test 9 combinations of both parameters. Two 3D scans were performed respectively before and after the test grinding to compare the height differences. After the test, the parameters of the A1 area were considered efficient, which was applied to the rest of the room as well as other areas for the floor grinding task (see Figure 10).

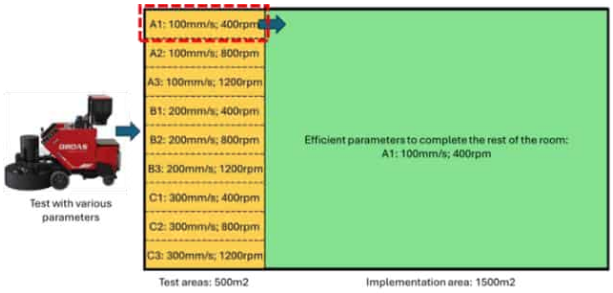

Figure 10. First-run study design for the floor grinding robot before implementation

3.3.2 Last Planner System for Robot Deployment

Due to their consistent performance, robots can help optimize construction processes and support the application of on-site lean construction. In this case study, robots were integrated into project planning through a flexible Last Planner System [28], with their deployment as key milestones integrated in the master schedule. Weekly work plans were developed using pull planning, supported by site preparation to ensure readiness. Daily coordination meetings between the robot operators and site team defined work scopes, while activity reports were submitted by operators and shared with stakeholders to enable systematic data collection and continuous improvement.

3.3.3 Evaluation Framework

After the first deployment, the R&D team developed a comparison and evaluation framework comprising quantitative and qualitative methods to measure the implications of the construction robots for various stakeholders on micro, meso, and macro levels based on the data collected in the deployment phase. In a case study, by evaluating the performance of wall plastering robot and interior spray painting robot using the evaluation framework, the R&D team reported that the robots have the potential to bring at least 17 lean related benefits that can reduce waste, increase value, and improve collaboration [7]. Specifically, for example, the plastering robot recorded a 462.5% productivity gain and 95.4% quality improvement (i.e., hollow rate reduction) compared to the conventional plastering method, whereas the spray painting robot achieved 28.6% productivity gain and 39.6% material saving [7].

3.4 Maintenance and Continuous Improvement

The lean methods used in the maintenance phase of robots are reported as follows.

3.4.1 Total Productive Maintenance

Total Productive Maintenance (TPM) is an equipment management method based on total

participation to maintain equipment to improve productivity, quality, and safety [29]. Due to its sophistication, all critical robotic equipment, whether in the lab (e.g., robotic arms, air compressors, automated guided vehicles, etc.) or deployed on site (illustrated in Figure 4), undergoes TPM periodically depending on its usage. TPM deeply connects to 6S methodology which ensures optimal total cost-efficiency, balancing between high preventive cost and high repair cost.

3.4.2 Kaizen Through Gemba Walk

Kaizen (Japanese term for "change for the better") is a lean philosophy that aims to make incremental, continuous improvements for long-term success. It is deeply rooted in the philosophy of Hansei (Japanese term for "self-reflection"), referring to deep introspection to identify own mistakes and pledge improvements. Gemba (Japanese term for "real place") Walk is a lean management term referring to physically going to the real site where leaders can identify areas for improvement and cultivate a culture of continuous learning [30]. On one hand, safety Gemba Walk by professional safety inspectors has already been implemented on a regular basis to ensure a safe working environment both in the lab and on site. On the other hand, Gemba Walk also plays a crucial role in the successful on-site implementation of construction robots.

For example, during a Gemba Walk session, the R&D team found two practical flaws of the spray painting robot: 1) Due to the inconsistent quality of certain brands of paint, solid impurities in the paint may clog the robot's nozzle, forcing the operator to stop and manually clean the nozzle before continuing to operate; 2) In some occasions, the cable carrier track of the vertical robotic movement which is slightly higher than the robotic arm may accidentally hit some fixtures hanging on the ceiling during operation, causing potential damage to building fixtures (see Figure 11). After the discovery of these two flaws, the R&D team requested the operator to provide feedback to the robot manufacturer, who decided immediately to improve the robot design in the next iteration by 1) adding a filter net in the paint feeding system and 2) flipping the cable carrier track to lower than the robotic arm.

Figure 11. Discovery of flaws during Gemba Walk for continuous improvement

4 Discussion

In this section, implications of this research are summarized. Furthermore, limitations are analyzed and future research directions are suggested.

4.1 Implications

This paper introduces ROLC as a practical guideline for integrating lean principles with the growing adoption of construction robotics. Through a case study in Singapore, it demonstrates how lean tools such as PDCA, Last Planner System, 6S, Gemba Walk, and TPM can guide the planning, development, deployment, and continuous improvement of construction robots while emphasizing respect for people, which resonates with the Lean Construction 4.0 initiative. The findings suggest that ROLC can enhance efficiency, safety, and collaboration, while reducing waste, eventually achieving an optimal balance between site preparation effort and robot development complexity (see Figure 12). As robotic applications become increasingly ubiquitous in the construction industry, further research, development, education, and standardization are needed to refine and expand this emerging interdisciplinary topic.

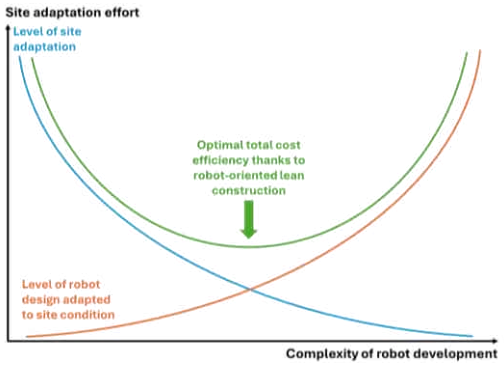

Figure 12. ROLC ensures an optimal balance between site adaptation and robot complexity

4.2 Limitations

Admittedly, limitations remain in this study. For example, the case study approach has several drawbacks, including challenges in generalization and replication (due to Singapore's unique policy environment and labor force structure), potential researcher bias, an intensive data collection and analysis process, and restricted scientific rigor [31]. Furthermore, more quantitative methods need to be employed to demonstrate evidence-based advantages and benefits of the proposed toolkit. In addition, other potentially promising lean methods and principles may not have been covered in this early-stage investigation. Further research is needed to refine and advance the topic.

4.3 The Pathway Forward

To overcome these limitations, the following aspects point to the directions and priorities for future research:

- Synergy between the two domains: Keep the upcoming ubiquitous adoption of construction robots in mind to optimize the process and flow of lean construction. Meanwhile, keep lean principles (e.g., respect for people, eliminating waste, optimizing process and flow, continuous improvement, increasing value for customers, etc.) in mind when developing robotic solutions.
- Education and training: Make training and education programs about the intersection of lean construction and construction robotics (i.e., ROLC) to construction managers, workers and students.
- Generalization and standardization: The feasibility of ROLC in other parts of the world needs to be assessed on a case-by-case basis. Furthermore, multi-case comparative studies in one region and cross-regional studies are necessary to further validate the effectiveness and performance of ROLC. In addition, the possibility of standardization especially related to construction robotics and lean construction needs to be investigated.
- More respect for people: The goal of implementing ROLC is not to replace human workers, but to empower the existing workers with emerging technologies to increase their work efficiency and enhance safety while mitigating labor shortages that are prevailing in the global construction sector. Therefore, the needs and fear of human workers towards AI and robotics need to be understood to increase the acceptance of emerging technologies.
- Continuous improvement of the toolkit: Admittedly, this paper only provides an introductory guideline for ROLC as a starting point. Further development is needed to enrich both theoretical and methodological aspects of the interdisciplinary field.

Abstract –

In high-context construction cultures like Japan, the Setup phase—comprising *nemawashi* (consensus-building) and *dandori* (operational preparation)—is critical for reliable execution. While BIM models are increasingly available, site engineers often lack the modelling expertise to evaluate them independently. This reliance on specialists creates bottlenecks, forcing planning back to manual quantity take-offs and 2D drawing-based scheduling. Adopting a Design Science Research (DSR) approach, this study proposes a "schedule-driven lightweight 4D simulation workflow" to restore practitioner agency.

The workflow enables engineers to author schedules using a cloud-based tool, export data as CSV, and automatically link it to simplified Revit Box mass elements via native Key Schedules. Crucially, these Boxes act as spatial filters, automatically calculating quantities for specific structural components—including girders, beams, columns, sub-columns, and dampers—while utilizing Revit Assemblies to accurately count lifting units. The system simultaneously generates color-coded, flipbook-style 4D visualizations without specialist intervention.

A pilot workshop with five practitioners from a Tier-1 general contractor validated the approach. Baseline surveys revealed that 80% of participants previously relied on manual quantity take-offs. Following system use, participants rated its effectiveness for quantity verification and stakeholder communication at 4.40/5.00. A small comparison with conventional practice suggested that equivalent quantity verification and 4D output generation could be completed in 15–20 minutes, with minor revisions in 2–5 minutes. These findings suggest that lowering technical barriers to BIM access through lightweight Process Information Models (PIM) can enable practitioner-led construction planning and help bridge the gap between digital planning intent and on-site execution.

1 Introduction

Production Planning and Control (PP&C) is a central yet challenging component of construction management due to the socio-technical nature of construction projects. To address uncertainty and variability in production, Lean Construction has advanced the Last Planner System (LPS), which emphasizes collaborative planning and reliable workflow as mechanisms for stabilizing execution [1,2].

Despite these advances, PP&C discussions have often been framed primarily around “planning” and “control,” while the transitional work that connects planning decisions to executable site actions remains under-specified. The importance of managing handoffs between specialists to achieve project goals has been highlighted [3]. However, intermediate coordination activities frequently lack formal structure, and assigning adequate staff to such work is known to be fraught with pitfalls [4]. In practice, this “in-between” work relies heavily on tacit knowledge and informal coordination, making it difficult to standardize processes or support them systematically.

To better conceptualize this gap, the Four-fold Framework for Process Information Management extends PP&C into four phases: Planning, Setup, Execution, and Control [5].

At the same time, BIM models from design and fabrication stages are increasingly available in contemporary projects and contain rich geometric and quantitative information that could support Setup-phase coordination. However, practical adoption remains limited when site engineers cannot directly utilize these models for production planning. A major barrier is the heavy reliance on BIM specialists to generate or modify BIM-based 4D outputs, which typically requires advanced modelling skills and familiarity with

specialized software environments. Prior studies have reported that such skill, workflow, and organizational barriers hinder both BIM implementation and the adoption of 4D modelling in practice [6,7]. As a result, iteration cycles during the Setup phase slow down, and planning frequently falls back to manual quantity take-offs and 2D-based coordination.

To address this problem, this study focuses on the accessibility of BIM-based planning during the Setup phase. Specifically, this paper proposes a schedule-driven lightweight 4D simulation workflow that enables site engineers without advanced BIM expertise to verify *dandori* and facilitate *nemawashi* by linking schedule information to existing models and generating time-based visual evidence for coordination. By reframing the difficulty of 4D simulation as an accessibility problem rather than a purely technical one, this research seeks to restore practitioner agency and support field-driven production planning.

2 Theoretical Framework: The Setup Phase and Process Information

2.1 The Four-fold Framework for PP&C

This study adopts the "Four-fold Framework for Process Information Management" proposed by Shigaki et al. [5], which extends the PP&C cycle into four distinct phases: Planning, Setup, Execution, and Control.

Within this framework, the Setup phase plays a pivotal role as the connective layer between abstract planning and value-adding execution on site. Rather than being a passive preparatory step, Setup is understood as an active phase in which planning assumptions are translated, negotiated, and validated before execution begins. The effectiveness of this phase directly influences workflow continuity, coordination efficiency, and the reduction of downstream disruptions. Table 1 summarizes the four phases and typical process information exchanged across them.

Table 1. Four phases and typical process information in PP&C (adapted from [5])

Phase	Representative information	Typical outputs
Planning	targets, constraints, work packages	plans (master/phase/lookahead)
Setup	zones, quantities, prerequisites, handoffs	nemawashi/dandori decisions
Execution	progress, actuals, issues	daily/weekly records
Control	variances, corrective actions	re-plans, improvements

2.2 Defining the Setup Phase: *Nemawashi* and *Dandori*

In high-context construction cultures such as Japan, the Setup phase is characterized by two interrelated practices: *nemawashi* and dandori. *Nemawashi* refers to the informal yet essential process of consensus-building among stakeholders, through which social, organizational, and contractual constraints are addressed before physical work begins. *Dandori*, in contrast, focuses on the technical and operational preparation required to realize planned activities. It involves verifying work-zone quantities, sequencing tasks, allocating resources, and confirming logistical feasibility.

Despite the availability of 3D BIM models in contemporary projects, both *nemawashi* and *dandori* often rely on manual, drawing-based methods. This disconnect occurs because BIM models exist but are not directly accessible to site engineers for independent evaluation. In current practice, engineers cannot independently verify quantities or test alternative construction sequences; instead, they depend on BIM specialists for iterative support. When digital tools fail to support independent exploration during this phase, the Setup phase becomes a bottleneck, disrupting workflow continuity and limiting the potential benefits of BIM-based planning.

Figure 1 illustrates the conventional Setup-phase workflow targeted by the proposed system. In existing practice, site engineers rely on manual quantity take-off for *dandori*, while 4D visualization for *nemawashi* requires manual task–element linking in tools such as Navisworks and Synchro. These workflows impose hidden coordination costs and often depend on BIM specialists.

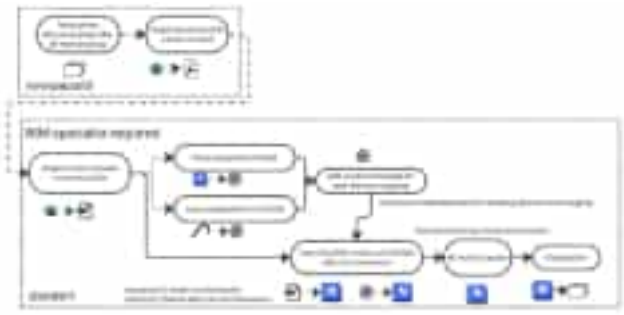

Figure 1. Conventional Setup-phase workflow showing manual quantity take-off and specialist-dependent 4D linking.

2.3 Process Information Model (PIM)

To rationalize the Setup phase, this study employs the concept of a Process Information Model (PIM) [12]. Unlike product-oriented BIM models that focus on "what" is being built, a PIM emphasizes "how" and "when" construction activities occur by associating dynamic process attributes with geometric elements. Typical PIM attributes include work zones, task identifiers, scheduling parameters, quantities, and labor requirements. By embedding such information into the model, PIM enables evaluation of spatial and temporal feasibility rather than purely geometric correctness.

In this research, a "lightweight" PIM is defined not merely by file size, but by its accessibility in three dimensions: (1) Cognitive: utilizing familiar planning concepts (e.g., zones) rather than complex BIM logic; (2) Technical: relying on standard software features (e.g., native parameter mapping such as Key Schedules) to avoid custom development; and (3) Operational: enabling rapid iteration by non-specialists. This contrasts with heavyweight PIM approaches that demand full BIM authoring capabilities and specialized knowledge.

The lightweight PIM is implemented by mapping schedule information to simplified volumetric elements (e.g., mass boxes). A scheduling tool is used as the planning interface, while mass elements are used to avoid complex geometric modeling, thereby maintaining the "lightweight" principle. This design enables the PIM to function as a bridge between scheduling logic and spatial validation, allowing site engineers to work within familiar concepts without specialist intermediaries. The lightweight PIM supports two key evaluations during Setup: (1) Spatial feasibility, confirming work-zone quantities and checking consistency for operational preparation (supporting *dandori*); and (2) Temporal feasibility, visualising sequences and communicating construction logic to stakeholders (supporting *nemawashi*).

3 Methodology（Design Science Research）

This study adopts the Design Science Research (DSR) approach presented by Hevner et al. [8] to address the heavy reliance on BIM specialists for generating 4D simulations during the Setup phase (*nemawashi* and *dandori*). Following the "build–evaluate" cycle described by March and Smith [9], we designed a practical artifact and evaluated it in a real project setting. The goal is to enable site engineers to verify quantities and explore planning scenarios independently, without requiring advanced modeling skills.

The artifact developed in this study is a schedule-driven lightweight 4D workflow. This workflow serves as an instantiation of the lightweight Process Information Model (PIM) interface described by Shigaki et al. [5]. Specifically, the system maps schedule data from GaNett (CSV) to simple Revit mass elements (Box) using standard Key Schedules and Dynamo Player automation. To ensure accessibility for non-specialists, we designed the workflow to be "lightweight" in three dimensions: (1) Cognitive: using familiar planning concepts (e.g., zones) instead of complex BIM logic; (2) Technical: using Dynamo Player as an execution interface to minimize setup and avoid custom plugin development for end users; and (3) Operational: enabling rapid iteration cycles to support dynamic site discussions.

To validate the utility and accessibility of the artifact, we conducted a pilot workshop with practitioners possessing diverse levels of BIM experience. Data were collected via post-workshop questionnaires (Likert-scale items and open-ended comments). In particular, the evaluation focused on accessibility, perceived usefulness, and practitioner agency (i.e., the ability to explore scenarios without specialist mediation) during Setup-phase coordination. We analyzed the results following DSR evaluation guidance recommended by Hevner et al. [8] and Peffers et al. [10] to examine whether the workflow effectively supports *nemawashi* and *dandori* activities.

4 Proposed System

4.1 System Overview and Design Rationale

The proposed system is a schedule-driven lightweight 4D simulation workflow designed to support Setup-phase coordination by site engineers without advanced BIM authoring expertise. In contrast to conventional 4D workflows that require detailed model authoring and specialist intervention, this system treats the BIM model as a verification and visualisation medium rather than the primary planning interface. The core design principle is to align the system with existing planning practices while minimizing cognitive, technical, and operational barriers.

The system focuses on two critical structural processes—steel erection and concrete placement—as representative high-impact activities where site engineers must verify quantities and communicate sequences under tight coordination constraints. By targeting these activities, the workflow supports simultaneous quantity verification and sequence visualisation, consistent with the lightweight Process Information Model (PIM) concept described in Section 2.3. Figure 2 illustrates the overall system architecture, highlighting the data flow from the scheduling tool to the 4D visualisation output.

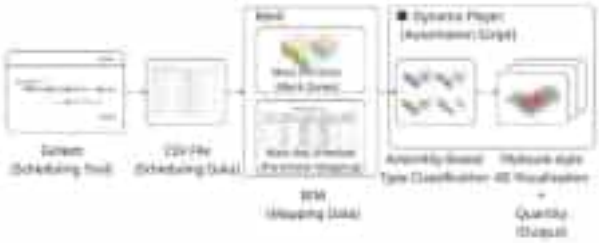

Figure 2. Overview of the schedule-driven lightweight 4D workflow (GaNett → CSV → Revit Key Schedule + Dynamo Player → flipbook output).

In contrast to the conventional 4D workflow illustrated in Figure 1 (Section 2), where manual task-element linking and specialist intervention are required, the proposed system eliminates these dependencies through spatial containment logic. This comparison highlights the reduction in cognitive and operational barriers achieved by the lightweight approach.

4.2 Schedule-Driven Workflow

The workflow begins with schedule authoring using an in-house cloud-based planning tool (GaNett) tailored for Japanese graph-based planning practices [11]. Site engineers define work packages using familiar concepts such as work zones, task identifiers, durations, and quantities. The schedule is then exported in CSV format, serving as the primary source of process information.

The Dynamo script includes a Python node that cleans and standardizes the exported CSV before Key Schedule mapping. Because this node is the sole adapter between the scheduling tool's export format and the Dynamo script's input schema, only this single node needs modification to support alternative tools (e.g., MS Project, Primavera P6); all downstream automation remains unchanged.

In the BIM environment, an existing structural model from design or fabrication stages is reused without modification. Instead of authoring detailed construction elements, site engineers define Box mass elements to represent work zones (*koku*). These volumetric elements act as lightweight spatial containers and are used as spatial filters to query structural and concrete elements located within their boundaries (e.g., girders, columns, braces, slabs, and walls). As shown in Figure 3, schedule attributes from the CSV file are linked to the Box mass elements using Revit's native Key Schedule functionality. This key–value mapping strategy associates each work zone with its corresponding task information, enabling consistent parameter population without custom plugin development.

Figure 3. Mapping schedule attributes to Box mass zones using Revit Key Schedules.

4.3 Automation and Execution

A pre-configured Dynamo Player script executes the core automation steps. The script reads the schedule CSV file, matches zone identifiers, and generates two key outputs—quantities and 4D visualisations—tailored to the targeted processes:

1. Automated quantity verification. The system applies calculation rules based on the material type found within the Box zones.

- Steel erection: The workflow calculates total weight and piece count, categorized by specific component types including Columns, Beams, Girders, Sub-columns, and Dampers. Piece counts are derived from Revit Assemblies, allowing users to pre-group multiple elements (e.g., a column and its brackets) into a single lifting unit. This supports detailed logistics planning for cranes and trucks (Figure 4).
- Concrete placement: The workflow calculates volume and area using geometric intersection between Box masses and concrete elements. This enables zone-based quantity take-off for slabs or walls split by zone boundaries (e.g., construction joints) without physically splitting BIM elements.

2. Flipbook-style 4D visualisation. Based on schedule timing information for steel and concrete tasks, the system generates time-indexed 4D outputs. To ensure intuitive comprehension, a simple color-coding scheme is applied to indicate three distinct states: Not Started, Under Construction, and Completed. These outputs are exported as sequential images, forming a flipbook-style representation of the construction process (Figure 5). This format was selected to support rapid review, comparison, and communication during Setup-phase discussions, prioritizing speed and clarity over high-fidelity animation.

Manual operations are limited to three actions: exporting the schedule CSV, defining Box mass zones, and executing the Dynamo Player script. All data linking, quantity aggregation, and visualisation generation are automated, maintaining the "lightweight" principle for end users.

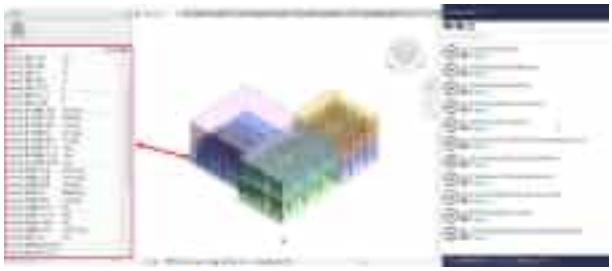

Figure 4. Automated Quantity Aggregation using Dynamo Player. The Dynamo Player (right) executes the spatial filtering logic, calculating quantities for each Mass element (centre). The system automatically aggregates piece counts and weights for specific element types—such as girders, beams, and columns—and populates the results directly into the Mass element's properties (left) for verification (*dandori*).

Figure 5. Example flipbook-style (*parapara manga*) 4D output for Setup-phase review (selected time steps).

4.4 Supporting Setup-Phase Activities

The proposed system directly supports the two core activities of the Setup phase defined in Section 2.2:

- Supporting *dandori* (operational preparation): Zone-based quantity aggregation enables site engineers to verify consistency between planned quantities and spatial work zones. By visualising quantities and sequences together, potential issues such as missing scope, incorrect zone definitions, or unrealistic sequencing can be identified early.
- Supporting *nemawashi* (consensus-building): The time-sequenced image outputs provide intuitive visual evidence that can be shared with stakeholders who do not use BIM tools. This facilitates discussion of construction logic, spatial constraints, and sequencing decisions without requiring specialist mediation. Through rapid re-execution of the workflow, practitioners can iteratively adjust schedules, regenerate visual outputs, and compare alternatives within short timeframes. This capability enables exploratory "what-if" discussions that are essential during the Setup phase.

4.5 Summary

By combining schedule-driven planning, lightweight spatial representation, and automated parameter mapping, the proposed system provides a practical implementation of a lightweight PIM for Setup-phase coordination. The system lowers barriers to BIM-based 4D reasoning and enables practitioner-led verification and communication, directly addressing the structural dependency on BIM specialists identified in Sections 1 and 2.

5 Evaluation and Results

5.1 Evaluation Design

The proposed system was evaluated through a pilot workshop conducted with a Tier-1 Japanese general contractor. Following the Design Science Research (DSR) approach described in Section 3, the evaluation assessed the perceived utility and accessibility of the artifact in an authentic Setup-phase planning context, rather than statistical generalization.

Five practitioners participated in the workshop, including site engineers and planning staff who are typically involved in *nemawashi* and *dandori* activities. Participants had diverse levels of experience with Revit and BIM-based workflows, ranging from limited exposure to routine use. No prior experience with BIM authoring or 4D simulation was required.

The evaluation focused on three criteria derived from the research objectives and theoretical framework: (1)**Accessibility:** whether practitioners perceived the workflow as usable without specialist support; (2) **Perceived usefulness:** whether the workflow supported quantity verification (*dandori*) and stakeholder communication (*nemawashi*) during the Setup phase; and (3) **Practitioner agency:** whether practitioners felt able to independently explore construction scenarios.

5.2 Data Collection

Data were collected using a post-workshop questionnaire consisting of Likert-scale items (five-point scale: 1 = strongly disagree, 5 = strongly agree) and open-ended questions. In addition, a short baseline questionnaire was administered prior to system use to capture participants' perceptions of current Setup-phase practices and challenges.

The questionnaire items addressed: (A) current challenges in quantity understanding and communication, (B) perceived improvements in stakeholder communication, (C) perceived improvements in evidence-based quantity takeoff, (D) perceived ability to independently explore scenarios, and (E) overall usability and intention to adopt the workflow.

5.3 Baseline Perceptions of Current Practice

The baseline questionnaire indicated that manual,

drawing-based work remains a major perceived bottleneck in Setup-phase planning. Specifically, 80% of participants reported that zone-based quantity understanding still relies on manual take-offs, and 80% reported difficulty explaining construction logic to stakeholders using static drawings alone.

These responses suggest that, even when BIM models are available, critical Setup-phase tasks related to *dandori* (quantity verification) and *nemawashi* (coordination) are widely perceived as difficult to support effectively using existing 2D-based practices.

5.4 Results After System Use (Quantitative)

After using the proposed schedule-driven lightweight 4D workflow, participants evaluated its contribution to Setup-phase activities. The mean rating for improving stakeholder communication (Question B) was 4.40/5.00, and the mean rating for enabling evidence-based quantity take-offs (Question C) was also 4.40/5.00. Participants rated the ease of operation of the workflow at 4.00/5.00, indicating that the system was perceived as accessible for practitioners without advanced BIM expertise. The intention to use the workflow in practice was rated positively (4.00/5.00), suggesting feasibility for real-world adoption. Crucially, participants evaluated the ability to independently explore construction scenarios (Question D) at 4.00/5.00, directly supporting the study's objective of restoring practitioner agency during the Setup phase. Table 2 summarizes the quantitative results.

Table 2. Summary of quantitative survey results (N = 5)

Metric	Related activity	Mean score (max 5.0)
Improvement in stakeholder communication (Q B)	*Nemawashi*	4.40
Improvement in quantity verification (Q C)	*Dandori*	4.40
Ease of operation (accessibility)	–	4.00
Ability to explore independently (agency)	–	4.00
Intention to use	–	4.00

5.4.1 Quantitative Efficiency Improvements

To further clarify the significance of the proposed workflow in relation to conventional practice, a small comparative time observation was conducted during the pilot workshop. Using one construction zone from a previously completed project prepared as workshop material, two participants were asked to count three structural element categories—columns, primary beams, and secondary beams—on 2D drawings using markers. The measured time per element category ranged from 3 to 9 minutes. This variation suggests that manual quantity take-off is partly operator-dependent, for example depending on whether the count is performed once or repeated for verification to avoid omissions.

Using the upper-bound value as a conservative estimate, counting three element categories for one floor would require approximately 27 minutes, and extending the same procedure across seven floors would require approximately 189 minutes. Although this was only a limited comparison, it indicates that the conventional workflow involves both substantial time burden and variability between operators.

By contrast, the proposed workflow enabled equivalent quantity verification and generation of 4D visual outputs in approximately 15–20 minutes. The time required for regeneration depended on the scale of the revision: minor modifications—such as resizing Box mass elements in Revit or changing the correspondence between schedule items and work zones—required approximately 2–5 minutes, whereas major modifications—such as changing the total number of work zones or restructuring the schedule in GaNett—required approximately 15–20 minutes.

In current practice, such full regeneration is rarely undertaken. The significance of the proposed workflow therefore lies not only in reducing task duration, but in making iterative scenario re-examination practically feasible for site engineers themselves.

5.5 Qualitative Observations from Open-Ended Responses

Open-ended responses further clarify why the workflow was valued. Participants noted that the system helped them interpret planning logic spatially and that the flipbook-style 4D outputs were easy to use when explaining plans to stakeholders who do not use BIM tools. Several participants also highlighted that rerunning the workflow after small schedule changes enabled "what-if" discussions during coordination meetings.

Importantly, multiple comments reflected a shift in perceived role: instead of waiting for BIM specialists to prepare visualisations, participants felt able to check scenarios by themselves and confirm whether the plan was reasonable at an early stage. These observations align with the quantitative ratings on independent exploration, supporting the interpretation that accessibility—rather than automation speed or visual fidelity—was the primary source of value.

5.6 Summary of Evaluation Results

The evaluation results indicate that the proposed schedule-driven lightweight 4D simulation workflow addresses perceived challenges in Setup-phase planning.

Participants reported that the workflow supports both *dandori*-oriented quantity verification and *nemawashi*-oriented stakeholder communication, while remaining accessible to practitioners without advanced BIM expertise. Taken together, the quantitative ratings, comparative observations, and qualitative responses suggest that lowering barriers to BIM-based 4D reasoning can restore practitioner agency and enable more repeatable and revisable planning cycles during the Setup phase. The workflow's value therefore lies not merely in automation speed, but in making practitioner-led iteration practically feasible.

6 Discussion

6.1 Restoring Practitioner Agency in the Setup Phase

The evaluation results indicate that the proposed schedule-driven lightweight 4D simulation workflow contributes to restoring practitioner agency during the Setup phase. Rather than positioning site engineers as passive recipients of BIM outputs generated by specialists, the workflow enables them to directly interact with spatial and temporal information and to explore construction scenarios independently.

This shift is particularly significant in the context of Setup-phase activities such as *dandori* and *nemawashi*, which require frequent iteration, negotiation, and validation. Participants valued the ability to "check by themselves" and to rerun the workflow after small schedule changes, supporting rapid "what-if" exploration. The quantitative results also suggest a positive perceived ability to explore scenarios independently (agency), consistent with this observation. These findings suggest that agency in this context is not defined by advanced modelling capability, but by the ability to access, interpret, and manipulate relevant process information at the moment decisions are made.

From this perspective, the proposed workflow does not merely automate existing tasks; it reconfigures the relationship between practitioners, BIM models, and planning decisions. By lowering barriers to engagement with BIM-based 4D information, the system allows agency to shift from specialists toward site-level practitioners who are directly responsible for coordination and execution.

6.2 Accessibility as a Design Principle for 4D Systems

A key contribution of this study is the articulation of accessibility as a central design principle for 4D simulation systems. The lightweight PIM operationalizes accessibility across three dimensions—cognitive, technical, and operational—providing a concrete framework for evaluating and designing practitioner-facing tools.

The evaluation results suggest that reducing these barriers can yield tangible benefits, even with a small-scale pilot. Participants reported high perceived usefulness and ease of operation, despite limited prior experience with BIM authoring. Importantly, the system's value was associated more strongly with accessibility and iteration speed than with visual fidelity or automation sophistication. This finding challenges the prevailing assumption that effective 4D systems must prioritize realism or optimization. Instead, for Setup-phase planning, the ability to quickly generate understandable visual evidence and to iterate collaboratively may be more critical than producing detailed simulations.

6.3 Limitations

This study has several limitations. First, the evaluation was a small-scale pilot (N = 5) in a single organization and therefore does not support statistical generalization. However, the workflow targets approximately 40–50 potential users in the organization, and the pilot cohort was selected to reflect variation in BIM usage frequency and understanding; thus, the findings should be interpreted primarily as evidence of feasibility and perceived usefulness.

Second, the study focused on Setup-phase activities and did not assess downstream impacts on Execution or Control (e.g., productivity or schedule reliability).

Third, the workflow was evaluated using simplified Box mass representations; future studies should test scalability with more complex models and coordination settings.

Fourth, although the system supports L-shaped and other non-rectangular mass geometries, zones containing interior voids (e.g., donut-shaped regions) still require manual workarounds. Moreover, spatial filtering is applied uniformly to all elements within a zone, and does not support element-type-specific selection (e.g., columns only), which limits the representation of phased erection sequences.

Therefore, semi-automated zone generation and element-type-based filtering remain important areas for future development.

6.4 Implications for Future Research and Practice

Despite these limitations, the lightweight PIM concept opens directions for comparative studies across projects and cultural contexts. For practice, embedding digital support within existing site workflows can expand practitioner access to BIM-based reasoning without

requiring adaptation to complex authoring environments. Following this formative pilot, we will conduct additional workshops to evaluate scalability across a broader range of roles and BIM literacy levels.

7 Conclusion

This study addressed a persistent gap between the availability of BIM models and their practical use in Setup-phase construction planning. While BIM and 4D simulation have been widely promoted, their adoption during *nemawashi* and *dandori* activities has remained limited due to heavy reliance on BIM specialists and the lack of accessible practitioner-facing tools.

To respond to this challenge, the study proposed a schedule-driven lightweight 4D simulation workflow grounded in a Design Science Research (DSR) approach. Building on the Four-fold Framework for Process Information Management, the system operationalized a lightweight Process Information Model (PIM) that prioritizes accessibility across cognitive, technical, and operational dimensions. By treating schedules as the primary driver and BIM geometry as a verification and visualisation medium, the workflow aligned digital support with how planning decisions are actually made in practice.

Evaluation through a pilot workshop suggested that the proposed workflow can effectively support Setup-phase activities. Participants reported improvements in zone-based quantity verification and stakeholder communication, as well as a strengthened ability to independently explore construction scenarios. These results suggest that the value of 4D simulation in this context lies not in high-fidelity visualisation or advanced automation, but in enabling practitioner-led iteration and decision-making.

The primary contribution of this research is the articulation and empirical grounding of restoring practitioner agency as a key objective for digital tools in construction planning. Rather than replacing human judgment, the proposed system repositions BIM-based 4D information as a resource that site engineers can directly access, interpret, and use to negotiate planning decisions during the Setup phase.

From a broader perspective, this study suggests that accessibility-focused design can play a critical role in bridging the gap between planning intent and executable site actions. By lowering barriers to BIM-based reasoning, lightweight systems such as the one presented here have the potential to support more resilient, field-driven Production Planning and Control practices. Future research can extend this work by examining longitudinal impacts on project performance and by exploring how lightweight PIM concepts transfer across different organizational and cultural contexts.

Abstract

Construction activities depend on multiple interrelated flows, materials, labor, equipment, workspace, and precedence, which introduce significant complexity into planning and control processes. Current simulation approaches typically focus on activity-level information while overlooking how these flows interact and evolve within the project environment. As a result, project managers lack effective tools to visualize and understand on-site flow dynamics and their impact on activity execution.

This paper presents an Activity-Flow Model Simulation, a modeling and visualization approach that integrates activity- and flow-related data into a unified simulation environment. The method builds on the Activity-Flow–Based Model to capture essential information used in planning and control processes and employs an OpenBIM workflow combined with a Unity-based environment supporting agent-oriented flow simulation. The proposed model was tested using a pilot construction project to simulate and visualize on-site flows, including activity precedences, materials, labor, equipment, and workspace. Results show that the approach enhances the identification of flow interactions and reveals opportunities to improve activity sequencing and flow coordination. Overall, the study demonstrates the potential of activity-flow–based simulation as a complementary decision-support tool for construction planning and control.

1 Introduction

The construction industry is widely recognized as one of the least productive sectors in terms of technological adoption and digital transformation, particularly when compared to manufacturing and other industrialized domains. Despite significant advances in construction management methods and digital tools, projects continue to suffer from inefficiencies related to poor planning, limited visibility of execution constraints, and inadequate coordination of resources and site logistics [1, 2].

Construction activities are inherently complex, as their execution depends on multiple interrelated variables and requirements, including labor, materials, equipment, workspace, and precedence relationships. The interaction and variability of these elements introduce uncertainty and make planning and control processes particularly challenging [3]. To manage this complexity, planning and control methods such as the Critical Path Method (CPM) and the Last Planner System (LPS) have been widely adopted to structure construction sequences and improve workflow reliability [4, 5]. While these methods provide a solid foundation for defining activity logic and commitments, they primarily focus on activity-level information and often treat resource and spatial constraints implicitly or in a fragmented manner.

More recent approaches have extended traditional planning paradigms by explicitly considering flows as essential elements for activity execution [6]. Flow-based perspectives emphasize that activities cannot start unless their required flows—such as space, labor, materials, and equipment—are available and properly coordinated [3]. Methods such as the Location-Based Management System (LBMS) incorporate spatial continuity and production flow into planning and control, improving workflow stability and reducing interference between crews [7]. Building on this perspective, the Activity-Flow Based Model (AFM) integrates multiple on-site flows into planning and control processes, enabling a more holistic representation of activity variability and construction complexity [8].

Despite these methodological advances, planning and control processes based on activity-flow concepts still lack adequate visual and simulation-based support. Building Information Modeling (BIM) has enabled the development of construction simulations, most notably through 4D models that link schedules to 3D geometry and support the visualization of activity sequencing over

time [9, 10]. However, conventional 4D simulations typically focus on activity precedence and timing, while overlooking the explicit representation of flows and their interactions within the construction site.

As a result, project managers and planners lack tools that allow them to visualize how activity-related flows move, interact, and compete for space and resources during project execution. This limitation reduces the ability to anticipate logistical conflicts, workspace interferences, and flow-related constraints that emerge during construction. Addressing this gap requires simulation approaches that integrate planning and control information with spatial and flow-based representations of construction processes.

Therefore, this paper proposes an activity-flow–based modeling, visualization, and simulation framework that builds on AFM principles and leverages OpenBIM workflows and a Unity-based simulation environment. The proposed approach enables the explicit representation and visualization of on-site flows—workspace, labor, materials, equipment, and precedences—within a unified simulation environment. The framework is demonstrated through a pilot construction project, illustrating its potential to support planning and control processes by enhancing the understanding of activity execution, flow interactions, and site logistics.

2 Theoretical Background

2.1 Planning and control processes

Planning and control processes are crucial in construction projects and have been extensively studied to improve project effectiveness [1, 10]. Project effectiveness is often hindered by multiple constraints or unmet requirements that prevent activities from starting as planned. Therefore, planning and control processes must be proactive and rely on iterative planning actions to identify, manage, and remove constraints in order to prepare tasks for execution [11]. The nature of construction activities involves multiple requirements which, if not properly planned, may become constraints during execution. These requirements are commonly referred to as flows [3] and can be managed and tracked using planning and control methods.

Production Control Plans rely on established planning approaches, such as the Critical Path Method (CPM) [4, 7] , to define construction sequences while considering multiple activity-related variables. These approaches attempt to represent the intrinsic complexity and variability of construction tasks. More advanced approaches have reformulated planning and control processes by incorporating not only activity-related information but also the flows required for execution. For instance, the Location-Based Management System (LBMS) integrates spatial flow considerations [7], whereas the Activity-Flow–Based Model (AFM) extends this perspective by explicitly including materials, equipment, labor, and workspace requirements [8]. Through a more holistic tracking of both activities and their associated flows, AFM seeks to capture the inherent variability of construction tasks and, consequently, their underlying complexity [8].

2.2 Activity Flow Based Model

The Activity-Flow–Based Model can be understood as an ontology that provides a robust conceptualization of the nature of construction activities—not only in terms of the activities themselves but also the flows that enable them, constrain them, and transition between them [12]. By analyzing flows, AFM allows for a broader understanding of project behavior during construction, moving beyond task-based logic.

Through the tracking of multiple variables, AFM strengthens planning and monitoring processes, supporting the transition toward more predictable projects with improved control over activity outputs. However, despite its robustness in capturing and structuring activities and flows, AFM does not provide a means to understand the interactions among flows.

Understanding the multivariable problem in which flows enable activities, and activities in turn release flows, remains complex. Although AFM captures this relationship conceptually, it lacks tools that facilitate the interpretation and interaction of these variables. For instance, the interaction between workspace and labor may result in trade stacking or labor collisions within the same workspace [13], which can be referred to as flow clashes.

Currently, AFM offers no visual support nor a simulation environment to complement planning and control processes. While traditional 4D simulations may partially represent sequencing, the effort invested in planning and tracking flows remains underutilized unless it is paired with flow-aware visualization. Therefore, a dedicated visualization and simulation framework is required to enhance the understanding of construction operations and address less predictable execution aspects.

2.3 Simulations in Construction

Simulation has become a valuable tool in the AECO industry to improve the understanding of complex construction tasks and to support and optimize planning and control processes [2, 14]. Building Information Modeling (BIM), through 3D models enriched with additional dimensions, has enabled the development of a wide range of simulation applications. Among these, 4D simulations are particularly effective in visually

representing construction logic by linking activity sequencing with spatial–temporal information [9].

Nevertheless, current 4D simulations typically consider only activity-based information—primarily precedence relationships—derived from the selected planning and scheduling method. As a result, they overlook the explicit representation of the flows required to execute each task.

On the other hand, numerous studies have explored the development of agent-based and discrete-event simulations to represent construction process logic [15, 16]. Agent-based simulations model individual agents (workers, equipment, or entities) as autonomous decision-making agents that interact within a virtual environment [16], while discrete-event simulations represent operations as a sequence of events that occur over time based on predefined rules and state changes. Although both approaches provide valuable approximations of flow behavior, they often remain disconnected from the activities that structure project execution and from one another, limiting their ability to capture the integrated nature of construction operations [15, 16].

To address this gap, this study proposes an activity-flow–based modeling process that integrates flow-related data into construction simulation and visualization frameworks.

3 Conceptual Model

During the planning phase, planners begin structuring a detailed schedule which, aligned with the Last Planner System, decomposes milestones into phases and progressively breaks them down into activities represented in look-ahead plans and weekly work plans [5]. In some cases, planning processes expand their scope beyond activities and precedence logic to incorporate limited flow-related considerations [12]. However, even when based on logically sound construction sequences, such plans cannot fully represent all required flows. As a result, planners lack certainty regarding flow behavior and whether plans are truly flow-clash-free, which increases uncertainty during project execution.

For this reason, the conceptual model begins with the development of a flow-aware schedule, using AFM to establish the principles governing activity–flow relationships. Activity information (precedences, planned start, and planned finish) and flow-related information (flow name and flow predecessor) are structured and embedded into 3D models through OpenBIM software, following IFC semantic export rules. The result is an IFC model enriched with AFM attributes, which is then instantiated within a Unity scene. This environment utilizes tools such as C#, semantic model classification, NavMesh pathing, and the Unity engine to guide activity execution and flow interactions.

In the simulation environment, flows are conceptualized as agents, resources, or spaces associated with activities. These representations are constrained through Unity-generated colliders, which regulate interactions between agents, between agents and resources, and between agents and activity elements. This enables the simulation of construction processes with spatial insight, uncovering interactions among flows and between flows and activities. In addition, the model incorporates performance metrics to support decision-making by identifying clashes that directly impact activity durations or the overall schedule. Initial metrics include agent–agent collision counts and travel distances.

Simulation outputs serve as iterative feedback during early planning, enabling progressively more realistic process definitions. Likewise, when applied to 4–8 week look-ahead windows, the model strengthens project control by supporting the weekly definition of work plans through a perspective that is flow-aware and, more importantly, flow-clash-aware as field conditions evolve.

3.1 Flow and activity visualization

The visual representation of flows constitutes the core pillar of the proposed conceptual model, where each flow is physically mapped and linked to activities within the Unity simulation environment. Figure 1 presents the interaction diagram illustrating how flows and activities are linked and represented within IFC models and the Unity simulation environment. Activities are visualized as IFC model elements—similar to traditional 4D simulations. Each element, and therefore each activity, is enriched with parametric data describing the required flows and the corresponding flow predecessors.

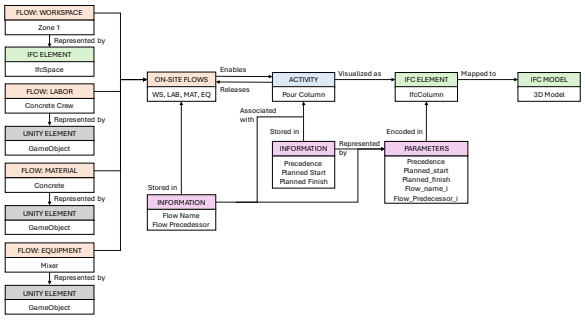

Figure 1. Flow and activity visualization process

Workspace flows are modeled as IfcSpace elements that define the volumetric boundaries of each execution zone. The remaining flows are instantiated as GameObjects inside the Unity scene—labor and equipment are modeled as autonomous agents, while materials are treated as resources consumed or transported by those

agents.

Finally, each flow is associated with its respective activity through the parametric information embedded in the IFC elements.

4 Methods

Figure 2 illustrates the overall workflow of the proposed activity-flow–based modeling and simulation framework. The process begins with AFM-based activity and flow definitions, followed by OpenBIM modeling and IFC-based data integration. The enriched model is then translated into a Unity environment to support agent-based simulation, enabling the visualization and analysis of flow interactions. The framework supports iterative planning refinement based on simulation outputs.

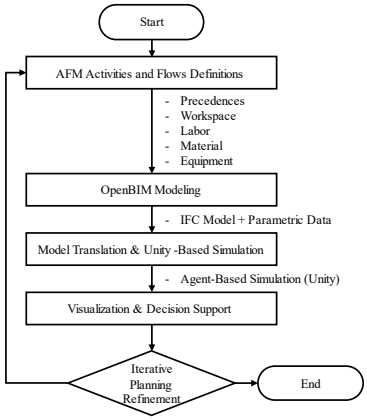

Figure 2. Workflow of the proposed activity-flow–based modeling and simulation framework.

4.1 AFM Information Tracking

The definition of the planning and control method is directly linked to the simulations to be executed, as the information established during planning and control determines what can be simulated and subsequently used to support decision-making processes. Accordingly, in this study, the Activity-Flow–Based Method (AFM) is adopted as the planning and control approach to enable the simulation of activity and flow-related information.

AFM allows tracking multiple variables associated with different off-site and on-site flows [8]. Although off-site flows may influence activity performance and execution, they are not considered within the scope of this framework. Instead, this study focuses exclusively on on-site flows, namely workspace, labor, equipment, and materials. For each flow, two key variables were considered: flow name and flow precedence. This means that, for each flow i, the model identifies an id and the activity that was using the flow prior to the start of the current activity (t–1) [17].

This structure enables the representation of both activity information and on-site flow interactions for workspace, labor, equipment, and materials, supporting the simulation of on-site logistics. Using this approach, information was extracted from a pilot project consisting of a sequence of 7 activities of 3 types, involving 3 crews and 3 workspaces. The modeled information is presented in Figure 3, Table 1 and Table 2, which illustrates the project layout, contains detail of the activity's sequences, and its flows.

MAT: Materials required to execute the activity; MAT_PRED: Material-related precedence defining material availability dependencies.

4.2 Open BIM Modeling

Based on the planning results obtained using the

Activity-Flow–Based Method (AFM), the corresponding information is embedded into 3D models in accordance with the proposed methodology. The framework is grounded in OpenBIM principles, whereby parametric information is incorporated into Industry Foundation Classes (IFC) models for information exchange. This approach ensures that the framework remains independent of any specific authoring or modeling software used for simulation

The proposed workflow begins with the definition of activity and flow related key parameters: activity_start, activity_finish (actual_start and actual_finish, may be added for control processes), labor_name, labor_predecessor, and workspace_name, workspace_predecessor, material_name, material_predecessor. These parameters are embedded into the 3D models.

4.3 Unity Simulation and Visualization Development

The implemented methodology integrates the import of BIM/IFC models with an agent-based simulation system. The workflow begins with the semantic classification of IFC elements through rule-based algorithms, enabling the structured interpretation of model geometry and parametric information within the simulation environment. Subsequently, a precedence management system, derived from the Activity-Flow–Based Method (AFM), orchestrates task execution by dynamically assigning activities to autonomous agents. These agents are capable of navigating the virtual environment, executing construction tasks in real time, and interacting with other agents and site constraints. Scene assembly and simulation logic are implemented within the Unity engine, where IFC models are converted into FBX format and enriched with property data. Agent navigation and routing are defined using a NavMesh-based pathfinding system, allowing agents to move realistically across the construction site while respecting spatial constraints and task dependencies.

5 Results

Results are presented using both qualitative observations and basic quantitative indicators to demonstrate the analytical capabilities of the proposed activity-flow based simulation framework. The framework enables the representation of activity precedence relationships comparable to traditional 4D simulations, while explicitly visualizing workspace, material, labor, and equipment flows within a unified environment. In addition to qualitative observations, basic quantitative indicators were extracted from the simulation.

The simulation was implemented in a pilot project using a simplified activity sequence and predefined work trains. Despite this simplified setup, the simulation revealed logistical and coordination issues associated with each flow type that would not be evident from precedence-based schedules alone. Figure 4 illustrates the simulation output, including crew differentiation, worker movement paths, material and equipment locations, and associated indicators.

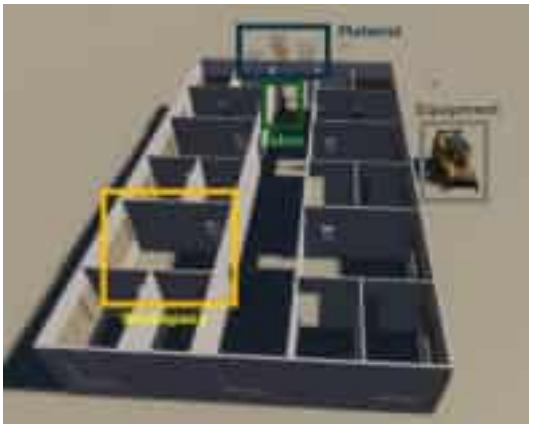

Figure 4. Representation of activity-flow elements (workspace, labor, material, and equipment) within the simulation environment.

To complement the visual analysis, quantitative indicators were extracted from the simulation. The model identified 14 labor collisions during the simulated execution of the pilot scenario. The average travel distance per crew was approximately 338 m, while the maximum distance traveled by a crew reached 374.4 m. These results confirm that the proposed framework enables the detection of flow-related inefficiencies that are not visible in traditional activity-based simulations. Figure 5 shows the simulation environment, highlighting the spatial representation of labor agents and their movement paths within the construction layout. The green lines represent the routes followed by workers as they navigate between activity locations. The interface also displays performance metrics, including collision counts, travel distances, and efficiency indicators, which provide quantitative insight into flow interactions. This visualization enables the identification of inefficient movement patterns, workspace interferences, and potential coordination issues that are not observable in traditional activity-based or 4D BIM simulations.

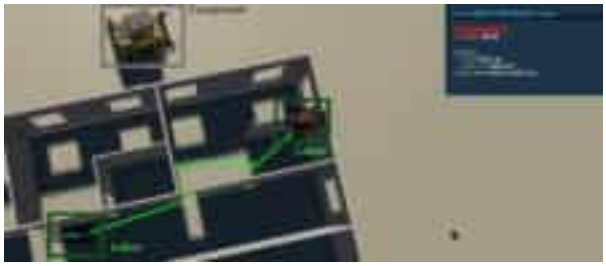

Figure 5. Visualization of labor movement and flow interactions with associated performance metrics.

5.1 Workspace Visualization

The simulation of workspace flows using the Activity-Flow–Based Method (AFM) enables the explicit definition of project sectorization. In the illustrative example, individual rooms (Room 1 to Room 6) and the corridor are clearly identified, along with the available area associated with each space.

In addition, the proposed framework incorporates the definition of activity construction areas, making it possible to explicitly represent the space required to execute each activity. This allows planners to assess whether multiple activities can be performed simultaneously within the same workspace without spatial conflicts.

Based on this information, AFM-based simulation strengthens planning and control processes by enabling project managers to make execution decisions aligned with available workspace conditions. This helps prevent schedules that overlook spatial constraints or rely on unrealistic activity durations derived from work crews that collide or interfere with one another, which can lead to delays for one or multiple crews.

5.2 Material Visualization

Material visualization enabled the identification of material storage areas, which determine both the location and the transportation distances of materials within the construction site toward each activity to be executed. In addition, it facilitated a clearer understanding of the material requirements associated with each activity.

This capability supports project managers in optimizing construction layouts, defining storage zones, and sequencing activities to reduce internal material transportation and establish material storage areas.

5.3 Labor Visualization

Labor visualization is complemented by workspace visualization, enabling the explicit representation of crew sizes and the observation of how labor moves across different zones to execute specific activities. This enhances the understanding of activity relationships, particularly start–start precedence relationships, which can be tracked through labor movements. For example, start–start relationships between structural and masonry activities can be defined through precedence logic and reinforced by visualizing crew movements. In such cases, minimum separation distances between crews can be enforced—for instance, masonry crews should remain at least two floors behind structural crews—and alerts can be generated when these constraints are violated, such as when masonry crews exhibit higher productivity rates.

Regarding finish–start precedence relationships, labor visualization also provides valuable visual support in scenarios involving multiple crews engaged in the same or interdependent activities, improving coordination and sequencing clarity.

In addition, the proposed framework incorporates a physical representation of labor within the Unity simulation environment. This enables the visualization of crew mobilization and movement paths and supports the identification of interferences or conflicts between circulation routes and activity execution areas using bounding or shape-based representations around workers.

Overall, this capability supports a clearer definition of activity and crew sequencing by facilitating the design of efficient internal circulation paths and the explicit definition of workspace buffers, particularly for start–start relationships. Similarly, for finish–start relationships, the simulation enables more effective planning of crew entry into the construction site and individual workspaces, reducing waiting times and minimizing labor-related inefficiencies and costs.

5.4 Equipment Visualization

Through the proposed framework, the simulation represents and facilitates the understanding of equipment transportation and movement for planning and optimization purposes, as well as equipment availability across activities. In addition, it enables the analysis of internal equipment circulation within the construction site.

Consequently, this capability provides a clearer perspective for defining activity trains that ensure the availability of the required equipment at activity start times, playing a relevant role in equipment resource allocation within the scheduling process.

6 Discussion

The primary contribution of this research is the extension of the Activity-Flow Model (AFM) through the explicit visualization of flows as they physically move on-site while being consumed and released by activities. By embedding activity- and flow-based planning logic within a spatial simulation environment, the proposed framework makes visible how workspace, materials,

labor, and equipment are mobilized, circulate, and interact with the physical layout of the construction site during execution. This shifts planning representations from abstract descriptions of activities and resource assignments toward a physically grounded understanding of how work is actually carried out in space.

From a Lean Construction perspective, this contribution directly supports Koskela's Transformation–Flow–Value (TFV) theory by operationalizing the flow view of production [18]. While Lean theory emphasizes the importance of managing flow continuity and reducing flow interruptions, planning methods often lack mechanisms to explicitly represent how flows manifest and interact on-site. The proposed framework bridges this gap by making AFM flows visible as physical phenomena, enabling planners to observe how transformations (activities) depend on and are constrained by the availability, movement, and interaction of flows within the construction environment.

The results show that the explicit representation of AFM flows provides significant value for planning. Even in a simplified pilot scenario, the framework reveals conflicts, circulation constraints, and infeasible sequencing conditions that are not apparent in precedence-based schedules.

Compared to traditional 4D BIM approaches, which primarily focus on activity sequencing, the proposed framework enables the explicit representation and analysis of flow interactions. This allows the identification of workspace conflicts, resource interferences, and flow inefficiencies that are not detectable in conventional 4D simulations.

By showing where flows originate, how they move, where they accumulate, and when they are released, the framework supports more realistic reasoning about workspace availability, internal logistics, and crew coordination. In this sense, visualization functions not merely as a communication aid, but as a planning instrument that externalizes assumptions related to flow availability, continuity, and interaction.

The framework is particularly valuable during phase and look-ahead planning, when sequencing, layout, and resource decisions can still be iteratively refined. At this stage, simulation outputs support informed trade-offs among activity sequencing, flow allocation, and spatial configuration, allowing planners to align execution strategies with Lean objectives such as reducing waiting, unnecessary movement, and interference among trades.

Beyond visualization, the framework establishes a foundation for deeper integration between simulation and Lean Construction research. While the present study focuses on making flows visible, the spatial representation of labor, equipment, and material as situated entities enables future exploration of how flow interactions give rise to emergent behaviors. From a TFV perspective, such behaviors reflect the dynamic coupling between transformations and flows, where local disruptions may propagate across the system and affect overall value generation. Future work will therefore extend the framework toward agent-based simulation of interacting flows, with the objective of understanding and mitigating flow disruptions and supporting the design of construction plans that are more robust, reliable, and aligned with Lean principles.

7 Limitations

This framework represents a pilot implementation for the visualization and simulation of activities and flows and, as such, its applicability cannot yet be generalized. The framework was demonstrated using a simplified activity sequence within a conceptual residential project, which limits the ability to extrapolate the findings to real projects or to different construction typologies and site conditions.

8 Conclusion

The proposed framework extends the Activity-Flow Model (AFM) by enabling the explicit visualization of construction flows as they move and interact within a spatial simulation environment. By linking activity and flow information with 3D geometry and agent-based simulation, the framework provides a physically grounded representation of construction processes, supporting a more realistic understanding of how activities are executed on site.

The results demonstrate that even in a simplified pilot scenario, the visualization of flows allows the identification of conflicts and inefficiencies that are not evident in traditional precedence-based schedules. In particular, the simulation revealed labor collisions, inefficient travel paths, and workspace interferences that would remain implicit in conventional planning representations.

Compared to traditional 4D BIM approaches, which primarily focus on activity sequencing, the proposed framework enables the explicit representation and analysis of flow interactions. This provides planners with additional insight into spatial constraints, resource coordination, and internal logistics, supporting more informed decision-making during planning and control processes.

From a Lean Construction perspective, the framework contributes to operationalizing the flow dimension of production by making flow behavior observable within the execution environment. This supports the identification of waste related to movement, waiting, and interference among trades, particularly during phase and look-ahead planning.

The framework is especially valuable during early planning stages, where simulation outputs can be used to iteratively refine activity sequences, flow allocation, and site layout. This enables planners to align execution strategies with actual site conditions and reduces the risk of flow-related disruptions during construction.

Riverbed Depth Measurement Method Combining Visual SLAM-Based Camera Pose and Ultrasonic Slant Range

Norihito Kishi[1]

Abstract –

Heavy rains and flooding due to global warming are becoming more frequent, increasing the risk of scouring and riverbed deformation. Low-cost and simple techniques can be effective for detecting these damages at an early stage, however, water currents, turbidity, and waves make surveys difficult. Therefore, we devised a method to measure riverbed depth with spatial distribution by combining the device pose estimated by Visual SLAM with the slant range measured using underwater ultrasonic. This paper describes the results of land-based tests aim to integrate pose data and slant range data.

Keywords –

Riverbed Depth; Visual SLAM; Camera Pose; Ultrasonic; Slant Range

1 Introduction

In recent years, the frequency of heavy rainfall events has increased due to global warming in Japan [1]. Heavy rainfall that causes river flooding increases the risk of scouring around bridge piers and riverbed deformation, which is a global problem [2]. To mitigate these damages, it is important to understand the current conditions, and various survey techniques have been developed. For example, ALB (Airborne LiDAR Bathymetry) can efficiently survey wide areas with high precision, but it faces issues such as susceptibility to turbid water, the need for skilled operation, and high equipment costs [3]. A method that combines a remote-controlled boat and sonar, as in [4], can safely survey wide areas, but there are issues such as limited maneuverability in fast-flow environments. Many small, inexpensive remotely operated vehicles have been sold, and their use for infrastructure inspections has become more widespread, but underwater surveys in rivers with currents and turbidity remain difficult. A simpler and cheaper method is a float-type sonar with GNSS. In Japan, the Ministry of Land, Infrastructure, Transport and Tourism is working on applying it to disaster surveys, and its low cost and ease of use compared to other technologies are considered factors in its adoption. Furthermore, as an advanced version of this, research has been conducted on tethering the sonar using an unmanned aerial vehicle for bathymetry observation of inland water bodies [5]. We have also used a similar sonar and confirmed that it can measure water depth with an error of a few centimeters in flatwater. However, there are issues such as inaccurate depth measurement caused by surface waves, and poor GNSS reception near bridges or other structures.

For these reasons, we considered that a survey technique with "precision and data density comparable to float-type sonar, inexpensive, simple, and unaffected by water currents and waves" would be useful. Therefore, we devised a method to measure riverbed depth with spatial distribution by combining device pose estimated by Visual SLAM (Simultaneous Localization and Mapping) with slant range measured by underwater ultrasonic [6]. This paper describes the results of land-based tests that aim to integrate trajectory (a time-series of poses) and slant range data.

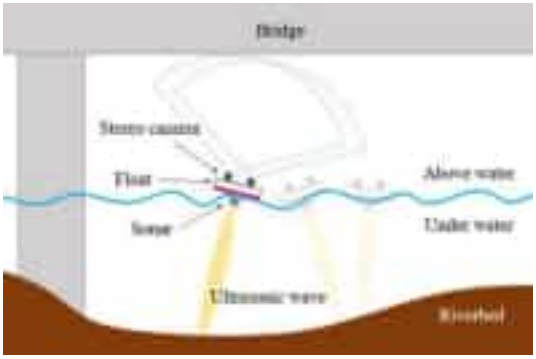

Figure 1. The schematic of proposed method

2 The Overview of Proposed Method

As mentioned above, the sway of device caused by water currents and waves makes surveys difficult. Therefore, we devised a method to measure riverbed depth spatially by swinging the ultrasonic beam transmitted from the sonar in multiple directions, taking advantage of the device's sway, and combining the device pose with underwater slant range data. A schematic of the proposed method is shown in Figure 1.

The measurement device is expected to have a simple configuration consisting of a stereo camera mounted on the top of the float, a SBC (Single Board Computer) inside the float, and a sonar attached to the bottom of the float. When surveying areas near structures such as under bridges, GNSS reception may be poor, but the structure is likely to be within the camera's field of view. Figure 2 shows an example of the underside of a bridge, which contains many feature points. For this reason, we considered that by specifically targeting environments containing structures that provide sufficient visual features, the camera pose obtained by Visual SLAM could serve as the device's pose.

Figure 2. An example of the underside of a bridge

Figure 3. The measuring unit

Table 1. Devices

Device	Specification
SBC	Raspberry Pi 5, 8GB
Stereo camera	ELP-USB3DGS1200P01-H120, angle of view 120 deg
Ultrasonic distance sensor	HC-SR04

3 Measuring Unit and Analysis

3.1 Measuring Unit

The measuring unit and devices are shown in Figure 3 and Table 1. The camera was fixed to the top of the SBC with its optical axis facing vertically upward, intended to capture images of the underside of the bridge. The ultrasonic distance sensor was fixed to the underside of the SBC with its axis facing vertically downward, intended to measure the riverbed depth. Since this was a land-based test to verify the feasibility of the method, we used an airborne ultrasonic distance sensor instead of an underwater sonar.

3.2 Measurement and Analysis

The SBC was used for data acquisition only, and the SBC and smartphone were connected via Wi-Fi, allowing the measurement application to be launched and operated on the smartphone. The data were post-processed on another laptop PC. The laptop PC ran Ubuntu 20.04, and ORB-SLAM3 [7] was used for Visual SLAM. The stereo_euroc program included in ORB-SLAM3 was used to perform the SLAM processing, and the depth was calculated using formula (1).

$$depth = camera_pos + R_q \cdot sensor_dir \cdot sr \quad (1)$$

where
camera_pos is the vector of camera position,
R_q is the rotation matrix obtained from the camera orientation quaternion [q_x, q_y, q_z, q_w],
sensor_dir is the vector of the ultrasonic sensor relative to the camera coordinate system,
as shown in equation (2), (3) and (4), respectively, and *sr* is the slant range.

$$camera_pos = \begin{bmatrix} p_x \\ p_y \\ p_z \end{bmatrix} \quad (2)$$

$$R_q = \begin{bmatrix} 1-2(q_y{}^2+q_z{}^2) & 2(q_xq_y-q_zq_w) & 2(q_xq_z+q_yq_w) \\ 2(q_xq_y+q_zq_w) & 1-2(q_x{}^2+q_z{}^2) & 2(q_yq_z-q_xq_w) \\ 2(q_xq_z-q_yq_w) & 2(q_yq_z+q_xq_w) & 1-2(q_x{}^2+q_y{}^2) \end{bmatrix} \quad (3)$$

$$sensor_dir = \begin{bmatrix} 0 \\ 0 \\ -1 \end{bmatrix} \quad (4)$$

For camera calibration, OpenCV's pinhole camera model [8] was used.

4 Position Accuracy Validation

4.1 Experimental Conditions and Setup

In order to evaluate this measuring unit, we conducted simple tests. The schematic of the experimental setup is shown in Figure 4. The measuring unit was moved between Y = 0.00 m and Y = 1.00 m along the rail while recording images and slant range data. The ultrasonic distance sensor transmitted vertically downward so that the distance to the floor were measured. The distance between the sensor and the floor measured with a steel tape, was 0.77 m.

Figure 4. The experimental setup

4.2 Experimental Result

The position estimated by ORB-SLAM3 is shown as the red line in Figure 5. The actual traveling distance in the Y direction was 1.00 m, while the estimated distance was 0.898 m. The actual change in the Z direction was 0.00 m, whereas the estimated change was 0.036 m at Y = 0.898. The average absolute trajectory error of Stereo SLAM on the ORB-SLAM3 EuRoC dataset is reported to be 0.084 m [7], and our results in the Y direction in this experiment were similar. On the other hand, the estimated Z value tends to increase with increasing distance from Y = 0.00. This was considered to be due to the use of the pinhole camera model for camera calibration. Therefore, the estimated Z value was corrected using formulas (5) and (6). Coefficients a, b, c, d, e, and f were calculated using the least squares method. In this validation test, a, c, and d were fixed to zero because the measuring unit could not move in the X direction. The corrected Z value is shown as the blue line, with Z = 0.004 at Y = 0.898.

$$Z_{fit} = ax^2 + by^2 + cxy + dx + ey + f \quad (5)$$

$$Z_{corrected} = Z_{estimated} - Z_{fit} \quad (6)$$

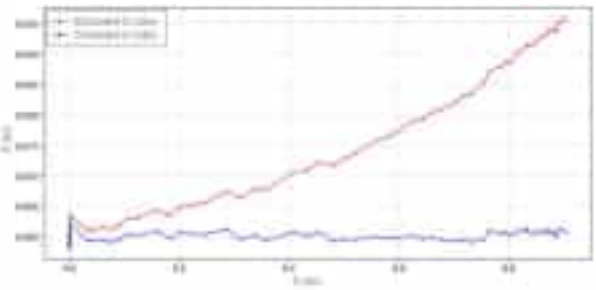

Figure 5. Changes of Z value

5 Depth Measurement

5.1 Experimental Conditions and Setup

This measuring unit was set on a flatbed cart, and

Figure 6. The experimental setup

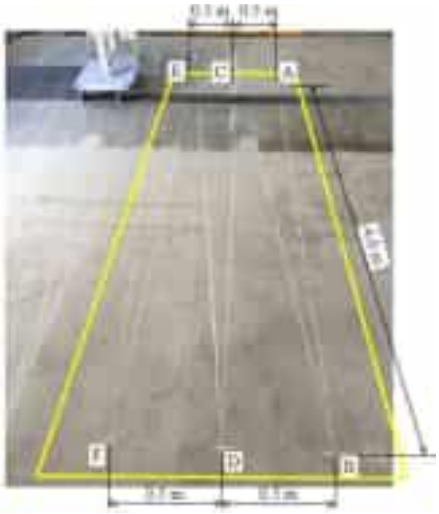

Figure 7. Marker lines

depth data (the distance between the ultrasonic distance sensor and the floor) was measured while the cart was moving in a laboratory. The experimental setup is shown in Figure 6. The measuring unit is expected to be used while floating on the water surface with waves. Therefore, we built a stand using an aluminum frame on a cart and suspended the measuring unit from the stand with polyester string and rubber bands to allow it to swing more easily. Marker lines were drawn on the floor of the laboratory as shown in Figure 7, and measurements were taken by moving the cart through points A to F in order, with the measuring unit passing over the mark lines. The floor was made of concrete and was flat but had small irregularities, and while the cart was moving, the measuring unit shook by a few centimeters. The resolution of the input images was 1280 × 720 pixels, with a frame rate of 10 fps. The distance from the bottom of the ultrasonic distance sensor to the floor was measured with a surveying staff and was 1.20 m.

5.2 Experimental Result

The results are shown in Figure 8. The blue lines represent the corrected trajectory of the measurement unit, the red lines represent the slant range from the ultrasonic distance sensor to the floor surface, and the green dots indicate the depth calculated using formula (1). The contour lines generated from the depth data are also

displayed. The points A' and F' are the positions of the measuring unit when the cart started and stopped moving, respectively, and points B' to E' are the positions of the measuring unit when the cart changed direction. Each point corresponds to point A to F in Figure 7. There are loop-shaped sections of the trajectory near points C' and E', which occurred when the cart changed direction by turning its wheels, and they closely represent the actual movement. The minor fluctuations in the trajectories represent the sway of the measuring unit. The Z value at point F', the farthest point from the starting point, was 0.01 m, and the distortion was significantly reduced through the correction process. The depth data had an average of -1.17 m, a minimum of -1.21 m, a maximum of -1.14 m, and a standard deviation of -0.01 m.

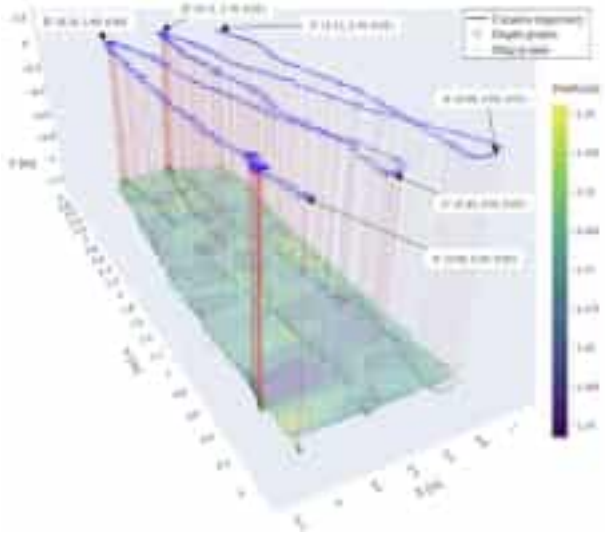

Figure 8. The trajectory and depth points

6 Conclusion

We devised a method to measure the riverbed depth around bridges and other structures in spatially by combining the pose data obtained through Visual SLAM with the underwater slant range data, and verified its feasibility through land-based tests. The result showed that even in images taken when the measuring device is shaking by a few centimeters, pose estimation by SLAM works, and depth can also be calculated from the slant range. Regarding horizontal accuracy, the error was approximately 0.1 m; however, since these results were obtained under limited indoor conditions, further verification is required to assess the generalization of the drift correction over a wider area and under actual bridges. Furthermore, by correcting the distortion of the SLAM output data using a two-variable quadratic polynomial, it became possible to estimate depth on the order of centimeters. However, since factors contributing to errors in the depth data (e.g., pose error, range noise, and mounting geometry) and the effects of actual underwater conditions (e.g., water waves and bottom return characteristics) remain to be investigated, we plan to conduct underwater tests using a underwater sonar to verify these factors. The sampling density along the trajectory provided by Visual SLAM is on the order of several centimeters. However, the effective spatial resolution of the depth map is constrained by the sonar's footprint. For instance, a 7-degree beam width used for a float-type sonar with GNSS, results in a footprint of 0.25 m at a depth of 2 m and 0.61 m at 5 m. Since the SLAM-based sampling density is finer than these footprint sizes, the system's overall horizontal resolution is dominated by the sonar's beam width.

Abstract–

Machine guidance using total stations (TSs) and global navigation satellite systems (GNSSs) is implemented to reduce labor and improve productivity in excavation work. However, a challenge with existing methods is that obstacles can interfere with guidance. Direct measurement of excavation surfaces using LiDAR can solve this problem, but it requires a point cloud registration method capable of functioning even in feature-poor environments, such as tunnels. We developed a registration method that can be used feasibly in excavation sites and built a system that visualizes the excavation status using LiDARs. The proposed robust registration method utilizes a specialized jig and a TS, specifically designed for feature-poor excavation sites. The system achieved a measurement accuracy of ±20 mm in field trials, satisfying the requirements set by site staff (±50 mm in every 250-mm pitch and a refresh rate of <30 s) and overcoming the limitations of conventional TS/GNSS methods in tunnel environments.

Keywords

LiDAR; Point cloud; Machine guidance

1 Introduction

To improve productivity in response to construction labor shortages [1], researchers have proposed machine guidance (MG) for presenting the excavation status to operators and machine control (MC) for autonomous excavation [2]–[4]. Systems detecting heavy machinery positions using global navigation satellite systems (GNSSs) or automatic-tracking total stations (TSs), and systems estimating boom and bucket postures via tilt sensors, are already being used in practice as MC and MG methods. In actual construction sites, especially open-cut sites, GNSSs may be unusable and struts or existing structures may obstruct optical signals, compromising MG/MC implementation. In addition, construction management is difficult because only the operator can view the MG/MC screen, so site staff cannot confirm the construction status in real time. A potential solution is to measure the excavation surface directly using dense point

Figure 1. System configuration

Figure 1. Tokyo Gaikan Expressway Keiyo Junction G ramp

cloud data obtain from 3D LiDAR (hereinafter "LiDAR") and transmit the data to the cloud in real time instead of estimating machine posture by tracking prisms. Although previous studies have proposed point cloud registration methods utilizing feature points and BIM, there are very few examples of these methods being applied to MG or autonomous construction [5]–[7]. Because point cloud registration may fail in feature-poor sites, such as tunnels, we propose a method for transforming point clouds from multiple LiDARs into the site coordinate system using a jig and TS measurements. We constructed a point cloud measurement system using this method in an actual open-cut tunnel site and performed measurements. This paper describes the proposed system and the evolution of measurement conditions.

2 System Configuration and Site Overview

Figure 1 illustrates the configuration of the proposed system. It comprised a LiDAR (Livox HAP [8]) for point cloud measurement, a PC (ASUS NUC) for data processing, and a Power over Ethernet hub and mobile router for data transmission to the cloud (AWS S3 server). The field of view of the LiDAR was 120° (horizontal) × 25° (vertical), and its detection range was 150 m. The system was installed at the Tokyo Gaikan Expressway Keiyo Junction G ramp construction site in Ichikawa City, Chiba Prefecture. In this open-cut tunnel construction site, excavation proceeds within diaphragm walls supported by struts. Figure 2 presents an overview photograph of the site. Measurements were conducted at three locations (Sections 1–3) according to the construction progress. The basic system configuration was consistent across all measurements, but the LiDAR installation and registration methods differed slightly between sections, as described in the subsequent subsections.

Figure 3. LiDAR and type I jig

3 Measurement Method and Result

3.1 Measurement in Section 1

Figure 4. LiDAR installation in Section 1

Measurements in Section 1 were conducted in July 2024. Point clouds were acquired using three LiDAR units (#110, #111, and #113) installed within an area of approximately 10 m × 10 m. Figure 3 shows the appearance of the LiDAR and the jig (type 1), and Figure 4 shows the LiDAR installation status. The LiDAR-obtained point clouds, which were in a local coordinate system centered on the LiDAR's optical origin, were transformed into the survey coordinate system. Mainstream methods for point cloud registration, such as RANSAC and ICP matching [9][10], estimate LiDAR position and orientation based on feature points. However, construction sites commonly have identical, equally spaced pillars or feature-poor environments, such as in tunnels.

We address this problem using the method illustrated in Figure 5. First, the TS instrument point was determined using prisms #1-1 and #1-2, which were placed at two or more known points. Next, three or more prisms or reflective sheets (#2-1 to #2-3) attached to the jig were measured in the site coordinate system. Finally,

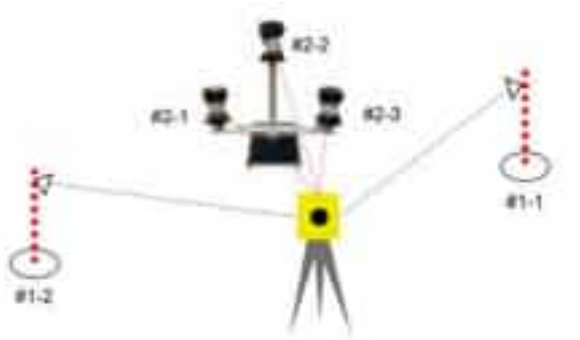

Figure 5. LiDAR position estimation

we estimated the LiDAR's optical origin and yaw, pitch, and roll angles by calculating the rigid-body transformation matrix required to align the coordinates of the prisms on the jig. Rigid-body transformations were used to determine the LiDAR origin and orientation from the three prisms. Let p_i denote the coordinates of the three prisms in the LiDAR coordinate system (where i is the prism number; i = 1, 2, 3), and let q_i denote the coordinates of the prisms in the common coordinate system. The relationship between p_i and q_i is given by Equation (1):

$$q_i = Rp_i + t \tag{1}$$

where R is a 3 × 3 rotation matrix and t is the translation vector of the LiDAR origin. R is obtained using the covariance matrix and singular value decomposition; further details are available in a previous study [11].

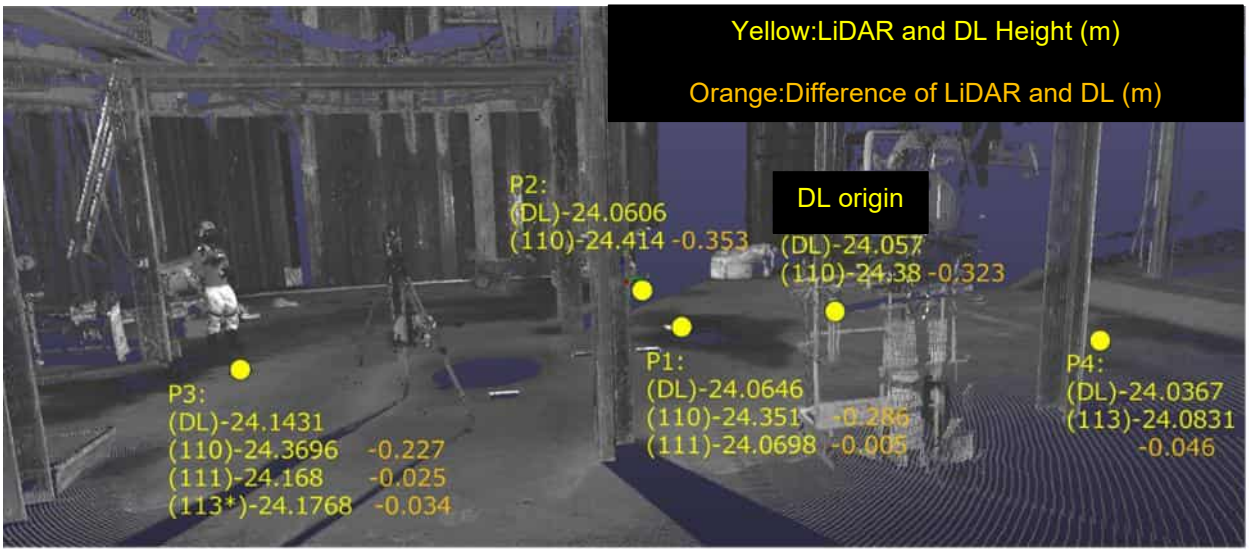

Figure 6. LiDAR and DL heights

From the obtained rotation matrix R, quaternions were calculated and the roll, pitch, and yaw angles were estimated [12][13]. Figure 6 compares the height of the acquired point cloud with the height measured by a digital level. The background in Figure 6 was obtained using a terrestrial laser scanner. The error was ~5 mm in high-accuracy areas but reached 400 mm in others. The excavation depths at this site were currently monitored at fixed points approximately 10 m × 5 m grids with ±50 mm accuracy by level gauge, and similar or higher accuracy and resolution were expected from the MG system. The TS used for prism surveying (TOPCON GT-1003) had an error of 2.1 mm when measuring distances in the nonprism mode from 50 m away; hence, the LiDAR origin and orientation were calculated using coordinate values incorporating this error. Therefore, each coordinate in Equation (1) contained this error, potentially causing position and orientation estimation errors. Furthermore, for example, acquiring point clouds from a distance of 10 m with an accuracy of 20 mm or less requires an accuracy of 2/1000 ~ 0.11° or less. Consequently, the coordinate values of the prism, which were in millimeters, would not have enabled angle estimation with the necessary precision. Given the difficulty of estimating the LiDAR position and angle solely using the prisms attached to the jig, we concluded that sufficient MG/MC would not be feasible under these conditions.

Furthermore, installing the LiDAR at a near-horizontal angle relative to the ground surface resulted in significant point cloud occlusion by obstacles and required frequent adjustments to the device angle and position as the excavation deepened. Therefore, we explored an installation method that would enable continuous measurement of the same area to the greatest extent possible.

3.2 Measurement in Section 2
