Measurements in Section 2 were conducted from November 2024 to August 2025. The measurement area was approximately 10 m wide and 30 m long. One LiDAR unit was installed between each strut, for a total of seven units (#1–#7). For LiDARs #1–#5, the fabricated aluminum frame jig (type 2) differed from that in Section 1. Figure 7 shows this LiDAR jig, and Figure 8 shows the LiDAR installation status. The measurement coverage in Section 2 was improved relative to that in Section 1 by positioning the LiDAR near ground level and directing it toward the excavation surface; in Section 1, it was placed at a near-horizontal angle near the excavation surface.

For point cloud registration, in addition to calculating the LiDAR position and orientation from three or more prisms or reflective sheets (Section 1), we placed reflective sheets on the excavation surface during installation and measured their coordinates using a TS. We then fine-tuned the numerical values such that the LiDAR and TS-measured coordinates matched. Figure 9 illustrates the fine-tuning of the LiDAR orientation. The measured point cloud data were processed using a PC installed inside an on-site distribution board and transmitted to the cloud via an LTE connection. When performing MG, it is necessary to display point clouds of the excavation surface to the operator in real time and with the highest possible resolution. However, attempting to display the point cloud data as is presents challenges such as noise in the point clouds and the sheer volume of data. For this system, field construction staff requested a resolution of 250-mm intervals and a refresh rate of 30 s or less. Therefore, rather than displaying the point cloud data directly, we decided to accumulate the measured point cloud data within a 250-mm square grid for 30 s and display the average value, resolving the issues of point cloud noise and data transmission volume. The cloud data were visualized as contours and displayed on tablets in the heavy machinery operator's cab and on monitors in the site office every 30 s. Additionally, LAS data were uploaded to the cloud once a day for viewing in KOLC+ [14], balancing utility for MG/MC and convenience for daily construction management. Figure 10 shows the MG screen, and Figure 11 shows the visualization in KOLC+. Parts of the area are occluded by elements such as the horizontal struts. Figure 12 shows the progress of the final excavation in the measured area. The contours represent the difference between the measured data and the BIM model data; purple indicates high areas, yellow-green/green indicates areas within the control values, and blue indicates low areas. Evidently, the excavation surface lowers over time. Additionally, some areas appear high due to temporary soil stockpiles or heavy machinery. Activities occurring in parallel with excavation, such as the spreading of crushed stone, are also visible.

Regarding measurement accuracy, Figures 13 and 14 show a comparison of LiDAR and TS data, which was conducted during LiDAR installation, and a histogram of the errors relative to the TS data (data for #5 and #7 are missing), respectively. The errors were generally approximately ±20 mm, falling within 40 mm at most. For #6 and #7, relatively larger errors likely occurred because the jig was the same as in Section 1 and the installation dates were different. LiDAR accuracy may have varied due to the irradiation distance, strut displacement, and vibrations caused by the heavy machinery or wind. Moreover, manual fine-tuning was time consuming, and registration accuracy relied on operator subjectivity. These limitations highlighted the need for a method that would determine positions and angles with high precision, eliminating operator dependence.

3.3 Measurement in Section 3

Measurements were performed in Section 3 from October 2025 to January 2026. In Section 2, workability problems occurred due to the placement of reflective sheets on the excavation surface during installation to fine-tune the LiDAR orientation based on their coordinates. Therefore, we fabricated a type 3 jig (Figure 15) from sheet metal. It had a tribrach at the bottom, a circular bubble level on top, and two reflective sheets attached to its top and side. The roll and pitch angles were precisely set to 90° and 45°, respectively, by leveling the jig using the bubble level. Once the coordinates of the two reflective sheets were determined, the LiDAR's optical origin and yaw angle were calculated. The origin and angles (X, Y, Z, θ, φ, γ) of this LiDAR are expressed as shown in Equation (2) using the coordinates (X_1, Y_1, Z_1) of the upper reflective sheet and the coordinates (X_2, Y_2, Z_2) of the lateral reflective sheet.

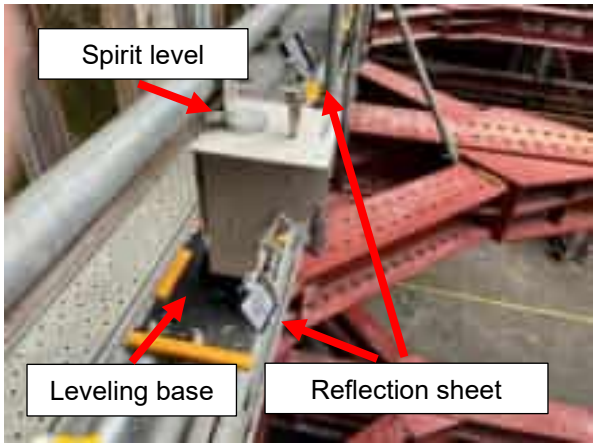

Figure 15. LiDAR and type 3jig

$$
\begin{aligned}
X &= X_1 - 0.005\ sin\gamma \\
Y &= Y_1 - 0.005\ cos\gamma \\
Z &= Z_2 - 0.005, \\
\theta &= -\frac{\pi}{2} \\
\varphi &= \frac{\pi}{4} \\
\gamma &= atan2((Y_2 - Y_1), (X_2 - X_1)).
\end{aligned} \tag{2}
$$

An example of the results is shown in Figure 16. Without manual fine-tuning, the height was generally within 20 mm, but the error exceeded 100 mm in the planar direction. This large error may have been resulted from the difficulty of determining the yaw angle using a prism (Section 3.1). In future, we plan to investigate methods for estimating yaw angles without using a prism.

4 Discussion and Future Work

Unlike conventional registration methods in general robotics applications, point cloud registration often relies on feature-based matching algorithms, such as RANSAC and ICP [6][7]. However, the environments in open-cut tunnel construction sites have repetitive geometric features (e.g., equally spaced earth-retaining struts) and feature-poor surfaces (e.g., flat excavation bottoms or shotcrete walls). In such environments, conventional algorithms tend to fall into local minima, leading to significant registration errors. Furthermore, construction management requires not only relative-map merging but also transformation of point clouds into the absolute site coordinate system for comparisons with BIM model data. Our proposed method, which utilizes a jig and TS measurements, ensures robust point cloud transformation into the site coordinate system, regardless of the geometric features of the environment. This reliability is a critical requirement for practical construction management and MG.

The measurement results from Sections 1 and 2

Figure 16. Accuracy verification of type-3 jig

highlighted the significant impact of LiDAR installation geometry on measurement accuracy. In Section 1, the LiDAR was installed at a low position, at a near-horizontal incidence angle relative to the excavation surface. This configuration caused two issues: (1) significant occlusion by obstacles due to the shallow angle and (2) frequent adjustment of the LiDAR angle with each excavation step. By contrast, the setup in Section 2, where the LiDARs were mounted facing downward on the struts, minimized occlusions and ensured a high incidence angle. The achieved accuracy of approximately ±20 mm in Section 2 satisfied the general tolerance for rough excavation, confirming the system's applicability to MG.

The primary challenge identified in Section 2 was the operational complexity of fine-tuning. This method required installing three or more reflective sheets on the excavation surface and performing labor-intensive calculations of the rigid-body transformation matrix, either manually or via programming, which disrupted construction activities. The type 3 jig addressed this issue by incorporating the bubble level and the fixed tribrach. By mechanically constraining the roll and pitch angles to known values (leveling), we simplified the positioning problem to determining only the translation and yaw angle. This improvement will significantly reduce installation times and eliminate the need to access the excavation floor, thereby enhancing safety and operational efficiency.

Static accuracy was verified while the system operated in a dynamic environment. The slight errors observed in Section 2 (Figures 13 and 14) may be attributed to sensor noise and strut vibration caused by heavy machinery and the minute displacement of the struts over time. Because the LiDAR was mounted on the struts, any shoring deformation directly affected the point cloud coordinates. Future work must distinguish between sensor registration errors and actual structural displacement to utilize this system for the safety monitoring of earth-retaining walls.

5 Conclusion

This study proposes a practical LiDAR-based MG system designed for open-cut tunnel excavation sites, where GNSS signals may be unavailable and geometric features are repetitive. By integrating multiple LiDAR sensors with a TS using a specialized registration jig, we established a workflow for accurately transforming point cloud data into the absolute site coordinate system.

Our field trials demonstrated the critical importance of sensor placement and registration method. The initial trial (Section 1) suffered from occlusion and a low incidence angle, but the improved setup in Section 2—with the LiDARs mounted vertically on earth-retaining struts—achieved a measurement accuracy of approximately ±20 mm. This accuracy is well within the tolerance required for excavation, validating the system's effectiveness for real-time MG. Furthermore, the development of the leveling-enabled (type 3) jig addresses the operational bottleneck of manual fine-tuning, offering a solution that significantly reduces installation time and labor costs.

In conclusion, the proposed system enables precise construction management in environments with limited features. Furthermore, it enhances safety and facilitates efficient site management by minimizing the need for site foremen to enter excavation areas. Future research will verify the efficiency of the type 3 jig in ongoing projects and investigate its potential application to other measurements, such as those involved in concrete placement and the structural displacement monitoring of retaining walls, contributing to comprehensive site safety management.

Abstract -

This paper introduces a graph-based method for deriving robot-executable task structures from Building Information Models (BIM). While BIM models are widely employed to coordinate design and planning, they are seldom used to facilitate on-site automation. A key challenge is that they typically describe building elements and properties, but not the stepwise procedures required for robotic construction. Existing BIM-to-robot pipelines therefore encode process logic in external artifacts (e.g., schedules, scripts, skill libraries) and connect this logic to BIM elements through ad-hoc mappings, which limits reuse across elements and projects. We propose a workflow that integrates BIM-derived product data with reusable construction method templates and performs systematic refinement into task structures. The BIM model is represented as a labeled property graph, construction methods are modeled as parametrized construction process templates, and graph transformations instantiate element-specific task structures. These graphs capture ordering, dependencies, and required parameters, and are mapped to Behavior Trees (BTs), resulting in an execution-level control structure for on-site robotic tasks. A case study on a multi-story building illustrates that the workflow can be applied at building scale, generating element-specific task structures and corresponding BTs from a single, integrated product-process representation.

BIM; Graph Modeling; Task Decomposition; Behavior Tree; Construction Robotics

1 Introduction

In construction projects, digital design intent must be translated into explicit tasks before it can be executed. Digital models support this transformation by coordinating information across disciplines and project stages. Building Information Models (BIM) have become the dominant representation for this purpose [1], informing planning and scheduling [2] as well as on-site progress monitoring during execution [3]. At the same time, construction work remains largely manual, even as robotic systems are beginning to demonstrate their potential for on-site tasks [4].

Despite its broad use, BIM remains sparsely used to enable on-site automation. These models contain geometric descriptions of building components and semantic information ranging from component properties (e.g., materials) to higher-level objects such as stories and zones. However, they often lack the procedural details needed to derive robot-executable tasks. According to the taxonomy of Everett and Slocum [5], construction processes are typically defined at the activity level, whereas robotic execution needs fine-grained tasks and elemental motions. This mismatch in abstraction leaves a gap between the information available in BIM and the task-level information required for robotic execution.

Recent research has sought to derive actionable information for robotics directly from BIM. Examples include extracting work locations and object context from Industry Foundation Classes (IFC) geometry [6], or combining BIM with onboard sensing to perceive workpiece geometry and update motion plans under changing conditions [7]. While these studies demonstrate the value of BIM-derived information, they remain narrowly scoped. They often address a single task or building element and rely on manually engineered mappings from BIM entities to robot actions. This limits their transfer beyond the specific task setting for which the mapping was designed.

The underlying challenge is representational. Product data, schedules, and robot actions are typically stored in separate artifacts, such as schedules in CSV files, loosely defined process graphs, and hard-coded task scripts. This fragmentation prevents systematic reuse and the consistent capture of process logic at the building scale. Addressing this challenge calls for a unified, higher-level representation that links construction processes and their task structures across building elements, while remaining compatible with robotic execution-level control structures. Graph modeling is identified as a promising approach to represent products, processes, dependencies, and their evolution over time in a single formalism [8].

This paper proposes an integrated product-process representation that links BIM-derived product data, construc-

tion methods, and graph-based process modeling to systematically derive element-specific task structures. These structures remain connected to their source BIM data and are mapped to execution-level representations for robotic systems. The remainder of the paper discusses related research on BIM for construction automation and process modeling with graphs. It then presents the proposed workflow and graph representation and illustrates their application in a case study. It concludes with a discussion of contributions, limitations, and directions for future research.

2 Background

2.1 Deriving Robotic Tasks from BIM Data

Existing BIM-to-robot pipelines mainly differ in where procedural knowledge is represented and at what granularity it becomes executable. A common pattern is to encode process logic in an external artifact and use BIM primarily to supply geometric and semantic parameters. Zhu et al. [9] represent construction intent in a CSV schedule that specifies task sequences per element. Execution parameters, such as IDs or locations, are retrieved from the BIM model. Terzer et al. [10] similarly derive mission-specific parameters from IFC data for wall painting, where high-level missions are decomposed into subtasks and executed using Behavior Trees (BTs) [11]. These approaches demonstrate the value of BIM as a contextual data source for robotic execution. However, process logic is generally defined outside the BIM model and linked to BIM entities through manual mappings. This makes the resulting task structures application-specific and limits their reuse.

A second pattern brings task planning closer to the BIM environment by embedding task definitions in scheduling workflows and linking actions to robotic skills. Oyediran et al. [12] integrate robotic task planning into 4D BIM by associating actions with skill identifiers stored in an external database. This database also specifies additional modeling inputs, such as pickup locations or installation reference frames, which have to be manually added to the BIM model. While this improves traceability and ties tasks more directly to building elements, it still depends on manual modeling inputs and does not provide a general, reusable representation of process logic.

Across these approaches, BIM serves as a repository of product data and execution parameters, while procedural knowledge is spread across heterogeneous artifacts (e.g., schedules, mission scripts, skill libraries, BTs). This split complicates the systematic refinement of product-level descriptions into reusable task structures. It therefore motivates representations that connect element context with explicit process logic in a unified form.

2.2 Graph Representations in BIM and Construction Robotics

Graph representations have increasingly been explored as a way to integrate heterogeneous information and to make relationships between products, processes, and resources explicit. Knowledge graphs are used to support semantic integration and reasoning by translating IFC-derived scene information into graph form and linking it to task and agent models. Chen et al. [13], for example, propose the iSTA (Scene-Task-Agent) model for inspection tasks. The model represents scene context extracted from IFC in a Resource Description Framework (RDF) format combined with robotics ontologies and a custom task ontology to support reasoning and task allocation. In a related fashion, Zhu et al. [9] use a Linked Building Data (LBD) approach to integrate building models and construction schedules by converting IFC and CSV schedule data into RDF graphs. The information stored in the LBD graph is queried by a Robot Construction Action Node (RCAN) system, which serves as an intermediate layer between BIM and robotic execution in ROS and supports task allocation and execution. These approaches highlight how graphs can unify and query contextual data, rather than generating task structures for robotic execution.

Beyond knowledge graphs, task graphs have been used to encode process dependencies more directly. Atanasova et al. [8] introduce a directed graph model for cooperative human-robot assembly. Unlike prior works focused on inspection or static task sequences, their approach captures real-time task dependencies, agent assignments, and evolving assembly states. This example demonstrates how graph models can capture dynamic process logic and dependencies relevant for execution.

Taken together, prior work shows that BIM information can parametrize robotic actions, while graph representations can make process relations and dependencies explicit. Yet these research directions remain insufficiently connected at the step where procedural knowledge is linked to element context. What remains unclear is how this connection can be established systematically and represented in a form that supports robotic execution.

2.3 Control Structures for Execution

Behavior Trees (BTs) organize robotic behavior in a modular hierarchy that separates control flow from execution nodes and provides runtime reactivity [11]. Complex missions are decomposed into executable actions, organized by control logic and supplied with the parameters needed for those actions. This makes BTs relevant not only as an execution formalism, but also as an indicator of what task representations must contain to support robotic execution.

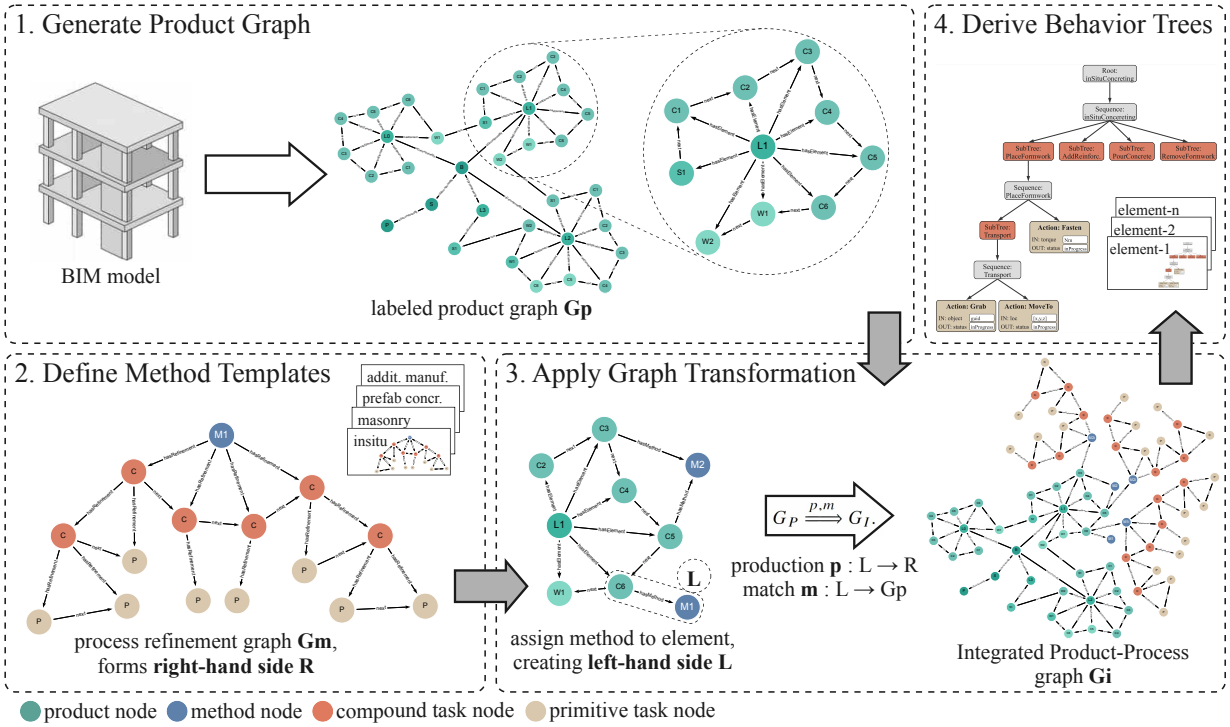

Figure 1. **Overview of the proposed method**: (1) represent a BIM model as a labeled product graph G_p; (2) decomposed construction processes as method templates G_m; (3) user-assigned methods link each product to its method and transform G_p into an integrated product-process graph G_I; and (4) derive Behavior Trees.

In construction robotics, BTs are used as execution structures for tasks parametrized from BIM. Terzer et al. [10] use BIM to provide semantic and geometric parameters for wall painting missions. Similarly, Tandon et al. [14] apply BTs to inspection missions, where BIM data provides target elements and inspection poses, and subsequently generate BTs for navigation and visual inspection. These examples show that BTs are a suitable target structure for describing construction processes. This motivates structuring the task graphs discussed in sec. 2.2 so that element context and process logic can be mapped to BTs, supporting a refinement workflow from BIM-derived product data to execution-level control.

3 An Integrated Product-Process Representation for Robotic Construction

This study proposes a unified workflow that uses graphs to link product data derived from BIM with procedural knowledge and refine this link into task structures suitable for robotic execution. As shown in Fig. 1, the workflow represents the BIM model as an LPG and models construction methods as parametrized templates. Binding these templates to elements triggers graph transformations that create task structures for each building element, yielding an integrated product-process graph. The resulting graph is then converted into a robot-executable format using Behavior Trees. The following sections detail these stages in turn, beginning with product representation, progressing to process structuring and generation, and finally deriving execution-level control structures.

3.1 Representing BIM Data as a Product Graph

We represent the building as a product graph, modeled as an LPG from semantic and geometric information contained in Industry Foundation Classes (IFC) models. This choice aligns with prior work showing that graphs can unify heterogeneous information within a single model [13, 8]. The LPG provides a transformable basis for deriving task structures that can later be converted into robot-executable control structures. Because we focus on construction methods for load-bearing elements, the resulting graph inherently represents the building's structural shell.

The graph follows the IFC spatial hierarchy, grouping building elements under their respective building stories, as illustrated in the upper-left section of Fig. 1. Nodes are labeled as either *SpatialElement* or *BuildingElement*, with their IFC subtype retained as a second label. Spatial elements include the site, building, and its stories, while

relevant building elements include, but are not limited to, beams, walls, columns, and slabs. The representation can be extended with *Resource* nodes (e.g., robots, equipment, or material supply points). The combined labels enable queries not only over spatial and containment relations, but also over specific element types.

Edges capture spatial decomposition and containment relationships from IFC, ensuring that each element remains embedded in its spatial and physical context. We additionally enrich the graph with adjacency relations between neighboring elements, and inter-element ordering relations that can be used to represent a construction sequence. When the graph is extended with process information, typed edges (e.g., *needsResource*) can connect tasks to required resources to support later allocation and feasibility checks. Together, the labeled nodes and edges form the product graph $\boldsymbol{G_p}$. This graph is fine-grained enough to associate construction methods and task structures with individual elements, yet abstract enough to be applicable to typical IFC models. Coarser representations, such as zones, do not expose individual elements as task targets. In contrast, finer decompositions, such as fasteners, are often absent in design-phase models and therefore cannot be assumed.

3.2 Capturing Construction Processes as Method Templates

A construction method describes how a building element is realized in practice, expressed as an ordered sequence of processes. In this work, we adopt this notion for four construction methods: *in-situ concreting, prefabricated concreting, masonry,* and *3D concrete printing*. Each method is modeled as a parametrizable template that organizes its process steps into a reusable structure. The template is element-agnostic at first, becoming element-specific task structures only when bound to a building element. This separation allows the same method to be reused across multiple elements while still adapting to their individual properties. However, construction processes are still too abstract to directly instruct robots [5]. We therefore refine them into tasks (e.g., Grab), which ultimately provide the lower-level units from which executable actions are derived.

3.2.1 Task Decomposition

We structure method templates using Hierarchical Task Network (HTN) planning [15] principles. HTN offers a hierarchical modeling approach that breaks high-level activities down into ordered subtasks. In HTN terminology, high-level activities are *compound* tasks, which can be refined into other compound tasks or into *primitive* tasks. Primitive tasks are directly executable actions such as *Grab, MoveTo,* or *Fasten*. In a graph representation, compound tasks map to internal nodes, and primitive tasks map to leaf nodes. Primitive task nodes specify the required operational properties, such as locations, tolerances, and element IDs. These properties are instantiated, that is, receive their values, when the method template is bound to a specific building element.

In the proposed representation, a construction method is formalized as a directed acyclic graph (DAG) $\boldsymbol{G_m}$, shown in the bottom-left quadrant of Fig. 1. The DAG consists of compound and primitive task nodes linked by refinement (parent-child) relations. For each compound task, the order of its child tasks defines the local execution sequence among siblings. This captures hierarchical decomposition and task ordering in a form that can later be converted into an executable control structure. A partial template example for in-situ concreting is shown below.

Partial in-situ template

```
InSituConcreting
├─ PlaceFormwork
│  ├─ Transport
│  │  ├─ Grab
│  │  └─ MoveTo
│  └─ Fasten
├─ AddReinforcement
├─ PourConcrete
└─ RemoveFormwork
```

3.3 Integrating Product and Process Data

Up to this point, product data and procedural knowledge have been represented separately. The transition from abstract method templates to actionable task structures requires associating these templates with the product data of each element. As shown in the bottom-right quadrant of Fig. 1, we achieve this in two steps: first, a method template is bound to a building element, and second, graph transformation rules instantiate task properties and transfer the template structure, yielding an element-specific task structure.

3.3.1 Method Binding

Assigning construction methods to elements is treated as a design decision and is therefore user-defined. Each assignment is stored in the product graph as a directed *hasMethod* edge from the element node to a *ConstructionMethod* node representing the chosen method. Elements that use the same method reference the same *ConstructionMethod* node, which reflects that the method is a reusable template rather than an element-specific object. Each element-method pair then forms the left-hand side pattern matched by the transformation rules.

3.3.2 Graph Transformation

After assigning a construction method to an element, we apply graph transformation rules [16] to generate element-specific task structures:

$$p : L \rightarrow R, \tag{1}$$

where $\boldsymbol{L}$ denotes the element-method pattern, and denotes $\boldsymbol{R}$ the right-hand side graph that introduces or enriches task nodes and edges according to the method template. We consider four kinds of rules: (i) rules that create task instances for all tasks in the method template and designate the root task for the bound element, (ii) rules that transfer refinement and sequencing relations from the template to the instances, (iii) rules that instantiate primitive task properties using product data, and (iv) rules that link instantiated task nodes to *Resource* nodes where resource requirements are specified. A match

$$m : L \rightarrow G_P, \tag{2}$$

selects an occurrence of the pattern $\boldsymbol{L}$ in $\boldsymbol{G_p}$ (created by the element-method assignment). Applying a rule $\boldsymbol{p}$ under a match $\boldsymbol{m}$ transforms the product graph $\boldsymbol{G_p}$ into an integrated product-process graph $\boldsymbol{G_I}$:

$$G_P \overset{p,m}{\Longrightarrow} G_I. \tag{3}$$

The transformation does not delete or rewrite the product side. Instead, it extends the graph with task structures anchored to building elements. The resulting integrated product-process graph $\boldsymbol{G_I}$ links spatial and physical building information with sequenced construction tasks and forms the basis for the execution model.

3.4 Deriving a Robot-Executable Control Structure

The integrated product-process graph specifies which tasks are required and how they are ordered, but its task structures still need to be expressed as an execution-level control structure. We therefore map the task structures to Behavior Trees (BTs) [11] that preserve the higher-level process logic captured in the graph. While typically the internal control program of a single robot, we use BTs as a shared representation of the construction process.

Compound tasks become *control* nodes (e.g., sequence or parallel) that organize their children according to the refinement and precedence relations in the DAG $\boldsymbol{G_m}$, preserving the hierarchical and ordered structure introduced in Sec. 3.2.1. Primitive tasks become *action* nodes that carry over the element-specific properties. To promote reuse and modularity, recurring compound tasks are represented as standalone *subtrees* that can be referenced from higher-level Behavior Trees (see Fig. 2). A project-level tree then composes the element-specific trees and orders them according to inter-element dependencies, providing a single entry point for execution. The resulting BT is generated per project from the integrated product-process graph, preserving traceability to elements and task data while providing a robot-executable control structure.

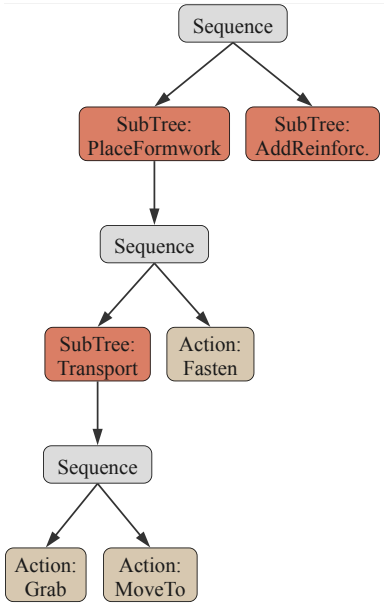

Figure 2. Part of an exemplary Behavior Tree for an in-situ concreting method, illustrating control nodes (sequence), action nodes, and reusable subtrees.

4 Case Study

To illustrate the proposed workflow, we apply it to a multi-story building model and demonstrate how BIM-derived product data, construction method templates, and graph transformations are combined to generate element-specific task structures and Behavior Trees.

4.1 Setup

The case study uses an IFC model of a three-story building, shown in Fig. 3. We restrict the scope to load-bearing elements and consider 51 beams, 36 columns, six walls, and four slabs. The product graph preserves the IFC spatial hierarchy and is enriched with adjacency relations by checking intersections between element axis-aligned bounding boxes. Four construction methods are considered: *in-situ concreting, prefabricated concreting, masonry,* and *3D concrete printing*. Their method templates follow the structure described in sec. 3.2. For the case study, method bindings are assigned manually to illustrate the workflow, for example, in-situ concreting for

slabs and beams, 3D concrete printing for columns and walls, and masonry for walls. The workflow was implemented in Python, using IfcOpenShell for IFC processing, Neo4j for graph storage and transformation, and a custom Python script to query the graph and write Behavior Tree XML files.

Figure 3. BIM model used for case study.

4.2 Instantiating the Product-Process Graph

The resulting product graph G_p contains seven spatial nodes with six spatial decomposition relationships, 97 building-element nodes and containment relationships, 223 adjacency relationships, and 96 precedence relationships between elements. We obtain the element precedence relationships through a simple centroid sorting along the Z, Y, and X axes. These relations are not intended to represent an accurate construction sequence, but provide an initial project-level order that can later be replaced by more explicit sequencing rules.

Method binding is realized using an interactive IFC viewer [17], where users select building elements and assign a construction method to each of them. Applying graph transformation rules yields the integrated product-process graph G_I, where method templates are instantiated and each element is linked to a rooted task structure. For the case study model, the transformations generate 1,138 task nodes, comprising 396 compound tasks and 742 primitive tasks, connected by 1,480 refinement edges and 792 precedence edges. On average, the in-situ concreting, prefabricated concreting, and masonry templates contribute 10, 7, and 5 primitive tasks per element, respectively, reflecting differences in method complexity. The resulting task structures are acyclic and anchored to their elements, indicating that the method templates can be reused consistently at the building scale.

4.3 Deriving Behavior Trees from Task Structures

The task structures in G_I provide the basis for deriving Behavior Trees that describe the construction process independently of a specific robot platform. They specify *what* must be done and in which order, while robot selection determines *how* tasks are executed. This separation is important because the considered methods may be realized using different platforms (e.g., in-situ concreting via a pump, prefabrication using lifting and placement equipment such as a crane, masonry with a bricklaying robot, and 3D concrete printing with a mobile printing system).

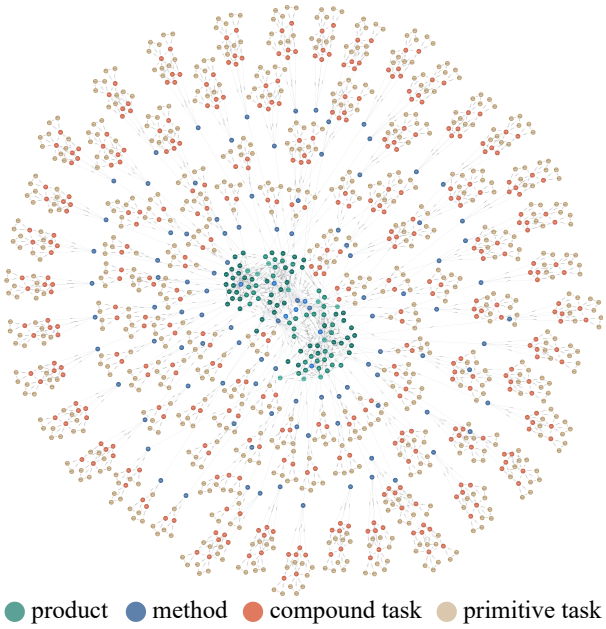

Figure 4. Product-Process Graph for a Simple Building with Multiple Methods.

For each element-method pair, the rooted task structure is mapped to a BT subtree. Compound tasks become control nodes, while primitive tasks become parametrized action nodes. This mapping is applied to all elements with assigned methods. Fig. 5 shows a representative BT for an element assigned to the in-situ concreting template. Its action (leaf) nodes carry the parametrized values of a particular element, for instance the element ID and target location used by the *GrabObject* and *MoveTo* actions.

Across the case study, the workflow generates 98 BTs: one BT per element in scope plus one project-level BT. These BTs preserve the method template structure and remain linked to their corresponding building elements. This demonstrates that the refinement of BIM-derived product data and procedural knowledge into task structures carries through to an execution-level control structure.

5 Discussion

The case study shows that construction method templates can be reused to generate element-specific task structures systematically. A small set of methods is applied across the load-bearing elements, and graph transformations instantiate rooted task subgraphs for each element from the corresponding method binding. This indicates that reusable method templates are applied consistently at

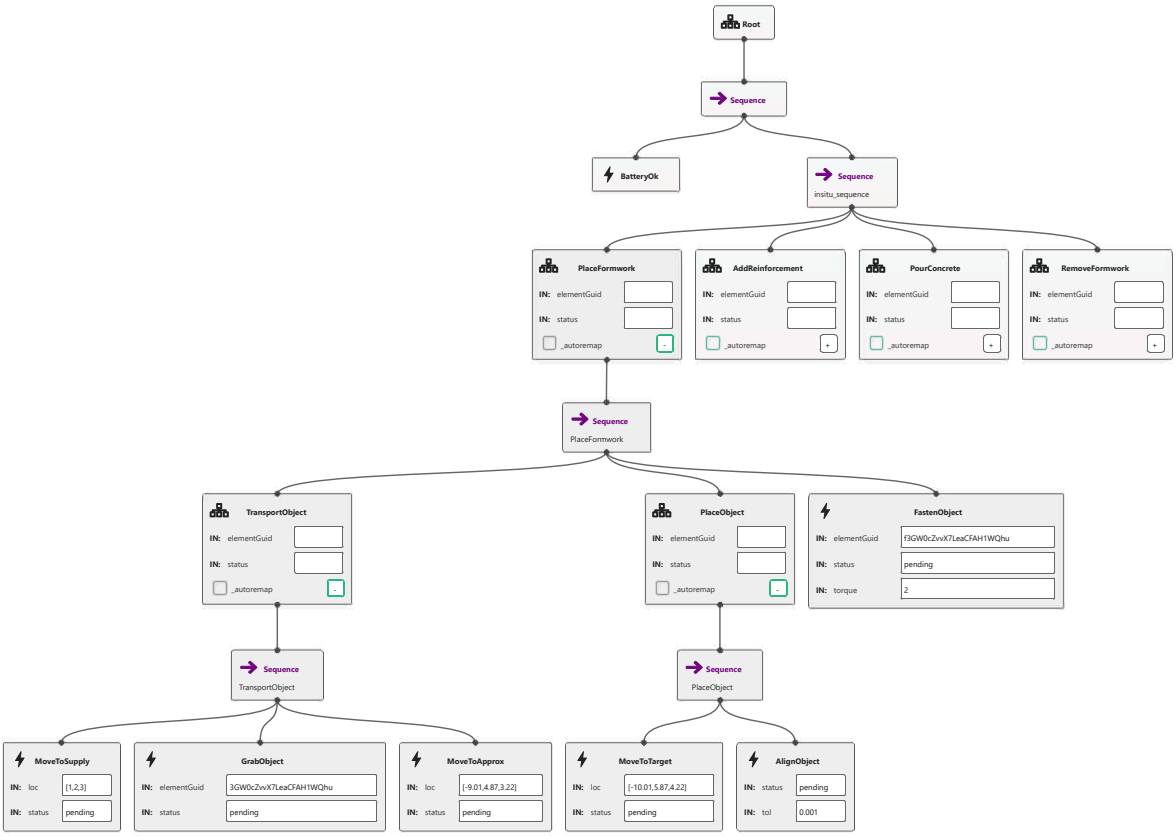

Figure 5. Behavior Tree derived from product-process graph.

the project level.

The proposed representation complements knowledge graph approaches in BIM [9, 13] by linking product information and process knowledge in a form that can be mapped to execution-level control structures. Instead of distributing process information across schedules, mission scripts, or skill libraries, the integrated product-process graph stores task decomposition and ordering together with element context. Queries can therefore access process semantics (e.g., predecessors, successors, refinement relations) alongside product attributes. The same graph structure can be extended with additional dimensions such as resources or temporal constraints. This creates a flexible layer for future functionalities such as robot-task allocation or discrete-event simulation.

Despite its merits, the current approach has limitations. LPGs are flexible and easy to extend, but their schemaless nature offers limited guarantees about validity and structure. A closer alignment with the IFC schema would not only provide more structure but also support more complex reasoning. For example, this would enable spatial reasoning, where queries could infer whether a robot can reach a target pose by passing through doors of sufficient width, or traverse terrain such as stairs. Such queries would extend the current lightweight representation beyond element-specific task generation toward a richer representation of construction context. Additionally, method templates are defined manually, which raises questions of modeling effort and scalability as more construction methods are added. Finally, the present work stops at Behavior Tree generation and does not yet validate runtime execution. Future work will therefore focus on more systematic template definition and on evaluating the generated structures in simulation and with physical robots.

6 Conclusion

This paper presents a refinement workflow that links BIM product data with procedural knowledge to generate element-specific task structures for robotic construction. Product data is represented as a labeled property graph (LPG), and construction methods as parametrized templates. Graph transformations instantiate element-specific task structures, which are then mapped to Behavior Trees (BTs) as execution-level control structures. We evaluate the approach on a multi-story building model. For the load-bearing elements, we build an integrated product-process graph, reuse a small set of method templates across

many elements, and generate one BT subtree for each element to match the intended process logic. This reduces the need for hand-crafted BTs and keeps each subtree explicitly linked to its source element. Because tasks and product context share a single graph, the model can be extended with resource and timing constraints, used for robot-task allocation, or updated during execution by integrating perception feedback.

In summary, the proposed workflow consolidates fragmented product, process, and execution artifacts into a single product-process model that yields robot-executable task structures. It supports systematic refinement and reuse across elements and provides a foundation for reuse beyond a single project, paving the way for more scalable BIM-to-robot workflows in construction robotics.

Abstract -

This paper presents a low-cost, high-precision laser-line sensor designed for construction-robotics applications such as on-site tiling, leveling, and tool localization. Unlike similar projects built around custom electronics and hardware, our approach uses a off-the-shelf microcontroller with camera module and a semi-transparent projection screen to measure the vertical position of a laser line from distances of 1–6 m with sub-millimeter accuracy. We introduce a complete sensing pipeline, including controlled illumination, and subpixel peak extraction across multiple camera modes. A fully automated data-collection framework cycles through sensor resolutions, records timing jitter and peak-detection stability, and quantifies achievable measurement precision. Results show that a consumer-grade imaging system can provide consistent, high-frequency height measurements suitable for indoor construction tasks, offering an accessible alternative to specialized CCD-based receivers or high-end laser trackers.

Construction Robotics; Absolute Localization; Laser Plane Sensing; Digital Fabrication

1 Introduction

Precision alignment is essential in robotic construction tasks such as floor tiling, concrete smoothing, and wall rendering, where sub-millimeter tolerances are sometimes required. While many pose estimation methods exist, few can reliably achieve this level of precision, and those that can—such as laser trackers or robotic total stations—come at high cost and with significant deployment complexity. In practice, many robotic processes do not require high precision in full 6-DOF. Instead, they can be aligned relative to a fixed planar reference. Examples include controlling floor tile placement for horizontal level or guiding wall plastering tools to stay plumb.

This paper introduces a low-cost laser-plane height sensor that leverages the geometric consistency of construction-grade laser levels. The method uses a camera in combination with a near-field projection screen to detect where a laser plane intersects the screen surface. By analyzing the position of this projected line at subpixel resolution, the sensor estimates height deviation relative to the plane with high precision. This paper focuses on the design and characterization of the sensing system itself, while integration into a complete robotic workflow is left for future work.

The main contributions of this work are: (1) a reproducible open-hardware sensor comprising only a camera module, a 3D-printed housing, and a paper screen; (2) a lightweight processing pipeline including lens focusing, calibration, and real-time peak detection; and (3) an experimental evaluation of the sensor's performance across multiple resolutions and distances, demonstrating accuracy suitable for integration into on-site robotic workflows.

2 Related Work

Robotic construction applications often rely on external positioning systems to achieve high accuracy over large workspaces. Commercial systems such as robotic total stations and laser trackers offer sub-millimeter precision by optically tracking a retro-reflective target [1]. These systems have been used in mobile construction robotics to localize manipulators relative to a site-fixed reference. Similarly, ETH Zurich's Robotic Fabrication Laboratory has deployed a Nikon iGPS system to localize robots and objects in a shared workspace [2]. While these systems enable full 6-DOF pose tracking, they impose significant infrastructure demands: tripod-mounted cameras or lasers, calibrated room-scale volumes, and line-of-sight requirements. Motion capture systems provide similar accuracy in indoor settings but require multi-camera arrays mounted on trusses or frames and are less suitable for deployment in dynamic construction sites.

Marker-based vision systems have been developed as low-cost alternatives to motion capture or total station tracking. For example, a camera mounted on the robot's end-effector can detect fiducial markers placed in the construction environment [3]. However, vision-based localization methods require sufficient lighting, careful calibration of the optical system, and stable environmental geometry. Their accuracy is inherently dependent on resolution, lens distortion, and viewing angle—factors that

limit their effectiveness for long-range height sensing.

Planar Laser Sensing in Field Robotics More recently, several construction robots company have developed robots with laser line sensors, rely on laser planes as spatial references. Unfortunately, many of them are not published and their methods remain undisclosed. Published examples include a mobile robot that follows a laser line projected onto a raised-floor grid, achieving 2–3 mm positioning error using a custom-built sensor tuned to the laser profile [4]. While effective for gross alignment tasks, these sensors do not support sub-millimeter resolution or customizable processing. Only until recently, a custom laser receiver was developed for detecting the intersection of a construction-grade laser plane [5]. Using custom electronics and hardware, their spinning CCD sensor array is capable of sensing a laser plane height with accuracy of 25 µm(max) and 5.5 µm(average).

Other researchers have explored triangulation-based laser systems, where static beacons emit laser patterns and mobile receivers triangulate their position. However, such systems require multiple calibrated emitters and suffer from cumulative line-of-sight and angular ambiguity issues, particularly on cluttered sites. Camera-based sensing systems have also been used to monitor structured-light patterns or detect projected lines in manufacturing. These systems often require structured lighting conditions and are not intended for on-site construction tasks or over large distances.

3 Sensor Design and Implementation

3.1 Sensor Concept

The sensor we developed detects the vertical position of a laser plane by capturing the intersection of the laser beam with a near-field projection screen. The screen is positioned orthogonally to the incoming laser plane such that the projected line appears as a nearly straight segment across the visible field. As the sensor moves relative to the laser, the projected line shifts vertically along the screen surface. Since the sensor only measures the height of the laser line within its fixed field of view, the system effectively slides the laser intersection vertically over the screen. This converts the 3D spatial deviation relative to the plane into a 1D pixel displacement observable by the camera.

3.2 Hardware Architecture

The hardware consists of three components:

- OpenMV H7 Plus microcontroller with integrated OV5640 camera sensor, which supports resolutions up to 2592×1944. The board is officially priced at USD 95, though alternative sources offer it for approximately USD 40.The stock lens is replaced with a generic 5MP HD650 M12 lens (3.5 mm focal length, f/2.8) offering a 90° horizontal and 60° vertical field of view. The lens structure follows a 2G2P configuration and is marketed as "zero-distortion." The lens is readily available online and costs approximately USD 4.
- Mechanical enclosure and screen: The microcontroller is mounted to a custom 3D-printed PLA enclosure using two screws. The enclosure maintains a fixed 20 mm spacing between the lens and the screen. The case can be fabricated using an entry-level FDM 3D printer with a 0.2 mm layer height. No supports or post-processing are required.
- The screen is cut from standard 80 g/m^2 printing paper and adhered to the front of the housing using adhesive tape. The visible size of the screen is 30 × 40 mm

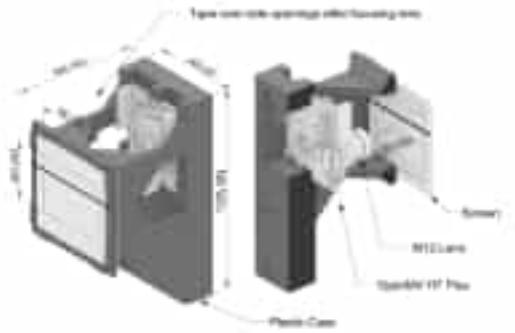

Figure 1. Dimensioned drawing (left) and cut-away (right) of the sensor hardware

After lens focusing is completed, the side openings are covered with black tape to prevent light from reaching the screen from the back side. The sensor geometry and dimensions are illustrated in Figure 1.

4 Software Architecture

The onboard firmware runs MicroPython scripts using the OpenMV IDE environment. An SD card is not required; all scripts execute from internal flash.

Lens Focusing Procedure To assist with focusing at the 20 mm working distance, a custom script is provided. The user replaces the white screen with a temporary pattern-printed paper (provided in the repository). The focus script evaluates local contrast in five image regions and computes

a focus score that is displayed in real time. The user adjusts the lens manually until the score is maximized, then locks the lens in place. After focusing, the pattern is replaced with a blank screen, and all side openings are taped over to block ambient light. The focusing aid is designed to be reproducible and requires no test targets beyond the printed pattern

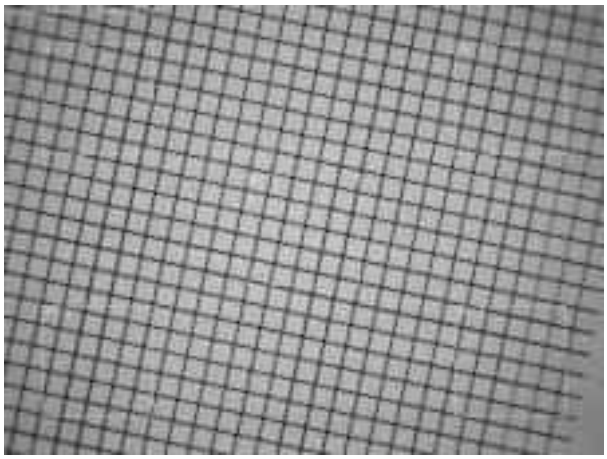

Figure 2. Frame displayed during lens-focusing. White square indicates multiple regions of interest.

Laser Line Detection Pipeline The laser detection script includes the following steps:

- Image acquisition: The sensor operates in grayscale mode at VGA resolution. Exposure and gain settings can be manually configured, though automatic exposure and gain are preferred.
- Brightness thresholding: Pixels with a brightness value below 80
- Row reduction: The captured image is collapsed into a 1-dimension vertical brightness profile. For each image row, a local mean brightness is computed using OpenMV's ROI statistics.
- Adaptive smoothing: A moving average filter is applied to the row profile. The window size is selected automatically using a statistical thresholding function (`auto_window`) that estimates the width of the bright region based on mean and variance. This step is essential for converting any flat-top area (caused by the thickness of the laser beam) into a brightness profile with well-defined peak.
- Peak detection: The smoothed profile is passed through a peak detector (`argmax`) to identify the brightest row, which corresponds to the laser line.
- Subpixel fitting: Two estimators are implemented:
  - Three-point fit: A quadratic curve is fit to the peak row and its neighbors using the standard parabola formula.
  - Five-point fit: A more robust version using five neighboring values and an approximation of a Savitzky–Golay filter, offering better stability on symmetric profiles.

The moving average smoothing helps the peak detection algorithm being insensitive to variation in image brightness. We demonstrate the robustness of the method by setting the brightness threshold to different values (from 20% to 80% at 10% increment) and confirmed that the detected peaks are identical (Fig.3). It is worth noting that the precision and repeatability produced by peak estimation does not require the laser line to have a symmetrical brightness.

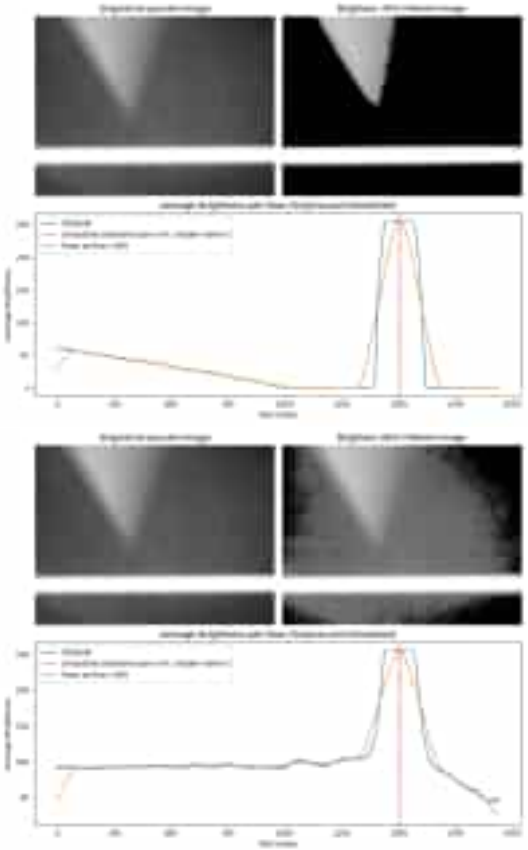

Figure 3. The project laser line (white horizontal stripe) as seen by the camera (top left) and after threshold (top right) at 20% and 80%. The brightness peak (dotted red) is identical after smoothing (orange) the raw brightness data (blue).

T9	Long-range (Concrete Floor)	VGA	5.0 (fixed)	1000–11000	S2	Jitter (§5.5)

5 Experimental setup

To evaluate the accuracy, stability, and geometric response of the sensor across a wide range of conditions, a set of structured experiments was conducted. These tests were designed to isolate variables such as image resolution, emitter distance, ambient lighting, and laser beam geometry, and to quantify their effect on the sensor's measurement performance.

5.1 Data Collection Apparatus

Experiments were conducted using combinations of a motorized linear size (for varying emitter distance, d), manual micrometer stage (sensor height, z), fixed or pendulum-mounted laser emitters, and varying site conditions. Three types of laser emitter setups were used (also refer to Figure 4): **S1**: Static red laser emitter on linear track: used in T3, T4, and T6 for controlled Z-sweeps and emitter-distance tests. **S2**: Pendulum green laser level (construction grade): used in T7, T9, and T10 for long-range jitter and linearity tests under passive self-leveling conditions. **S3**: Stationary green laser level: used in T8 for comparison against pendulum-based emitters on raised flooring. Ten datasets (T1 to T10) were collected during development (see Table 1); Note 1: T1, T2, and T5 were later discarded due to instability or redundancy. The remaining seven datasets (T3, T4, T6–T10) are used throughout the evaluation. Note 2: "7 res." indicates resolution sweep across QQVGA (160x120) to WQXGA2 (2592x1944).

6 Results and Discussion

6.1 Calibration linearity across resolutions

To verify the geometric behavior of the sensor, we evaluate whether the relationship between sensor height z and detected laser line position is linear across all resolutions. Dataset T4 was collected by sweeping z from 0 to 14 mm (in 15 steps) using a micrometer stage, while cycling through seven resolutions at each height. For each resolution, the mean subpixel peak position (using 3-point subpixel estimator) was fit with a linear regression against ground-truth z, and residuals (representing error) were computed per sample (in µm). Figure 5 shows the calibration lines and residuals for all resolutions. Results confirm consistent linearity across the entire range, with residuals bounded within ±20 µm.

6.2 Subpixel estimator comparison

We compare three peak detection methods: integer row index, 3-point quadratic fit, and 5-point fit. Using dataset T3 (dense 101-step Z sweep at VGA), each method's peak position is compared against the calibration curve from T4, and RMS residuals are computed. Figure 6 plots RMS error (µm) and normalized linearity error for each method and resolution. Integer peak performs worst (50–60 µm

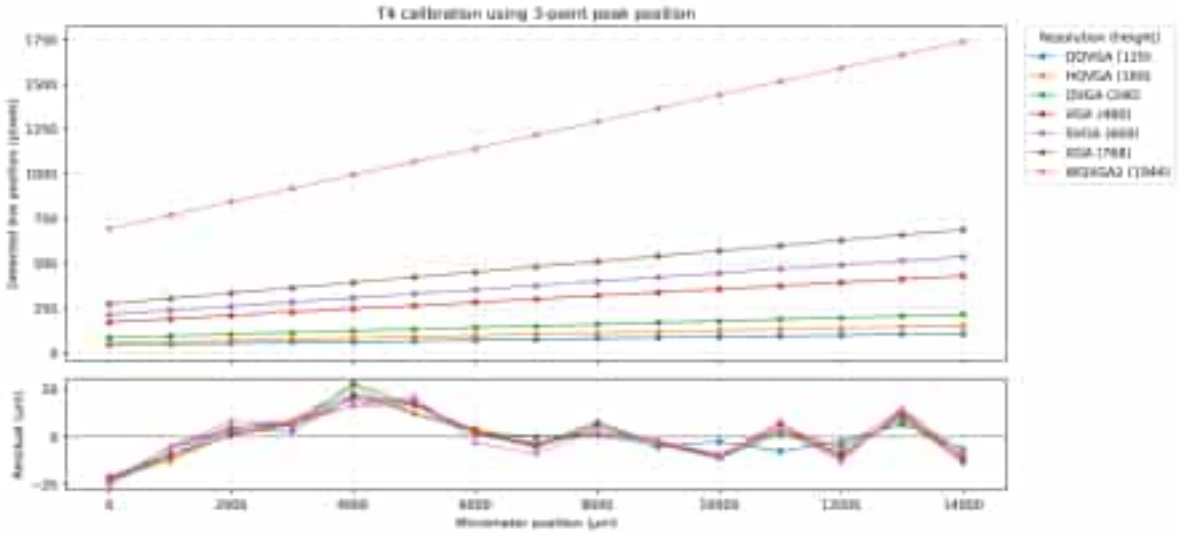

Figure 5. Calibration curves and residuals for all resolutions (dataset T4).

error), 3-point significantly improves accuracy (8–12 µm RMS), and 5-point yields no meaningful gain. The 3-point fit is therefore optimal.

6.3 Measurement error distribution at VGA

To characterize noise in a typical usage case, we analyze residual errors at VGA resolution using dataset T3. Measured heights are compared to the linear fit from T4, and residuals are converted to µm. Figure 7 shows a histogram of residuals along with symmetric percentile intervals. The median error is near zero; 90% of samples lie within ±38 µm and 95% within ±51 µm. The distribution is non-Gaussian with heavy tails but centered and repeatable. This defines the practical noise floor for VGA.

6.4 Sensitivity to emitter distance (short range)

Dataset T6 varies emitter distance from 60 mm to 860 mm while keeping sensor height fixed. At each distance, the laser line is detected and its height computed using calibration from T4. Figure 5.4 shows the mean deviation and frame-to-frame jitter versus emitter distance. A slow drift (200 µm) is observed over 800 mm, attributed to mechanical straightness of the linear track. Frame jitter remains low (¡10 µm), confirming that emitter distance has negligible impact on local precision within 1 m.

6.5 Long-range jitter on different floor types

To evaluate long-range performance under realistic conditions, we compare datasets T7–T9. The sensor is positioned at a fixed height (fixed micrometer) observing a laser emitter at large distances (up to 13m). At each testing condition, multiple observations were made (T7, T8: 10 samples; T9: 200 samples) to compute the jitter. Figure 9 shows jitter vs. distance on raised floor (T7–T8) and concrete floor (T9). The raised floor amplifies vibration and pendulum motion, leading to jitter of 50–300 µm at 8–13 m. On concrete, remains below 32 µm, an order of magnitude more stable than the test performed on raised floor. The jitter in T9 also grows linearly with distance, indicating that environmental stability, not sensor performance, dominates long-range error.

6.6 Long-range linearity

Dataset T10 tests linearity at 6 m emitter distance using 21 micrometer height steps (0–5 mm, 50 repeats each). Figure 10 shows the linear fit and residuals. The system maintains a consistent slope with RMS residuals of 14–21 µm and no curvature. Even at long distances, geometric linearity is preserved, and measurement accuracy remains stable.

7 Discussion and Conclusion

The sensor achieves sub-millimeter accuracy across a range of distances using only low-cost, readily available components. Its performance remains highly linear across all resolutions and working distances, with 95% confidence bounds of ±0.026 mm at 400 mm and ±0.050 mm at 6 m. While long-range jitter is observed, the reason is attributed to floor stability and emitter mounting instead of the sensor's internal precision. Note that, the present evaluation was conducted in indoor conditions and does not include direct sunlight or strongly mixed artificial lighting. Dust, debris, partial occlusion, and stronger ambient light can be further evaluated in future work. Such work

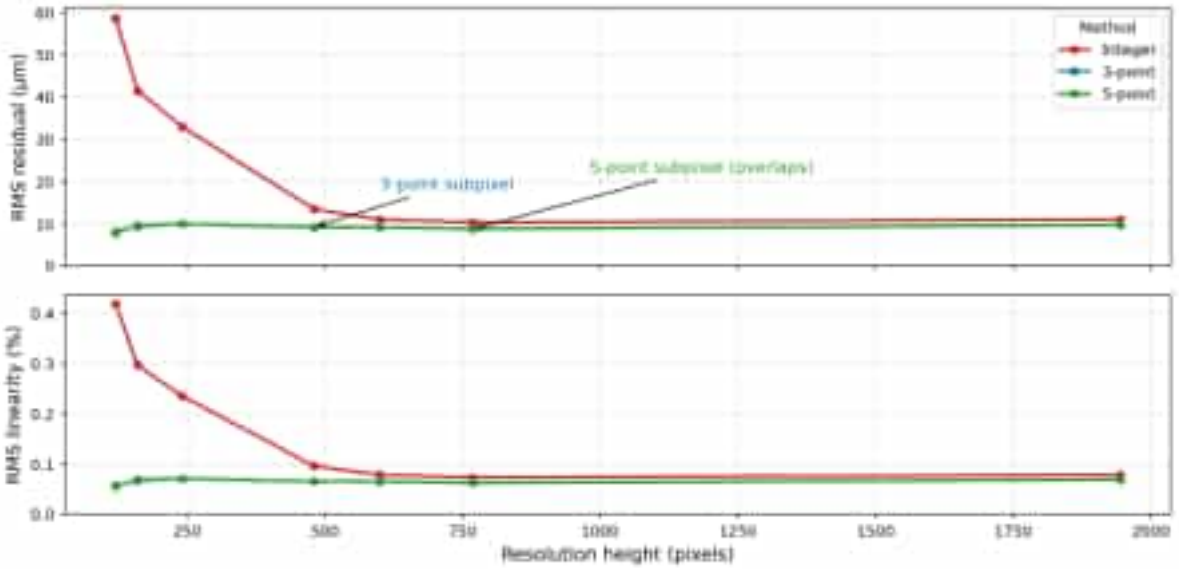

Figure 6. Comparison of integer, 3-point, and 5-point peak estimators (dataset T3). 3-point method achieves near-optimal precision with minimal complexity.

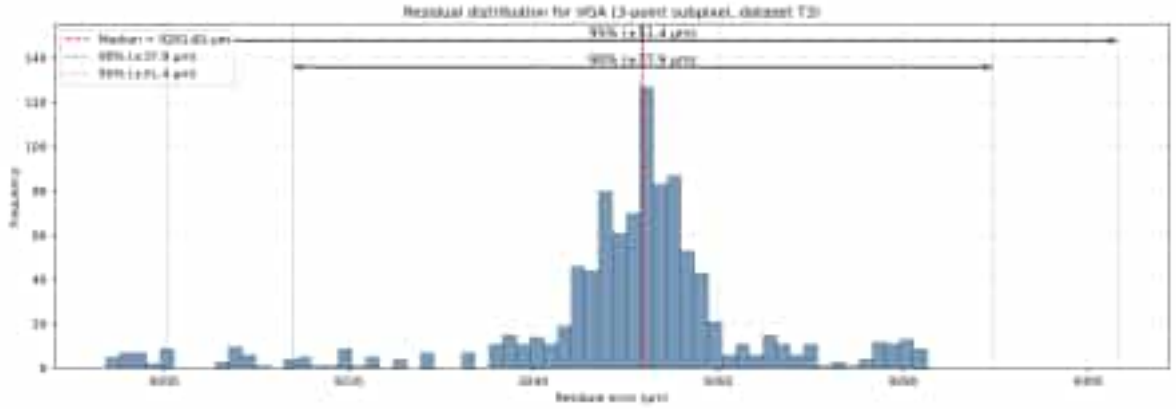

Figure 7. Histogram of residual errors at VGA (dataset T3). 90% and 95% intervals are marked with arrows; most samples lie within ±50 µm.

can try to expand towards a general hypothesis that if the human eye can discern a projected laser line in a specific environment, the camera should also be equally capable.

The measurable height span of a single sensor is bounded by the choice of screen dimensions, camera field of view, and calibration range. Thus the present prototype should be understood as one specific design while other design choices are likely possible. At longer emitter distances, usable performance is likely to be limited by laser visibility, signal-to-noise ratio and further exacerbated by environmental vibration. However, their effect is yet to be characterized.

Our method uses low-cost construction-grade laser planes as laser emitters, which lowers the financial barrier for system integration. For example, in robotic floor tiling, the sensor can be mounted on a tile gripper to regulate height relative to a site-fixed laser plane. Other sensing modules, such as accelerometers, can handle tile levelness. In addition, it also allows robots to share the same planar references used by human workers, potentially opening up new avenues for human-robot collaboration.

Our sensing method is reproducible, does not rely on optics calibration, and is intended to complement other sensors such as inclinometers or marker tracking [6]. The real-time subpixel pipeline runs entirely onboard the OpenMV camera module and requires no host computation, mak-

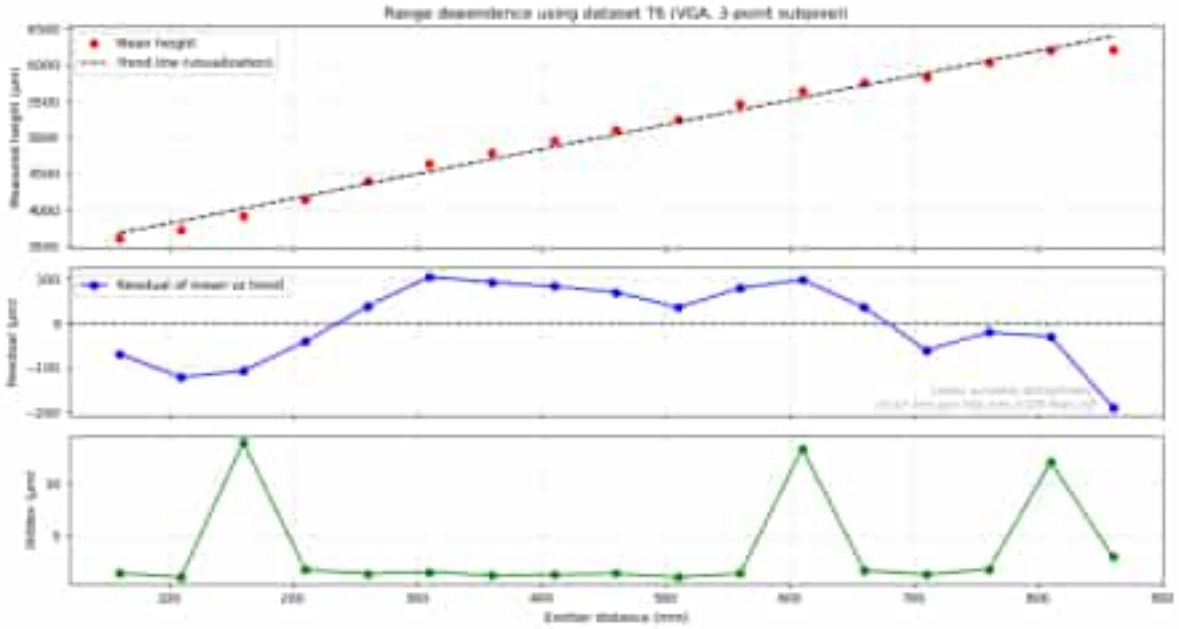

Figure 8. Measured height deviation and jitter vs. emitter distance (dataset T6). Drift remains ¡200 µm across 800 mm; jitter stays below 10 µm.

ing it suitable for embedded applications. All hardware and software are released in an open-source repository `https://github.com/yck011522/laser_line_sensor/` to encourage adoption. The system avoids any custom circuit design, soldering, or firmware recompilation, and is intended to be assembled with only basic tooling and a consumer-grade 3D printer.

Future work can consider adapting the detection al-

gorithm to other embedded camera systems such as the ESP32-CAM or Seeed Studio XIAO ESP32S3. More broadly, the work illustrates how existing on-site tools can be reinterpreted—through near-field sensing and lightweight computation—to enable accessible precision feedback in construction robotics.

Abstract – Scan-to-BIM procedures using terrestrial laser scanning (TLS) are accurate but require significant time and financial investment. This study evaluates a faster alternative utilizing mobile device-based LiDAR and a mobile application built on the Apple RoomPlan API. The research first assesses geometric reliability through point-cloud-to-BIM confidence indices, specifically Coverage, Distribution, and Distance. Additionally, it employs BIM-to-BIM matching metrics, including 3D-IoU and 3D-Compactness, to compare the mobile output against a TLS baseline in residential and office buildings. Results demonstrate that the mobile pipeline reduces total scan-to-BIM time from 3.5 min/m² to 0.1 min/m². Although the mobile application provides reliable room layouts with space 3D-IoU scores reaching 0.93, it exhibits limitations regarding wall thickness accuracy and positional drift. Consequently, based on these initial findings, this workflow shows potential for facility management and initial retrofit assessments where rapid data acquisition is prioritized over high geometric precision.

Keywords – Scan-to-BIM, Mobile LiDAR, TLS, Mobile Device, Geometric Accuracy

1 Introduction

Scan-to-BIM procedures are key to generate digital models containing geometry and core semantic information that support a range of applications. These BIM models support retrofit design, energy modelling, and facility management (including digital-twins or digital-logbooks).

Most scan-to-BIM workflows start from reality capture data, in which point clouds are the dominant representation used to capture the existing conditions as a reference geometry for creating parametric BIM objects. They provide high-resolution geometric information, and point clouds are usually generated using terrestrial laser scanning (TLS) and mobile laser scanning (MLS). TLS captures dense and accurate geometry. However, it requires multiple stations with subsequent data registration, which can slow down the data collection procedure. By contrast, handheld systems can be faster to deploy, yet their accuracy depends on the stability of tracking on the scene structure, which can lead to drift and misalignment based on the long scanning paths.

Recently, lidar sensors have become available on mobile devices, particularly on iPhone Pro and iPad Pro models. These devices are low-cost compared with professional scanners and easy to deploy for quick capture tasks [1]. Many studies have assessed the feasibility of lidar-integrated mobile devices for scan-to-BIM workflows by comparing output point clouds against TLS reference data [1][2][3][4]. They show that, while, like MLS, they can acquire data more rapidly than TLS and can achieve promising local precision in indoor settings. Beyond standalone indoor scans, some studies merge mobile lidar with other sensing sources, such as TLS, UAV lidar or photogrammetry, principally to improve completeness [5][6].

Figure 1. Framework of the proposed assessment method

However, regardless of whether the scan comes from TLS, MLS, or mobile device lidar, most workflows require post-processing followed by geometric and semantic modelling, hereafter BIM modelling. In these studies, the BIM model is typically reconstructed through manual or semi-manual/automated modelling.

It must be noted that, besides lidar depth sensing, mobile devices also provide RGB camera data, another modality containing useful information about the scene. This data can also be leveraged to detect and segment

various elements in the scene, such as architectural elements (e.g., windows, doors) and furniture (e.g., tables, chairs) [7].

A key recent development in the use of mobile device lidar is Apple's RoomPlan [8]. Specifically, RoomPlan is an API that uses the device camera and lidar scanner to create parametric 3D room scans, including room dimensions and recognized furniture, producing a structured room representation rather than only raw points or a mesh. Several commercial apps use this type of pipeline, including Polycam [9], Magicplan [10] and Metaroom [11]. Even though many studies evaluate iOS lidar in terms of point cloud or mesh quality, few studies evaluate the full pipeline of RoomPlan using standardized and quantitative BIM-level metrics. Recently Mortazavi et al. [12] proposed an assessment system with criteria, a rating scheme, and utility value analysis to compare site-scanning methods for creating a BIM model, including Magicplan and Polycam against TLS and MLS. While this is valuable for tool selection, it mainly supports comparative scoring and does not report explicit geometric accuracy metrics for the produced models, such as deviation-to-ground-truth measures or systematic BIM-to-BIM overlap measures.

To address this gap, this study proposes an assessment of a smartphone-based scan-to-BIM application built using the RoomPlan API, focusing on the full pipeline from on-device capture to BIM model output. For evaluation, we adopt quantitative, geometry-focused metrics at two levels. First, we use point-cloud-to-BIM confidence indices to assess matching reliability by integrating Coverage, Distribution, and Distance measures [13]. Second, we use BIM-to-BIM matching metrics based on 3D-IoU and 3D-Compactness to compare the outputted BIM model against a reference BIM model, following the benchmark design of Liu et al. [14]. By combining these evaluation layers, the study aims to clarify the challenges and opportunities of fast scan-to-BIM for future research and practice, especially for reliable as-built modelling.

2 Method

This section outlines the method employed for the assessment of a smartphone-based scan-to-BIM workflow, as summarised in Figure 1.

2.1 TLS-based BIM Modelling

The traditional scan-to-BIM methodology utilises TLS to establish an accurate geometric baseline of the existing environment. As illustrated in Figure 1, the workflow follows a sequential, multi-stage process to transform physical space into a digital representation.

Reality capture is performed using a static, multi-station laser scanning approach. The scanner is strategically positioned at various locations throughout the building to ensure comprehensive coverage and minimise data gaps caused by occlusion shadows. Following the acquisition, the individual point clouds from each station are registered into a single coordinate system. This stage results in a high-density unified point cloud that serves as the precise geometric reference of the as-built conditions. Finally, the registered point cloud is used as a spatial reference for manual BIM modelling. During this phase, semantic BIM objects are created by interpreting the point cloud data to represent the building's geometry and components accurately. The resulting manually-created model serves as a validation reference (TLS-BIM) against which the automated outputs of the mobile workflow are quantitatively measured.

2.2 Mobile-app-based BIM Modelling

The mobile-app-based method focuses on the creation of automated BIM models using an app that deploys the RoomPlan API on a mobile device. Unlike the traditional workflow above, this procedure employs a continuous and integrated real-time data acquisition and processing process, which depends on the selected app. RoomPlan API was released by Apple in 2022 for generating a parametric 3D floor plan of an indoor environment using mobile scanning. The capture is performed using iPhone or iPad devices equipped with an RGB camera and a lidar scanner. The API simultaneously conducts real-time scanning and device pose tracking, also known as Simultaneous Localization and Mapping (SLAM). During scanning, RoomPlan combines RGB-D frames and associated camera poses to create semantic point clouds. Then, by using learning-based estimators, the framework creates walls, openings, doors, windows, and furniture objects.

Indoor environment reconstruction is composed of two parts: 3D room layout estimation and 3D object (e.g., furniture) detection. Room layout estimation detects walls, floors, ceilings, openings, doors, and windows in real time. Walls are first predicted as 2D lines in bird's-eye view and then extruded into 3D surfaces based on the distance between the detected floor and ceiling. All spaces bounded by walls, ceiling, and floor are also additionally defined. Doors and windows are detected using multimodal (RGB and lidar) data, and projected into 3D using projection information and camera position. The 3D object detection pipeline recognizes 14 object categories, in addition to windows and doors. These are furniture objects and include: tables, chairs, cabinets, fridges, etc. The object detection combines a local and global detector. Local detector is operating during scanning on a seen camera view, and a global detector is working after scanning on the full reconstructed scene to fuse results (which is particularly necessary for larger

items). All detected objects are then associated with the space within which they have been detected.

The output of the API is thus not only geometric, but also includes semantics, including object types and some object relationships (relationships of walls, ceilings, doors, and furniture with spaces). The results of indoor capturing can be exported in Universal Scene Description (USD) formats. Some apps also map the information into IFC. As previously mentioned, there are various apps in the market that leverage this API, including Polycam [9], Magicplan [10] and Metaroom [11].

To maintain consistency and data integrity during the acquisition process, the following best-practice procedures were followed during scanning:All doors and windows within the scan area were closed.Curtains and blinds remained open to ensure visibility of windows. Scanning was performed using a slow vertical oscillation (up and down movement) to capture ceilings, walls, and floor slabs. A maximum scanning distance of 5 meters from the device to the surface was maintained.Scanning was performed during maximum daylight conditions.The device camera remained open and active from start to end of the scanning.

2.3 Evaluation Criteria

To assess the proposed scan-to-BIM pipeline, an evaluation is conducted at two levels. The point cloud (PCD)-to-BIM evaluation measures how well the BIM elements created using the mobile app match the TLS PCD, and the BIM-to-BIM evaluation compares the mobile app-based BIM model against the BIM model manually created from the TLS PCD. The scope of this evaluation is limited to assessing the geometric fidelity and spatial placement of the core architectural elements

2.3.1 PCD-to-BIM Comparison

Before comparing the TLS PCD to the mobile-app BIM model, they must be aligned in the same coordinate system. We have done this using the 4-Plane Congruent Sets (4-PlCS) method [15] (see implementation at https://github.com/CyberbuildLab/4PlCS). The algorithm extracts planar patches from both the input point clouds and the BIM model. It randomly searches for bases of four planes where three are not pair-wise parallel and the fourth is not co-planar. To handle potential matching failures and reject outliers, the algorithm replaces standard RANSAC with a custom two-step support evaluation method. It first assesses centroid support by checking if the centroids of the point cloud patchs project inside the matched model patches. It then evaluates plane support by calculating the percentage of all remaining point cloud planar patches that support the transformation. Finally, it groups similar transformations and presents a ranked list of the most likely alignments for the user to quickly verify and select the correct one. While this semi-automated approach improves efficiency, manual alignment remains an alternative that does not affect subsequent analyses of this study

Then, for PCD-to-BIM comparison, we adopt the framework of confidence indices proposed by Ersöz and Bosché [13] (see implementation at https://github.com/CyberbuildLab/pcd-bim-matching-confidence).This framework evaluates matching reliability by computing an overall Confidence Index (I-confidence) per BIM element. This is achieved by integrating Coverage (I-coverage), Distribution (I-distribution), and Distance (I-distance) indices, which assess how well scan points align with visible BIM surfaces..Detailed mathematical definitions and algorithmic procedures for these indices are thoroughly described in [13].

2.3.2 BIM-to-BIM Comparison

To assess the geometric similarity between the MOBILE-BIM and TLS-BIM models, we employ the model-to-model evaluation metrics introduced by Liu et al. [14] (see implementation at https://github.com/CyberbuildLab/bim-bim-matching). This approach utilizes two complementary metrics: 3D-IoU and 3D-Compactness. 3D-IoU measures the spatial alignment and Boolean volume overlap between strictly matched semantic classes in the Ground Truth and estimated models. Meanwhile, 3D-Compactness penalizes many-to-many geometric mappings to evaluate whether the reconstructions align in a clean, one-to-one correspondence (highlighting over-segmentation or over-merging). Detailed definitions and the underlying computation logic for these volumetric metrics are provided in [14].

3 Experiments, Results, and Discussion

3.1 Test Environments

To evaluate the mobile device-based scan-to-BIM mobile-app pipeline, we conducted a comparative study across two distinct building typologies representing varying levels of geometric and semantic complexity. The residential case (RES) consists of a single-storey residential unit characterized by medium clutter with an area of approximately 50 m^2. This environment features standard furniture and opaque partition walls, representing a controlled baseline for occlusion. In contrast, the office case (OFF) involves a two-storey university facility characterised by high levels of clutter. The corresponding dataset is split into the first floor (OFF1) and the second floor (OFF2), both with an area of approximately 150 m^2.

3.2 TLS Workflow

To establish a GT baseline, we employed a Leica BLK360 terrestrial laser scanner. The scanner was positioned at multiple stations throughout each room and corridor to capture overlapping point clouds, which were then registered into a unified, high-density point cloud to serve as the precise reference of existing conditions. Using this registered point cloud as an underlay, BIM models were then manually created in Autodesk Revit (Figure 2) and then exported in IFC format. To ensure consistency and eliminate operator variability, the modelling was performed by a single BIM professional with over five years of specialized scan-to-BIM experience. The modelling scope was defined at a Level of Development (LOD) 300, focusing specifically on the elements (walls, floors, doors and windows) necessary for a direct comparative analysis with the mobile application's output.The TLS point cloud and resulting TLS BIM model jointly represent the reference GT.

3.3 Mobile device-based Scan-to-BIM Workflow

After the TLS data collection, the same environments were captured using a lidar-enabled iPad Pro 13-inch (M4) running iPADOS Version 18.1.1. Metaroom version 7.2.1 app, built on the RoomPlan API, was used for modelling [11]. The scanning protocol presented in Section 2.2 was strictly followed to ensure data consistency. While the residential unit was captured in a single continuous session, the complex two-storey office required a segmented approach. Initial attempts to scan both floors in a continuous sequence revealed a limitation in the device's vertical localization ability, where the algorithm struggled to maintain accurate floor-to-floor height consistency during the transition via the staircase, resulting in vertical misalignment (demonstrated in Figure 4a). Consequently, to ensure geometric integrity, we adopted a strategy where each floor is scanned and analysed separately.

Unlike the TLS workflow, no post-acquisition registration or modelling is required; the application performed real-time semantic segmentation, instantly generating and extruding 3D components (walls, doors, windows) into a parametric model immediately upon scan completion. Then, BIM models were exported from the app in IFC format.

3.4 PCD-to-BIM Geometric Confidence Analysis

We first computed the confidence indices of the generated BIM models against the TLS data using the PCD-to-BIM confidence indices. The confidence indices provide a granular view of how well the BIM geometries align with the reality capture data.

Following the method established by Ersöz and Bosché, wall elements were selected as the primary reference for evaluating the confidence indices due to their significant prevalence and geometric diversity within the datasets, and grouped as interior and exterior walls. The results are tabulated in Table 1 and Table 2. Note that the I-confidence reported in these tables is calculated by simply multiplying the I-coverage, I-distribution, and I-distance indices.

The main observation is that MOBILE-BIM models have lower values for all indices in all three cases (Table 1). This highlights the geometric deviation inherent in the mobile device tracking and reconstruction process, which spatial data patterns suggest is primarily driven by SLAM drift. As the device is moved, the real-time tracking over longer trajectories or within texture-poor scenes accumulates small errors, resulting in a cumulative SLAM drift (positional shift). Consequently, while individual wall segments are all detected successfully, their relative placement within the global coordinate system deviates from the GT. This in turn results in fewer TLS points being matched to the MOBILE-BIM elements (which is limited to 5 cm) which results in the observed lower index values.

Exterior Wall Challenges: Table 2 reveals significantly lower confidence scores for exterior walls across both TLS and MOBILE models (e.g., I-confidence ranging from 0.05 to 0.18). This is because scanning was performed indoors, so that the exterior faces of these walls were not scanned. Furthermore, a noteworthy observation in Table 2 is that the MOBILE-BIM appears to demonstrate higher confidence indices for exterior walls compared to the TLS-BIM. This is in fact misleading and is due to chance. Indeed, due to the global positional drift in the mobile workflow, the external faces of the MOBILE-BIM exterior walls were often positioned wrongly (Figure 3) in a way that they ended up residing close and were matched to the available point cloud of the interior wall surface to calculate the indices. The true confidence index values for those walls should have instead been lower than for the TLS-BIM.

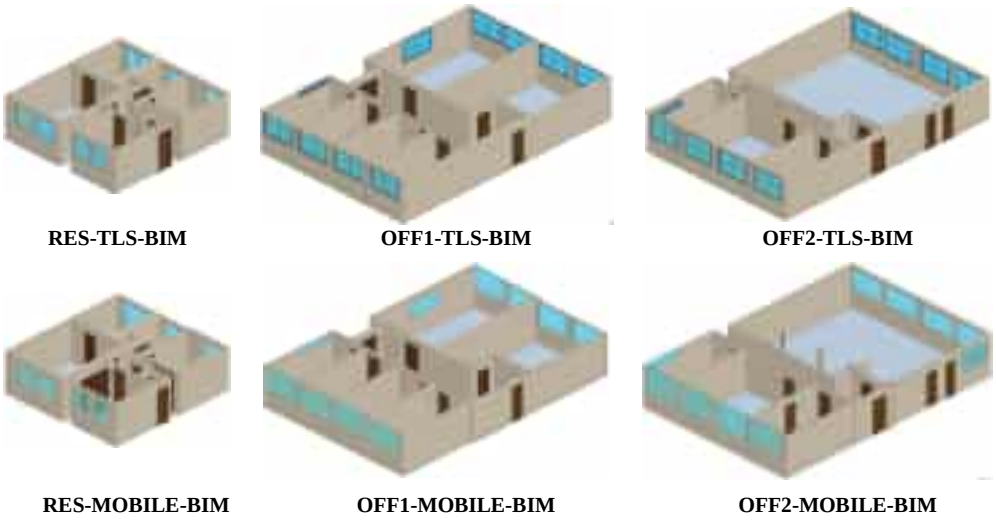

Figure 2. TLS, BIM models created via the TLS and mobile app-based workflow

3.5 BIM-to-BIM Geometric Comparison

We evaluate the BIM model's geometric fidelity using the 3D-IoU and 3D-Compactness indices. A comparative analysis of 3D-IoU and total area difference across the datasets reveals a critical distinction between volumetric precision and quantitative estimation.

Table 1. PCD-to-BIM confidence indices for interior walls

BIM Models	I-cov	I-distri	I-dista	I-confi
RES TLS	0.64	0.70	0.74	0.36
RES MOBILE	0.55	0.63	0.57	0.24
OFF1 TLS	0.71	0.94	0.64	0.44
OFF1 MOBILE	0.50	0.84	0.45	0.20
OFF2 TLS	0.71	0.91	0.67	0.45
OFF2 MOBILE	0.42	0.67	0.47	0.18

Table 2. PCD-to-BIM confidence indices for exterior walls

BIM Models	I-cov	I-distri	I-dista	I-confi
RES TLS	0.36	0.36	0.76	0.10
RES MOBILE	0.48	0.70	0.50	0.18
OFF1 TLS	0.29	0.48	0.55	0.08
OFF1 MOBILE	0.40	0.66	0.49	0.15
OFF2 TLS	0.24	0.42	0.49	0.05
OFF2 MOBILE	0.36	0.54	0.47	0.13

For both residential and office buildings the results were tabulated in Table 3 to Table 5. The total areas presented in the tables are calculated based on specific geometric projections. For vertical components, windows, doors, and walls, the areas are calculated using the projection of the 3D geometry onto their respective wall planes. The areas for space elements are determined by projecting the volumes onto the horizontal (Z) plane, which represents the net floor area.

Walls: Across all three datasets, for the wall elements, the mobile app achieved relatively low m3D-IoU scores, ranging from 0.20 (Office Floor 1) to 0.32 (Residential). Such low IoU values typically indicate issues with wall thickness and positional shift. However, the area difference remains remarkably low. For instance, in the Office Floor 1 dataset (Table 4), the predicted wall area (243.18 m^2) is nearly identical to the ground truth (242.87 m^2), with a difference of only 0.31 m^2. This highlights that the mobile application is highly effective at capturing the existence and length of walls (hence the accurate total area) but struggles with the precise placement and thickness (hence the low 3D-IoU).

Furthermore, as illustrated in Figure 4b, the app misinterprets square columns as short, isolated wall segments rather than distinct column elements, because the API does not have the capability to specifically detect columns. This error directly contributes to lower 3D-Compactness scores for walls, as the one-to-one correspondence between the TLS-BIM wall and the MOBILE-BIM geometry is broken by these false-positive wall segments.

Spaces: In contrast, the room spaces demonstrate better performance, with m3D-IoU scores reaching 0.90-0.93 and 1.00 for compactness in the office datasets. This confirms that the primary strength of the mobile app-based approach lies in room layout estimation. The app successfully generates watertight, logically correct room volumes and topology, making it highly reliable for space management where room boundaries and connectivity are more critical than the precise thickness of the partitioning walls. Top views of the space elements are shown in Figure 3.

Doors: In the residential dataset (Table 3), door elements exhibit a significant difference between directional compactness scores. The TLS-to-MOB score is high (0.88), indicating that the app successfully

detected most existing doors. However, the MOB-to-TLS score is notably lower (0.64), and the predicted door area (20.36 m^2) exceeds the reference TLS model (13.34 m^2). This indicates a high rate of false positives (redundancy). Indeed, the mobile app misinterpreted other wall features (e.g., storage) as doors, as shown in Figure 4c. This suggests that while the app has high recall (finds real doors), its precision is compromised by environmental clutter and class similarities.

Windows: Across all datasets, windows achieved very low 3D-IoU scores. This poor volumetric performance is a direct effect of the misplacement particularly observed for exterior walls. Since most windows are hosted on exterior walls, which suffer from positional shifts due to global drift, the generated windows inherit these spatial offsets. Consequently, even if a window is correctly sized, its 3D volume does not intersect correctly with the TLS-BIM, resulting in a low, even zero IoU score. Despite the positional failure, the area difference remains relatively stable, which implies that the detection logic (fusion of camera and lidar) successfully identifies the presence and dimensions of the openings. The failure is therefore not one of recognition, but of spatial dependency: the openings are correctly seen but placed in incorrectly modelled exterior walls (inadequate thickness).

3.6 Comparison of Workflow Efficiency

Table 6 illustrates the comparative analysis of workflow efficiency of TLS and mobile app workflows. The total time spent decreased from 20 hours for the TLS workflow to 32 minutes for the mobile app-based workflow. When normalized by floor area, this represents an efficiency improvement from 3.5 min/m² to 0.1 min/m².

All steps of the TLS workflow are time consuming. While acquisition required 4 hours (necessitated by the logistics of static setups, target placement, and repositioning to minimize occlusion), point cloud registration took 6 hours, and manual BIM modelling took 10 hours. This 10-hour duration reflects the efficiency of an experienced professional generating a tightly scoped LOD 300 architectural model. This baseline time could vary depending on operator proficiency or if higher LODs were required. In contrast, the mobile app conducts data acquisition, registration and modelling jointly in real-time. In particular, the mobility of the devices means that interior environments consisting of many rooms and occlusions can be visited very fast.

Table 3. Residential House BIM-to-BIM metrics

	m3D-IoU	3D-Comp (TLS-to-MOB)	3D-Comp (MOB-to-TLS)	m3D-Comp	TLS El. Count	MOB El. Count	TLS Total Area (m^2)	MOB Total Area (m^2)
Doors	0.34	0.88	0.64	0.76	8	11	13.34	20.36
Walls	0.32	0.60	0.61	0.61	29	31	143.19	145.86
Windows	0.05	0.25	0.29	0.27	8	7	9.14	8.57
Room spaces	0.84	1.00	1.00	1.00	8	8	49.48	47.04

Table 4. Office Building Floor 1 BIM-to-BIM metrics

	m3D-IoU	3D-Comp (TLS-to-MOB)	3D-Comp (MOB-to-TLS)	m3D-Comp	TLS El. Count	MOB El. Count	TLS Total Area (m^2)	MOB Total Area (m^2)
Doors	0.40	1.00	1.00	1.00	8	8	15.65	13.58
Walls	0.20	0.46	0.42	0.44	20	38	242.87	243.18
Windows	0.03	0.10	0.10	0.10	10	10	22.00	25.08
Room spaces	0.90	1.00	1.00	1.00	7	7	143.96	134.96

Table 5. Office Building Floor 2 BIM-to-BIM metrics

	m3D-IoU	3D-Comp (TLS-to-MOB)	3D-Comp (MOB-to-TLS)	m3D-Comp	TLS El. Count	MOB El. Count	TLS Total Area (m^2)	MOB Total Area (m^2)
Doors	0.32	0.88	0.78	0.83	8	9	13.34	13.95
Walls	0.26	0.57	0.48	0.53	22	29	209.36	209.97
Windows	0.00	0.00	0.00	0.00	9	10	21.40	26.32
Room spaces	0.93	1.00	1.00	1.00	5	5	148.16	140.40

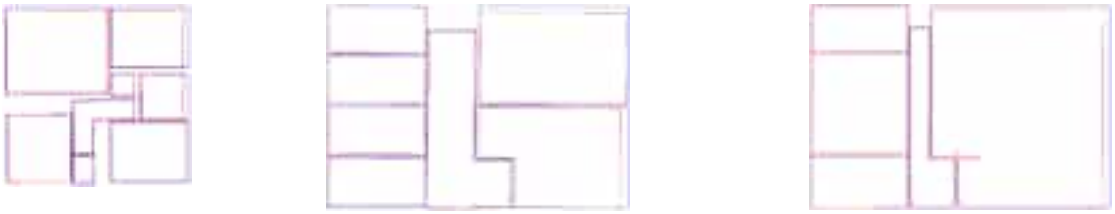

Figure 3. Room space comparison (Blue color: TLS-based BIM , Red color: Mobile-based BIM)

In conclusion, while the TLS workflow prioritises geometric precision at the cost of time, the Mobile device-based Scan-to-BIM prioritises immediacy and semantic readiness, suggesting it could be a suitable option for applications where accuracy is not so important (e.g., retrofit assessment, facility management).

Table 6. Total time required for Residential and Office Building

Workflow Stage	TLS-based	Mobile device-based
Data Acquisition	4 hr	
Data Processing	6 hr	32 min
Modelling	10 hr	
Total	20 hr (3.5 min/m^2)	32 min (0.1 min/m^2)

4 Conclusion

This study presented a quantitative assessment of a mobile app-based Scan-to-BIM workflow utilising a mobile app that uses lidar & RGB camera for data acquisition. The results were benchmarked against TLS scan data and BIM models generated from them. By applying PCD-to-BIM and BIM-to-BIM matching metrics across residential and office environments, we have assessed the capabilities and current limitations of this pipeline.

The major finding of this research is the improvement in workflow efficiency. The mobile app-based pipeline demonstrated a reduction in total production time of 97%.

Despite the observed issues with wall thickness and positioning precision, the high 3D-IoU scores for room space elements confirm that the generated watertight room volumes are accurate. Moreover, the minimal area differences observed for windows and walls indicate that the system is effective at identifying the existence and gross dimensions of building elements.

This makes the workflow uniquely suited for applications where room layouts and asset counts are prioritized over highly accurate geometric fidelity. The mobile app-based solution is also significantly cheaper.

However, this automation introduces geometric trade-offs that must be considered. A primary technical constraint identified in this study is the inaccuracy of wall thickness estimation. The system often struggles to determine actual wall thickness due to factors such as accumulated SLAM drift, frequently reverting to default thicknesses or misinterpreting the distance between finished surfaces. Future research utilizing independent, high-precision localization tracking (e.g., via ground control points) is recommended to quantitatively decouple sensor depth noise from algorithmic SLAM drift. As errors in wall thickness aggregate, the relative positioning of adjacent rooms shifts away from the ground-truth global coordinates. For practitioners, this implies that while the model is reliable for floor area calculations and interior finish schedules, it may require manual adjustment where exact wall-thicknesses are critical.

Another observed challenge is operational scalability. The current API operates on real-time processing with significant memory constraints, which typically limits accurate single-session captures to areas of approximately 15m x 15m; larger floor plans often force a scan completion to preserve data integrity. Furthermore, as evidenced by the vertical misalignment observed in the continuous scanning test, the lack of robust loop closure for vertical transitions yields significant elevation and rotational drifts between floors.

This study evaluates geometric fidelity by utilizing the mobile pipeline's semantic classifications to establish valid, class-strict correspondences between the ground truth and estimated models. Consequently, semantic errors inherently penalize the geometric evaluation; for instance, misidentifying columns as walls creates unmatched false positives that directly lower compactness scores. Building on this integrated approach, future research can incorporate dedicated semantic metrics, such as precision, recall, and confusion matrices, to quantify the system's ability to categorize complex indoor components alongside its geometric reconstruction.

yashviunadkat13786@gmail.com, varunreja@iitb.ac.in, arnab.jana@iitb.ac.in

Abstract –

Digital Twin (DT) is an emerging technology that can be used for Indoor Environmental Quality (IEQ) optimization. However, its application in educational buildings, especially in the Indian context, is limited. Students spend a significant amount of their total time indoors in educational buildings, making effective IEQ management critical for their health, comfort, performance, and productivity. This study proposes a bi-directional Digital Twin framework that integrates BIM models, IoT sensors, and actuators to enable real-time monitoring, analysis, and control of the indoor environment. The framework uses real-time data on temperature, humidity, air velocity, and CO_2, which are analyzed using Predicted Mean Vote (PMV) and Percentage People Dissatisfied (PPD), ensuring compliance with ASHRAE 55 and ASHRAE 62.1. To validate the proposed framework, it was implemented in a shared office space at IIT Bombay. Results show stable system performance, reliable real-time data synchronization, visualization, and standards-based IEQ assessment. The monitoring and analytical components were experimentally validated, while the actuation and control layer was established at the framework level for future deployment.

Indoor Environmental Quality, Thermal Comfort, Indoor Air Quality, Digital Twin, Building Information Modeling, Internet of Things, BIM-IoT Integration, IEQ Optimization

1 Introduction

IEQ plays a crucial role in ensuring the health, cognitive performance, and thermal comfort of occupants. People spend 80-90% of their time indoors, and students spend a large portion of this time in educational buildings. Hence, maintaining optimal IEQ in educational buildings plays a critical role in reducing long-term health risks and increasing quality performance [1]. IEQ consists of four parameters: Thermal comfort, Acoustic comfort, Indoor Air Quality (IAQ), and Lighting comfort [2]. Out of these, thermal comfort and IAQ are considered for this study. Currently, people use conventional methods for IEQ optimization that are often manual, inaccurate, inconsistent, and lack seamless information exchange between the physical and digital environments. Therefore, there is a need to enable accurate, efficient, and bi-directional data exchange, which is where DT serves the purpose.

DT is "a digital representation of a physical asset, updated with real-time data, collected using a network of IoT sensors" [2]. In the IEQ monitoring context, DT helps us set up a seamless exchange of real-time information between the physical and digital environments and control the facility. In this way, implementing DT in educational buildings will provide a better indoor environment for students, increasing their productivity, performance, and reducing the health risks.

To develop a DT, BIM-IoT integration plays a foundational role [5]. The primary role of BIM in developing a DT is to produce a virtual extension of a real-world item [6]. On the other hand, the IoT devices help sync the physical and virtual states by enabling real-time data measurement, which supports IEQ optimization in real-time [7], and forms the base of the DT. But the framework for the implementation of DT to optimize IEQ in developing countries is still limited, especially for educational buildings.

To tackle this limitation, this study proposes a framework for the deployment of a DT to monitor, analyze, and control IEQ in an educational building unit. DT enables enhanced dynamic spatial and temporal data visualization and monitoring, which is achieved using a DT software called Autodesk Tandem in this study. The real-time analysis of the sensor data helps the system to make decisions as per standard guidelines. The thermal comfort analysis utilizes two indices: Predicted Mean Vote (PMV) and Percentage People Dissatisfied (PPD), and the ASHRAE 55 standard. On the other hand, IAQ analysis is done as per ASHRAE 62.1 standard

compliance. The decisions made as per the analysis are used to control the physical environment using suggested actuators like the IR Blaster. The results of this study provide a unified framework for DT, serving as a bridge between monitoring, analysis, and control to achieve a healthier environment.

The paper is broadly divided into five sections: in Section 1, we introduce the problem statement, Section 2 reviews current approaches for IEQ monitoring, DT implementation, and identifies some research gaps. In Section 3, we will examine the proposed methodology and case study for deploying a DT for IEQ monitoring. In the last two sections, we will move on to the results, draw some conclusions, discuss future work, and summarize the study.

2 Literature Review

This section reviews existing studies on IEQ optimization techniques, their drawbacks, and how the application of DT, BIM, and IoT can serve the purpose. The review identifies technical research gaps and limitations that form the basis for the proposed framework.

2.1 IEQ Monitoring Techniques

IEQ has gained attention over the past few years, particularly in educational buildings, due to its direct impact on students' cognitive performance [8]. Especially in developing countries like India, the deteriorating outdoor environment quality significantly affects the indoor air quality, which is one of the 10 leading causes of illness [1]. Hence, monitoring and improving IEQ in buildings is a widely studied topic. Several studies have focused on assessing IAQ and thermal comfort in educational buildings, highlighting inadequate ventilation, high CO2 concentrations, and thermal discomfort, particularly in the Indian context [1]. IEQ monitoring studies generally follow two approaches: objective and subjective. Objective methods include field measurements, and subjective methods are based on personal judgment surveys [9]. Many of the studies rely on survey-based assessment and hence provide limited insight into the dynamic behaviour of the indoor environment.

Poor IAQ is reported as the second major health threat in India, after poor water quality and hygiene [1]. And thermal comfort directly affects user performance, which is why these two are included in this study. Thermal comfort depends on indoor environmental conditions as well as the subjective factors of occupants, like clothing and metabolic rate [2]. If we look into objective methods to measure IEQ, the technologies used to measure thermal comfort are directed towards data-driven models based on networks of connected sensors. [10]. Similarly, methods used to monitor IAQ include Wireless Sensor Networks (WSN) and IoT. But few parameters revealed that the performance of these systems is low compared to real-time and dynamic monitoring IoT systems [11]. Hence, integration of real-time IoT data acquisition with building models is important to monitor IEQ.

2.2 BIM, IoT, and Digital Twin for IEQ Optimization

BIM is an important component for information management, focusing on data interchange between different stakeholders, and has wide applications. BIM-based approaches improve spatial context but are generally disconnected from real-time data streams and control strategies. Therefore, IoT-based systems are being used to collect real-time data. IoT has made buildings go from ordinary to smart buildings by integrating everyday objects with digital controllers; such improvements have made it possible to create a controllable and integrated network supporting decision-making and human well-being [11]. However, most of these systems operate using one-way communication, where data flows only from the physical environment to digital dashboards for visualization, not for control. DT technology has emerged as a bridge between this gap by enabling bi-directional communication. Other industries have been using DT for many years, but it came to attention in the Architecture, Engineering, Construction, and Operations (AECO) industry with the concept of smart buildings and smart cities [4].

Recent studies have demonstrated the potential of DTs for monitoring thermal comfort, energy consumption, and IAQ in buildings. There are three stages of DT development:

1. Digital Model, which is a static representation of the physical environment, independent of sensor data, and cannot be changed [12].
2. Digital Shadow, which has one-way data flow, i.e., the model updates automatically when any change in the physical system is detected, but not the other way around [13].
3. Digital Twin, which is “a virtual replica of a physical asset that collects and sends real-time information”. It is a two-way communication loop, within which dynamic data flows and optimizes the physical environment [2]. DT effectively fills the communication gap between the physical and digital environments and creates a digital replica by integrating real-time IoT data with a BIM model. For example, a classroom with sensors sending real-time data and actuators like IR blasters controlling the devices based on the decisions made.

Data analysis serves as the core of the decision-making process, utilizing ASHRAE 55 and ASHRAE

62.1 guidelines. Nevertheless, most existing DT experimental setups are limited to residential or commercial buildings. DT application in educational buildings is very scarce, particularly in the Indian context, where educational buildings often operate under high occupancy and mixed-mode ventilation, making IEQ management more challenging under poor outdoor air quality conditions. Moreover, many studies have limited emphasis on automated actuation. Given these limitations, there is a strong need for a standardized and deployable framework to set up a DT for IEQ optimization in educational buildings. Therefore, this study aims to develop a DT by integrating a BIM model with real-time IoT data and actuators for a shared office space at IIT Bombay. The key contribution of this study includes:

1. Integration of BIM-IoT data to set up bi-directional communication.
2. Framework for the development of a deployable DT for IEQ Monitoring in educational buildings.
3. Mechanism for real-time optimization of IEQ.

3 Methodology

This section presents the proposed methodology for developing a BIM-IoT integrated Digital Twin framework for real-time IEQ monitoring and optimization. It describes the workflow, system architecture, data acquisition process, analysis approach, and actuation strategy. The methodology is further tested and demonstrated till the actuation part through a case study conducted in an educational building unit at IIT Bombay. The workflow of the proposed DT framework is shown in Figure 1. It illustrates the process from real-time data acquisition to BIM-based visualization, analysis, and actuation, forming a continuous loop.

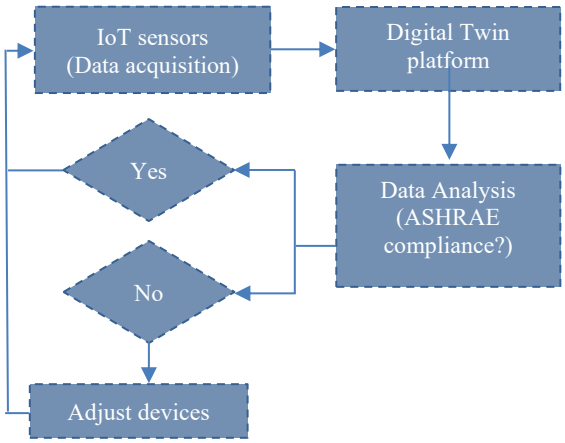

Figure 1. Proposed system workflow

3.1 DT Framework Architecture

The DT framework proposed in this study consists of five interconnected layers that collectively establish a bi-directional communication loop between the physical environment and its digital representation. These layers are described as follows:

1. Physical Layer: The physical layer comprises real-world assets like the building and IoT sensors. This layer is responsible for sensing, collecting, and providing real-time physical data for subsequent processing.
2. Data Transfer Layer: The data transfer layer enables the transmission of collected sensor data from the physical environment to the DT platform. This layer integrates real-time IoT sensor data with the BIM model on the digital twin platform, facilitating the creation of a synchronized DT.
3. Visualization Layer: The visualization layer supports real-time visualization of incoming data, allowing users to monitor system performance, observe alerts, and analyze historical trends through dashboards and charts.
4. Analysis Layer: The analysis layer plays a critical role by interpreting the received data to support informed decision-making. The outcomes of this layer form the basis for the actuation layer, as the results are translated into control commands for the actuation layer.
5. Actuation Layer: The actuation layer implements control actions based on analyzed results. Actuators, like IR Blasters, can be used to control devices like fans and ACs to maintain optimal IEQ. The integration of this layer is designed to enable closed-loop control of the system.

Together, these five layers establish a bi-directional DT system, forming a continuous feedback loop that spans real-time data acquisition, transfer, analysis, visualization, and control. The interrelation and sequence of action of all these five layers are as shown in Figure 2. These layers support some specific tasks, which are discussed below.

3.1.1 Data collection and transfer

The methodology adopts an integrated approach for developing a DT of an educational building unit to optimize Indoor Air Quality and Thermal Comfort. The framework integrates the above-mentioned five layers to enable a bi-directional DT. However, in the current stage of implementation, the focus is on real-time monitoring, visualization, and standards-based analysis, while the actuation logic is designed and planned to be deployed in upcoming stages. The data to be collected using IoT sensors must first be selected based on the requirements of the analysis. For assessing thermal comfort and IAQ,

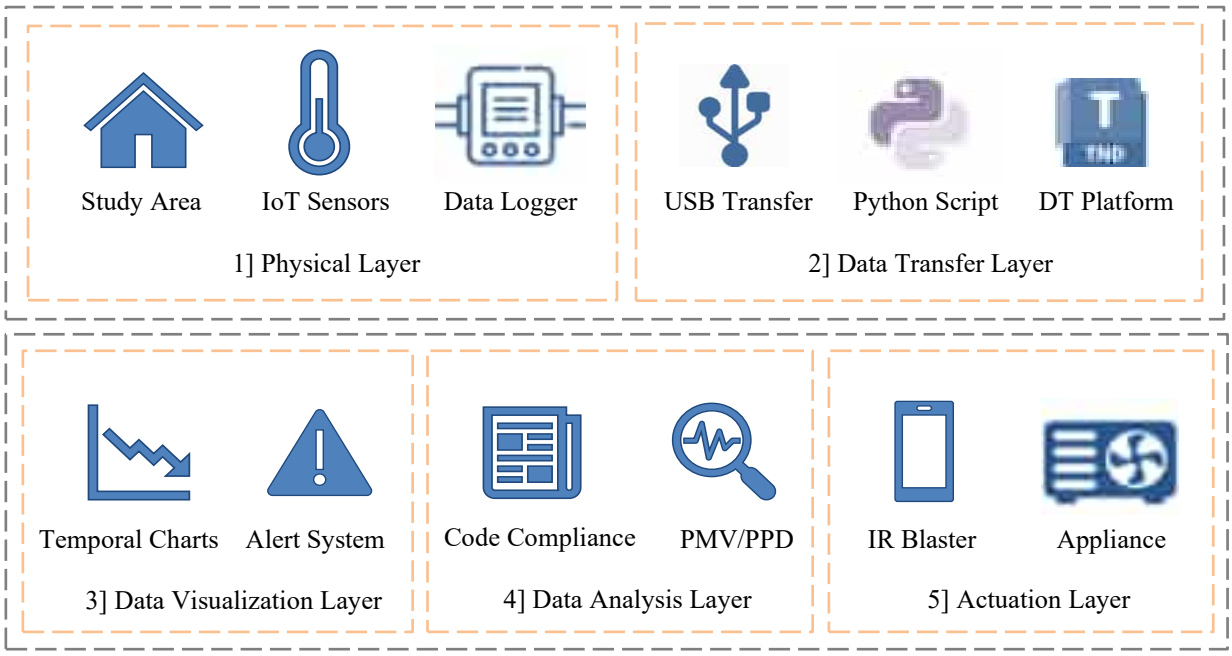

Figure 2. DT framework architecture

specific parameters should be chosen in accordance with ASHRAE standards and relevant research, as presented in Table 1 below.

Table 1. Selected parameters to assess thermal comfort and IAQ [14],[15], [16], [17]

Parameters	Description
Air Temperature (°C)	Directly impacts human perception of a hot/cold environment
Radiant Temperature (°C)	Radiative heat exchange from surfaces
Relative Humidity (% RH)	Affects Thermal comfort and sensation
Air speed (m/s)	Directly impacts the rate of convective and evaporative heat loss
CO2 (ppm)	Has an impact on cognitive performance

These parameters will be collected in real-time using IoT sensors, where thermal comfort parameters will be analyzed using indices PMV, PPD, along with checking compliance with ASHRAE 55. On the other hand, IAQ parameters will be analyzed by checking compliance with ASHRAE 62.1 standards. There are two more such parameters like: Particulate Matter (PM) and Volatile Organic Compounds (VOCs), which are responsible for IAQ, but this study utilizes only CO_2.

Real-time data acquisition is carried out using IoT sensors, where sensor selection and placement play a critical role in data accuracy and reliability. Selection criteria for IoT devices include measurement accuracy, availability, and cost-effectiveness. Sensor positioning follows ASHRAE guidelines with sensors placed near the occupant's breathing zone, working/sitting zones, and other representative points of the space. To develop a DT, the digital representation of the physical environment should be created first. A detailed BIM includes the architectural elements, furniture layout, and represents the physical environment, occupants' zones, and spatial layout. The BIM model is then to be integrated with real-time environment data collected from sensors deployed within occupant zones. These sensors continuously measure key IEQ parameters related to thermal comfort and IAQ, as mentioned in Table 1.

3.1.2 Data Visualization and Analysis

Real-time sensor data is transferred from the physical layer to the digital environment via the data transfer layer, enabling synchronization between the two systems. There are different software programs available to develop a DT, like Bentley iTwin, Autodesk Tandem, Ansys Twin Builder, etc. We can use any software that provides easy integration of BIM and Real-time IoT sensor data, and that offers multiple ways to visualize spatial and temporal data. For this study, we have worked on Autodesk Tandem because Tandem and Revit are released by the same software company, favoring the cross-platform compatibility and enabling Autodesk Tandem to read the Revit model correctly [6]. The

incoming data is mapped to corresponding zones, Zone A and Zone B, as shown in Figure 3, to allow users to visualize IEQ conditions using temporal charts, heatmaps, and customizable dashboards. These visualization tools help us study the trends for the selected parameters, which may help in future prediction as per historic trends. Additionally, the Autodesk Tandem provides a feature that triggers an alert whenever the parameter data exceeds the assigned permissible range as per ASHRAE 55 and ASHRAE 62.1.

Later, an analysis layer processes the sensor data to assess the compliance with thermal comfort and IAQ standards. Thermal comfort is evaluated using the PMV and PPD indices in accordance with ASHRAE 55, and IAQ parameters are assessed in accordance with ASHRAE 62.1. The permissible limits of all the selected parameters are shown in Table 2. The analysis layer then determines the corrective actions based on the predefined decision rules.

Table 2. Permissible range of thermal comfort and IAQ parameters as per ASHRAE, WHO guidelines [15],[16],[17]

Parameters	Permissible limit
Average Air Speed (m/s)	< 0.20 m/s
Air Temperature (°C)	22 °C - 26 °C
Mean Radiant Temperature (°C)	+2 °C of air temperature (Ta)
Relative Humidity (%RH)	30-60 %RH
CO_2 (ppm)	≤ 1000 ppm above outdoor (~1400 ppm max.)

3.1.3 Actuation Strategy

To enable bi-directional communication, the methodology incorporates an actuation layer that transforms the analytical decisions into control signals for the physical devices. These signals are generated to be transmitted to actuators like IR Blasters, which can regulate devices such as ACs and fans in a deployed setup. IR blaster devices work just like a normal remote, but based on the signals it receives from the analysis layer. This actuation strategy closes the loops between monitoring, analysis, and control, thereby distinguishing the proposed system from conventional one-way monitoring approaches.

It also provides the basis for the future evaluation of energy consumption impacts and occupant well-being improvements. In this study, the actuation workflow was defined and validated conceptually but not physically executed.

3.2 Case Study

This case study demonstrates the proposed framework to deploy a DT in an educational building unit. The selected unit is a shared office space at the Department of Civil Engineering at Indian Institute of Technology Bombay, which is a 50-year-old building with faculty offices, classrooms, conference rooms, and laboratories.

3.2.1 The study area

The study area shown in Figure 3 is a room occupied by research scholars for an average of 6 to 8 hours on weekdays. The space has an area of 25.6 m² (8m x 3.2m x 3m). A glass partition wall divides the room into two parts, each measuring 12.2 m² and 13.4 m², occupied by the professor and students, respectively. The walls are of brick masonry with plaster finish, while the floor is tiled, and the finished ceiling contains lighting fixtures and a fan. The partition wall with a door allows partial transparency and limited air circulation between the two spaces. Both zones are equipped with wooden desks with computer systems, chairs, and storage shelves.

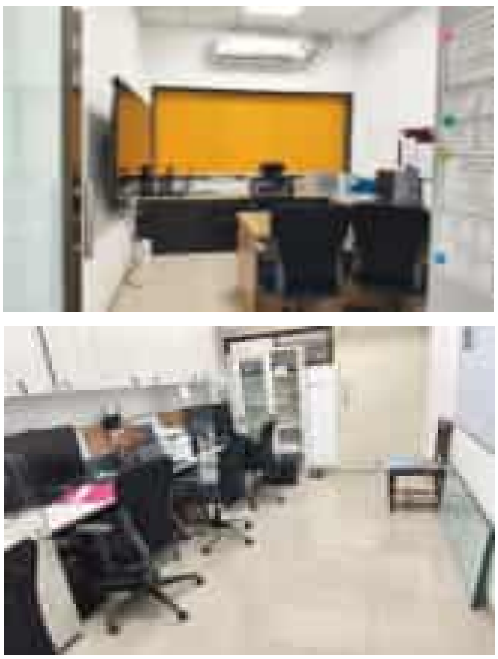

Figure 3. Selected study area

The Zone A (professors' seating area) has a split-type air conditioner unit, along with ceiling fans and a glass window on the wall. Zone B, occupied by research scholars, is equipped with a fan which is remote controlled. The BIM model (architecture and furniture layout) for the study area cabin was created using Autodesk Revit, as shown in Figure 4.

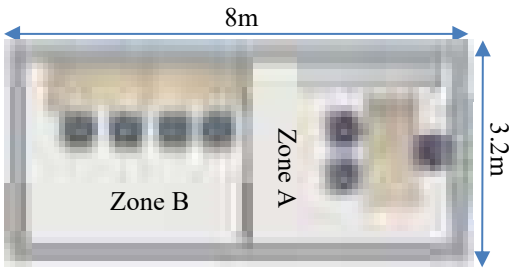

Figure 4. Study area model

3.2.2 Data Acquisition and Visualization

To capture real-time data, a Testo multi-sensor kit was used due to its high measurement accuracy, availability, and its compliance with ASHRAE standards. These sensors were deployed within the occupants' breathing zone using tripods set up as per ASHRAE 55 and ISO 7762 guidelines. The Testo multi-sensor kit, as shown in Figure 5, consists of some sensors and components as mentioned in the list below:

1. Globe Temperature sensor
2. CO_2 sensor
3. Air Velocity vein sensor
4. Air Temperature/ Humidity sensor
5. Testo 480 data display

Figure 5. Sensors used to collect data

The sensors recorded real-time data for temperature, humidity, air velocity, and CO_2 at predefined intervals of 30 seconds which were shown on Testo 480 display device. The data is then sent to the computer system on Easyclimate software via USB connection. The updated version of Easyclimate software allows users to send real-time data, but the available older version was not compatible with Autodesk Tandem. Therefore, to send real-time data, a pipeline using a Python script and Node-RED was created to transfer the average of collected data at an interval of 2.5 minutes; this frequency is selected as per ASHRAE standards. As the data arrives at the DT model, the visualization can be done in the form of heatmaps, temporal stream charts, and an alert system based on the set threshold values, as shown in Figure 5.

3.2.3 Data Analysis and Actuation

Next, the analysis layer will compute the thermal comfort indices (PMV and PPD) using ASHRAE 55, assuming a standard metabolic rate of 1.0 met (activity: sitting and typing) and clothing of 1.0 clo unit (can vary from case to case). IAQ parameters will be checked for compliance with ASHRAE 62.1 using a Python script. IAQ analysis is done based on CO_2 only. Other parameters like PM and VOCs can be used to get more accurate IAQ optimization. For thermal comfort analysis, if at any time thermal comfort indices (PMV and PPD) are going out of the permissible range, the parameters affecting thermal comfort indices will be checked, and whichever parameter is deviating will be adjusted by controlling the respective device. For example, if the temperature is going out of range, the AC temperature can be controlled. When any parameter deviates from the threshold values, the actuation layer is designed to be triggered. To enable automated control, an IR blaster has to be deployed within the study area. A Python script-generated signal can be sent to the IR Blaster via Wi-Fi network, thereby regulating thermal conditions and air quality in real-time. The actuation part is planned to be deployed. The IR blaster selected for use is the BroadLink RM4 Mini, due to its compatibility with Python and Node-RED, its widespread use in research, and its Wi-Fi-based design. This creates a bi-directional loop, as the adjusted data will be collected again through sensors on predefined intervals, and the entire procedure is designed to be repeated upon deployment.

3.2.4 Validation Strategy

Validation strategy to evaluate system performance under real-world conditions includes:

1. Assessing improvements in IEQ indicators before and after automated control.
2. Testing the responsiveness of the control system by measuring the time lag between the detection of parameter deviation and the actuation response.
3. Comparison of manual vs automated operation modes and reduction in electricity use.

The results will demonstrate the feasibility and effectiveness of deploying a bi-directional DT framework for IEQ monitoring and control in educational buildings within the Indian context.

4 Results and Discussion

This paper provides a framework for monitoring IAQ and thermal comfort in educational buildings using a DT. The results demonstrate the feasibility and effectiveness of integrating BIM and IoT systems to develop a DT for IEQ optimization. The proposed framework of DT successfully established continuous

data flow between the physical environment and the digital model. Real-time sensor data collected at a defined interval was found to be sufficient to capture meaningful variations in parameters. Despite software compatibility constraints, the integrated pipeline using Python and Node-RED enabled stable data synchronization. The observed latency between physical data acquisition and digital visualization remained within acceptable limits for facility management use cases, indicating quick system responsiveness. The DT platform enabled real-time visualization of IEQ parameters using temporal stream charts, color-coded heatmaps, and an alert-based system. The BIM-integrated visualization provided enhanced spatial awareness for facility managers, as shown in Figure 6.

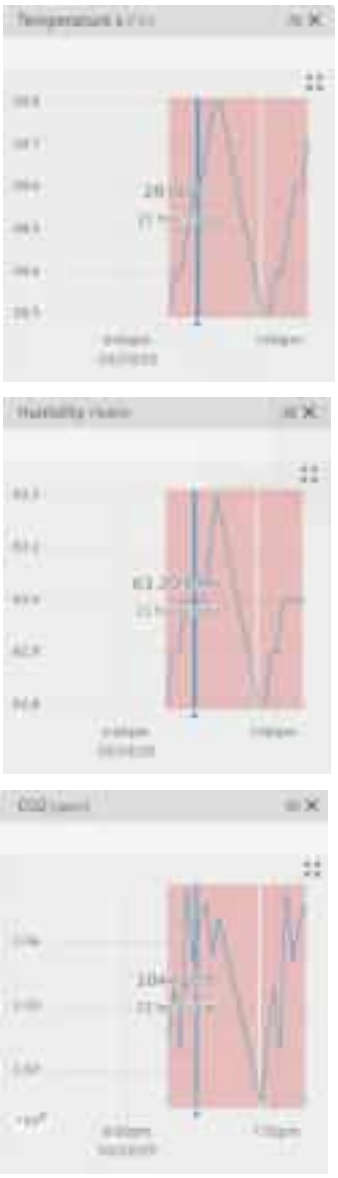

Figure 6. Visualization of real-time data on Autodesk Tandem

Despite the absence of the field-level actuation, the successful integration of monitoring, analysis, and control logic demonstrates framework readiness.

5 Conclusion and Future Work

This paper presents a bi-directional Digital Twin framework for monitoring and optimizing IEQ in educational buildings by integrating BIM, real-time IoT sensor data, analytical models, and actuation logic. The proposed approach addresses the limitations of conventional IEQ management systems by enabling continuous data exchange between the physical and digital environments and supporting standards-based decision-making in real time. The case study conducted at IIT Bombay demonstrates the feasibility of deploying the proposed framework in an educational setting. The DT enabled real-time visualization of thermal comfort and indoor air quality parameters through BIM-integrated dashboards and alert systems, with acceptable system responsiveness despite software compatibility constraints. The results confirm that real-time monitoring combined with ASHRAE 55 and ASHRAE 62.1 compliance assessment can effectively identify thermal comfort and air quality deviations. By incorporating an actuation strategy, the framework establishes the foundation for closed-loop control, distinguishing it from

traditional one-way monitoring approaches. This capability has the potential to improve occupant comfort and well-being while supporting more efficient building operations and energy use. Overall, the proposed Digital Twin framework offers a scalable and practical solution for intelligent IEQ management in educational buildings.

Although the present study validates the monitoring, visualization, and standards-based decision framework, physical actuator integration remains to be implemented and tested under real world conditions. Further extensions will include quantification of energy consumption impacts resulting from automated control actions and comparative analysis between manual and automated operation modes. Additionally, IAQ parameters, such as PM and VOCs, will be incorporated to enhance IAQ assessment. Occupant feedback surveys will be integrated to correlate objective IEQ indicators with subjective comfort responses.

Abstract – Bridge infrastructure is highly susceptible to deterioration due to continuous exposure to harsh environmental conditions and increasing traffic volumes and loads, necessitating frequent inspections to ensure structural safety and serviceability. Traditional bridge inspection approaches are often time-consuming, labor-intensive, error-prone, and disruptive to traffic operations, highlighting the need for more efficient, reliable, and non-invasive inspection solutions. Although several studies have proposed sensor-based and unmanned aerial vehicle (UAV)-assisted inspection systems, limited research has focused on the systematic identification, classification, and quantitative assessment of surface crack severity using image-based approaches. To address this gap, this study develops an integrated UAV-based framework for automated crack detection and classification within a bridge monitoring system. The proposed framework advances existing approaches through the integration of crack identification using gray-scale pixel-based image analysis and crack classification based on geometry, orientation, and severity. The methodology comprises four main stages: UAV-based data acquisition, image preprocessing and crack detection, quantitative crack characterization and classification, and validation through laboratory testing and a real-world bridge case study. Preliminary case study results show that the proposed gray-scale pixel-based algorithm achieves minimum errors of 2.9% and 5.5% and maximum errors of 17.9% and 16.0% for crack length and width estimation, respectively. Severity classification was consistent for moderate and extended cracks (2 out of 4 segments), while fine cracks exhibited higher misclassification rates due to reduced contrast and image quality. Orientation profiling showed correct or partial agreement for most detected crack segments. Higher errors under real-world conditions highlight the need for improved image acquisition stability.

1 Introduction

Bridge infrastructure is a critical component of highway transportation systems and plays a vital role in ensuring connectivity, safety, and economic development. Due to continuous exposure to harsh environmental conditions, heavy traffic, and aging, bridges are highly susceptible to deterioration and damage, necessitating regular inspection and maintenance [1,2]. However, transport authorities often operate under strict time and budget constraints, which limit the effectiveness and frequency of traditional inspection practices [1]. Conventional bridge inspection processes rely primarily on visual and manual inspection, making them labor-intensive, time-consuming, subject to personal judgment, and potentially dangerous for inspectors [3]. In addition, these inspections often require road closures and may fail to identify hard-to-reach or hidden defects, resulting in incomplete condition assessments [4]. To address these limitations, recent research has increasingly focused on non-contact and non-destructive testing (NDT) technologies for bridge inspection and monitoring, including photogrammetry, infrared thermography, and unmanned aerial vehicles (UAVs) [5,6]. Infrared thermography has also been used in combination with machine learning techniques to estimate crack properties such as crack width from temperature variations captured in thermal images [7]. Among these technologies, UAV-based inspection has received considerable attention due to its ability to safely access difficult-to-reach locations, reduce inspection time and cost, minimize traffic disruption, and provide high-resolution visual data for structural assessment [4,8]. UAV-mounted visual imaging systems have been widely applied for crack detection, surface damage

identification, and geometric measurements of bridge elements, with several studies reporting accuracy comparable to that of conventional field measurements [9]. UAV-based images further enable the reconstruction of three-dimensional (3D) models from overlapping images, supporting improved localization and quantitative assessment of surface defects [10]. Photogrammetry-based approaches have been successfully applied to generate textured 3D models of concrete elements and extract crack characteristics such as crack length, width, and deformation behavior from image data [11]. Previous studies have demonstrated the potential of UAV imagery for crack detection, deformation monitoring, corrosion assessment, and post-disaster damage evaluation of bridge infrastructure [12]. Despite these advances, UAV-based inspection approaches remain sensitive to imaging conditions such as lighting variability, image blur, and surface texture, which can affect the reliability of crack detection and measurement [13]. At the same time, significant efforts have been made to automate the crack detection using image processing and computer vision techniques. Traditional image-based methods rely on filtering, thresholding, edge detection, and morphological operations to extract crack features and estimate their dimensions [14]. More recently, artificial intelligence and deep learning approaches have been introduced to improve detection accuracy under changing environmental conditions [15]. However, such data-driven methods typically require large, well-labeled datasets and extensive training, which are often unavailable in practical bridge inspection scenarios.

Moreover, many existing crack detection approaches primarily focus on identifying the presence of cracks rather than systematically characterizing crack geometry and orientation [16]. In particular, limited attention has been given to extracting quantitative crack properties such as crack length, width, and orientation while simultaneously interpreting crack patterns relative to bridge components and infrastructure condition assessment. Such detailed crack characterization is essential for supporting maintenance planning and structural evaluation of bridge infrastructure.

1.1 Research Gaps

Despite significant progress in UAV-based bridge inspection, several research gaps remain in the current literature. First, many existing studies focus on individual techniques or standalone inspection methods and lack integrated, image-based frameworks that support systematic crack identification, profiling, and quantitative assessment within an automated and updatable bridge monitoring workflow [17]. Second, while crack detection has been widely investigated, limited attention has been given to extracting and utilizing gray-scale pixel-level information for robust crack identification and quantitative characterization of crack properties such as length, width, and orientation.

Finally, most existing UAV-based crack detection approaches emphasize automated detection but rarely incorporate systematic analysis of crack orientation patterns or their relationship with specific bridge components [13]. The geometric orientation of cracks, such as horizontal, vertical, and diagonal patterns, can provide valuable insight into potential structural behavior and deterioration mechanisms. However, this contextual interpretation is often missing in existing automated inspection frameworks. Therefore, there remains a need for integrated methodologies that combine crack identification, quantitative crack characterization, and orientation-based crack profiling to support practical bridge inspection and maintenance decision-making.

1.2 Objectives and Contributions

To address the identified research gaps, this study aims to develop a UAV-based bridge monitoring framework using image-based techniques for crack detection and assessment. A UAV-based image analysis approach is implemented for concrete highway bridges to support surface crack detection, characterization, and classification. Unlike many existing UAV inspection approaches that rely heavily on deep learning models requiring large labeled datasets, the proposed framework utilizes gray-scale pixel-based image analysis to detect crack features and extract their geometric properties. The methodology integrates crack detection with quantitative characterization of crack attributes and orientation-based profiling to enable a more comprehensive interpretation of crack patterns relevant to bridge infrastructure assessment. The specific objectives of this study are to 1) develop a gray-scale pixel-based approach for identifying surface cracks from UAV-acquired images; 2) extract quantitative crack characteristics, including length, width, and orientation, from detected crack features; and 3) profile cracks based on their geometric orientation (horizontal, vertical, and diagonal) to support systematic assessment of bridge infrastructure; 4) determine crack severity levels (e.g., low, moderate, and extended) by integrating gray-scale crack identification and geometric crack profiling results to support condition assessment of bridge components. The main contribution of this study lies in the development of an integrated UAV-based inspection framework that combines gray-scale image analysis with orientation-based crack profiling and quantitative crack characterization within a unified monitoring workflow. This approach enables systematic crack assessment without relying on extensive training datasets typically required by deep learning models. The methodology is verified through a real-world bridge case study conducted in the United Arab Emirates (UAE),

demonstrating its applicability to automated, non-invasive bridge inspection.

2 Materials and Methods

This study develops a UAV-based image analysis methodology for bridge condition assessment focused on surface crack detection and characterization. UAV-assisted inspection provides a non-contact and non-invasive means of acquiring high-resolution visual data, enabling access to hard-to-reach bridge components while reducing inspection time, cost, and traffic disruption. The proposed framework follows a sequential, image-driven workflow, as illustrated in Figure 1, consisting of six main actions: acquiring UAV images, detecting surface cracks, extracting crack geometry, profiling crack orientation, classifying crack severity, and supporting informed inspection and maintenance decision-making. First, high-resolution images of bridge components are acquired using a UAV under controlled environmental conditions to ensure adequate image quality. Second, the acquired images are directly processed using a gray-scale pixel-based crack detection algorithm to identify potential crack regions. Third, quantitative crack geometry, including crack length and width, is extracted from the detected crack features. Fourth, cracks are profiled based on their geometric orientation as horizontal, vertical, or diagonal. Fifth, crack severity levels are determined by integrating crack geometry and orientation information to distinguish between minor and more critical surface defects relevant to bridge inspection. Finally, the extracted crack characteristics are used to support systematic interpretation of bridge surface condition and inform inspection and maintenance considerations.

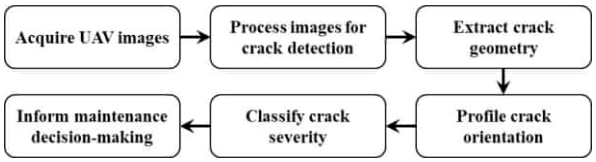

Figure 1. Research methodology framework

2.1 Acquire UAV Images

The data acquisition stage focuses on collecting sufficient high-resolution visual information to support reliable image-based crack detection and quantitative crack characterization of bridge surface defects. UAVs are employed to capture high-resolution, overlapping images of bridge components from multiple viewpoints, ensuring adequate coverage and redundancy for image processing and crack analysis [10,18]. Careful flight planning is undertaken to achieve appropriate image overlap, viewing angles, and spatial resolution required for reliable crack identification and measurement. Data acquisition planning considers environmental conditions, including lighting variability, wind speed, and operational constraints, to minimize image blur and distortion during flight. Particular attention is given to capturing close-range images of critical structural components to support gray-scale, pixel-based crack identification and the subsequent extraction of crack characteristics, such as length, width, and orientation.

2.2 Process Images for Crack Detection

The acquired UAV images are directly processed using image processing techniques without relying on 3D surface reconstruction. Images are converted to gray-scale format and analyzed based on pixel intensity variations to enhance crack features relative to the surrounding surface texture. Preprocessing operations, including noise suppression and contrast enhancement, are applied to reduce the influence of illumination variability and background irregularities. This processing stage establishes a consistent basis for crack detection by improving the separability of crack pixels from non-crack regions. The processed images are then prepared for segmentation, enabling reliable identification of crack features across different bridge components and imaging conditions.

2.3 Extract Crack Geometry

Following crack detection, quantitative crack geometry is extracted from the segmented crack regions. Crack length is computed based on the spatial extent of detected crack features, while crack width is estimated using pixel-based geometric analysis techniques. These measurements provide objective and repeatable metrics for characterizing crack extent and severity. The extracted geometric properties form the quantitative foundation for crack profiling and severity classification. By relying on gray-scale pixel information and geometric measurements, the methodology enables consistent crack characterization without the need for prior training data or complex learning-based models.

2.4 Profile Crack Orientation

Detected cracks are subsequently profiled according to their geometric orientation and classified as horizontal, vertical, or diagonal. Orientation profiling is performed by analyzing the spatial alignment of crack features relative to the image coordinate system. This classification supports systematic comparison of crack patterns across different bridge components and aids in interpreting crack behavior with respect to structural configuration, as different crack orientations may be associated with different damage mechanisms or

structural responses. In addition to orientation profiling, crack severity is classified into three discrete levels, namely fine, moderate, and extended, based on quantitative crack width measurements. These severity categories are defined using width thresholds commonly adopted in bridge inspection practice, enabling consistent differentiation between less critical and more significant surface defects. The combined use of crack orientation and severity classification provides contextual information essential for systematic condition assessment of bridge infrastructure.

2.5 Classify Crack Severity

Crack severity is classified by integrating quantitative crack geometry and orientation information. Severity is defined using three discrete categories, namely fine, moderate, and extended, which are determined primarily based on crack width thresholds commonly adopted in bridge inspection practice [14], enabling differentiation between less critical and more significant surface defects. The integration of crack geometry and orientation supports a structured and interpretable severity assessment framework. This classification approach facilitates consistent evaluation of crack conditions across bridge elements and supports prioritization of defects that may require closer inspection or maintenance intervention.

2.6 Inform Maintenance Decision-Making

The combined outputs of crack detection, geometric extraction, orientation profiling, and severity classification are used to inform the interpretation of bridge surface condition. By providing quantitative and contextual crack information, the proposed methodology supports inspection reporting and maintenance planning, enabling engineers and asset managers to better understand defect characteristics and their potential implications. Although the framework does not replace engineering judgment, it provides a transparent and systematic basis for supporting inspection decisions and identifying areas that may require further investigation or monitoring.

3 Methodology Implementation

This section presents the implementation of the proposed methodology described in Section 2. The methodology is applied to a real-world bridge case study to demonstrate its practicality and effectiveness for bridge condition assessment. The implementation includes site reconnaissance, UAV-based data acquisition, execution of the image-based crack detection and quantification process, and validation through laboratory testing and field application.

3.1 Site Reconnaissance

A prestressed concrete highway bridge located in Ghalilah, Ras Al Khaimah, UAE, was selected to implement and evaluate the proposed UAV-based bridge inspection methodology. The bridge is located along the E11 highway and comprises four traffic lanes supported by six simply supported spans, each 11.5 m long, resulting in a total length of 71 m and a vertical clearance of approximately 9.1 m. The superstructure consists of a precast reinforced concrete deck supported by cast-in-place concrete piers and closed abutments with wingwalls, with expansion joints, parapets, and safety barrier railings provided along the deck edges. The bridge was selected due to the availability of historical inspection reports, which supported validation of the proposed methodology, as well as its representative lighting conditions and limited surrounding obstructions. The inspection records were reviewed to obtain information on structural characteristics, component geometry, and previously reported defects, aiding UAV flight planning and identification of damage-prone areas. As shown in Figure 2, reported defects included concrete efflorescence, spalling, and vertical and horizontal cracking on the bridge deck. A site reconnaissance survey was conducted to identify potential hazards to UAV operations, including traffic flow and nearby obstructions, and to determine suitable take-off and landing locations. A preliminary visual inspection was also performed to identify bridge elements requiring close-range UAV imaging. Required approvals for UAV operation were obtained from the relevant authorities, and pre-flight checks were conducted in accordance with regulatory and manufacturer guidelines to ensure safe UAV operation during data acquisition.

Figure 2. Condition of the bridge structure extracted from inspection reports

3.2 Acquire UAV Images

A UAV-based data acquisition strategy was adopted to capture high-resolution images suitable for image-based crack analysis. Data collection was conducted under favorable environmental conditions, including

sufficient lighting, low wind speeds, and moderate ambient temperatures. A DJI Inspire 2 quadcopter vertical take-off and landing (VTOL) UAV equipped with a Zenmuse X7 camera featuring a 24-megapixel, 35-mm sensor was used for image acquisition. Live video streaming provided a first-person view of the UAV trajectory and enabled real-time identification of areas requiring additional inspection. Due to proximity to structural elements and the presence of GPS-denied environments beneath the bridge deck, the UAV was operated in manual flight mode with approximately 80% horizontal overlap. Manual operation allowed adaptive flight-path adjustment and improved control during close-range imaging. The UAV was flown at an average distance of approximately 2m from the bridge surface with an inclination angle of about 15º. An initial flight focused on imaging the underside of the bridge deck, followed by two additional flights targeting cracked and spalled regions identified during site reconnaissance. In total, 64 high-resolution images and two video sequences were acquired for subsequent analysis.

3.3 Process Images for Crack Detection

The acquired UAV images were processed using MATLAB®-implemented image processing algorithms. Images were directly analyzed without three-dimensional reconstruction. Each image was loaded into the processing interface, where resizing was applied as required to reduce computational demand. Image preprocessing included smoothing, Gaussian filtering, and adaptive histogram equalization to suppress noise, reduce image disturbances, and enhance contrast while limiting amplification of background noise.

Primary segmentation was performed using gray-scale thresholding to convert the image into a binary representation, highlighting potential crack regions. A global gray-scale threshold was applied to separate dark crack pixels from the surrounding concrete surface based on pixel intensity differences following preprocessing operations. The threshold value was determined empirically during algorithm calibration to enhance crack visibility while suppressing background noise. In the context of the conducted experiments, the fine-tuned gray-scale threshold value was set to 90, based on empirical calibration across representative sample images, where threshold values between 70 and 120 were evaluated to achieve optimal separation between crack pixels and background intensity levels. Secondary segmentation employed an active contour region-growing approach to refine crack boundaries and separate crack features from the background.

3.4 Extract Crack Geometry

Post-processing operations were applied to reduce false detections, including area-based filtering to remove small, isolated segments and mean-intensity-based dark-blob filtering to eliminate regions insufficiently distinct from the background. Following post-processing, quantitative crack geometry was extracted from detected crack segments. Crack length was determined using skeletonization, which extracts crack centerlines while preserving topological continuity. Crack width was estimated using a distance transform approach, whereby distances from crack boundaries to the centerline were averaged and converted to physical dimensions. These geometric measurements provided objective metrics for crack characterization. Based on the laboratory validation results, the smallest crack width successfully detected during laboratory validation was approximately 0.72 mm under controlled imaging conditions. Under field conditions, the effective detectable crack width may increase due to image resolution limitations, UAV vibration, lighting variability, and perspective distortions during image acquisition.

3.5 Profile Crack Orientation and Classify Crack Severity

Detected cracks were profiled based on geometric orientation and classified as horizontal, vertical, or diagonal according to predefined angular thresholds. Crack segments with orientation angles less than 30° or greater than 150º were classified as horizontal cracks. Segments with angles between 30º and 70º or between 110º and 150º were classified as diagonal cracks, while remaining orientations were classified as vertical cracks.

Crack severity was subsequently classified by integrating crack width measurements with predefined severity categories. Crack width thresholds were defined as fine cracks (0.1-1 mm), moderate cracks (1-5 mm), and extended cracks (>5 mm), consistent with commonly adopted bridge inspection practices [19].

3.6 Inform Maintenance Decision-Making and Validation

The extracted crack geometry, orientation profiles, and severity classifications were used to inform the interpretation of bridge surface condition. By providing quantitative and contextual crack information, the methodology supports inspection reporting and identification of areas requiring closer monitoring or intervention. Validation was performed at both laboratory and field scales. Laboratory validation used four concrete beam specimens (50×15×15cm) with vertical cracks induced through four-point flexural testing. Crack dimensions were measured using an electronic handheld digital microscope with a maximum magnification of 1600x, and corresponding images were captured under controlled conditions (Figure 3).

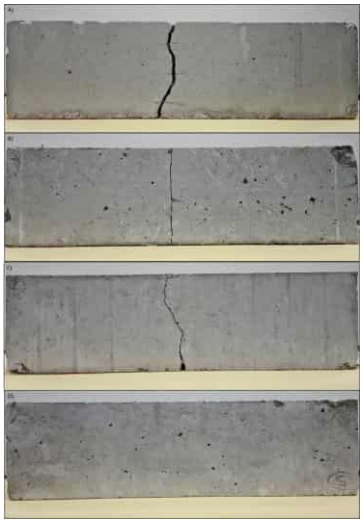

Figure 3. Images of cracked beam: A) specimen 1, B) specimen 2, C) specimen 3, and D) specimen 4

The crack delineation results obtained using the MATLAB®-based algorithm are illustrated in Figure 4. In all specimens, the algorithm successfully identified crack segments. Minor background noise, including surface discoloration, markings, and small spalled regions, was occasionally misclassified as cracks. However, these artifacts were excluded through manual refinement. Manual intervention was primarily required to remove false-positive regions and recover crack segments that were partially undetected due to low image contrast or segmentation discontinuities. In the laboratory validation stage, manual refinement was limited to excluding a small number of non-crack segments, representing less than approximately 10% of detected regions. This indicates that the majority of crack detection and geometric characterization was performed automatically by the algorithm, while manual intervention was limited to correcting segmentation artifacts and refining crack boundaries. The algorithm correctly identified crack orientation in all laboratory specimens. Quantitative validation results indicate that crack length and width estimation errors were less than 17.9% and 16.0%, respectively. Specimen 3 exhibited the highest accuracy, with errors of 2.9% for crack length and 5.5% for crack width. In contrast, specimen 4 exhibited the most significant errors, highlighting the increased difficulty in identifying very fine cracks that exhibit limited contrast relative to background noise. These results indicate that uncertainty in crack detection arises from several factors, including image resolution, crack visibility relative to background texture, segmentation threshold sensitivity, and UAV image acquisition stability. In particular, motion-induced image blur and non-perpendicular viewing angles may reduce the detectability of fine cracks and introduce measurement uncertainty in crack geometry estimation.

A comparison between measured and estimated crack dimensions is provided in Table 1.

Table 1. Comparison of measured and estimated crack dimensions

Specimen #		Original	Estimated	Percent Error (%)
1		16.100	16.710	**3.789**
2	Length	16.700	17.395	**4.162**
3	(cm)	18.200	18.742	**2.978**
4		6.300	5.171	**17.921**
1		0.280	0.251	**10.357**
2	Width	0.100	0.092	**8.000**
3	(cm)	0.072	0.076	**5.556**
4		0.025	0.029	**16.000**

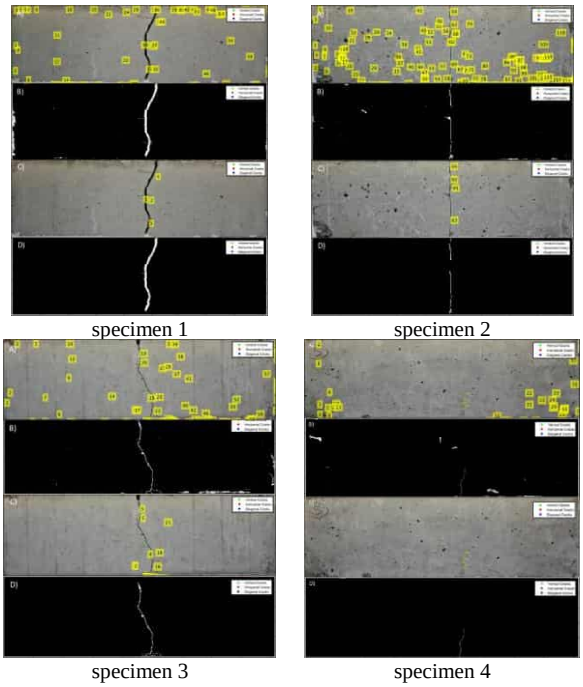

Figure 4. Overlay and binarized crack detection results for laboratory specimens before and after manual enhancement.

Following laboratory validation, the crack detection algorithm was applied to UAV-acquired images of the bridge deck. Visual inspection identified multiple cracks within an approximately 80×100cm region of the deck surface. As shown in Figure 5, diagonal fine cracks were observed in segments 1 and 2, a vertical extended crack in segment 3, and a horizontal moderate crack in segment 4. This image region is presented as a representative example to illustrate the implementation of the proposed crack detection and classification methodology. The algorithm was applied to several UAV-acquired images collected during the inspection campaign; however, the selected region was used to demonstrate the step-by-step crack detection process and the interpretation of crack geometry, orientation, and severity classification results.

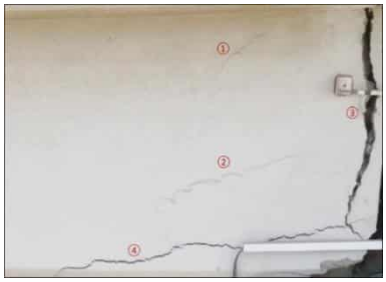

Figure 5. Cracks identified on an image of the bridge deck extracted using a UAV

Automated crack detection results are presented in Figure 6. Initial segmentation results revealed incomplete crack delineation and misclassification of certain background elements as cracks, particularly in regions containing fine cracks. Manual refinement was therefore performed by marking undetected crack regions and excluding background elements such as cables and spalled areas. Manual adjustments were required primarily for two of the four crack segments detected in the case study, particularly for fine cracks where contrast between crack features and surrounding concrete surfaces was limited. The initial identification and geometric extraction of crack features were performed automatically by the algorithm, while manual refinement was applied only to correct segmentation artifacts and improve crack continuity in challenging regions. Despite these adjustments, some crack segments remained partially disconnected due to image blur and non-perpendicular viewing angles during image acquisition.

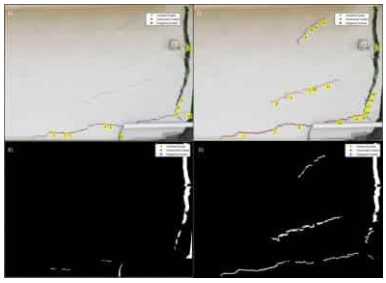

Figure 6. Images obtained from crack detection analysis, showing automatic segmentation and corresponding overlay results before and after manual refinement.

The dimensional statistics reported by the algorithm are summarized in Table 2. Crack segments 3 and 4 were correctly classified in terms of both orientation and severity, while segments 1 and 2 were misclassified as moderate cracks and partially misidentified as horizontal cracks. These discrepancies are attributed primarily to UAV vibration, image blur, and perspective distortion, which reduced crack visibility and contrast in fine and moderate crack regions.

Table 2. Comparison of crack dimensions, orientation, and severity

Segment #	Width (mm)	Height (mm)	Dimension		Orientation	
			Original	Classified	Original	Classified
1	3.87	223.08	Fine	Moderate	Diagonal	Horizontal / Diagonal
2	4.93	403.94	Fine	Moderate	Diagonal	Horizontal
3	7.32	646.02	Extended	Extended	Vertical	Vertical
4	3.87	750.17	Moderate	Moderate	Horizontal	Horizontal

4 Conclusions and Future Work

This study presented a proof-of-concept UAV-based bridge inspection framework for crack assessment that integrates gray-scale pixel-based crack detection, geometric characterization, and severity classification. The framework was implemented and evaluated through preliminary laboratory experiments and a real-world bridge case study in the UAE to demonstrate its feasibility and practical applicability under controlled and field conditions.

The preliminary results indicate that the proposed image-based approach is capable of identifying crack geometry, orientation, and severity trends, with acceptable accuracy under laboratory conditions and increased uncertainty under real-world imaging constraints. These findings highlight both the potential and current limitations of UAV-acquired imagery for detailed crack assessment, particularly when image clarity and acquisition stability are affected. Sources of uncertainty include variations in lighting conditions, image blur caused by UAV vibration, surface texture variability, and perspective distortion during image acquisition. These factors may affect the reliability of crack segmentation and introduce uncertainty in crack geometry estimation, particularly for very fine cracks. Based on the laboratory validation results, the smallest crack width successfully detected using the proposed methodology was approximately 0.72 mm under controlled imaging conditions. However, under field conditions, the effective detectable crack width may increase due to image resolution limitations and environmental factors affecting image clarity.

By combining crack geometry and orientation profiling with severity classification, the framework supports context-aware interpretation of surface cracks relevant to bridge components and inspection reporting. The methodology, therefore, provides a structured and transparent basis for identifying crack patterns and prioritizing areas that may require closer inspection or maintenance intervention.

Overall, the proposed methodology demonstrates the feasibility of a non-invasive, image-driven approach for UAV-based bridge inspection and provides a foundation for more comprehensive and robust implementations. Although the presented results focus on a representative

example image region to illustrate the methodology, further validation using larger annotated image datasets would enable more comprehensive statistical evaluation of detection and classification performance. Future research will therefore focus on expanding the dataset and incorporating quantitative performance metrics such as precision, recall, and confusion matrices to provide a more rigorous assessment of algorithm performance.

Abstract –

Service robots have been increasingly deployed across several infrastructure applications. ROS2 has become the widely used operating system for service robots due to its performance and compatibility. However, its default configuration lacks authentication, encryption, or access control. While prior studies have highlighted general ROS2 security weaknesses, the feasibility of reconnaissance attacks in realistic service robot deployments remains underexplored. A controlled setup using ROS2 Humble was developed, in which a custom publisher node continuously transmitted robot positional data (i.e., real time location) over data distribution service (DDS) topics. Fast DDS Spy was used to discover domain participants, topics, data writers, while wireshark captured and analyzed underlying real-time publish–subscribe (RTPS) traffic. The experiments were repeated across ten independent simulation runs to ensure consistent observations. The results demonstrate that in all ten simulation runs, an unauthorized entity on the same network could access eight types of sensitive operational data (e.g., robot's internet protocol (IP)) with consistent observation across trials. These findings highlight integrity and confidentiality risks in default ROS2 deployments and emphasize the need for stronger security controls to safeguard service robots particularly in collaborative environments. These observations can serve as valuable guidance for researchers and practitioners designing and utilizing autonomous service robots. In addition, the study's findings provide valuable insights and significantly complement the smart city initiatives and the UAE vision of a resilient, secure, sustainable, and intelligent infrastructure ecosystem.

1 Introduction

Service robots are increasingly deployed to perform task-oriented functions across a wide range of real-world environments, including infrastructure inspection, facility management, hospitality, healthcare, and public services. These robots are designed to execute specific operational tasks such as monitoring, inspection, navigation, or human interaction, with development efforts primarily focused on achieving reliable application-level functionalities. As a result, less attention is often given to the underlying operating system and security architecture that support these capabilities, particularly in early-stage development and deployment [1]. In many cases, service robots operate while connected to shared or public wireless networks, remaining continuously exposed to the internet as they roam through open environments, which significantly expands their attack surface. In architecture engineering construction and operations (AECO) industry, robots and drones are used for site inspection, progress monitoring, and hazard detection. In indoor built environments such as commercial buildings and facilities, service robots support environmental monitoring, security patrols, and asset inspection [2][3]. Comparable task driven deployments are observed in hospitality and healthcare sectors, as well as in emerging autonomous transportation systems. The practical importance of these applications is reflected in city-level initiatives; for example, Dubai aims to transition 25% of its transportation systems to autonomous modes by 2030, signaling the growing reliance on robotic systems within critical urban infrastructure.

To enable communication and coordination among robotic components, the Robot Operating System (ROS) is widely adopted as a modular software framework for robotic development. Since its initial open-source release in 2009, ROS1 facilitated rapid prototyping and system integration by providing reusable libraries and

standardized interfaces across heterogeneous hardware and software platforms. However, ROS1 was not designed with security or real-time guarantees as primary considerations, and its key limitations are discussed in detail in Section 2.2 [4]. To address these drawbacks, ROS2 was introduced as a redesigned framework targeting modern service robot requirements. ROS2 improves real-time performance, supports multi-robot and distributed deployments, and adopts middleware technologies such as the Data Distribution Service (DDS) to enable scalable communication [4] [5]. DDS is a middleware standard that enables real-time, reliable, and scalable data exchange between distributed systems using a data centric publish subscribe communication model.

Despite these architectural improvements, many ROS2 deployments continue to operate using default middleware configurations that do not enforce authentication, encryption, or fine-grained access control. As service robots largely operate over shared wireless networks or public Wi-Fi, these default configurations expose communication channels to passive and active adversaries. Vulnerabilities at the operating system or middleware level can compromise confidentiality, integrity, and availability of robotic data and control flows, potentially affecting mission execution and human safety [6]. Therefore, systematic analysis of network-level exposure, protocol behavior, and security weaknesses in ROS2-based systems is essential. This applies to all service robot deployments, since continuous connectivity and human interaction can increase risks, potentially affecting the confidentiality, integrity, and availability across all layers of robotic operation. This study addresses this gap by examining the type of security relevant information that can be identified using currently available tools. Unlike prior studies that limited their analysis to traffic observation and protocol identification, this study uniquely combines Fast DDS Spy at the middleware layer with Wireshark at the network layer to systematically enumerate eight categories of sensitive operational data extractable through passive reconnaissance, without authentication or direct system interaction. It also serves to enhance the awareness among business stakeholders by demonstrating how the under prioritization of these risks can lead to significant financial and operational consequences incase of potential cybersecurity incidents involving service robotic operation.

2 Literature Review

The reviewed literature indicates that although ROS2 introduces significant improvements over its predecessor such as enhanced modularity and the adoption of DDS based communication, its security architecture is still not fully mature [7]. Multiple studies such as [5],[6],[8] report persistent weaknesses, including 1) insufficient authentication mechanisms between nodes, 2) limited or optional encryption configurations, and the 3) absence of built-in intrusion detection capabilities. As a result, ROS based systems remain vulnerable to a range of cyber threats. These threats can affect the performance of any service robot, regardless of its application, by putting the robot's primary tasks at risk. These threats can lead to several potential impacts on robotic systems, including 1) disruption of service continuity, 2) degradation of system performance, and 3) compromise of one or more elements of the Confidentiality, Integrity, and Availability (CIA) triad [9]. Furthermore, the literature highlights that the security posture of a ROS2 system is strongly influenced by the underlying DDS middleware implementation.

For the safe operation of service robots, multiple aspects were examined from prior studies to identify key findings and research gaps. The review begins at the build environment level, where Section 2.1 discusses operating environments, followed by Section 2.2, which analyzes the prominent DDS in robot communication. The discussion then extends to the larger system level, where Section 2.3 focuses on network-level communication and analysis based on relevant studies. This motivated the division of the literature review into three sections: 2.1 Analysis of different types of environments used to assess vulnerabilities of service robots in ROS2, 2.2 Analysis of DDS suppliers, i.e., the middleware entities, to examine the state-of-the-art literature in this domain, and 2.3 Review of studies related to understanding the network operability of service robots. Additionally, the review aimed to critically analyze the current literature to identify gaps in ROS2 security research, highlighting areas where cybersecurity risks and vulnerabilities have been underexplored. Together, these sections offer a cohesive understanding of the environment, middleware characteristics, and network interactions, highlighting opportunities to expand on existing research

2.1 Analysis of Environment Type

A total of 25 recent highly relevant studies were reviewed and discussed in detail to examine the experimental environments used in prior ROS2 and service robot research. The main objective was to examine the types of experimental environments used in previous studies such as simulations, hybrid or live deployments. Table 1 summarizes the distribution of experimental environments across the reviewed studies.

Simulation based experiments were the most adopted approach, with 13 out of 25 studies conducted entirely in simulation. Tools such as Gazebo and Webots, alongside virtual machines running Ubuntu, were employed for

fully virtual testing and system modeling. The prevalence of simulation reflects its practicality due to lower costs, reduced logistical complexity, and the ability to safely conduct experiments without disrupting operational service robots. Simulation also allows the construction of diverse scenarios, including potential attack vectors and operational conditions, enabling systematic testing that closely mirrors real-world interactions [10]. This controlled approach ensures repeatable and consistent results, providing confidence in the findings and supporting their relevance to operational service robots. 5 out of 25 studies adopted a hybrid approach, combining simulation with validation on mobile robots such as TurtleBot3 and MiR100. This method balances the safety and flexibility of simulation with the realism of physical testing, addressing some limitations of purely simulated environments. 7 studies performed experiments entirely on physical robots, including UR5 robotic arms and Unitree G1 humanoids, or conducted real-world usability evaluations and security audits. While real-world testing provides high-fidelity insights, it is often limited by high costs, complex integrations, and the potential for disrupting operational service robots [9].

Table 1 : Frequency (out of 25) of the most recently reviewed literature based on environment type.

Environment Type	Frequency
Simulation	13
Hybrid	5
Physical robot	7

Given that simulation is the most widely adopted and practical experimental environment, this study focuses on simulation-based experiments to assess ROS2 vulnerabilities using reconnaissance i.e. active or passive information gathering. By focusing on simulation, this study can construct multiple scenarios yet independent, systematically test ROS2-based systems in a controlled, repeatable, realistic, and safe manner.

2.2 Analysis of DDS suppliers

This section examines the most widely used DDS middleware in ROS2 deployments as elaborated in the latest most relevant literature. Figure 1 summarizes the middleware distribution across the reviewed literature. The analysis focuses on identifying the DDS middleware used in each study, as middleware selection directly influences communication behavior and security characteristics in ROS-based systems. Out of the 25 studies, 9 explicitly stated the use of the default DDS middleware provided by ROS2. These studies primarily focused on system performance and communication behavior without modifying the default middleware configuration. Since the default middleware is widely adopted and explicitly mentioned in previous studies, minimal additional setup is required, making it a practical choice for this study. Consequently, we proceeded with the default Fast DDS implementation. In 13 of the 25 studies, the DDS middleware was either not treated as a primary variable or was not explicitly mentioned, often marked as not applicable (N/A). This highlights a gap in literature, suggesting that middleware selection is frequently overlooked and security is not the primary focus, as most studies concentrate on application-level aspects of the robot. Only one study specifically analyzed Cyclone DDS, indicating limited attention to alternative DDS implementations, while two studies were based on legacy ROS1, which does not natively support DDS.

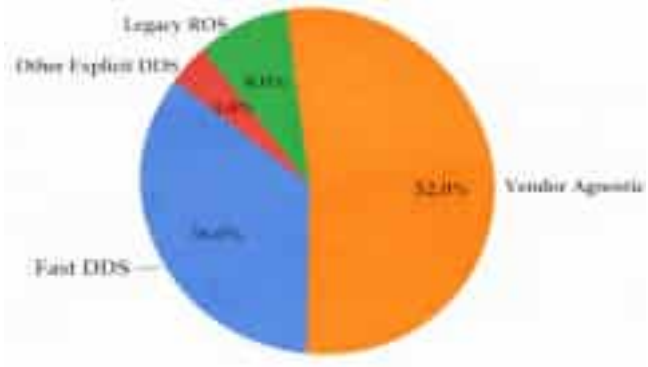

Figure 1: Frequency (in % out of 25) of the most recently reviewed literature based on Middleware distribution.

Fast DDS not only requires minimal configuration but also provides a standardized and widely supported environment ensuring consistency with existing studies. According to [11], it facilitates a focus on security analysis and scenario development without altering underlying communication mechanisms. Overall, there is a clear research gap in the explicit analysis and comparison of DDS middleware implementations in ROS2, particularly regarding security and network communication properties. Therefore, this study leverages the use of Fast DDS, a widely adopted and well documented middleware, while focusing on addressing security concerns that have been largely overlooked.

2.3 Relevant Studies related to Network Analysis

In several studies [12], [13], and [14], network analysis tools such as Wireshark were employed to capture and analyse data packets, including Address Resolution Protocol (ARP), Dynamic Host Configuration Protocol (DHCP), Domain Name System (DNS), Multicast DNS (mDNS), as well as traffic related to the Real-Time Publish–Subscribe (RTPS) protocol. These works demonstrated the effectiveness of network-level monitoring in exposing communication behaviors within ROS-based systems and highlighted

interoperability considerations at the middleware layer. However, their analysis largely remained at the level of traffic observation and protocol identification, without extending to an evaluation of how such observable communications could be exploited or how they might affect robots during active operation. For instance, the potential impact of network-level vulnerabilities on robots performing active tasks such as sensing, navigation, or service delivery was not investigated. In particular, the implications of reconnaissance and passive observation attacks on robots operating over shared or public networks remain unexplored.

Furthermore, a common pattern emerges i.e. regardless of the robot's specific application, whether collecting environmental data in a corridor or delivering goods within a neighborhood the underlying system architecture remains predominantly consistent. This architectural similarity implies comparable attack surfaces, especially at the network and middleware layers. Nevertheless, prior research has only partially examined these shared vulnerabilities, stopping short of evaluating their significance in operational service robot deployments. Accordingly, a representative network-based reconnaissance scenario involving a service robot system is included in the methodology section to contextualize the discussion. Notably, no prior study has systematically quantified the specific types of sensitive operational data that can be passively extracted during an active reconnaissance phase targeting a ROS2-based service robot.

3 Methodology

The main goal of this study is to evaluate network level vulnerabilities in ROS2 based service robots by combining middleware level monitoring with operational use-case validation. Figure 2 illustrates the overall methodology, designed to address the critical gaps identified in sections 2.1, 2.2 and 2.3. The methodology is structured into four main steps as described below. Step 3.1 describes the experimental environment and the tools required to conduct the study. Step 3.2 focuses on standard reconnaissance scenario, detailing the tools used and the validation process to determine the type of observational data that can be collected. Building on this, Step 3.3 applies the approach to a specific use case i.e. robot position monitoring in ROS2 using Fast DDS Spy to assess how the observations translate into practical insights. Finally, Step 3.4 synthesizes and analyzes the additional operational data collected across the experiments, highlighting the implications for system security and exposing potential attack surfaces. Together, these steps form a cohesive framework that combines controlled experimentation, scenario-based evaluation, and operational analysis, enabling a comprehensive assessment of network-level behaviors in ROS2 service robots.

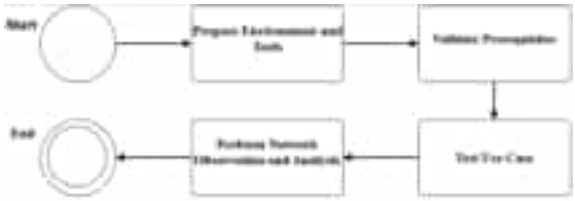

Figure 2: Methodology Diagram

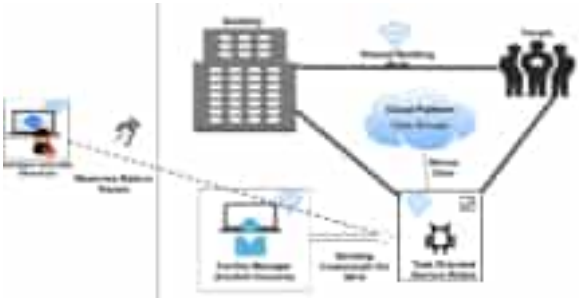
3.1 Prepare Environment and Tools



The experimental setup used Ubuntu 24.04 LTS as the host operating system, ROS2 humble as the robotic framework. To analyze communication at the middleware and network layers, multiple diagnostic tools were employed. Fast DDS spy was used on the Ubuntu system to monitor and inspect Data Distribution Service (DDS) communication between ROS2 nodes, enabling visibility into topic discovery and messages exchange at the middleware level. To capture those packets, a software tool called wireshark was executed on a separate windows-based host to capture and analyze network traffic across different machines, supporting cross-host packet-level inspection. For simulation-based evaluation and validation, the Webots 3D robot simulator was used to provide a physics-based virtual environment for modeling, programming, and testing robotic systems. In addition, Turtlebot3 platform was utilized to asses navigation, sensing, and control behaviors under realistic operational conditions. Together, these tools provided a practical setup for simulation and analysis within ROS2 systems.

3.2 Validate Prerequisites

Figure 3 depicts a task-oriented service robot operating within an open wireless network (e.g., Wi-Fi), where it communicates bidirectionally with human operators and smart building infrastructure to support routine operational functions. Such communication may include status updates, sensor data exchange, and control or coordination messages required for normal robot operation. The figure also introduces a potential intruder (left) who gains physical access to the building premises and comes into proximity of the service robot. Without interacting directly with the robot or its control systems, the intruder passively monitors the network by running standard diagnostic tools, such as Wireshark, on the same wireless network. Through this passive observation, the intruder can capture and inspect network traffic associated with the robot's ongoing operations, thereby gaining visibility into various forms of operational and communication data. For the purposes of this study, the attacker is assumed to be an external, unprivileged individual with no prior knowledge of the target system's

architecture or credentials. The attacker is assumed to have physical proximity to the shared wireless network and is equipped only with standard, publicly available diagnostic tools. No active interaction with the robot or its control systems is assumed, confining the threat model to passive network observation consistent with a reconnaissance-phase adversary.

Figure 3: Overview of the network-based reconnaissance

targeting of a task oriented service robot operating in built environment

The scenario depicted in Figure 3 is validated using a controlled experimental environment with a limited set of tools. The validation setup consisted of an Ubuntu 24.04 LTS system running ROS2 with the default DDS middleware, Fast DDS (Fast RTPS), complemented by a Windows host system running Wireshark for capturing and analyzing network traffic. This setup enables observation of operational communications in a controlled manner while reflecting the reconnaissance scenario introduced earlier. Three terminal sessions were opened within the Ubuntu environment. The first session was used to source the ROS2 environment, while the second and third sessions were used to execute ROS2 publisher and subscriber nodes, respectively. ROS2 communication was generated. The execution of these nodes resulted in continuous RTPS communication over user datagram protocol (UDP) using the Fast DDS middleware. Simultaneously, Wireshark was used to capture network traffic on the active network interface, where RTPS packets corresponding to ROS2 communication were successfully observed and identified. This validation confirms that ROS2 DDS based communication can be passively captured and analyzed at the network level using standard packet inspection tools. That is, RTPS traffic generated by ROS2 nodes was captured using Wireshark on the host system by monitoring the shared network interface of the virtualized Ubuntu environment.

Figure 4 illustrates a Wireshark capture of RTPS traffic generated by a ROS2 system using the Fast DDS middleware. The capture shows multiple RTPS packets exchanged over UDP between a ROS2 participant and a multicast destination address. The packets are identified as RTPS data messages, including INFO_TS and DATA sub messages, which are characteristic of DDS based communication. For example, this RTPS packet exchange corresponds to a service robot operating in built environment publishing laser scan data on /scan (similarly odometry and velocity commands).

Figure 4: Captured RTPS traffic from a ROS2 system observed using Wireshark

The source IP address (192.168.1.38) corresponds to a ROS2 node within the system, while the destination address (239.255.0.1) indicates multicast communication used for DDS participant discovery and data dissemination. The transport layer is UDP, with the destination port set to 7400, which is the default port range used by DDS/RTPS. The packet lengths range between approximately 500 to 600 bytes, reflecting periodic data exchange between ROS2 nodes. For instance, DDS multicast communication compromises the robot's real-time position and sensor state (e.g., door access). The consistent timing and repetition of packets demonstrate continuous publisher–subscriber communication, confirming active ROS2 node interaction over the network.

From the captured RTPS traffic, several key reconnaissance insights were obtained through active network monitoring. The analysis revealed critical communication details, including the source and destination IP addresses, as well as the corresponding source and destination ports used by ROS2 nodes. These observations expose the internal network structure and confirm the use of multicast-based communication for data distribution [15]. Furthermore, the protocol and packet characteristics allows the identification of the DDS middleware in use, which in this setup was eProsima Fast DDS. In addition, application layer information embedded withing the RTPS traffic discloses the username of the source system account from which the ros2 nodes were executed. Interestingly, these findings also demonstrate that, even without active interaction, an external observer can extract sensitive system and operational details during the reconnaissance phase, highlighting the exposure present when DDS communication is left unencrypted. Building upon the observed and validated ability to passively capture RTPS traffic, the subsequent phase of this study examines what

additional operational information can be obtained during reconnaissance usingaxz standard tools and configurations.

3.3 Test Use Case

Robot position monitoring in ROS2 via Fast DDS Spy is presented as a foundational and representative monitoring scenario for evaluating data exposure in DDS-based robotic systems. Access to a robot's positional data is critical because position information underpins core robotic functions such as navigation, task execution, collision avoidance, and interaction with the surrounding environment.

The base platform used was ROS2 Humble, with a custom python publisher node (publisher.py) that generates random robot positions at one second interval. The published topic was rt/robot_position with advanced features. The tools used in this experiment include: 1) ROS2 humble, serving as the foundational operating system 2) Fast DDS Spy with version 1.4.0 , a command line introspection tool developed by eProsima for discovering DDS entities such as participants, topics, writers, and readers, 3) Wireshark, a network traffic analyser utilized to capture RTPS packets, 4) Webots Simulator, and 5) TurtleBot3, both serving as robot simulators for generating motion data. The procedure for conducting this experiment is as follows: 1) Publisher Setup: A Python based ROS2 node was developed within the robot_position_publisher package to publish three dimensional coordinates (x, y, z) at a fixed frequency of 1 Hz on the rt/robot_position topic. The node generated randomized positional data to simulate real time robot movement, enabling subsequent monitoring and analysis. 2) ROS2 Workspace Setup: The ROS2 workspace was sourced and built using colcon build, ensuring that the robot_position_publisher package and its associated nodes were correctly recognized and accessible within the ROS2 environment. This setup facilitated seamless execution and integration of the publisher node into the DDS based communication network.

Continuous access to this data provides deep insight into a robot's movement patterns or operational behaviour. By observing positional data over time, an external entity can track where a robot is moving, infer routines, predict future locations, or identify areas of operational importance. This capability is particularly relevant for autonomous service robots operating across multiple locations, including smart buildings, hospitals, or industrial facilities, where positional awareness directly correlates with sensitive operational workflows. For example, during building audits or patrol operations, knowledge of robot trajectories may inadvertently reveal restricted zones, high-value assets, or confidential activities [5][16]. If such information is exposed without appropriate protection, it can enable targeted security, privacy, or safety-related attacks. In this study, robot position data is deliberately selected as a baseline DDS data stream to demonstrate non-intrusive monitoring within a ROS2 environment. The experiment focuses on capturing and analysing position updates published on DDS topics to verify real-time data flow, timing behaviour, or observability without interfering with system operation. While the implementation monitors three-dimensional coordinates (x, y, z) as a proof of concept, the same monitoring methodology is directly applicable to other operational DDS topics, including sensor readings, task states, navigation goals, or interactions with smart building infrastructure. As such, this scenario establishes a reusable framework for analyzing DDS-level data exposure beyond positional information alone.

3.4 Perform Network Observation and Analysis

The following observations were recorded, and the results are illustrated in the Figure 5 below and are explained in detail as follows.

Figure 5: Participants recorded by Fast DDS Spy

1) Participants: In the context of DDS and ROS2, a participant refers to a robot or software application actively engaged in network communication. Each participant is associated with a Globally Unique Identifier (GUID), which serves as a digital identifier to distinguish individual nodes or applications. For instance, a participant may have an ID such as 01.0f.ae.c2.03.75.b4.90.00.00.00.00, uniquely identifying that specific robot or program within the DDS domain.

2) Topics: Each line represents a topic discovered on the DDS network. rt/robot_position is the topic to which the Python publisher was publishing simulated robot positions, with type Point (from geometry_msgs). (1|0) indicates one DataWriter publishing while no DataReaders are subscribed. [0.780132 Hz] indicates the publishing frequency. Topics such as rt/parameter_events and rt/rosout are standard ROS2 topics for parameter updates and log messages.As shown in Figure 6, Fast DDS Spy monitored the DDS network as a passive introspection tool, discovering active

participants, topics, data writers, and data readers without impacting running nodes. This confirmed that the rt/robot_position topic was broadcasting successfully at 0.78 Hz.Analysis of the topics and participants highlights potential cybersecurity implications. For example, an inspection robot continuously collecting position and environmental data in a corridor could be passively observed by an external party, revealing the robot's location, movement patterns, planned paths, and sensor feeds without interfering with its normal operation. This study focuses on read-only access to evaluate how much operational detail can be inferred; data modification and write access are reserved for future research. This setup demonstrates the capability of Fast DDS Spy to audit ROS2 systems at the DDS middleware level, emphasizing the importance of securing communication infrastructure

3.4.1 Key Inferences

While the observability of unencrypted DDS traffic is broadly acknowledged in ROS2 documentation, this study advances beyond this general observation by systematically identifying and validating eight specific categories of sensitive operational data extractable through passive reconnaissance, demonstrating the practical extent of exposure in a realistic service robot deployment scenario. Using basic reconnaissance tools, it was possible to successfully observe and capture 8 forms of sensitive operational data from the ROS2 system. This included source and destination IP addresses, source and destination ports, user identity associated with the source system, the underlying DDS middleware in use, as well as DDS participants, ROS2 nodes, and active publisher nodes. These findings demonstrate that even limited, non-intrusive tools can reveal critical system and communication details without requiring authentication or direct interaction with the target robot. Such exposure highlights a significant attack surface, where reconnaissance alone can serve as an effective entry point for subsequent attack phases, including command-and-control (C2) based attacks.

4 Conclusions, Future work and Limitations

This study demonstrates that effective reconnaissance of a ROS2-based robotic system is feasible using a minimal set of passive, non-intrusive tools when the attacker is positioned within the same network domain. By deploying Fast DDS Spy and Wireshark on a shared network, it was possible to discover DDS participants, enumerate active topics, and observe real-time robot telemetry without modifying the target system or requiring authentication. Through this process, eight distinct types of operational data were identified, including positional information transmitted over the rt/robot_position topic. The conclusions are strictly confined to the reconnaissance phase; references to subsequent attack phases such as C2, spoofing, and man-in-the-middle attacks are intended solely to contextualize reconnaissance as a precursor and do not form part of the claims of this study. Future work will extend beyond reconnaissance to evaluate C2 feasibility, focusing on correlating velocity and positional data to reconstruct full motion trajectories in real time, enabling a deeper assessment of integrity and availability risks [18][19]. Further research will explore active attack techniques including man-in-the-middle attacks, message replay, and topic spoofing, as well as mitigation strategies such as DDS-Security, network segmentation, and secure ROS2 configurations. Practitioners are advised to enable DDS-Security plugins, restrict DDS domain IDs, and isolate robotic systems from shared networks as immediate best practices. While Fast DDS Spy proved effective for passive discovery and monitoring, the experiment has several limitations. First, the tool operates only with DDS implementations compatible with eProsima Fast DDS and relies on default ROS2 middleware configurations. The experiments were conducted exclusively using Fast DDS, which was selected based on its status as the default ROS2 middleware and its prevalence in the reviewed literature. Whether alternative DDS implementations such as Cyclone DDS exhibit different reconnaissance behaviors under similar conditions remains an open question and is identified as a direction for future investigation. Furthermore, the experimental scope was intentionally limited to default ROS2 configurations, reflecting the most commonly encountered real-world deployment conditions. A comparative evaluation between default and security-enabled DDS configurations is recognized as an important direction and is explicitly identified as part of the planned future work.Systems using alternative DDS vendors, customized discovery settings, or secured DDS (DDS Security) profiles may not be fully observable using this approach[20]. Second, Fast DDS Spy is primarily an introspection tool and does not natively support message manipulation or injection, limiting its use to reconnaissance rather than active exploitation. The experiment also focused on positional data only and did not evaluate the impact of QoS policies, encryption, authentication, or access control mechanisms

that may be present in hardened deployments. Finally, the experimental setup was conducted in a controlled environment, and real-world conditions such as packet loss, network segmentation, or intrusion detection systems were not considered. Performance-related metrics such as data rates and traffic patterns fall outside the scope of this reconnaissance-focused study and are reserved for future work.

Abstract -

Unobserved worker motions on active construction jobsites contribute to injuries, near-misses, and productivity loss; however, continuous monitoring remains difficult under real deployment constraints. This study presents a real-time worker activity monitoring framework that integrates lightweight Temporal Convolutional Networks (TCN) with wearable sensing and zone-level localization to enable continuous and deployable behavior monitoring. The proposed system employs a three-IMU configuration mounted on the wrist, neck, and back to capture complementary upper-body motion while maintaining compatibility with personal protective equipment. Each sensor streams six-axis inertial data at 50 Hz and performs sliding-window inference using a TCN architecture with dilated causal one-dimensional convolutions and residual connections, supporting low-latency and memory-efficient processing suitable for edge deployment. Task-relevant construction activities are recognized using anatomically grounded motion patterns without relying on vision-based monitoring. To incorporate spatial context, Bluetooth Low Energy beacons provide RSSI-based zone localization that is temporally smoothed and synchronized with activity predictions to generate unified "what-and-where" behavioral labels. The framework is validated through a real factory deployment, demonstrating robust performance under occlusion, signal interference, and natural task variability. Results show that the system achieves reliable real-time inference with average accuracies of 76.28% at the motion level and 78.62% at the activity level, supporting scalable and privacy-preserving activity analytics in real construction environments. The field deployment further identifies key operational challenges, including sensor placement tradeoffs, signal occlusion effects, and user comfort constraints—and provides practical implementation guidelines for wearable monitoring systems in construction environments

1 Introduction

Construction jobsites continue to experience injuries, near-misses, and productivity losses caused by unsafe or inefficient worker actions that often remain unobserved. Supervisors are typically responsible for monitoring multiple crews across dynamic work zones, making continuous observation difficult and limiting the ability to provide timely interventions. Although automated monitoring systems have been widely explored, many remain challenging to deploy in real construction environments due to occlusion, privacy concerns, infrastructure requirements, and operational disruptions.

Wearable sensing has emerged as a promising alternative for continuous worker monitoring because it is less sensitive to environmental visibility constraints and better supports privacy-preserving data collection. However, practical field deployment requires balancing recognition performance with usability, latency, and robustness. Many existing wearable monitoring approaches rely on dense sensor configurations or non-causal inference pipelines, which increase worker burden, computational requirements, and system complexity, thereby limiting adoption on active jobsites. To address these challenges, this study adopts a lightweight wearable configuration consisting of three sensing devices and applies a causal Temporal Convolutional Network (TCN) to enable low-latency motion recognition suitable for real-time edge deployment.

While motion recognition provides valuable behavioral information, it offers limited situational awareness without spatial context. Understanding where worker actions occur is critical for safety monitoring, task compliance evaluation, and productivity assessment. To provide this contextual information, the proposed framework integrates motion recognition with zone-level localization, enabling simultaneous interpretation of worker activities and spatial positioning.

This paper presents the first field-evaluated wearable

framework that tightly integrates causal TCN-based motion recognition with BLE zone-level localization into a unified real-time behavioral monitoring pipeline, validated on an active construction site with professional workers performing real installation tasks. The system is evaluated through laboratory testing and a real-world field case study to assess deployment feasibility and operational performance under realistic construction conditions. Rather than focusing on algorithmic development, this study emphasizes deployment-oriented evaluation through field implementation. Specifically, this case study investigates: (1) the minimum wearable sensor configuration that maintains monitoring performance while remaining acceptable to workers, (2) the reliability of activity recognition under uncontrolled field variability, including task transitions and signal noise, (3) deployment barriers that emerge during continuous real-time monitoring, and (4) stakeholder perceptions regarding the usefulness and usability of integrated activity and localization monitoring systems.

2 Literature Review

2.1 IMU based Human Motion Recognition

Wearable IMU-based motion recognition has been widely studied due to its robustness to visual occlusion and independence from environmental lighting conditions [1, 2]. High recognition accuracy has been reported in controlled laboratory settings, often using multiple IMUs distributed across the body [3, 4]. Kim and Cho [5] demonstrated automatic recognition of highway construction worker motions using wearable inertial sensors and Long Short-Term Memory (LSTM) networks, highlighting the effectiveness of deep sequence models for construction activity recognition.

Despite these advances, dense sensor configurations introduce challenges for field deployment, including increased setup time, user discomfort, interference with personal protective equipment, and maintenance overhead. To reduce sensing burden, prior studies have explored sparse sensor configurations or upper-body placements [3]. While these approaches improve usability, they often exhibit reduced robustness under natural task variability, motion transitions, and inter-subject differences. Most wearable sensing research remains laboratory validated, with limited reporting of long-duration field deployment outcomes.

In addition, many deep learning-based motion recognition methods rely on long temporal windows, non-causal inference, or offline post-processing [6]. These assumptions limit applicability for real-time field deployment, where bounded latency and causal operation are required. These gaps motivate the development of motion recognition systems designed explicitly for continuous on-site operation using minimal wearable instrumentation.

2.2 BLE-based Localization

Bluetooth Low Energy (BLE) beacon systems have been widely adopted for indoor localization due to their low infrastructure cost and deployment flexibility [7]. In construction and industrial environments, BLE-based approaches offer advantages where fixed camera systems or dense infrastructure are impractical. However, RSSI-based distance estimation is sensitive to multipath effects, body shadowing, and environmental interference [8], which are common on active jobsites.

As a result, many studies favor zone-level localization rather than high-precision tracking, using calibration and temporal filtering to improve robustness [7]. Zone-level localization aligns well with safety and productivity applications, where presence within a designated work area is often sufficient. Despite this, BLE localization is frequently evaluated independently of activity recognition systems, limiting its ability to provide actionable behavioral context. Integrating localization with motion recognition remains an open challenge for field-ready worker monitoring.

2.3 Construction Productivity

Construction productivity and safety research increasingly emphasizes the need for continuous and scalable monitoring systems [9]. Vision-based approaches provide rich contextual data but face persistent deployment barriers related to occlusion, privacy concerns, and maintenance in dynamic environments [10]. Wearable-based systems address these challenges but often focus on either motion recognition or localization rather than their integration.

Recent work highlights that actionable field monitoring requires joint understanding of worker actions and spatial context [11]. Knowing what motion is being performed and where it occurs enables zone-specific risk assessment, task compliance monitoring, and productivity analysis. However, many existing systems remain confined to laboratory validation or depend on complex sensing and computation that are difficult to sustain in the field. There remains a gap for field-ready frameworks that integrate lightweight motion recognition, practical localization, and real-time visualization while operating under realistic deployment constraints.

3 Methodology

The system is designed as two components: (1) IMU-based Motion Recognition, (2) BLE-based Localization. Each Personal Protection Unit (PPU) embeds one IMU and a Bluetooth signal receiver within a single microcontroller-based device, and workers are equipped with three PPUs to enable distributed motion and localization sensing.

Figure 1. TCN Network Inference Pipeline

3.1 Motion Recognition

As illustrated in Figure 1, the motion recognition module performs real-time inference using a three-device wearable configuration. Three PPUs are mounted on the wrist, rear neck, and lower back to capture complementary distal and proximal body movements while remaining compatible with personal protective equipment. Each PPU integrates a 9-axis IMU consisting of an accelerometer, gyroscope, and magnetometer. Prior to deployment, the accelerometer and magnetometer are calibrated to correct hard-iron and soft-iron distortions by rotating the IMU along a spherical trajectory and fitting the sampled data to a sphere, yielding offset parameters and a correction matrix. The gyroscope is calibrated by averaging 500 stationary samples and subtracting the resulting bias from subsequent measurements. Although each IMU provides nine-axis data, only six-axis inertial measurements from the accelerometer and gyroscope are streamed at 50 Hz for inference, while magnetometer channels are excluded due to magnetic interference commonly encountered near steel structures and powered equipment on construction sites.

IMU streams are segmented into short sliding windows to bound latency and memory usage. Each window is processed independently using channel-wise z-normalization to reduce inter-subject variation and sensitivity to mounting differences. This design avoids reliance on long-term state, which can drift during extended field deployment, and preserves responsiveness during motion transitions.

A Temporal Convolutional Network (TCN) is used as the core recognition model. The network consists of three dilated residual blocks with 64, 64, and 128 channels, a kernel size of 5, and dilation rates of 1, 2, and 4. Input windows span 100 samples (approximately 2s at 50 Hz). All convolutions are causal, and predictions depend only on past samples within each window. No future frames, bidirectional context, or offline smoothing are used. Causality is enforced through right padding and truncation, ensuring consistent alignment between input windows and output predictions. This structure enables parallel computation and predictable inference time suitable for edge deployment.

The TCN outputs per-window motion probabilities, and a lightweight temporal smoothing step is applied over recent outputs to stabilize predictions during short transitions. This smoothing operates only on past predictions and introduces no look-ahead latency. The resulting pipeline achieves reliable real-time motion recognition while balancing accuracy, responsiveness, and deployability for field use.

3.2 Training Configuration

Model training and evaluation follow the protocol established in prior work to balance recognition performance and deployment practicality. IMU data are segmented into short sliding windows and processed using identical preprocessing across all experiments. Two training strategies are evaluated: a fixed single-split configuration with an 80:20 train/test split, and a leave-one-subject-out (LOSO) configuration for cross-subject generalization analysis. All models use the same Temporal Convolutional Network architecture, windowing parameters, and optimization settings so that observed differences reflect only sensor combinations and training strategies.

Seven sensor combinations are evaluated, as summarized in Table 1, including single-IMU, dual-IMU, and tri-IMU configurations. In-lab results indicate that multi-sensor configurations consistently outperform single-sensor setups. The wrist provides strong discriminative cues for upper-limb motion, while the neck and back contribute complementary proximal information. Among all tested configurations, the Neck+Back+Wrist (NBW) combination achieves the most stable performance across accuracy and F1 metrics in repeated in-lab inference trials. Although certain dual-sensor configurations achieve comparable peak accuracy, the NBW configuration demonstrates greater robustness during motion transitions and sustained operation.

Based on these results, the single-split (8:2) model trained with the NBW sensor combination is selected for the real-world case study described in Section 4. The single-split model is chosen over the LOSO model because

Table 1. Combinations and Lab Test Results

ID	Selected IMUs	Acc.	ID	Selected IMUs	Acc.
1	Neck+Back+Wrist (NBW)	0.8326	5	Neck (N)	0.7720
2	Neck+Back (NB)	0.7785	6	Back (B)	0.6878
3	Neck+Wrist (NW)	0.8353	7	Wrist (W)	0.7363
4	Back+Wrist (BW)	0.7926			

the case study evaluates continuous system performance under a fixed deployment setup rather than cross-subject generalization. This selection prioritizes temporal stability and real-time inference reliability, which are critical for evaluating system behavior during live monitoring in a factory environment.

3.3 Zone-Level Localization

Zone-level localization is implemented using commercial BC04P Bluetooth Low Energy (BLE) beacons deployed across the worksite. All beacons operate with identical advertising frequency and transmission intervals to maintain consistent signal behavior across zones. Transmit power is adjusted based on beacon placement height to balance coverage and signal stability. Beacons placed near floor level are configured at low transmit power (-16 dBm) to limit signal overlap and reduce multipath effects. Beacons mounted on ceilings higher than 10 ft are configured at higher transmit power, up to +4 dBm, to ensure adequate coverage across open work areas. The selected transmission settings also ensure long operational stability, with beacon battery life exceeding six months under the configured test conditions and extending beyond one year when operating at minimum transmit power.

Each wearable PPU continuously scans for BLE advertisements and records received signal strength indicator (RSSI) values from nearby beacons. Relative distances to beacons are estimated using a calibrated RSSI-to-distance model established during site configuration. To improve distance estimation accuracy, the PPUs apply an environment-specific signal propagation constant in the log-distance path loss model, which characterizes indoor attenuation conditions. This constant is determined experimentally by measuring RSSI values at multiple known distances from each beacon prior to deployment and typically ranges between 2 and 3 for indoor environments. The calibrated distance estimates are combined with known beacon coordinates defined on a preconfigured worksite map, and the PPU computes its instantaneous planar position (x_i, y_i) at each sampling step. Localization is performed at the zone level rather than high-precision tracking to reduce sensitivity to short-term RSSI fluctuations while remaining sufficient for safety and productivity analysis.

To improve robustness against signal noise, body shadowing, and transient interference, raw position estimates are temporally smoothed on the server side using a weighted averaging scheme. Let (x_i, y_i) denote the estimated planar position at time step i within a sliding window of length $N = 10$. Each estimate is assigned a confidence weight w_i derived from the corresponding BLE signal quality, such as normalized RSSI magnitude or beacon visibility count. The displayed position $(\bar{x}, \bar{y})$ is computed as:

$$\bar{x} = \frac{\sum_{i=1}^{N} w_i x_i}{\sum_{i=1}^{N} w_i}, \qquad \bar{y} = \frac{\sum_{i=1}^{N} w_i y_i}{\sum_{i=1}^{N} w_i} \tag{1}$$

This weighted averaging reduces the influence of low-confidence measurements while preserving responsiveness suitable for real-time visualization.

The resulting localization output is used to support higher-level site analytics. First, worker positions are compared against predefined work zone boundaries to determine whether a worker remains within assigned task areas or enters unauthorized zones. This enables detection of potential safety violations and unintended access. Second, temporal changes in estimated position are used to quantify travel distance and dwell time. By correlating movement distance with recognized motion labels, the system distinguishes between walking-intensive tasks and stationary work patterns. This joint interpretation of spatial displacement and motion recognition provides additional context for assessing task compliance and productivity without requiring fine-grained positioning accuracy.

4 Case Study

A case study was conducted at a warehouse construction site for window and door installation in Atlanta, Georgia, USA.

4.1 Data Collection for Feasibility Study

The case study was conducted at an indoor showroom construction site. At the time of deployment, major structural elements such as drywall partitions had already been installed, while interior construction activities were ongoing. Compared to large-scale building projects, the site covered a relatively small area with multiple workers operating in close proximity and dense wall structures, creating constrained movement paths and frequent line-of-sight interruptions. On the test date, workers were engaged in glass wall and door installation. Other tasks such as painting and silicone moulding were present, but the door installation team was selected because their work involved more dynamic and varied movements.

A floor map of the site was manually generated using laser-based distance measurements to define work zones

and beacon locations. The environment included reinforced concrete walls and large metallic components that were frequently repositioned during installation, introducing potential signal obstruction and multipath interference. This setup provided a realistic and moderately challenging indoor environment for evaluating zone-level localization performance.

Figure 2. Workers wearing PPUs during work

4.2 Case Study Description

Three workers participated in the study, all of whom were professional contractors employed by Stellar W&D. Two participants served as test subjects for the case study evaluation, while data from the third participant were collected to support further refinement of the training model. All participants were right-handed and performed collaborative tasks related to glass wall and door installation. Each worker was equipped with three Personal Protection Units (PPUs) mounted on the rear neck, lower back, and right wrist, as illustrated in Figure 2. Each PPU integrates an ICM-20948 IMU. The wrist unit measures approximately 80mm in diameter and weighs under 100g including the battery, with a continuous operating life exceeding 4 hours at the configured 50 Hz streaming rate. Seven beacons were selected based on site geometry and empirical calibration to achieve full coverage of the installation work zone while minimizing signal overlap between adjacent zones.

The total study duration was 2 hours and 13 minutes. Seven Bluetooth Low Energy (BLE) beacons were deployed across the test site at floor level with transmit power 16dBm and advertising interval of 100ms, as shown in Figure 3, where blue markers indicate beacon locations. Four fixed cameras were installed to capture the full work process. These recordings were used solely for offline annotation and ground truth labeling of worker motions to support accuracy analysis and evaluation of the recognition model.

5 Result

5.1 Deployment Feasibility

Qualitative feedback was collected through interviews with a workers who wore the PPUs during the case study to assess wearability and potential interference with daily tasks. The participant reported that the PPUs mounted on the back and neck using clip attachments did not interfere with work activities. However, the wrist-mounted PPU was perceived as slightly bulky during tasks involving frequent wrist motion, such as hammering. The participant suggested that reducing the device size to approximately 50mm in diameter could further improve comfort and usability.

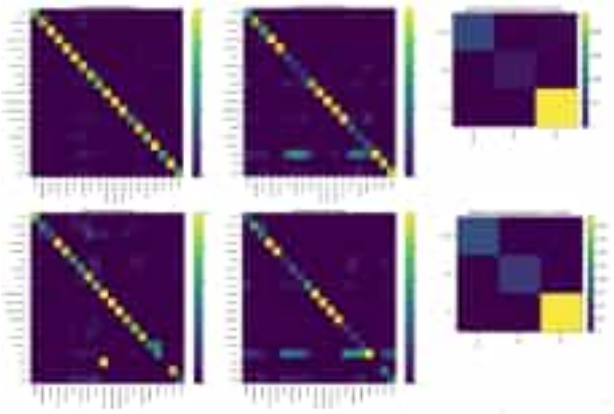

Figure 3. Worker 1 and 2 Confusion Matrices

In addition, the real-time worker localization and motion recognition interface was demonstrated to the site business owner to obtain feedback on practical value. The owner indicated that the combined presentation of worker location and motion provided meaningful insight for managing productivity and manpower allocation. In particular, the ability to observe where workers are located and what they are performing was identified as useful for task assignment and future planning. The owner also expressed interest in incorporating walking distance and task-specific activity distribution as additional indicators for more comprehensive productivity monitoring.

5.2 Feature Accuracy

Motion-level performance analysis was conducted using recognition data obtained from the pretrained Temporal Convolutional Network (TCN) model developed through in-lab data acquisition. The model was trained and validated under scripted laboratory scenarios, where in-lab inference tests achieved an average accuracy of 83.26%. This pretrained model was then deployed without modification during the case study to evaluate its feasibility and reliability under real field conditions.

Figure 3 presents confusion matrices for the case study results, with the top row corresponding to Worker 1 and the bottom row corresponding to Worker 2. The left column shows row-normalized confusion matrices, which reflect recall-oriented behavior by indicating how true motion classes are confused by the model. The middle column shows column-normalized confusion matrices, which emphasize precision by indicating how often predicted classes are correct. The right column presents joint-level accuracy, where shoulder- and elbow-related motions are concatenated to evaluate whether the model correctly identifies the active joint rather than the exact motion subtype. This analysis was performed to assess robustness under uncontrolled site conditions, which differ substantially from structured laboratory settings. The resulting motion-level accuracy shown in Table 2 was 75.86% for Worker 1 and 76.70% for Worker 2, demonstrating stable performance and supporting the feasibility of deploying the model on active construction sites. The lower F1 observed for Worker 1 is primarily attributed to the lab-to-field domain gap and a task composition dominated by overhead hammering sequences, which involve coupled elbow and shoulder motions that are historically the most confused class pair in training evaluation. Worker 2's higher F1 reflects a task distribution more consistent with the training set. Class-weighted training and domain adaptation are identified as direct future remedies.

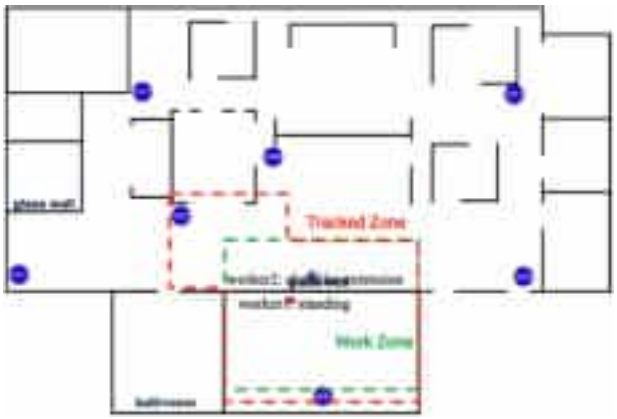

Figure 4. Work Zone and Tracked Zone Coverage

Activity-level accuracy was evaluated to examine the viability of the proposed method for assessing worker productivity in a more realistic setting. Activities performed during the test period were manually annotated, and each activity was defined as a sequence of constituent motion primitives, as illustrated in Figure 4. A recognized motion was considered correct if it corresponded to any motion primitive associated with the annotated activity at the given time frame. The resulting activity-level accuracy was 80.07% for Worker 1 and 77.16% for Worker 2, indicating that individual motion patterns influenced recognition performance while maintaining sufficiently high accuracy for practical productivity assessment.

Table 2. Motion/Activity Recognition Performance

Metric	Worker 1	Worker 2
Motion Level Accuracy	75.86%	76.70%
Motion F1-Score	0.5510	0.6401
Activity Level Accuracy	80.07%	77.16%

Figure 5. Task to Motion Breakdown

Localization performance was evaluated using area coverage as the primary metric. The designated work zone for the installation task covered approximately 774.8ft^2, while the area in which workers were visualized on the web-based interface covered approximately 563.5ft^2, as shown in Figure5 and Table3. Quantified localization error was not computed in this study as the primary objective was zone-level presence detection. The tracked area fully overlapped the defined work zone, resulting in 100% work zone coverage. However, approximately 27.27% of the tracked area corresponded to spatial estimates outside the intended zone. These inaccuracies are primarily attributed to variations in line-of-sight conditions between the wearable PPUs and nearby BLE beacons. For example, when a worker's body orientation obstructed direct signal paths, multiple PPUs occasionally received stronger RSSI measurements from an adjacent beacon, leading to temporary location estimates biased toward that beacon.

Table 3. Area Inspection Summary

Area Inspection	
Work Zone	$\approx$ 774.8 ft^2
Tracked Zone	$\approx$ 563.5 ft^2
Work Zone (WZ) Coverage	100%
WZ Portion	72.73%

6 Discussion

The case study evaluated the feasibility of deploying the proposed system under real field conditions and assessed its performance in real-time motion recognition and zone-level localization. Results indicate that the system can operate continuously in an active work environment using

a minimal wearable configuration and lightweight localization infrastructure. Motion-level predictions remained stable throughout the deployment, and zone-level localization provided consistent spatial context suitable for safety monitoring and preliminary productivity assessment.

Activity-level analysis was conducted through manual annotation of motion sequences rather than automated inference. Individual activities were identified by aggregating consecutive motion-level predictions based on visual inspection and task context. While this approach enabled initial evaluation of task execution under real field conditions, it does not scale and introduces subjectivity; developing automated activity aggregation from motion primitives is therefore a direct priority for future work. Furthermore, productivity assessment requires distinguishing work-related actions from idle or unrelated behaviors, which is not explicitly addressed at the motion level. Developing automated activity aggregation and work-behavior classification methods is therefore essential for scalable productivity analytics.

Several deployment lessons emerged from the field study. The three-PPU configuration successfully captured overall body motion patterns with acceptable accuracy; however, detecting fine-grained arm movements without a dedicated forearm sensor remains challenging. In such cases, upper-limb activity must be inferred indirectly from torso inclination and whole-body kinematics, which may reduce sensitivity for localized hand tasks. Worker compliance also affects the interpretation of productivity metrics. Natural behaviors such as standing, conversing, or checking mobile devices occur intermittently during work hours and must be separated from task-related actions to avoid overestimation of productive time. In addition, the case study was limited to three workers within a single task team, and activity-level analysis was manually annotated. Although feasibility was demonstrated, scalability claims refer to the lightweight system architecture rather than the current validation scope. Future work will extend deployment to multiple task types, larger worker groups, and varied site conditions to substantiate broader applicability. The current evaluation is limited to two workers, which precludes formal statistical comparison across worker profiles or task types; future work will expand the cohort size.

Based on observations from the field deployment, several practical recommendations are identified to support future implementation of the wearable IoT system in construction environments:

- Sensor Placement: Wrist-mounted IMUs provide strong discriminative information for upper-limb motion but may introduce minor comfort concerns during repetitive hand-intensive tasks. Neck and lower-back placements offer stable proximal motion signals with minimal interference to worker movement and personal protective equipment. Multi-location sensing improves robustness under natural task variability and motion transitions.

- Beacon Deployment: Zone-level localization can be achieved using low-power BLE beacons strategically positioned to reduce signal overlap. Floor-level placement improves zone discrimination in partitioned indoor environments but may introduce location bias due to line-of-sight obstruction. Elevated placement increases coverage in open spaces but may require additional installation effort. Beacon spacing and transmit power should be adapted to site geometry and obstruction conditions to maintain localization reliability.

- Calibration and Field Deployment: RSSI calibration and IMU calibration should be conducted during initial system setup to capture site-specific signal propagation characteristics and improve data accuracy. Periodic verification of signal quality is recommended to account for environmental changes, material interference, and body-shadowing effects that may arise during active construction. In addition, standardized worker onboarding and device fitting procedures should be established to ensure consistent sensor placement, maintain data reliability, and reduce variability caused by improper attachment.

7 Conclusion

This paper presented a field-evaluated wearable framework that integrates real-time motion recognition and zone-level localization to support continuous worker monitoring in construction environments. By combining a lightweight Temporal Convolutional Network with a reduced IMU configuration and BLE-based localization, the system demonstrated stable performance under real deployment conditions without relying on cameras or dense sensing infrastructure. Results from a factory case study showed reliable motion-level and activity-level recognition, as well as consistent spatial coverage suitable for safety and productivity analysis. While activity-level inference and productivity assessment were conducted manually in this study, the findings highlight the feasibility of the proposed framework and motivate future work on automated activity aggregation and work-related behavior classification. Overall, the results suggest that the proposed approach provides a practical foundation for scalable, privacy-preserving worker monitoring on active construction sites.

M.A.MosteiroRomero@tudelft.nl

Abstract -

A detailed understanding of the Urban Heat Island is crucial for energy efficiency, renewable integration, building system automation and demand response in district energy systems. Satellite images provide high resolution information about land surface temperatures (LST) at urban scale, but do not provide information about air temperature (AT), which affect energy performance and thermal comfort. This paper presents a methodology to estimate AT at urban scale for the case of Seoul, South Korea. A Multi-Layer Perceptron (MLP) neural network was developed to convert satellite-derived LST to AT using 12 years of satellite imagery and air temperature measurements from local automatic weather stations (AWS). The method is then independently tested by comparing the predicted temperatures to the measurements from 1000+ distributed "Seoul Data of Things" (S-DoT) sensors in the city. The model was found to achieve an R^2 value of 0.968 during validation using the AWS data from the period 2013–2024. The mean difference during the independent testing was 0.98°C, with an R^2 of 0.807, confirming the model successfully predicts actual air temperatures rather than sensor-specific values.

Keywords -

Urban Heat Island; Air Temperature; Remote Sensing; Multi-Layer Perceptrons

1 Introduction

Rapid urbanization and industrialization have intensified the challenges posed by global warming. As population in cities increases, urban areas have become significant contributors to greenhouse gas emissions while simultaneously experiencing the adverse effects of climate change. Among these effects, the increased air temperature of a city compared to the surrounding rural area, known as the Urban Heat Island (UHI) [1], exacerbates global warming by amplifying energy demands and deteriorating air quality.

A detailed understanding of the UHI in urban areas is crucial for urban planning decisions to support both energy efficiency [2] and renewable integration [3] As urban temperatures increase, space cooling demand increases, with implications on the design and operation of buildings and energy systems. Effective building automation and demand response in district energy systems require accurate load forecasting, where a detailed understanding of the expected air temperatures during operation is crucial. In spite of the considerable effects of the urban environment on local air temperatures, such data is rarely available at sufficient spatial resolution, creating a gap between climate analysis and practical urban energy applications.

1.1 Measuring the UHI

The most direct way to measure the UHI is through weather stations that record air temperature at standard heights within the urban canopy, from ground level to the tops of trees and buildings [4]. However, weather stations have limited spatial coverage, while the effects of the urban climate can be highly localized based on street layout and building materials. Another solution is adding low-cost weather sensors. For example, Schatz and Kucharik [5] installed 150 temperature and humidity sensors at 3.5 meters height on streetlights and utility poles in Madison, USA, to capture fine-scale temperature variations.

One of the most widely used methods for obtaining precise temperature data in UHI studies is using satellite imagery. Satellite imagery can provide a very high spatial coverage of urban land surface temperatures by measuring thermal radiation from surfaces compared to weather stations. Thermal remote sensing has been used for decades to assess the UHI, to perform land cover classifications and in models of urban surface atmosphere exchange [4].

Ground-based weather stations, while providing accurate point measurements, typically offer sparse spatial coverage in urban areas, often one station per several square kilometers. This spatial limitation makes it challenging to capture the fine-scale temperature variations essential for understanding urban heat island effects and their relationships with UFEs at the building or neighborhood scale. Satellite thermal imagery offers complete spatial coverage at resolutions of 30-100m, providing temperature information for every pixel across entire cities. However, satellites

measure surface temperature rather than air temperature, necessitating conversion methods to obtain the air temperature values required for building energy analysis and human comfort assessment. Combining these data sources can offer the spatial completeness of satellite data while maintaining relevance to energy consumption patterns and urban planning applications.

1.2 Converting Land Surface Temperature to Air Temperature

The most fundamental approach to obtain urban-scale air temperature from satellite data involves simple linear regression between LST and air temperature [6]. Multiple linear regression (MLR) incorporates additional predictor variables beyond LST to improve accuracy [7]. Chen et al. [8] developed an enhanced empirical regression method that incorporated multiple predictors and achieved an average error within ±2.5K for 98% of weather stations. Another option is Regression Kriging (RK), which applies regression to establish relationships between temperature and auxiliary variables, and kriging to spatially interpolate based on their spatial structure. RK has been successfully implemented to generate temperature maps at high resolution [9]. However, it assumes linear relationships in trend, while temperatures have complicated non-linear relationships, making it infeasible to analyze detailed relationships [10].

Among machine learning methods, Random Forests (RF) have emerged as a powerful method for air temperature estimation [11]. The RF algorithm has a great ability to handle non-linear relationships and multiple variables, making it particularly suitable for complex urban environments. However, RF can create artificial spatial patterns due to its tree-based structure, which may be problematic for continuous temperature mapping. Also, RF significantly underestimates temperature extremes and struggles to recover finer scale spatial resolution.

Neural networks have also been successfully implemented. Choi et al. [12] used Artificial Neural Networks (ANN) and achieved high accuracy, though they noted that model performance is highly dependent on input variables and network architecture. Multi-Layer Perceptron (MLP) neural networks have shown superior performance for air temperature estimation, particularly in challenging conditions [13]. MLP can effectively combine LST with auxiliary variables like NDVI, elevation and solar angles to create comprehensive air temperature maps [7].

While more advanced algorithms and neural network architectures could be explored, MLP was selected in this work due to its robustness, lower data requirements and demonstrated performance in air temperature predictions. MLP produces smooth, continuous temperature surfaces by learning the underlying physical relationships between variables. MLP can capture the non-linear relationships between LST and air temperature that vary with surface types, time of day and weather conditions. The ability to integrate multiple input variables simultaneously is another key strength. MLPs work well with standard table-formatted data and do not need special data structures to perform effectively [14].

1.3 Scope of this paper

This paper presents an MLP-based methodology for the conversion of LSTs from satellite images to air temperatures at urban scale for energy planning and system operation. While many studies have examined the UHI effect and building energy consumption, several research gaps remain in current approaches. Most research analyzes these phenomena over short periods, missing long-term urban transformations and their cumulative impacts [15]. While Raj and Yun [16] analyzed surface UHI effect in Seoul over 20 years using remote sensing, they specifically focused on LST rather than air temperatures. Furthermore, few studies validate their models using independent, spatially dense sensor networks.

These limitations highlight the need for an integrated, long-term approach that can handle complex non-linear relationships while providing practical insights for urban planning. Long-term analysis capturing actual urban transformations, rather than static snapshots, is essential for understanding how development patterns influence environmental outcomes. In this context, this research aims to contribute to these gaps through: (1) the integration of long-term satellite and ground-based datasets over a 12-year period; (2) the use of independent high-density IoT sensor networks (S-DoT) for external validation; and (3) the demonstration of spatially continuous air temperature mapping suitable for urban energy applications. Thus, this research provides a first step towards a more detailed understanding of the UHI in Seoul and its effects on urban energy systems.

2 Methodology

The methodology employs a two-stage approach, as shown in Figure 1. Stage 1 focuses on training the MLP using 39 AWSs data as ground truth. Air temperature measurements at 11:12 AM from 2013 to 2024 are matched with the Landsat 8 overpass time. The MLP model learns the complex non-linear relationships between 4 input variables: Land Surface Temperature (LST), Normalized Difference Vegetation Index (NDVI), Digital Elevation Model (DEM) and Solar Zenith Angle (SZA), and the measured air temperature from AWSs. Stage 2 tests the trained model using independent data from over 1,100 S-DoT sensors across Seoul since 2021. This independent test-

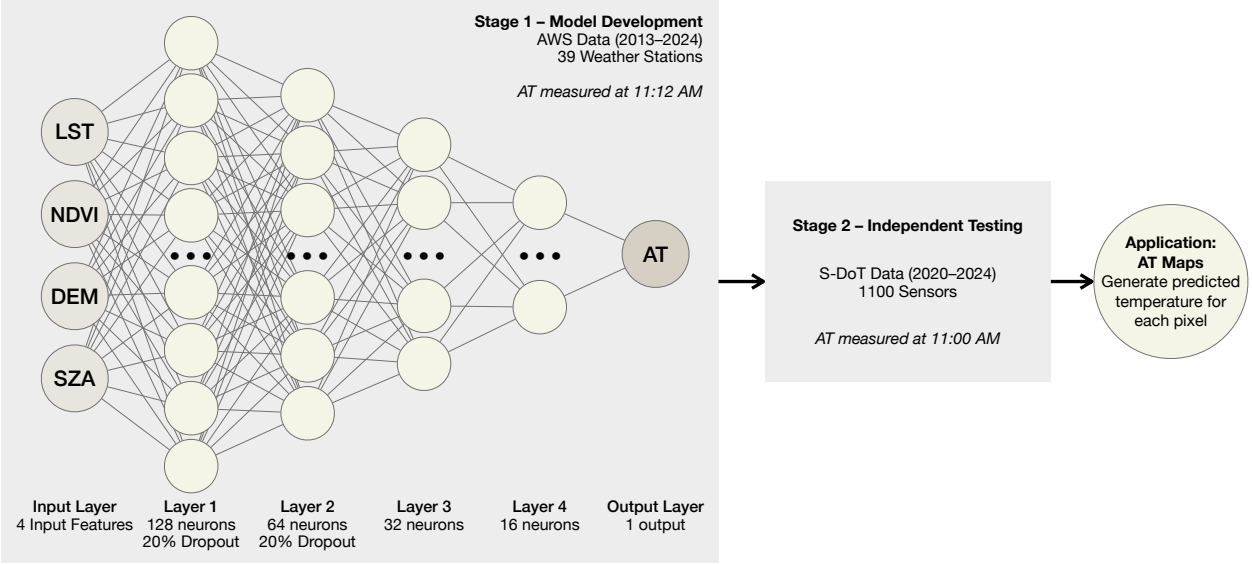

Figure 1. Model development and testing methodology showing the five-layer MLP architecture with dropouts

ing confirms the model's performance on a spatially dense network not used during training.

2.1 Data collection

2.1.1 Satellite data

This research uses Landsat 8 due to its extensive temporal coverage of over 10 years and high spatial resolution of 30 by 30 meters. From Landsat 8, the digital elevation model (DEM) and solar zenith angle (SZA) can be acquired, while LST and normalized difference vegetation index (NDVI) can be calculated using three spectral bands: Band 4 (red), Band 5 (near-infrared, NIR) and Band 10 (Thermal Infrared) [17]. This research uses Google Earth Engine to collect these bands and calculate the LST and NDVI of the research area.

Landsat 8 orbits the Earth every 16 days, which means that the satellite only captures the area 1 or 2 times per month. Seoul is captured at around 11:12 in the morning, which is close to the peak temperature in a day. This temporal limitation means that the model outputs consist of single monthly values derived from these satellite observations at their specific capture times rather than continuous temporal data.

Satellite images from Landsat 8 were collected from March 2013 (the first available month) to December 2024. During this period, 118 images were collected, however not all satellite images from Landsat are useful for temperature calculations. Satellite imagery is very vulnerable to cloud cover, which can obscure most of the land area. Thus, only images where the cloud coverage was less than 30% sky and the research area was fully visible were selected. When no suitable images were available within this threshold for specific time periods, the cloud coverage limit was incrementally increased if acceptable quality images could still be obtained. As a result, we were able to collect 7 valid images per year, which corresponded to 7 valid images per month over the 12-year period of study.

The input features for the MLP model are shown in Fig. 2. Land Surface Temperature (LST) serves as the primary input, providing thermal information measured by Landsat 8 bands at 11:12 AM. The Normalized Difference Vegetation Index (NDVI) represents vegetation greenness, which significantly affects the LST and air temperature relationship through the evapotranspiration process. NDVI values range from -1 to 1, with higher values indicating denser vegetation. The Digital Elevation Model (DEM) represents terrain elevation, affecting air temperature through the environmental lapse rate where temperature decreases approximately 6.5°C per 1000 m elevation gain. Elevation influences wind exposure and cold air pooling, making it an essential predictor for temperature estimation. Finally, the Solar Zenith Angle (SZA) represents the angle between the sun and the vertical direction, which determines the intensity of solar radiation. It influences the amount of solar radiation reaching the surface, affecting both LST and air temperature.

2.1.2 Weather data

The Korean Meteorological Administration (KMA) operates 554 automatic weather stations (AWSs) throughout the country that record air temperatures, wind speed, pressure and other climatic factors at subhourly scale [18]. Out of these, 28 AWSs are installed in Seoul, shown in Fig. 3. Although the spatial resolution of the AWS is low com-

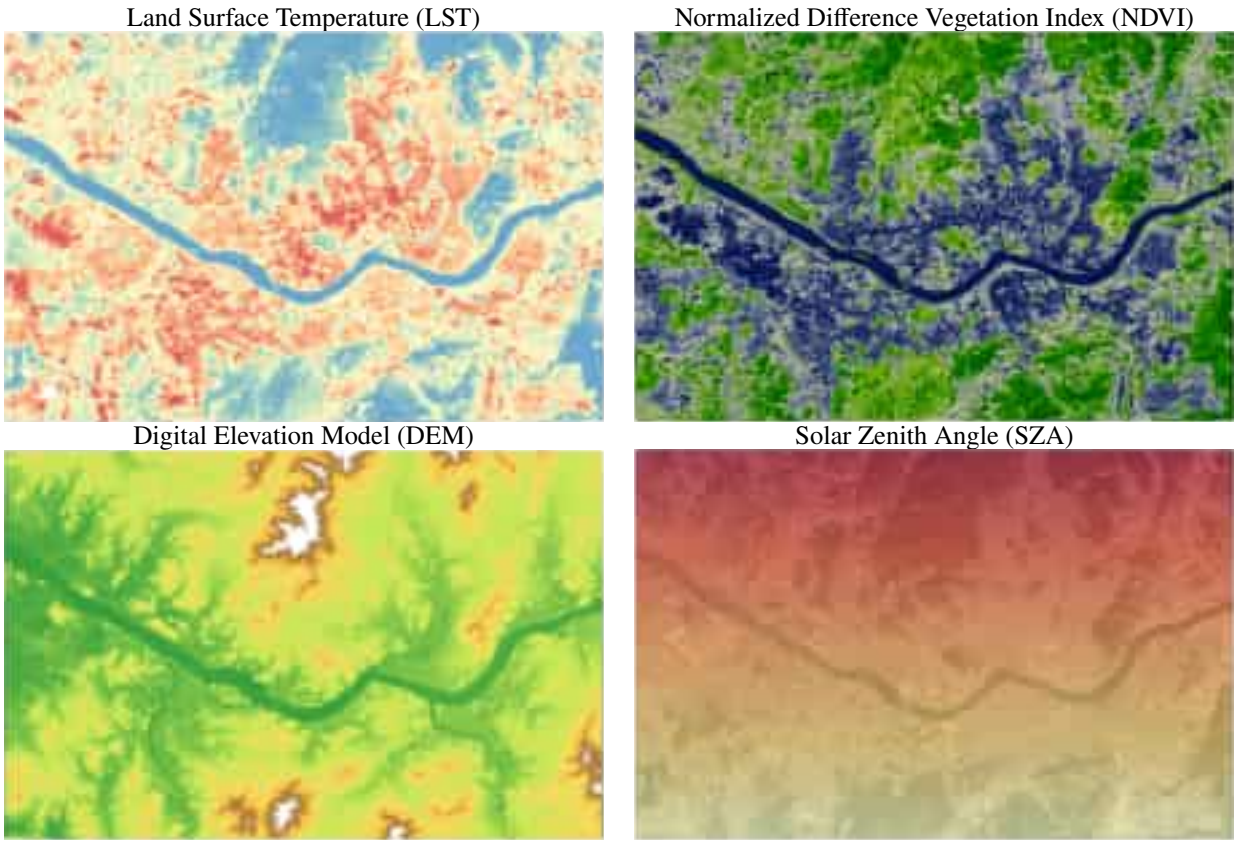

Figure 2. Examples of the four input features in the MLP model

pared to the satellite imagery (28 AWSs in Seoul, which has an area 605.25 km), it has a very high temporal resolution. This research additionally considers 9 AWSs near the Seoul border to increase spatial resolution.

In addition to these weather stations, the Korean government installed weather sensors in 2020 as part of an initiative called Seoul Data of Things (S-DoT). S-DoT is a city data sensor that collects various urban phenomena data, such as fine dust level, temperature, relative humidity, noise, illumination level, ultraviolet radiation, and other parameters at hourly scale [19]. As of 2024, 1159 sensors have been installed, as shown in Fig. 3.

2.2 Stage 1: MLP development

The MLP employs a four hidden layer architecture with an input layer of 4 features and an output layer that progressively reduces the number of neurons from input features to air temperature prediction. The choice of 128 neurons in the first hidden layer follows the common heuristic of having the first hidden layer size as a power of 2 between 2-5 times the number of inputs [20]. This architecture size has proven effective in similar atmospheric and environmental prediction tasks where the relationship between inputs and outputs involves multiple non-linear interactions [21].

Dropout is one of the most popular regularization methods for preventing neural network models from overfitting in the training phase [22]. 20% dropout is applied to the first 2 hidden layers. The Rectified Linear Unit (ReLU) activation function is used throughout the hidden layers. ReLU provides computational efficiency and addresses the vanishing gradient problem that affects traditional activation functions in deep networks [23]. The output layer employs linear activation, appropriate for continuous temperature prediction.

The MLP model follows the common 70-15-15 split for training, validation and testing sets [21]. The model's weights are updated during training using Adam optimizer, which adapts the learning rate for each weight individually and incorporates momentum, which helps the optimization process continue moving in productive directions and avoid getting stuck in local minima [24]. A learning rate of 0.001 is used in weight updates, which is a widely tested starting point that provides stable convergence for neural networks across various applications [25]. The model uses a batch size of 32, as it provides a sufficient gradient averaging to smooth out the randomness inherent in individual samples [26]. The model trains for a maximum of 200

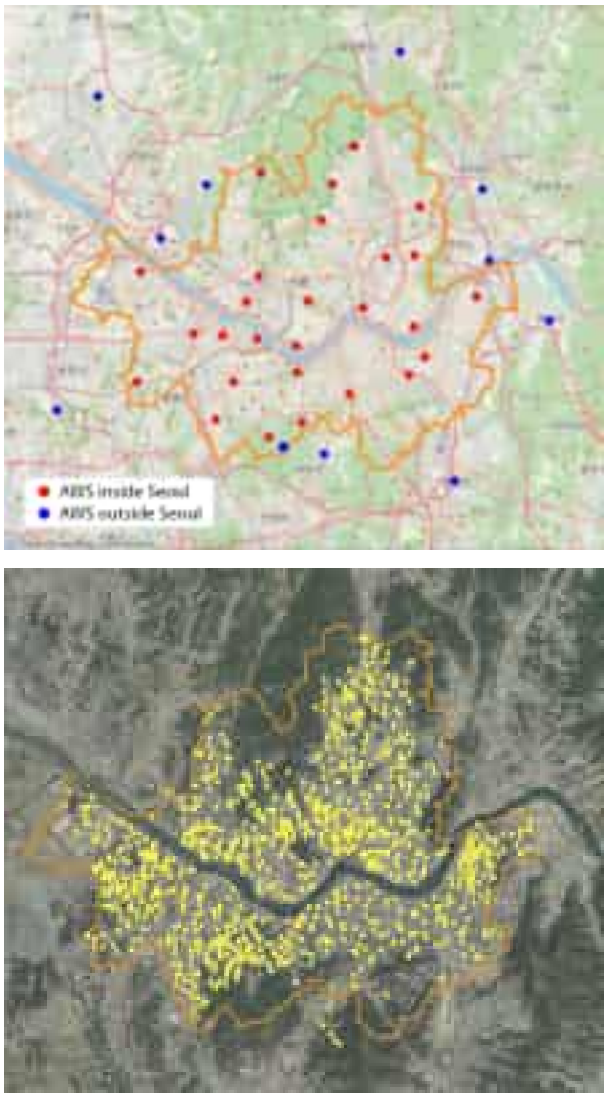

Figure 3. Location of AWS weather stations (top) and S-DoT sensors (bottom)

epochs, with an early stopping patience of 20 epochs to avoid overfitting.

2.3 Stage 2: Independent Testing with S-DoT Sensors

The independent testing begins after the MLP model has completed training using the AWS data. The trained model generates air temperature predictions at each S-DoT sensor location, and these are then directly compared with the actual air temperature measurements from the S-DoT sensors at 11:00 AM. The S-DoT sensors are more densely distributed across Seoul, which provides a spatial testing that the sparse AWS cannot provide. The dense network captures microclimate variations within the urban environment, testing the model's ability to predict air temperatures at locations far from any training stations.

3 Results

The MLP model for converting LST to air temperature was developed, validated and tested using AWS data (2013–2024) as ground truth and further tested using the S-DoT sensor data (2020–2024).

3.1 MLP model performance

Figure 4 shows the model training loss, showing how well the model fits the training data with each epoch, as well as the validation loss, which shows the model's performance on the held-out validation set. Both curves show successful learning behavior, as they decrease rapidly in early epochs as the model learns patterns, then gradually stabilize around the 25th epoch. The convergence of both training and validation curves at similar loss values indicates successful training without overfitting. The early stopping was activated at epoch 71 when validation loss showed no improvement for 20 consecutive epochs.

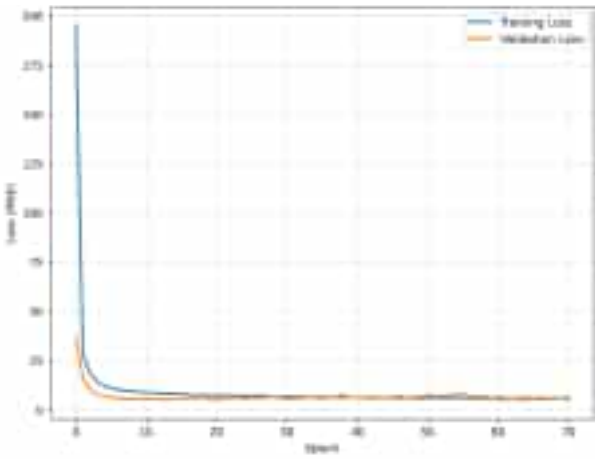

Figure 4. Training and validation loss curves during MLP development

The performance of the model is quantified in Table 1. The coefficient of determination (R^2) value of 0.968 indicates a well-captured nonlinear relationship between LST and air temperature. The performance of this MLP aligns with recent studies in urban temperature estimation, where Salih et al. [13]'s MLP model obtained an R^2 of 0.91. The Root Mean Square Error (RMSE) of 2.1°C is also in a similar range compared to other papers, where Choi et al. [12] got RMSE of 2.19°C using an artificial neural network (ANN). Finally, the Mean Absolute Error (MAE) of 1.62°C provides the average absolute difference between predicted and actual air temperatures.

Table 1. MLP performance metrics for each of the two stages

Data	Period	R^2	RMSE	MAE
AWS	2013–2024	0.968	2.10°C	1.62°C
S-DoT	2020–2024	0.807	4.73°C	3.87°C

3.2 Independent S-DoT testing results

The trained MLP model is further tested with independent S-DoT sensors for the period 2020–2024. Figure 5 shows the predicted versus observed air temperatures at S-DoT sensor locations, with points clustering along the 1:1 line. The mean difference is 0.98°C, with a standard deviation of 4.63°C. The performance of the model during independent testing (Table 1) is lower than for the validation test set, though the R^2 value of 0.807 still indicates a reasonable predictive capability. This is in spite of the fact that S-DoT sensors, unlike AWS, are not installed according to meteorological standards, adding to the uncertainty in their measurements.

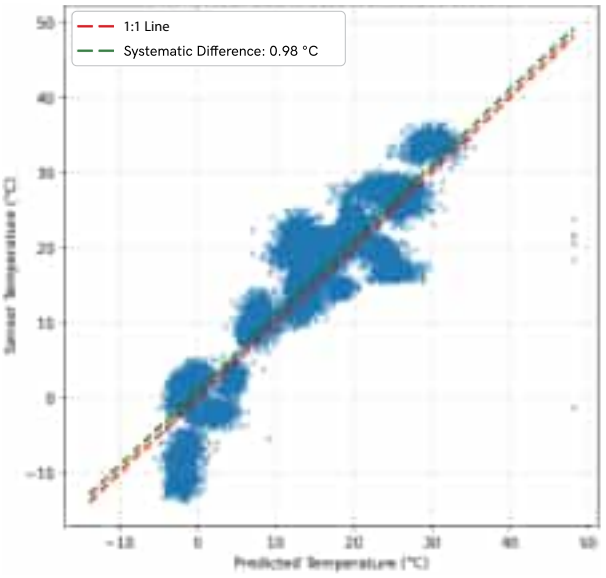

Figure 5. Predicted air temperature testing with S-DoT sensors (2020-2024)

3.3 Model application: Air temperature maps

Figure 6 shows a scatter plot of the measured LST from the satellite images and the predicted air temperature (AT) from the MLP model during the 12-year analysis period. The results show that the difference between LST and AT increases as the measured LST increases. This aligns with Naserikia et al. [27]'s findings, which observed greater temperature differences between LST and air temperature in built environments during warm days.

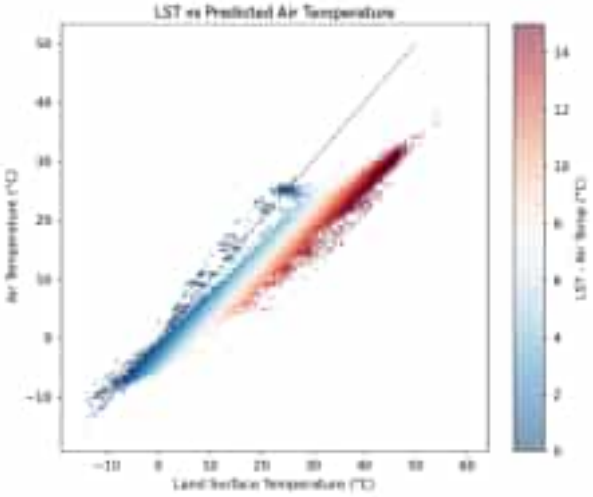

Figure 6. Scatter plot of land surface temperature and final predicted air temperature for the period 2013–2024

As shown in Table 2, the LST tends to be much larger than AT in the summer, with mean differences ranging from 3.94°C in winter to 12.24°C in summer. The larger summer difference reflects intense solar heating of urban surfaces during peak radiation hours, while winter's lower sun angle and reduced radiation result in smaller differences. This consistent seasonal pattern validates the model's physical realism and demonstrates that the MLP successfully captures the varying thermal relationships throughout the year. The finalized model is used to generate air temperature distributions based on LST, as shown in the maps in Fig. 7.

Table 2. Difference between land surface temperature and final predicted air temperature

Metric	Value
Mean Temperature Difference	7.78°C
Spring	9.40°C
Summer	12.24°C
Fall	7.51°C
Winter	3.94°C
Median Temperature Difference	7.58°C
Standard Deviation	3.88°C

4 Conclusions

The research successfully developed a Multi-Layer Perceptron model to convert satellite-based Land Surface Temperature (LST) to air temperature using Normalized Difference Vegetation Index (NDVI), Digital Elevation Model (DEM) and Solar Zenith Angle (SZA) us-

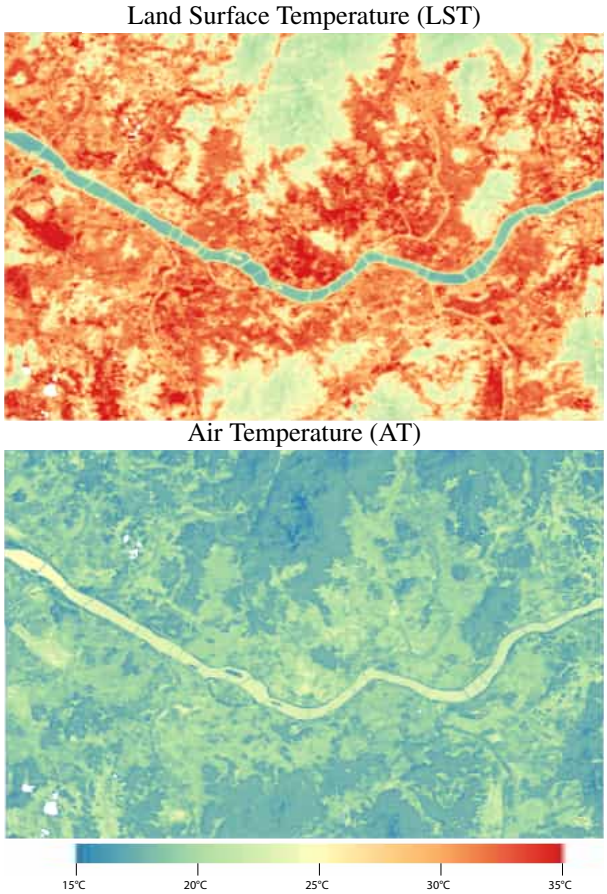

Figure 7. Land surface temperature and predicted air temperature on 25th May 2022 11:10:19

ing air temperature data from Automatic Weather Stations (AWSs) as ground truth data. The MLP model achieved an R^2 of 0.968 and tested with independent S-DoT sensor data. The independent testing was conducted using data from 1000+ S-DoT weather sensors for the period 2020–2024, achieving a mean temperature difference was 0.98°C and an R^2 of 0.807, confirming that satellite imagery provides a reliable method for urban temperature monitoring when ground-based stations are limited.

However, it is important to acknowledge that the analysis uses single hourly temperature observations, since Landsat provides only 1-2 images per month at a fixed time of 11:12 AM. Future research should focus on the development of methods to model diurnal variations in temperature distributions. The use of more frequent satellite observations, if available, could better capture temporal scales to demonstrate the cascading effects from urban form through temperature to energy consumption. Furthermore, more advanced machine learning methods or hybrid approaches combining satellite images with physical models to capture diurnal patters should be explored.

Despite these limitations, the decade-long analysis provides valuable insights into the spatial patterns and long-term trends that inform urban planning strategies. While many researchers have tried to use satellite imagery for urban temperature analysis, few have validated their models with an independent data source. The testing using S-DoT sensors, based on over 23,000 data points from a dense sensor network, shows that satellite-based approaches can accurately convert data to air temperature. Unlike most urban studies that analyze data over a short period, this research examines a full decade of data from 2013 to 2024.

The findings from this research provide specific, quantitative guidance for urban planning policies aimed at mitigating air temperature and managing energy consumption in dense urban districts.

Abstract -

Robotic facade installation across multiple floors necessitates millimeter-level geometric accuracy to ensure reliable anchor alignment and panel placement. The present paper proposes a survey-controlled sensing and modeling framework that integrates a construction tool with high-resolution close-range imaging to establish a consistent multi-floor reference frame. The utilization of facade anchors is facilitated through the employment of survey markers, which serve to localize these anchors. The registration of dense, image-based geometry to the survey frame enables the execution of precise height transfer and inter-floor alignment. The resulting survey-referenced geometry is aligned with an existing design Building Information Modeling (BIM)/Industry Foundation Classes (IFC) model and evaluated against survey ground truth to verify multi-floor consistency, error propagation, and anchor-level suitability for robotic facade installation. The proposed framework is predicted on the explicit addressing of multi-floor alignment and error propagation, thereby providing a reliable geometric foundation for robotic facade installation and reproducible accuracy evaluation across floors.

Keywords -

Construction, visual, localization, BIM, Measurement, installation, robotics.

1 Introduction

The installation of robotic facades across multiple floors necessitates geometric accuracy at the millimeter to centimeter level. Errors in inter-floor alignment, encompassing anchor positions, floor-to-floor height, and coordinate transfer, have the potential to accumulate and directly impact panel fit-up.

Recent advancements in fiducial-marker localization, high-precision surveying, and photogrammetric reconstruction have the potential to enhance on-site construction geometry. Specifically, markers facilitate reliable camera pose estimation, total stations facilitate the establishment of multi-floor control networks, and high-resolution imaging supports detailed facade and edge reconstruction. However, extant research has largely treated these components in isolation or focuses on documentation, with limited attention to survey-controlled multi-floor alignment and its direct integration into robotic facade installation.

The proposed framework integrates a construction tool with high-resolution imaging into a unified sensing and modeling pipeline with iterative robotic feedback. By anchoring measurements to a survey-defined reference frame, it ensures consistent multi-floor alignment and accurate execution-time synchronization between the physical construction and the design BIM.

2 Related Work

This part is devoted to a critical review of the extant literature concerning marker-based localization, high-precision surveying, photogrammetric building modeling, and BIM–robotics integration. It identifies the research gaps that this paper aims to address.

2.1 Marker-based localization

Visual fiducial markers are widely used for camera pose estimation and calibration in robotics and computer vision. AprilTag [1] provides reliable 6-DOF pose estimation from a single image and is robust to lighting changes and partial occlusion, with later versions improving detection accuracy and efficiency [2][3]. ArUco markers [4] offer a similar approach with built-in error correction.

Fiducial markers are also commonly used for sensor calibration, including camera–laser calibration and ChArUco boards that combine checkerboard features with marker IDs [5][6]. Prior studies have further evaluated detection robustness and pose ambiguity under challenging conditions [7]. Beyond pose estimation, recent work [8] shows that dense AprilTag grids can be used to reconstruct survey-grade facade geometry from calibrated images via triangulation and plane fitting, extending fiducial markers from local localization to large-scale geometric referencing in the built environment. In construction applications, markers are typically used for localization, while

workflows that integrate surveyed fiducials across multiple floors with BIM and geospatial datasets remain largely unexplored.

2.2 High-precision surveying and Scan-to-BIM in construction

High-precision surveying is a cornerstone of construction quality control. Recent studies have evaluated scan-to-BIM workflows based on terrestrial laser scanning (TLS), with a focus on the impact of scanner accuracy, registration strategy, and modeling choices on the quality of the resulting BIM model. Skrzypczak et al. [9][10] assess the accuracy of scan-to-BIM for a multi-story office building, while others demonstrate the application of scan-to-BIM in the context of historic churches and complex interior spaces. The study [11][12][13] demonstrates that achieving centimeter- or millimeter-level agreement with control measurements is contingent upon the meticulous design of the survey network. Related work on online data acquisition and building modeling for building renovation highlights the role of timely and built-in data integration in renovation workflows [14], which will be further improved in future research.

The majority of Scan-to-BIM studies concentrate on documentation of entire spaces and neglect to address the anchor-level, cross-floor alignment necessary for the installation of facade panels. Furthermore, there is a paucity of integration between total-station control networks and high-resolution close-range imaging in the context of survey-grade ground truth generation and rigorous validation of multi-floor alignment accuracy. In contrast to Scan-to-BIM workflows, which prioritize post-construction documentation or renovation, the present study focuses on execution-time geometric control in new building construction, where a design BIM is already available.

2.3 Image-based photogrammetric reconstruction

Image-based photogrammetry has been the subject of extensive research as a method for extracting geometric information from perspective imagery. Classical methods rely on multi-view geometry, camera calibration, and feature correspondence to recover three-dimensional structure from overlapping images, typically via structure-from-motion and projective reconstruction pipelines. These techniques facilitate the recovery of facade planes, edges, and relative spatial relationships directly from images without direct contact measurements.

Recent advancements in this field have extended classical photogrammetry by incorporating learning-based components and architectural priors to enhance its resilience under conditions of limited viewpoints, occlusions, and complex urban scenes. The viability of such approaches has been demonstrated in the reconstruction of facade geometry and metric relationships from sparse or street-level imagery at large scale, primarily for applications in mapping, visualization, and urban analysis [15][16][17]. Other studies infer heights and facade geometry from single images or panoramas using deep learning and geometric reasoning [18][19][20], and extend these methods to 3D city modeling and Scan-to-BIM pipelines [21][22].

Nevertheless, image-only photogrammetric methods are susceptible to camera pose uncertainty, scale ambiguity, and environmental conditions, which restrict their applicability for precision-critical construction tasks. Consequently, the present paper adopts photogrammetry as a complementary measurement modality within a survey-controlled framework. In this framework, image-derived geometric features are anchored to a stable reference system to support the accurate installation of robotic facades.

2.4 BIM–robotics integration

The integration of BIM and robotics is a pivotal subject in the domain of construction automation. BIM functions as a centralized information repository for robotic assembly, additive manufacturing, inspection, and autonomous construction systems, as evidenced by [23]. Bibliometric studies [24] indicate that the field of construction robotics is undergoing rapid growth and diversification, particularly in the domains of automated fabrication and mobile on-site platforms.

Research on BIM–GIS integration shows that combining spatial and semantic models enables robot navigation and planning in complex construction environments [25]. Recent work further extends BIM by incorporating laser scanning and photogrammetry to support digital twins and automated quality verification [21], while also providing essential geometric and semantic constraints for safe robotic operation [26].

The majority of extant studies presuppose a precise design BIM and concentrate on the manner in which robots consume BIM information. In contrast, this project focuses on generating as-built BIM/IFC models from survey control and image-based measurements, and on using the resulting geometry to support robotic multi-floor facade installation.

3 Problem Definition

3.1 Multi-floor alignment challenges

The installation of robotic facades across multiple floors necessitates the maintenance of consistent geometric alignment between anchors, panels, and reference frames over vertical distances. In practice, minor inaccuracies in floor-to-floor height transfer, control point propagation, or coordinate transformations can accumulate across

levels, resulting in misalignment between panels installed on different floors. These effects are of particular significance when facade elements span multiple storeys or must satisfy tight tolerance constraints at panel joints and anchors.

3.2 Challenges of maintaining consistent reference frames

In the context of multi-floor construction, geometric errors frequently emerge not from individual measurements but from inconsistencies in reference frames, transformation chains, and floor-to-floor transfer. Despite the fact that individual sensing modalities can offer reasonable local accuracy, minor inconsistencies in alignment, referencing, or propagation across floors can accumulate and result in misalignment at panel joints and anchors. The central challenge in robotic facade installation is therefore to maintain a consistent, traceable, and verifiable geometric reference across multiple floors throughout the planning and execution phases.

3.3 Requirements for precision in robotic installation

In new building construction, a detailed design BIM is typically available prior to facade installation. However, ensuring that robotic installation across multiple floors conforms to the design geometry remains challenging due to cumulative inter-floor alignment errors, reference frame inconsistencies, and execution-time uncertainties.

3.4 Need for BIM-constrained sensing and execution

Addressing these challenges necessitates a framework that integrates high-precision sensing with an existing design BIM to support execution-time alignment during robotic facade installation. In order to ensure consistent cross-floor alignment with verifiable precision, a unified pipeline combining survey control, image-based reconstruction, and BIM/IFC representation is necessary.

4 System Architecture

Fig.1 illustrates the execution-time workflow. The establishment of a global reference frame across multiple floors is the primary function of survey control. Based on this reference frame, images are acquired and utilized for photogrammetric localization, and the resulting measurements are registered to the survey frame to obtain survey-anchored geometry. This geometry is employed to generate robot commands for facade installation. Subsequent to the execution, re-localization and verification are carried out to effect an update to the geometric state. Subsequently, verified states and deviations are integrated with the existing design BIM/IFC model as as-built information. And Fig.2 offers a comprehensive overview of the proposed system architecture and data flow for robotic facade installation across multiple floors.

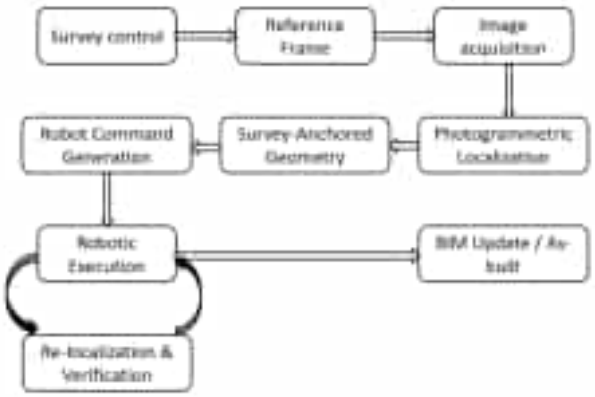

Figure 1. Survey-controlled workflow for multi-floor robotic facade installation

4.1 Survey-controlled reference framework

A Leica iCON iCS50 construction tool establishes a global reference frame that spans multiple floors and serves as the geometric backbone of the system. Each facade anchor is equipped with a Leica survey marker, enabling repeatable and survey-grade localization. By observing these markers across storeys, consistent floor-to-floor height transfer and inter-floor alignment are ensured. This survey-controlled reference frame provides stable geometric ground truth for subsequent sensing, fusion, and robotic operations.

4.2 High-resolution sensing and geometric reconstruction

High-resolution close-range images are captured using a Hasselblad camera to obtain dense geometric information of facade surfaces, anchors, and panel interfaces. Image observations are linked to the survey reference frame through fiducial markers, enabling reconstructed geometry to be expressed in global coordinates. This combination of sparse, high-accuracy survey measurements and dense image-based reconstruction supports both local installation verification and building-scale geometric analysis.

4.3 Robotic installation context

Robotic platforms operating on different floors are referenced to the same global coordinate system defined by the survey framework. This shared reference enables coherent spatial alignment during multi-floor facade installation

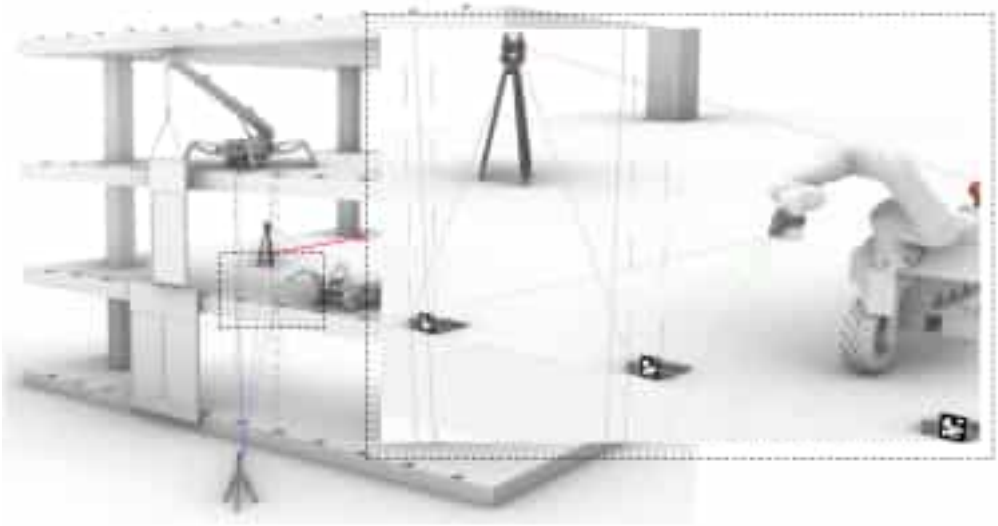

Figure 2. Conceptual illustration of a multi-floor robotic facade installation workflow

and reduces cumulative geometric errors. The architecture is designed to support installation planning, execution, and verification without assuming perfect design geometry, by grounding alignment and verification in survey control.

4.4 BIM / IFC integration

Survey- and image-derived measurements are integrated with an existing design BIM/IFC model to provide execution-time verification and structured documentation of as-built deviations during robotic facade installation. Anchor positions, facade geometry, and inter-floor relationships are stored within a unified BIM model, enabling comparison with design BIM and survey-observed as-built measurements. This integration supports automated quality documentation, traceability of geometric deviations, and downstream analysis throughout the building lifecycle.

5 Methodology

A methodology has been proposed for the systematic evaluation of millimeter-level accuracy in robotic facade installation across multiple floors. This methodology integrates controlled experiments, survey- and image-based sensing, data fusion, and evaluates the results against survey ground truth. Each methodological component addresses a specific aspect of the problem definition outlined in ***Problem Definition***, and collectively, they form a coherent evaluation pipeline.

5.1 Controlled and multi-floor experiments

Controlled experiments are conducted on buildings with multiple floors to evaluate whether robotic facade installation can satisfy millimetre-level geometric accuracy requirements. Anchors equipped with Leica survey markers are distributed across storeys and measured using a Leica iCON iCS50 construction tool, forming a vertically connected survey control network.

Survey-measured anchor coordinates are treated as ground truth. Image-based and fused measurements are evaluated relative to this reference in order to distinguish local single-floor errors from cumulative inter-floor alignment effects.

For the f-th floor, the mean vertical residual is defined as

$$r_f = \frac{1}{|\mathcal{A}_f|} \sum_{a \in \mathcal{A}_f} \left(z_a^M - z_a^S \right), \tag{1}$$

where $\mathcal{A}_f$ denotes the set of anchors on floor f, and z_a^S and z_a^M are the survey-measured and model-derived heights of anchor a, respectively.

The cumulative vertical drift up to floor F is expressed as

$$D(F) = \sum_{f=1}^{F} r_f. \tag{2}$$

The installation accuracy requirement is defined as

$$|D(F)| \leq \tau, \qquad \tau \in [2, 8] \text{ mm}, \tag{3}$$

reflecting typical tolerance limits for robotic facade installation.

Fig.3 illustrates how anchor-level vertical residuals are averaged at each floor and accumulate across multiple

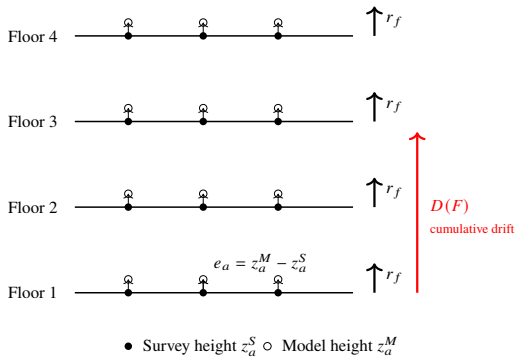

Figure 3. Illustration of equations(1)(2)(3)

floors into a cumulative vertical drift that affects multi-floor robotic facade installation accuracy.

5.2 Camera calibration and photogrammetry

The Hasselblad camera is calibrated using a standard photogrammetric procedure to estimate intrinsic parameters and lens distortion. Based on solid theory basic [27][28][29], Camera poses are initialized via fiducial marker detection and refined using bundle adjustment by minimizing reprojection error.

Given image observations $\mathbf{x}_{ij}$ of 3D points $\mathbf{X}_j$ in camera i, the optimization problem is formulated as

$$\min_{\{\mathbf{P}_i\},\{\mathbf{X}_j\}} \sum_{i,j} \left\| \mathbf{x}_{ij} - \pi(\mathbf{P}_i, \mathbf{X}_j) \right\|^2, \tag{4}$$

where $\pi(\cdot)$ denotes the camera projection model.

To enforce metric consistency with survey control, anchor points measured by the Leica iCS50 are incorporated as constraints:

$$\min \sum_{i,j} \left\| \mathbf{x}_{ij} - \pi(\mathbf{P}_i, \mathbf{X}_j) \right\|^2 + \lambda \sum_{k \in C} \left\| \mathbf{X}_k - \mathbf{X}_k^S \right\|^2, \tag{5}$$

where C denotes the set of survey-observed anchors and $\mathbf{X}_k^S$ their survey coordinates.

5.3 Leica and camera data fusion

Survey measurements and image-derived geometry are fused within the global coordinate system defined by the Leica iCON iCS50. Anchor-mounted survey markers serve as control points linking image space and survey space.

A rigid transformation $(\mathbf{R}, \mathbf{t})$ is estimated using weighted least squares:

$$\min_{\mathbf{R},\mathbf{t}} \sum_k w_k \left\| \mathbf{p}_k^S - (\mathbf{R}\mathbf{p}_k^I + \mathbf{t}) \right\|^2, \tag{6}$$

where $\mathbf{p}_k^S$ and $\mathbf{p}_k^I$ denote survey and image-derived coordinates of anchor k, and w_k represents measurement confidence [30].

To improve robustness against occlusions and misdetections, a robust cost function $\rho(\cdot)$ is applied:

$$\min_{\mathbf{R},\mathbf{t}} \sum_k \rho\left(\left\| \mathbf{p}_k^S - (\mathbf{R}\mathbf{p}_k^I + \mathbf{t}) \right\| \right). \tag{7}$$

The residual covariance after fusion is estimated as

$$\mathbf{\Sigma}_{\text{reg}} = \frac{1}{N-1} \sum_{k=1}^{N} \mathbf{e}_k \mathbf{e}_k^\top, \tag{8}$$

where $\mathbf{e}_k$ denotes the post-registration residual of anchor k.

5.4 Accuracy evaluation against survey ground truth

Geometric quantities derived from the fused survey–image model are evaluated against survey control measurements provided by the Leica iCON iCS50. Survey-measured anchor coordinates are treated as ground truth, enabling a direct assessment of anchor-level consistency and multi-floor error propagation.

For each anchor a, the vertical residual is defined as

$$\Delta z_a = z_a^M - z_a^S, \tag{9}$$

where z_a^S denotes the survey-measured vertical coordinate and z_a^M the corresponding model-derived value.

To assess suitability for robotic facade installation, a pass-rate metric is introduced:

$$\eta(\tau) = \frac{1}{M} \sum_{m=1}^{M} I\left(|\Delta z_m| \le \tau \right), \quad \tau \in [2, 8] \text{ mm}, \tag{10}$$

where M is the number of evaluated anchors and $I(\cdot)$ denotes the indicator function.

This evaluation focuses on anchor-level geometric consistency, inter-floor error propagation, and compliance with tolerance requirements relevant to precision-critical robotic installation.

To further characterize error distribution, standard statistics of the vertical residual Δz_a are evaluated:

$$\text{RMSE}_z = \sqrt{\frac{1}{M} \sum_{a=1}^{M} (\Delta z_a)^2}, \quad e_z^{\max} = \max_a |\Delta z_a| \tag{11}$$

In addition, full three-dimensional anchor deviation is defined as:

$$e_a^{3D} = \|\mathbf{p}_a^M - \mathbf{p}_a^S\|_2 \tag{12}$$

To assess cross-floor consistency, the inter-floor transfer error between adjacent floors is introduced:

$$E_{\text{transfer}}(f, f+1) = \left| (z_{f+1}^M - z_f^M) - (z_{f+1}^S - z_f^S) \right| \tag{13}$$

These metrics complement the pass-rate definition by capturing error magnitude and multi-floor consistency.

5.5 IFC data mapping

Survey- and image-derived as-built geometry [31][32] is mapped into IFC representations to enable structured storage, comparison, and documentation.

For each anchor a, the geometric deviation is expressed as

$$\Delta \mathbf{p}_a = \mathbf{p}^{\text{IFC}}_{a,\text{as-built}} - \mathbf{p}^{\text{IFC}}_{a,\text{design}}, \tag{14}$$

with the vertical component Δz_a explicitly recorded. These deviations are stored in IFC property sets and associated with anchors, panels, and floors.

6 Experimental Plan

The experimental plan represents the most critical component of the proposed future work, as it provides the quantitative evidence required to validate multi-floor alignment accuracy, error propagation behavior, and robustness under realistic construction conditions. Although experimental data will be acquired in later project phases, measurement layouts, marker placement rules, and observation strategies are defined in advance to ensure reproducibility and comparability.

6.1 Benchmark scenarios

Three benchmark scenarios are defined to progressively evaluate geometric accuracy from local to building-scale conditions:

- Single-floor scenario: This scenario evaluates local geometric accuracy within a single storey, isolating sensing, calibration, and fusion errors without inter-floor propagation. It establishes the baseline performance of the Leica-camera system.
- Cross-floor scenario: This scenario evaluates two adjacent floors jointly, focusing on floor-to-floor height transfer and coordinate consistency. It represents the minimum requirement for facade panels spanning multiple storeys.
- Full-height scenario: This scenario evaluates anchors distributed across the full building height. It exposes cumulative vertical drift and long-range error propagation, representing the most demanding case for robotic facade installation.

6.2 Marker placement strategy

Leica survey markers are placed on the facade following a regular grid layout to provide stable geometric control in both horizontal and vertical directions. The placement strategy defined to balance coverage, redundancy, and practical deployment constraints is as follows:

Table 1. Planned Leica marker layouts for benchmark scenarios.

Scenario	Floors	Spacing (m)	Grid (C×R)	Markers
Single-floor	1	2.0	3–4 × 2	6–8
Cross-floor	2	2.0	3–4 × 2	12–16
Full-height	3–5	2.0	3–4 × 2	18–40

- Horizontal and vertical spacing: 2.0 m.
- Markers are mounted at or near facade anchor locations where possible.
- At least one vertically aligned marker column is maintained across floors to support height transfer.
- All markers are observable from at least one construction tool setup.

6.3 Planned marker layout summary

The planned marker configurations for the three benchmark scenarios are summarised in Table 1.

6.4 Marker visibility and construction tool setup plan

To ensure reliable multi-floor alignment and redundancy in survey observations, a structured construction tool setup plan is defined for future experiments using the Leica iCON iCS50.

- Each marker is observed from at least two distinct station setups.
- Adjacent floors share common visible markers to form a continuous vertical control network.
- Station locations are selected to maximize facade coverage while avoiding shallow incidence angles.

6.5 Deviation measurement

Geometric deviations are quantified relative to survey-grade ground truth provided by the Leica iCON iCS50. Deviations are evaluated at anchor level, panel level, and across floors, with a focus on millimetre-level tolerances required for robotic installation.

Deviation metrics include local anchor residuals, inter-floor height differences, and cumulative vertical drift. All measurements are evaluated against predefined tolerance thresholds to assess installation feasibility.

6.6 Reproducibility and robustness testing

To assess reproducibility, experiments are repeated under varying acquisition conditions, including different

camera viewpoints, lighting conditions, and station configurations. Robustness is evaluated by introducing controlled perturbations such as partial marker occlusions and reduced visibility.

Statistical consistency across repeated trials is analysed using variance, confidence intervals, and failure rates relative to millimetre-level thresholds.

7 Conclusions

This paper presented a survey-controlled sensing and execution framework for robotic facade installation in new building construction, where a design BIM is available. By integrating a Leica iCON iCS50 construction tool with high-resolution close-range imaging and BIM-based representation, the proposed pipeline establishes a consistent multi-floor reference frame for precision-critical installation.

The framework defines a unified process that links survey control, dense image-based geometry, and BIM/IFC mapping, enabling reliable robotic facade installation and quantitative validation of multi-floor accuracy, error propagation, and installation tolerances against survey ground truth. The proposed pipeline is designed to address inter-floor alignment and error propagation within a survey-controlled framework, thereby providing a coherent and reproducible solution for precision-critical robotic facade installation across multiple floors.

The proposed framework contributes to the **AMALTEA** project by providing a survey-controlled execution pipeline for robotic facade installation in new building construction.

Abstract -

On active jobsites, unobserved worker motions drive injuries and near-misses, unsafe habits evade periodic audits, so reliable activity monitoring is essential to prevent delays and costly rework. In recent years, Inertial-Measurement-Unit(IMU) based motion recognition using Deep Learning approach is used widely in many domains. While the method has been proven to effectively recognize human motion using 5 to 21 IMUs, it is impractical to attach that many IMUs to construction workers. Minimal-sensing approaches using a single sensor are also proposed for limited motion patterns. To address these limitations, this paper presents a Temporal Convolutional Network (TCN) based real-time human motion recognition system that uses only three IMU sensors. TCN was chosen because it replaces recurrent states with small 1-D convolutions and dilations, keeping parameters and memory modest while inference runs in parallel on short windows, making it suitable for on-board deployment. Three IMUs are attached to the neck, back, and right wrist (NBW) that deliver 6-axis data at 50Hz, which are windowed for per-window z-normalized inference using a lightweight TCN with dilated, causal 1D convolutions and residual blocks. The model predicts 19 basic motion classes, classified by anatomical terms for body movements. This paper evaluated a lab-made 15-participant dataset, achieving the highest average prediction accuracy of 83.26% on the NBW combination in a single-split configuration, demonstrating the capability to achieve reasonable accuracy for field deployment. It also compares training results across diverse combinations of the three sensors to demonstrate the possibility of reducing sensor counts.

1 Introduction

Construction sites face frequent injuries, near-misses, and costly rework. Unsafe motions often occur between periodic audits, when supervisors cannot observe early warning signs[1]. Manual observation cannot scale across multiple crews or shifts. Paper based reports lag behind events, and fixed surveillance cameras struggle in dynamic construction environments[2]. Current practice relies on periodic visual audits, manual incident reports, and fixed cameras that lack continuous coverage across multiple crews. Unlike attendance-based check-in systems, the proposed approach requires no manual input from workers; the PPU devices automatically timestamp and stream sensor data continuously, enabling passive and unobtrusive monitoring. Real-time IMU-based motion recognition fills this gap by flagging hazardous postures before injuries occur, supporting ergonomic risk assessment through cumulative high-strain motion tracking, and quantifying task productivity without dependence on line-of-sight or observer presence.

Field-deployable human-motion recognition for construction workers remains constrained by sensor burden and latency, making many systems impractical on active jobsites due to donning time, discomfort, cost, battery swaps, RF congestion, and synchronization drift. Commercial motion-capture suits typically mount a large number of IMUs across the body[3] to achieve stable pose tracking, trading usability for coverage and drift robustness. Academic "sparse-IMU" efforts reduce sensor count but often depend on non-causal or offline temporal models that leverage future frames[4], additional sensing modalities[5], or heavyweight optimization pipelines compromising strict real-time operation on embedded hardware. The resulting gap is a method that delivers reliable, real-time recognition of a rich motion set with minimal sensor attachment and short, causal windows suitable for noisy and time-sensitive construction environments.

We addressed this gap by targeting three IMUs placed on the rear neck, lower back, and right wrist and en-

forcing strict causality with short windows (≈ 2 s at 50 Hz). Instead of relying on look-ahead or offline smoothing, our model is a lightweight Temporal Convolutional Network (TCN)[3] with dilated, causal 1D convolutions and residual blocks, providing a large effective receptive field without future context. The streaming pipeline performs per-window z-normalization and runs inference under low-memory conditions, targeting wearability and deployability on constrained edge hardware. Our working hypothesis is that the temporal structure of human motion can be captured by dilated causal convolutions over short windows when the three IMUs are chosen to provide complementary distal and proximal information. We compare several sensor configurations: neck+back+wrist (NBW), neck+back (NB), back+wrist (BW), neck+wrist (NW), and single sensor setups under matched computational budgets. We evaluate two training methods that reflect practical deployment: leave-one-subject-out (LOSO)[6] for cross-worker generalization and a single fixed split for rapid development. We measure accuracy, macro-F1, latency, and throughput, and perform ablation studies to characterize the trade-offs among different sensor sets and training methods. The selected sensor–training configuration is determined through a multi-objective criterion that jointly accounts for recognition reliability and field deployability, including performance, inference latency, model footprint, and sensor donning burden. Overall, our contributions are (i) a causal, edge-ready TCN pipeline for real-time worker motion recognition with only three IMUs, and (ii) a systematic ablation across seven sensor combinations and two training techniques that offer accuracy–practicality trade-offs for job site deployment.

2 Background

2.1 IMU based Human Motion Recognition

Wearable IMUs are widely used for human activity and pose estimation because they are inexpensive and robust to lighting or occlusion. Early and influential human activity recognition(HAR) systems paired multiple body-worn IMUs with deep neural networks and achieved high accuracy on curated datasets, but typically at the cost of many sensors and offline processing. Ordoñez et al. [7] proposed DeepConvLSTM, which demonstrated strong performance on multimodal IMU streams using a convolutional front-end and a recurrent back-end, establishing a deep-learning baseline for wearable HAR. Sparse-IMU pose estimators such as Deep Inertial Poser (DIP)[4] reconstruct full-body kinematics from six IMUs but rely on bidirectional temporal models and sliding windows with look-ahead, which limit strictly causal, real-time use on embedded devices. In manufacturing and construction-adjacent settings, multimodal systems often combine an IMU armband with video to improve accuracy, again trading off deployment simplicity for additional sensors and compute[8]. Prior construction-focused studies have shown that decomposing construction tasks into basic motion primitives enables detailed safety and productivity analysis, but these studies are often conducted in controlled settings, highlighting the gap between laboratory validation and field deployment[9]. Reviews and case studies report growing interest in using wearables for worker activity monitoring and safety, but note persistent barriers, such as the burden of multiple sensors, annotation costs, and synchronization challenges in dynamic construction environments. These factors point toward methods that minimize sensor count, remain causal, and operate with tight latency budgets while retaining recognition fidelity[10]. Recent construction focused IMU work by Park et al.[11] introduces the Scaffolding Worker IMU Time-series(SWIT) dataset for deep-learning recognition of hazardous and routine behaviors on scaffolds. The paper motivates IMU-based monitoring to overcome occlusion limits in camera systems and addresses the shortage of public, construction-specific datasets by releasing labeled 100 Hz time-series across ten behavior categories. State-of-the-art wearable HAR often assumes dense IMU coverage, which inflates cost and increases donning time and maintenance overhead[12]. On active construction sites many body-worn units hinder movement and PPE use and degrade reliability through frequent battery swaps, RF congestion, and synchronization drift. The gap is a method that uses few IMUs, runs causally in real time, and remains practical for noisy construction sites.

2.2 Deep Learning Methods in Motion Recognition

Given the constraints of existing wearable systems, deep learning has been widely explored to extract meaningful motion patterns from IMU signals. Architectures for IMU time series generally fall into three families. CNN–RNN hybrids[7] extract local temporal features with 1-D convolutions and model longer dependencies with recurrent units, but recurrent state adds memory overhead and can complicate low-latency deployment. Pure convolutional approaches, including Temporal Convolutional Networks (TCNs), replace recurrence with dilated causal convolutions and residual connections as they parallelize efficiently, support long receptive fields with short windows, and are well-suited to streaming inference on edge hardware[13]. Temporal convolutional stacks deliver strong accuracy with efficient inference on short windows[14] for action segmentation. TCNs have shown competitive or superior accuracy to recurrent models while preserving strict causality, motivating their use for real-time HAR from IMUs. Some approaches use multimodal fusion, pairing IMUs with cameras or audio to

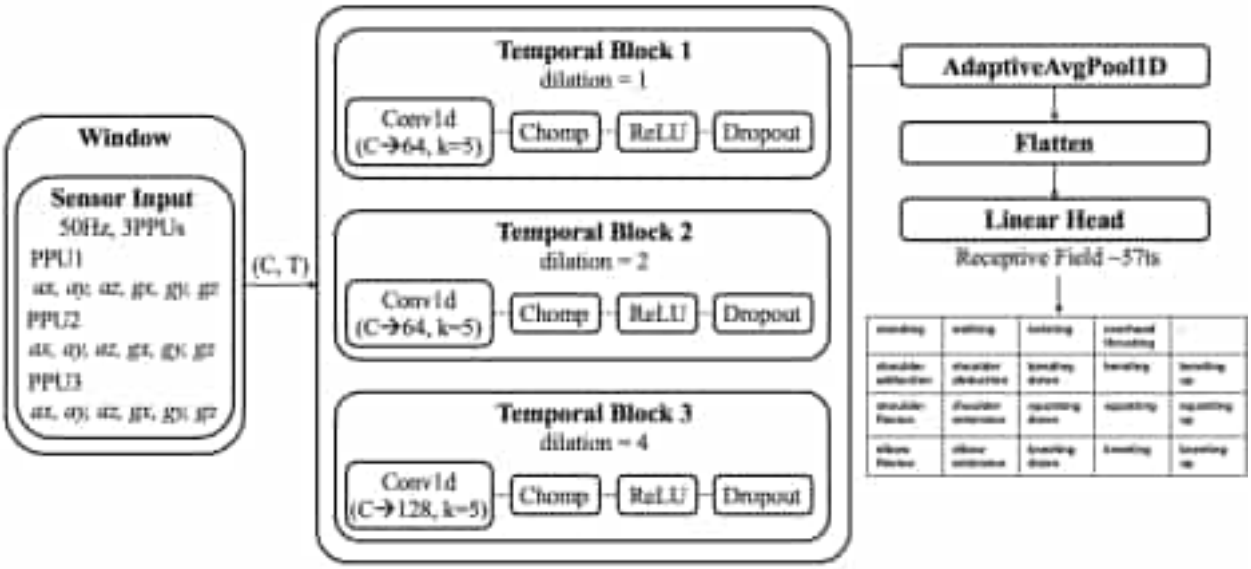

Figure 1. TCN Network Structure

improve recognition in controlled environments[6]. Another method explores optimization-based pose estimation from sparse IMUs, achieving high fidelity [9], but depends on non-causal inference or heavy priors that are hard to sustain on embedded systems. This leads to delayed monitoring time and extended computational cost. As a result, many existing approaches trade deployment practicality for accuracy or model complexity, assuming long temporal contexts or computationally intensive inference pipelines. These limitations underscore a gap in prior work for causal, lightweight temporal models that operate on short windows and support real-time inference with minimal sensor burden.

3 Methodology

3.1 Network Architecture

Our objective is to design and validate a light, edge-deployable system that recognizes 19 anatomically defined motion classes in real-time using three IMUs, while systematically identifying the most effective sensor combination and training protocol for downstream device design. We adopted TCN because it is causal, low-latency, and efficient on short windows typical of embedded streaming. Unlike bidirectional RNNs or Transformers, which require future context, a causal TCN operates on past data only and avoids recurrent state, making it easier to deploy in nonstationary jobsite conditions.

Our model described in Fig. 1 ingests a (C, T) IMU window (T=100≈2s at 50 Hz; C depends on the sensor combination). The backbone has three dilated residual blocks (channels 64/64/128, kernel 5) with shared dilations 1→2→4, ReLU+dropout, and 1×1 skips when needed. An AdaptiveAvgPool1d and a linear head produce logits for 19 motions. Right-padding and truncation ensure strict causality. This topology yields an effective receptive field of 57 steps (1.14 s), large enough to capture brief transients and sub-second pose evolution, helping separate look-alike actions like bend-down and kneel-down. We apply per-window, channel-wise z-normalization and a majority-vote smoother over recent outputs. Majority-vote smoother is a simple method of temporal post-processing where instead of displaying each prediction from time window independently, the smoother covers a short sequence(≈2s) of neighboring window predictions to select the most frequent label as output.

Computation scales modestly with kernel and channel counts, enabling real-time throughput on edge processors as memory is bounded by the fixed window. This balance of dilated temporal coverage, causal inference, and compactness suits field deployment with just three IMUs and tight latency under power budgets.

3.2 Sensors

Each ICM-20948 IMU is integrated into a wearable Personal Protection Unit (PPU) enclosure. We deploy three PPUs at the neck, lower back, and right wrist (Fig. 2). Upper-body placements such as the wrist, neck, and lower back have been shown to remain compatible with protective gear and routine work activities while maintaining user comfort[11, 15]. Prior work by Kim and Cho [12] systematically evaluated IMU quantity and placement on the body for deep learning-based worker motion recognition, identifying upper-body nodes as providing the best balance

ID	Motion	ID	Motion	ID	Motion	ID	Motion	ID	Motion

16	elbow extension	17	kneeling down	18	kneeling	19	kneeling up		

Table 1. Anatomical terms for movement classification

of complementary motion coverage and minimal donning burden. Alternative locations such as the thigh and ankle were excluded because they would interfere with kneeling activities, footwear, and lower-body PPE common on construction sites. The neck unit sits at the base of the neck on the dorsal side to capture head-torso coupling while avoiding helmet interference. The back unit is centered over L5 with a belt clip to track trunk orientation and large sagittal motions. The wrist unit is strapped proximal to the ulnar styloid to capture hand activity with minimal glove obstruction. All mounts use rigid, anti-slip interfaces with consistent arrow markings to control sensor orientation.

After mounting, a brief functional check confirms sensor placement and synchronization. Subjects then perform a standardized calibration motion consisting of slow trunk flexion, an arm raise, and a return to neutral. This sequence verifies orientation consistency across the neck, back, and wrist channels and helps detect any strap slippage. All PPUs time-stamp packets on-device, and a lightweight offset correction is applied at the receiver to keep inter-PPU clock skew within 100 ms. To support deployment on remote sites with limited or absent network connectivity, each PPU stores raw sensor data locally on an onboard SD card.

Figure 2. Neck, Back, Wrist PPUs Placement

3.3 Data Collection

Motion data was collected from 15 subjects in a height range of 153 cm to 185 cm and weight range of 44kg to 83kg. Subjects were directed to perform 13 classified motions(19 including -up, -down breakdowns) in a lab environment. Sensors streamed nine-axis IMU signals at 50 Hz to a local server; all devices were timestamp-synchronized with time tolerance of 100ms. Trials were executed in pre-defined and separate orders of motions for corresponding ground truth labels.

To address motions, construction related activities such as hammering, lifting, placing, and carrying were broken down into basic motions as described in Table 1. Motions were defined using standard anatomical terms (e.g., adduction/abduction and flexion/extension), and we split them into direction-specific phases (e.g., . . . -down and . . . -up) to disambiguate symmetric transitions where applicable. The specific classification of the motions are displayed on Table 1.

3.4 Training Configuration

We trained exclusively on six-axis IMU features (three-axis accelerometer and three-axis gyroscope) and excluded magnetometer channels, as magnetic interference from steel members and powered equipment can destabilize headings on active jobsites. Two evaluation regimes were used: (i) a single split with 80% train and 20% test (equivalently, 8:2 train:test) fixed across all experiments for ablation consistency, and (ii) leave-one-subject-out(LOSO), which withholds each participant in turn to assess subject-level generalization. Windowing and inference settings matched deployment (short, causal windows), and all models were trained with identical optimization hyperparameters so differences reflect only sensor combinations and split protocols.

Table 2. Sensor Combinations used for Training

combination	selected IMUs	combination	selected IMUs
1	Neck+Back+Wrist(NBW)	5	Neck(N)
2	Neck+Back(NB)	6	Back(B)
3	Neck+Wrist(NW)	7	Wrist(W)
4	Back+Wrist(BW)		

3.5 Model Inference

3.5.1 Combination of Sensors

To identify the minimal instrumentation that preserves recognition accuracy, we trained the TCN on seven sensor configurations as described in Table 2: three single-IMU baselines (wrist, neck, back), three dual-IMU pairs (wrist+neck, wrist+back, neck+back), and one tri-IMU set (wrist+neck+back). This factorial ablation isolates the marginal value of each body location and their complementarities for dynamic and quasi-static motions. For comparability, all runs used identical windowing, optimization settings, and preprocessing. Only the input channel count varied with the chosen combination (6 channels per IMU, excluding the magnetometer, as specified in 3.4). The tri-IMU model serves as an upper-bound reference, while dual and single configurations quantify the trade-off between wearability and performance needed for field deployment.

Table 3. Training results across combinations

Method	Comb.	Acc.	Bal. Acc.	Macro F1	Wtd. F1
single split	NBW	0.9670	0.9396	0.9402	0.9671
single split	NB	0.9526	0.9343	0.9249	0.9531
single split	**NW**	**0.9748**	**0.9451**	**0.9485**	**0.9743**
single split	BW	0.9644	0.9176	0.9253	0.9636
single split	N	0.9570	0.9276	0.9246	0.9570
single split	B	0.8874	0.8227	0.8227	0.8893
single split	W	0.9470	0.8783	0.8893	0.9448
LOSO	**NBW**	**0.9607**	**0.9315**	**0.9302**	**0.9608**
LOSO	NB	0.9266	0.8828	0.8845	0.9263
LOSO	NW	0.9522	0.9137	0.9155	0.9517
LOSO	BW	0.9494	0.9013	0.9032	0.9491
LOSO	N	0.9160	0.8653	0.8673	0.9159
LOSO	B	0.8714	0.8029	0.8042	0.8702
LOSO	W	0.9263	0.8565	0.8593	0.9247

3.5.2 Training Output

Table 3 summarizes single-split performance across sensor combinations. The results are evaluated in terms of Accuracy and Balanced Accuracy (weighted by the number of samples per class), along with F1 scores. The F1-score as defined in Equation (1) is a main machine learning evaluation metric that balances precision and recall into a single score to represent the harmonic mean. We selected the Macro F1-score, which is the unweighted average of the F1-scores computed independently for each class, and the Weighted F1-score which averages the F1-scores per class, weighted by the number of samples per class.

$$\mathrm{F1}_c = \frac{2 \cdot \mathrm{Precision}_c \cdot \mathrm{Recall}_c}{\mathrm{Precision}_c + \mathrm{Recall}_c} \tag{1}$$

$$\text{Macro-F1} = \frac{1}{C} \sum_{c=1}^{C} \mathrm{F1}_c \tag{2}$$

Table 4. Activity–motion lists used in the evaluation.

No	Activity	Motion
1	walking	walking squatting-down
2	brick lifting	squatting squatting-up elbow-flexion
3	carrying	walking
4	brick placing	bending-down bending-up
5	grab hammer in closet	shoulder-abduction thrusting shoulder-abduction
6	hammering	elbow-flexion elbow-extension shoulder-flexion shoulder-extension
7	grab heavy toolbox	kneeling-down
8	place toolbox on top	kneeling-down thrusting
9	stretching	twisting shoulder-extension shoulder-flexion

$$\text{Weighted-F1} = \frac{\sum_{c=1}^{C} N_c \cdot \mathrm{F1}_c}{\sum_{c=1}^{C} N_c} \tag{3}$$

Neck–wrist achieves the highest accuracy 0.9748 and the highest balanced accuracy of 0.9451. It also delivers the best Macro-F1 of 0.9485 and weighted F1 of 0.9743. The tri-sensor NBW configuration achieves a competitive accuracy of 0.9670 and a balanced accuracy of 0.9396. Neck–back and back–wrist trail by small margins across all metrics. Single-sensor settings degrade, with back only at 0.8874 accuracy and wrist at 0.9470. These results indicate that the wrist provides strong discriminative cues and that the neck complements it well. The limited gains of NBW over neck–wrist suggest a two-sensor design is sufficient for field deployment

3.5.3 Real-time Inference

In-lab performance test was conducted with three participants who did not participate in training data collection process. Performance test consists of a series of activities commonly observed in construction fields, and each activity is a combination of 1 to 4 basic motions defined for data collection. The test sequence of activities and their motion composition are described in Table 4.

4 Result

4.1 Result of Single Split

We outline an 8:2 ratio single-split TCN training using 7 sensor combinations to verify its accuracy on the inference test. Results in Table 5. show that the model achieves an average accuracy of 77.64%. The optimal combination is NBW, achieving an average accuracy of 83.26%,

Table 5. Single-split inference results

Combination	Run#1	Run#2	Run#3	Run#4	Run#5	Run#6	Run#7	Run#8	Run#9	AVG
NBW	**0.8182**	**0.8608**	**0.8356**	**0.8033**	**0.8194**	**0.8209**	**0.8361**	**0.8358**	0.8636	**0.8326**
NB	0.7848	0.7595	0.7848	0.7237	0.7722	0.7975	0.7910	0.8058	0.7879	0.7785

W	0.7342	0.7215	0.7260	0.6842	0.7342	0.7468	0.7761	0.7463	0.7576	0.7363

Table 6. LOSO inference results

Combination	Run#1	Run#2	Run#3	Run#4	Run#5	Run#6	Run#7	Run#8	Run#9	AVG
NBW	**0.7468**	**0.8075**	**0.7733**	**0.8226**	**0.8194**	**0.7971**	**0.7903**	**0.8060**	**0.8182**	**0.7979**
NB	0.6582	0.6076	0.6027	0.5672	0.5890	0.6076	0.6000	0.6119	0.5909	0.6039
NW	0.7179	0.7722	0.7534	0.7143	0.7361	0.7612	0.7869	0.7463	0.7576	0.7495
BW	0.7215	0.6582	0.6579	0.6212	0.6489	0.6418	0.6515	0.6716	0.6061	0.6532
N	0.6962	0.6709	0.6962	0.6557	0.6667	0.7206	0.6825	0.6866	0.7273	0.6892
B	0.5897	0.5949	0.5890	0.5385	0.5833	0.6119	0.6615	0.6567	0.6218	0.6053
W	0.6456	0.6582	0.6712	0.6190	0.6667	0.6418	0.6769	0.7313	0.6970	0.6675

confirming that three sensors provide robust performance. BW and NB form a middle tier with averages of 79.26% and 77.85%, indicating moderate loss when one sensor is removed. Among single-sensor setups, Neck performs best at 77.20%, while Wrist reaches 73.63% and Back remains lowest at 68.78%. Including the wrist consistently improves performance across all multi-sensor configurations. These results suggest that single-split training better captures richer temporal patterns, and that the NW configuration offers the best balance between accuracy and sensor reduction.

4.2 Result of LOSO

We present accuracy results for 7 sensor combinations and 19 motions for the TCN model trained using the LOSO method. Results show the model predicts with an average of 68.09% accuracy total. The optimal combination is NBW, with an average accuracy of 79.79%. Numerical results of accuracy are shown in Table 6. NW is the next strongest at 74.95%, which indicates a viable two-sensor option. Removing the wrist most adversely affects accuracy, with NB averaging 60.39% and BW dropping to 65.32%. For single sensors, the ranking is Neck at 68.92%, Wrist at 66.75%, and Back at 60.53%. Adding the wrist to the neck raises accuracy by 6.03 points, while adding the wrist to the back raises it by 4.79 points.

4.3 Sensor Combination x Training Method

Both single-split and LOSO training methods achieve the highest accuracy with the NBW combination, indicating that using all three sensor points is superior to leaving out one or two sensors during training. Single split training performed better across all 7 combinations than LOSO training in the current dataset, achieving an average accuracy of 83.26% in the NBW combination.

5 Discussion

The causal TCN is benchmarked across seven sensor configurations under simple single-split and leave-one-subject-out regimes. The LOSO method was applied to enhance person-to-person generalization. Although the LOSO method was expected to perform better due to its generalization to different human samples, the results indicate better inference performance on the simple 8:2 split. This result may have occurred due to a small number of training samples that were not large enough to ensure cross-person generalization with the LOSO method.

The results show that Neck+Back+Wrist(NBW) combination of sensors is optimal for worker motion monitoring with an average of 83.26%(8:2 split) and 79.79%(LOSO) accuracy. This indicates adding sensors to major nodes of body movement will increment motion prediction accuracy but not significantly. However, the hazardous nature of the construction field makes it difficult to add more sensors especially on body nodes since devices on movement nodes can interfere with natural movements. Excluding the NBW combination, Neck+Wrist(NW) combination also displayed reasonably high accuracy compared to the other 5 combinations, showing the possibility of reducing sensors while maintaining high prediction accuracy.

The results in both training methods reveal similar error sources: (i) predicting a single motion when the activity contains multiple motions, (ii) using a two-second window that can blur short transitional states, and (iii) misclassifying coupled motions such as elbow extension occurring with shoulder extension. The first and second error sources

share similar ground which means solving one is likely to solve the other together. The first issue can be addressed by scaling up the prediction to the activity level, where an activity is a combination of multiple consecutive motions. This will still predict motions, but inaccurate predictions may occur due to the order of predictions, or transition motions may be ignored on a larger scale. The third issue should be solved by weighting wrist gyro and acceleration data during training, as most of the confusion arises from elbow and shoulder actions that rely heavily on wrist PPU motion data.

To address the suggested problems while maintaining the project's real-time prediction concept, we plan to scale from motion to activity to align with practical field display. This is to define an activity as a combination of multiple basic motions; for example, brick lifting as a combination of squatting down, elbow flexion, and squatting up. Our data collection and inference were conducted in a controlled laboratory setting with scripted motion sequences and fixed timing. This environment is less dynamic and more predictable than active construction sites; thus, real-world variability, interruptions, and tool interactions may reduce performance. We will validate on live construction sites in future work. Our next step is to extend the TCN to predict real-world activities as time-ordered combinations of motions, and to embed a pre-trained model on a microcontroller for live construction-site deployment. On the hardware side, we are actively working to improve the wearability of the PPU system. Current efforts focus on reducing the wrist unit to approximately 2 inches in diameter through improved circuit design and power management, bringing it closer to the form factor of a standard wristband. This size reduction is a stepping stone toward embedding the sensing units into existing PPE such as hard hat liners and safety vests, which would eliminate separate donning steps and lower the adoption barrier on active jobsites.

6 Conclusion

This work presented a causal TCN for real-time worker motion recognition using three IMUs. The system uses short windows and per-window normalization, and it runs at 50 Hz with modest compute. Across seven sensor configurations, the NBW setup achieved the best accuracy. Single-split averaged 83.26% for NBW, and LOSO averaged 79.79%, which shows good cross-person generalization. NW was the strongest two-sensor choice and suggests a path to lower burden.

We will expand subjects and environments, add latency and power benchmarks, and deploy a compact model on a PPU. We will also study placement variants and class-weighted training to reduce upper-limb confusion. Overall, the results show that a small, causal model with three IMUs can support practical jobsite monitoring.

Abstract –

This study provides a review of the literature regarding unmanned aerial vehicles (UAV) surveying for emergency facility construction, with a focus on data collection and processing methods. Synthesizing publications between 2016 and 2025, this study categorizes the applications of visible-light cameras, thermal infrared cameras, light detection and ranging (LiDAR), and multi-source sensing configurations. Discussion of data processing highlights key methodologies in image analysis, point clouds, and multimodal fusion, emphasizing semantic segmentation, three-dimensional (3D) reconstruction, and simultaneous localization and mapping (SLAM) as pivotal for transforming raw data into geospatial information. Reported applications focus on natural disaster scenarios and support tasks such as survivor search, route planning, and emergency facility site selection and assessment. These findings provide a basis for the future development of UAV-integrated emergency response systems.

Keywords –

UAV; Emergency Facility Construction; Data Collection; Data Processing

1 Introduction

The global increase in the frequency and severity of disasters, particularly large-scale flooding, earthquakes, and extreme weather events, has placed critical infrastructure and human lives at escalating risk. In the immediate aftermath of such events, priorities shift toward humanitarian relief and the rapid restoration of essential services. Central to these efforts is the timely construction of emergency facilities such as temporary shelters, logistics hubs, and provisional access routes [1]. Effective planning for these facilities requires high-accuracy geospatial information. Yet, conventional ground-based surveying techniques are infeasible in disaster contexts, where access is restricted, terrain is unstable, and time is of the essence [2]. Insufficient terrain mapping can lead to suboptimal or even hazardous facility placement, increasing exposure to secondary risks (e.g., renewed flooding, landslides), and delaying aid delivery.

Unmanned aerial vehicles (UAV) have been adopted for rapid disaster response [3]. Their deployment in Hurricane Wilma [4] and the Lushan earthquake in China [5] demonstrated the value of aerial assessments for identifying damaged areas, guiding rescue teams, and supporting situational awareness. Existing reviews have documented UAV contributions across disaster management, search and rescue, damage detection [6, 7], and civil infrastructure monitoring[8]. However, these applications emphasize visual inspection and reconnaissance rather than the acquisition of high-precision geospatial information. The transition from general aerial awareness to reliable mapping introduces challenges, including stringent accuracy requirements, robust sensor calibration, complex data processing, and the need to operate under hazardous environmental conditions [9].

Recent technological advances are beginning to mitigate these limitations. UAV equipped with high-resolution sensors now facilitate the rapid generation of Digital Elevation Models (DEMs), orthophotos, and other high-fidelity geospatial products [10]. Nevertheless, the literature on UAV-based mapping specifically tailored to emergency facility construction remains fragmented, with limited systematic synthesis of technologies, methodologies, and validated practices

This study addresses this gap by synthesizing research from the past decade, guided by two core research questions:

(1) What recent advances in UAV sensing techniques improve data collection accuracy and speed in challenging environments?

(2) What advanced data processing methods ensure the geometric accuracy required for emergency facility construction?

The remainder of this paper is structured as follows: Section 2 details the methodology for the literature selection and analysis. Sections 3 and 4 present recent advances in UAV-based data collection and processing, respectively. Section 5 summarizes the paper and

highlights research gaps for future work.

2 Literature Search and Bibliometric Analysis

This study employs bibliometric analysis to evaluate English-language literature concerning UAV-based mapping for emergency facility construction published between 2016 and 2025. The search targeted core databases across engineering and technology, geoinformation science, and disaster management. A multi-dimensional search strategy was implemented, integrating UAV-related terms (e.g., unmanned aerial vehicle, UAV, drone); emergency facility-related terms (e.g., emergency infrastructure, disaster infrastructure, temporary facility, relief camp, emergency facility); and disaster scenario-related terms (e.g., disaster relief, post-disaster, post-disaster construction). To ensure a comprehensive dataset, subject terms, keywords, and abstracts were cross-referenced, initially yielding over 100 publications. Following a rigorous screening process to exclude papers with weak relevance to "core UAV mapping technologies" or "practical applications," 93 publications were retained. These were analyzed using CiteSpace for keyword co-occurrence and clustering.

Figure 1 presents the keyword co-occurrence network. High-frequency terms such as “disaster management” and “disaster response” delineate the operational context of emergency facility construction. The network also indicates that deep learning and computational modeling are prominent technical approaches. Because emergency facility construction relies on high-precision geospatial information, deep learning is used for image recognition, target segmentation, and disaster-feature extraction, while computational modeling, mainly referring to three-dimensional (3D) reconstruction, supports terrain simulation and facility layout optimization.

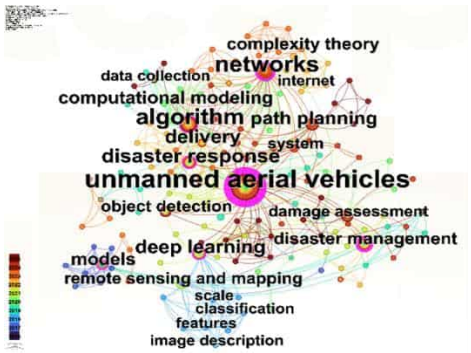

Figure 1. Keyword co-occurrence network

Using the log-likelihood ratio (LLR) algorithm in CiteSpace, seven clusters were identified (see Figure 2). The clustering results yield Q = 0.7455 (> 0.3) and S = 0.9473 (> 0.7), suggesting good separation among clusters and consistency within clusters. The data sensing cluster covers remote data collection and air–ground hybrid data collection, reflecting developments in data acquisition and sensor integration. The data processing cluster includes remote-sensing semantic segmentation and vision-based methods. The practical application cluster includes disaster rescue, security applications, and hazard-mitigation planning, reflecting the use of UAV in emergency facility construction.

Figure 2. Keyword clustering map

3 Data Collection techniques

Emergency facility construction requires survey data with high accuracy and short acquisition cycles, and the ability to accommodate changing disaster conditions. To meet these needs, UAV-based sensing techniques are used to collect different types of data.

3.1 Optical Sensing Technique

Optical sensors capture high-resolution spectral data essential for topographic mapping, feature identification, and damage assessment in emergency contexts.

3.1.1 Visible-light Camera

Visible-light cameras are widely used optical sensors. Eltner et al. [11] used a single UAV-mounted camera to capture optical imagery of small-scale topographic features, including slope micro-relief and debris-flow surface textures. Prokešová et al. [12] extended this approach to larger disaster settings by collecting imagery of landslide-prone areas. Galve et al. [13] investigated debris-flow and landslide sites along Spain’s A-7 highway using an UAV equipped with an ultra-high-resolution camera to collect multi-temporal imagery. To address challenges in pavement deformation measurement in landslide terrain, Cardenal et al. [14] used a mirrorless interchangeable-lens camera and

increased pixel density to support precise deformation measurements. However, visible-light imaging is sensitive to environmental interference. Atmospheric disturbances such as rain and fog can severely degrade image clarity and texture detail, or even obstruct imaging entirely. Furthermore, because visible-light cameras primarily capture planar data, they may not able to provide precise 3D spatial coordinates in occluded disaster environments.

3.1.2 Thermal Infrared Camera

Thermal infrared cameras detect the infrared radiation emitted by objects, translating temperature differentials into thermal signatures. This capability allows them to function in low-visibility conditions, including total darkness or light fog. Hoshino et al. [15] used thermal infrared imaging to exploit radiance differences between human bodies and surrounding backgrounds for victim detection and localization. This mitigates limitations of visible-light imaging in low light or smoke. Similarly, Dong et al. [16] mounted thermal cameras on UAV to collect data on victim postures and occlusions, which can improve survivor detection in earthquake rubble. Tavasoli et al. [17] demonstrated that thermal signatures can be used to map the spatial distribution of victims to prioritize emergency response. However, thermal infrared cameras typically feature lower spatial resolution than visible-light cameras.

3.2 Light Detection and Ranging (LiDAR)

Unlike optical sensors, LiDAR acquires dense 3D point clouds by emitting laser pulses and measuring returned signals. This provides 3D geometric detail along with spatial coordinates and distance measurements. LiDAR performance is largely independent of ambient lighting, making it suitable for nocturnal operations. Additionally, its multi-echo capabilities allow it to penetrate partial vegetation or debris cover, maintaining high ranging accuracy where optical sensors fail. Pellicani et al. [18] used LiDAR to collect high-density point clouds in landslide areas. Zhou et al.[19] used pre- and post-hurricane LiDAR point clouds to quantify damage to residential buildings, enabling assessment without additional contact with unstable structures during emergency operations. Despite these advantages, LiDAR systems remain high-cost, and their ranging precision can still be attenuated by extreme weather conditions.

3.3 Multi-Source Sensor Fusion

Table 1 summarizes the strengths and limitations of visible-light cameras, thermal infrared cameras, and LiDAR. In applications, these sensors are often combined to address the limitations of any single sensor.

Table1 Functions, limitations and factors of UAV-borne sensor types

Sensing type		Functions	Limitations	Factors
Optical sensor	Visible light camera	2D images	Poor adaptability to low-light and harsh weather; Only 2D information	Sunlight; Rainfall; Fog
	Thermal infrared camera	2D thermal radiation images	Low spatial resolution; No texture information	Heavy fog; Overcast and rainy; Severe dust
LiDAR sensor	LiDAR	3D spatial information	High cost; No spectral and thermal information	Heavy fog; Overcast and rainy
Multi-source sensor	Visible light camera+ Thermal infrared camera	2D texture and thermal radiation information	Dominated by 2D information; Limited data accuracy	Vegetation occlusion; Heavy fog
	Visible light camera+ LiDAR	3D spatial and 2D texture information	High cost; Poor adaptability to harsh weather	Heavy fog; Heavy rain
	Thermal infrared camera+ LiDAR	3D spatial and thermal radiation information	High cost; No texture information	Heavy fog; Overcast and rainy
	Visible light camera + Thermal infrared camera +LiDAR	3D spatial, 2D texture and thermal radiation information	Highest cost; Complex data fusion process	Extreme harsh weather (e.g., severe rainstorm and heavy fog)

Sensor fusion approaches combine sensors according to the data requirements of emergency surveys, disaster monitoring, and related tasks during raw data acquisition. Mineo et al. [20] used visible-light imagery

to reconstruct the 3D geometry and surface texture of landslides and integrated thermal infrared data to identify thermal anomalies in rock and soil. This combination supports characterization of landslide morphology while capturing subsurface- or surface-related thermal signals. Yu et al. [21] improved post-earthquake facility safety assessment by combining visible-light imagery of surface damage with LiDAR-derived 3D point clouds at millimeter-level accuracy. Cella et al. [22] used thermal infrared imaging to locate survivors and identify high-temperature hazards, while using LiDAR to generate 3D models to support spatial context in rescue operations. Shen et al. [23] integrated visible-light data for texture-based damage detection, thermal infrared data for thermal anomaly detection, and LiDAR for 3D geometric reconstruction, covering multiple information needs in post-disaster surveys. Overall, multi-source sensor fusion provides task-specific raw datasets that support subsequent data processing.

4 Data Processing Methods

Raw datasets acquired in disaster zones are typically voluminous, heterogeneous, and redundant. Data processing in this field focuses primarily on image and point cloud data.

4.1 Image Data Processing Methods

Processing of optical imagery emphasizes texture information and semantic attributes, and commonly uses deep learning to convert raw imagery into structured outputs. This section focuses on semantic segmentation and 3D reconstruction.

4.1.1 Deep Learning-based Image Semantic Segmentation

To improve semantic segmentation accuracy for UAV imagery, Zhou et al. [24] proposed a lightweight UAV frequency-aware and attention-enhanced network. Sui et al. [25] proposed the typical disaster bearing objects segmentation network semantic segmentation model, which can supported disaster target recognition in flood-related UAV imagery. To further enhance the specificity and precision of semantic segmentation, Stache et al. [26] combined a deep learning–based accuracy model with a UAV adaptive path-planning algorithm to link segmentation performance with data collection strategy, supporting decisions in emergency facility planning. However, the efficacy of these models remains contingent upon image quality, and the high computational overhead often hinders the real-time performance critical for immediate response.

4.1.2 3D Reconstruction using Structure from Motion (SfM)/Multiview Stereo (MVS)

With advances in computer vision, integrated SfM/MVS pipelines are widely used for 3D reconstruction from UAV imagery. These methods extract image feature points, estimate camera poses, generate sparse point clouds, and then perform dense reconstruction [27]. To mitigate computational latency, Zhang et al. [28] proposed an end-to-end latency optimization strategy that reduced modeling delay by about 40% while maintaining reconstruction accuracy. Wang et al. [29] used region-based parallel reconstruction and plane-detection optimization to improve efficiency and model completeness without requiring high-performance hardware. Despite these gains, SfM/MVS remains largely an offline, batch-processing approach, making it less suitable for incremental mapping in dynamic environments.

4.1.3 3D Reconstruction using Visual Simultaneous Localization and Mapping (SLAM)

Compared with SfM/MVS, visual SLAM supports real-time localization and incremental mapping, which aligns with the time constraints of emergency data processing [30]. To address accuracy and timeliness in post-disaster UAV surveying and mapping, Bi et al. [31] developed a UAV visual SLAM processing system based on ORB-SLAM2, improving both accuracy and real-time performance. Huo et al. [32] extended the workflow to include image correction and stitching, as well as obstacle detection. They further applied map fusion and path-planning algorithms to connect While visual SLAM aligns well with the time-sensitive nature of emergency response, it frequently struggles with feature-point matching in highly dynamic environments or areas with dense obstacles.

4.2 Point Cloud Data Processing Methods

Point clouds are the primary 3D data product collected by LiDAR, and their processing affects the accuracy of emergency surveying and mapping. This section reviews point cloud semantic segmentation and LiDAR-SLAM–based 3D reconstruction.

4.2.1 Deep Learning-based Point Cloud Semantic Segmentation

Deep learning methods for LiDAR point cloud semantic segmentation use neural networks to extract point-level features and assign category labels, providing semantic information for tasks such as 3D scene understanding and emergency mapping. Atik et al. [33] proposed the SegUNet3D ensemble approach, which converts point clouds into distance images and extracts

geometric features. Li et al. [34] addressed the trade-off between data complexity and processing efficiency in large-scale segmentation by proposing the slight filter learning network. However, a persistent challenge in this area is the heavy reliance on large, annotated datasets, which are often unavailable in unique disaster contexts.

4.2.2 LiDAR-SLAM–based 3D reconstruction

Compared with image-based reconstruction, LiDAR-SLAM does not require inferring 3D structure from 2D pixels. Instead, it uses the inherent spatial coordinates of point clouds to support geometric reconstruction and mapping [35]. Kaul [36] developed a compact quadcopter-based reconstruction method that generates dense point cloud maps using continuous-time SLAM. Real-time performance remains a constraint in many deployments. Mojtaba et al. [37] proposed a low-latency LiDAR-SLAM framework for incremental 3D reconstruction using lightweight point cloud segmentation and parallel matching, targeting high-dynamic, small-scale scenarios. Ćwian et al. [38] used geometric feature representations and factor-graph optimization to improve accuracy and efficiency in large-scale reconstruction. Together, these studies illustrate how LiDAR-SLAM pipelines can be adapted to different operational settings. However, positioning accuracy is often compromised in feature-sparse environments, as the scarcity of structural landmarks limits the algorithm's ability to maintain a stable spatial reference.

4.3 Processing Method for Fused Data

Image–point cloud fusion aims to combine complementary information: images provide texture and semantic cues, while point clouds provide 3D geometry. This section focuses on semantic fusion segmentation and SLAM-based 3D reconstruction using visual/LiDAR fusion.

4.3.1 Image–point cloud semantic fusion segmentation

Fusion-based segmentation methods vary by scenario and by the constraints of annotation, scale, and runtime. Dong et al. [39] proposed a parallel dual-stream (PD) network for semi-supervised semantic segmentation to reduce dependence on extensive labeled data in bimodal image–point cloud segmentation. Zhang et al. [40] proposed a deep learning-based image-point cloud fusion proposed an image–point cloud fusion scheme for large-scale 3D emergency scenarios to address segmentation error and missing information. Bultmann et al. [41] used a lightweight CNN with an embedded inference accelerator to integrate multimodal semantic cues into point cloud and image segmentation masks, producing global semantic maps suitable for time-constrained data processing. All these advances significantly improve the spatial resolution and reliability of semantic segmentation.

4.3.2 Visual/LiDAR SLAM–based 3D Reconstruction

By combining modalities, researchers can overcome the field-of-view limitations of LiDAR and the illumination sensitivity of vision [42]. Tong et al. [43] proposed a multi-sensor fusion framework that extends LiDAR-SLAM–based reconstruction to support emergency infrastructure surveying under complex conditions. Lou et al. [44] combined LiDAR with monocular vision to perform SLAM with 3D semantic reconstruction, addressing the limited semantic content of point clouds and supporting applications such as 3D surveying and post-disaster damage assessment. Consequently, this technology is well-suited for emergency infrastructure surveying and the assessment of building damage following seismic or fire events. However, the sophisticated fusion logic inherent in this technology imposes great demands on both algorithmic efficiency and hardware architectures.

5 Conclusion

This study applies bibliometric analysis to review research on UAV surveying and mapping for emergency facility construction published between 2016 and 2025. Using CiteSpace, keyword co-occurrence and clustering analyses were performed on 93 papers. The results indicate concentrations of research on sensor-based raw data acquisition and data processing methods based on deep learning and 3D reconstruction. For data acquisition, the review covers optical sensors (visible-light and thermal infrared cameras), LiDAR, and multi-sensor sensing/fusion configurations. For data processing, the literature centers on image data, point clouds, and multimodal fusion, with emphasis on semantic segmentation, 3D reconstruction, and SLAM-based approaches that convert raw data into geospatial information suitable for operational use.

The presented review focuses on sensors deployed on UAV platforms, related data processing methods, and their applications in emergency facility construction. Future work can assess endurance limitations and mitigation strategies to support sustained surveying and mapping in extended-duration operations, including landslide-prone and flood-affected areas.

Abstract -

Reconstructing internal structural elements remains a significant challenge in the construction industry due to limited access to concealed components. Muon tomography provides a non-destructive approach for capturing information about internal structural conditions, yet its application in construction remains limited, especially in 3D model reconstruction. This paper proposes a few-shot parameter calibration–based framework for automated segmentation and reconstruction of internal building elements from muon tomography data, with a focus on reinforcement bars. The proposed method learns geometric and spatial patterns from a limited number of annotated datasets and generalizes to unseen configurations, reducing reliance on large labeled datasets. Experimental results demonstrate improved accuracy in rebar identification compared to existing segmentation approaches. The reconstructed rebar elements can be converted into BIM-ready representations, enabling applications such as defect detection, structural condition assessment, and digital twin development.

Keywords -

Few-shot geometric calibration; Muon tomography; Point cloud segmentation; Internal reconstruction; Scan-to-BIM

1 Introduction

Reconstruction of the internal condition of concrete structures is essential for ensuring structural safety, assessing durability, and supporting maintenance and retrofit decisions throughout the lifecycle of built assets [1, 2]. Internal features such as reinforcement layout, voids, and concealed damage directly influence structural performance, yet they are often undocumented or difficult to access in existing buildings and infrastructure [3]. As-built documentation may be incomplete, outdated, or unavailable, particularly for ageing structures, further increasing uncertainty in structural assessment and decision-making [4].

To address these challenges, internal concrete structure reconstruction has become an important research topic in construction informatics and structural health monitoring, aiming to infer concealed structural components from indirect sensing data [2]. A range of non-destructive testing techniques has been explored, including ultrasonic testing, electrical resistance tomography, and electromagnetic sensing, with demonstrated potential for detecting internal anomalies and reinforcement [3, 5]. However, many existing approaches are limited in penetration depth, sensitivity to material heterogeneity, or scalability to large and densely reinforced structures [4]. In addition, the resulting outputs are often image-based or qualitative, which restricts their direct use in engineering-oriented digital workflows.

With the growing adoption of digital twins and as-built Building Information Modeling (BIM) in the construction industry, there is an increasing demand for internal sensing methods that can provide volumetric information at structural scale and support downstream modeling and analysis tasks [6]. This has motivated interest in alternative imaging techniques capable of overcoming the physical and practical limitations of conventional non-destructive testing methods [2]. Currently, muon tomography has emerged as a promising solution, offering a fundamentally different inspection mechanism based on naturally occurring cosmic-ray muons [7]. Due to the high penetration capability of muons, this technique enables internal inspection of large and dense concrete structures with millimeter-level accuracy that are difficult to assess using traditional approaches [8, 9].

When applied to construction assets, muon tomography produces volumetric datasets that encode internal material distributions at structural scale [9]. However, these datasets are inherently complex, characterized by large spatial dimensions, indirect measurements, and uncertainty introduced during tomographic reconstruction [10]. Although recent studies have demonstrated the feasibility of applying muon tomography to reinforced concrete structures and other civil infrastructure [6], the interpretation of such data remains largely limited to qualitative visualization or density-based assessment [11]. System-

atic methods for transforming muon tomography outputs into structured, engineering-compatible representations, such as those required for BIM models, have received limited attention, highlighting an important gap between sensing capability and practical construction informatics applications [12].

This paper proposes a few-shot geometric calibration framework for processing muon tomography data to enable automated segmentation and reconstruction of internal building elements, with a focus on reinforcement bars. The method learns geometric priors from a limited number of annotated samples and generalizes to unseen configurations, reducing reliance on large labeled datasets. It is evaluated against existing instance segmentation approaches and demonstrates superior accuracy and robustness in rebar identification and reconstruction. The segmented elements are further converted into structured geometric representations suitable for BIM integration, supporting downstream applications such as structural assessment, defect detection, and digital twin development. The proposed framework advances muon tomography–based construction informatics and provides a practical pathway for as-built internal structure modeling.

2 Literature review

2.1 Internal Concrete structure reconstruction

Reconstructing the internal condition of concrete elements, including reinforcement layout and hidden defects, is fundamental to structural assessment and maintenance. Prior work has primarily relied on non-destructive testing and imaging techniques to infer internal features from indirect measurements. Among these, ultrasonic-based methods are widely adopted due to their practicality for field inspection. Early studies demonstrated the feasibility of ultrasonic testing and acoustic emission for characterizing damage in concrete elements [13] and summarized ultrasonic techniques for reinforced concrete evaluation [3]. To obtain volumetric representations, ultrasonic tomography has been developed and applied at structural scale, including full-scale reinforced concrete inspection [1] and broader reviews of nondestructive acoustic tomography methods for concrete [2].

A major challenge in ultrasonic tomography lies in the ill-posed inverse problem, which has motivated research into improved reconstruction algorithms and regularization. Iterative reconstruction approaches were explored early for ultrasonic imaging in concrete [14]. Subsequent work adopted algebraic reconstruction techniques and iterative solvers to enhance stability and image quality for reinforced concrete inspection [15]. More recently, network-based strategies have been investigated to improve ultrasonic tomography performance [16], while group sparsity has been introduced to reconstruct velocity field images of internal bridge structures [17]. In parallel, methodological advances have been proposed to refine the reconstruction mesh and improve ultrasonic tomography fidelity [18]. A systematic review further confirms the active development of reconstruction strategies and highlights persistent limitations in resolution, robustness, and deployment in complex concrete environments [19].

Beyond ultrasound, complementary modalities have been explored for internal concrete feature detection. Electrical resistance tomography has been used to locate reinforcement and visualize damage-related conductivity changes [4, 20]. Electromagnetic approaches such as microwave imaging have also been investigated for reinforced concrete inspection [5]. For high-resolution material characterization, X-ray and neutron tomography have been applied to reconstruct concrete microstructures and internal features [21], while CT-based 3D reconstruction has been used to analyze pore structures in concrete-related materials [22]. These approaches demonstrate strong imaging potential, but may be constrained by equipment requirements, data complexity, or applicability to field-scale construction scenarios.

Recent studies have also introduced learning-based components to improve internal condition detection, including deep learning applied to ultrasound arrays for two-step detection of internal concrete conditions [23]. However, across sensing modalities, existing work typically outputs voxel-level images or qualitative visualizations rather than explicit, engineering-ready representations of structural components. This creates a gap between internal imaging and downstream construction applications, particularly for workflows requiring component-level reconstruction and integration into digital models.

2.2 Muon tomography technique and construction applications

Muon tomography, also referred to as muography, is a passive non-destructive imaging technique that exploits naturally occurring cosmic-ray muons to investigate the internal structure of large and dense objects [7, 10]. Due to their high energy and strong penetration capability, muons can traverse thick materials such as concrete, rock, and steel, making them suitable for imaging structures that are inaccessible to conventional sensing methods [7, 9]. As muons pass through matter, their trajectories are altered through attenuation and multiple Coulomb scattering, with the degree of deviation dependent on the density and atomic composition of the traversed material [10]. By measuring the incoming and outgoing muon tracks using dedicated detector systems, three-dimensional density distributions of the inspected object can be reconstructed via tomographic inversion techniques [9, 7]. These characteristics have established muon tomography as a robust imag-

ing modality in domains such as nuclear material monitoring, geological exploration, and underground structure inspection, providing a solid technical foundation for its extension to large-scale construction and civil infrastructure applications [7, 10].

In the context of construction and civil infrastructure, muon tomography has recently emerged as a promising technique for inspecting reinforced concrete structures that are difficult to assess using conventional non-destructive testing methods [8]. Early proof-of-concept studies demonstrated the feasibility of imaging the interior of reinforced concrete elements using muon tomography, showing that reinforcement layouts and internal features could be detected with a quality comparable to, and in some cases exceeding, that of ultrasonic and radar-based methods [8, 11]. These studies highlight muon tomography's potential to overcome the penetration depth limitations of traditional techniques when applied to large or densely reinforced concrete components [24].

More targeted investigations have focused on the detection and localization of reinforcement bars within concrete using muon scattering tomography. Simulation-based studies have shown that muon tomography can detect rebars of practical dimensions and distinguish between single and multiple reinforcement layers embedded at different depths [24]. Subsequent experimental and methodological developments further validated the capability of muon scattering tomography to identify reinforcement meshes within large-scale concrete objects and to resolve their relative spatial positions [11, 12]. These works demonstrate the viability of muon tomography for reinforcement detection and highlight its relevance for assessing ageing infrastructure where as-built documentation may be incomplete or unavailable [12].

Beyond reinforced concrete inspection, muon tomography has also been explored for broader infrastructure monitoring applications, including the structural health assessment of large civil assets such as dams. Field deployments have shown that muon-based density imaging can reveal internal deterioration and material loss within massive concrete structures, supporting its potential role as a complementary tool for long-term structural health monitoring [6, 7]. While these studies primarily focus on sensing feasibility and density imaging, they collectively establish muon tomography as a powerful technique for construction-scale internal inspection [9].

Overall, existing research confirms the potential of muon tomography for construction applications, particularly for imaging internal conditions of large reinforced concrete structures. However, most studies emphasize sensing principles, detector development, and qualitative density reconstruction [10]. The extraction of explicit structural components and their integration into engineering-oriented workflows, such as as-built modeling and digital twins, remains largely unexplored, motivating further research on advanced interpretation and reconstruction methods for muon tomography data [12, 6].

2.3 Research gaps

Existing non-destructive inspection methods for reinforced concrete (e.g., ultrasonic and electrical resistance tomography) support internal inspection, but their outputs remain image- or voxel-level and are difficult to convert into component-based models for scan-to-BIM and digital twin workflows [1, 25]. Muography offers high penetration for imaging dense reinforced concrete, yet current construction-oriented studies mainly focus on sensing feasibility and qualitative density reconstruction rather than automated extraction of discrete reinforcement elements for BIM-ready modeling [8, 12].

Few-shot segmentation enables recognition under limited labeled data, typically via meta-learning, but such paradigms rely on large pretraining datasets and are sensitive to domain shifts, making them less applicable to sparse and geometry-driven muon tomography data. Therefore, this study adopts a few-shot geometric calibration strategy, using limited annotated rebar exemplars to extract geometric priors and calibrate segmentation parameters for data-efficient and interpretable reinforcement extraction.

Meanwhile, conventional clustering or model-fitting methods may fragment or merge rebars in dense layouts, while fully supervised learning remains constrained by scarce labeled muon datasets. Thus, approaches that leverage geometric priors and limited supervision are needed to robustly extract reinforcement components and support BIM-oriented internal structural modeling.

3 Proposed method

This section presents an AI-enabled framework for internal structure reconstruction from muon tomography data, designed to enable robust segmentation and BIM-ready representation of internal structural elements, with a focus on reinforcement bars. Figure 1. provides an overview of the proposed framework workflow.

The proposed few-shot parameter calibration method identifies reinforcement bars from a large point cloud by leveraging a small number of labeled rebar examples as geometric references rather than relying on extensive supervised training. Each few-shot sample is first analyzed to estimate its principal axis, radius, length, and straightness using PCA-based geometric analysis. When the number of labeled points is insufficient, the sample is automatically augmented by retrieving geometrically consistent points from the full point cloud. These augmented few-shot examples are then used to compute representative

Figure 1. Enhanced workflow diagram of the AI-enabled framework

statistics, including typical rebar radius, axial variation, local orientation deviation, and radial noise. The proposed few-shot geometric calibration method identifies rebars in large point clouds using a small number of labeled rebar exemplars as geometric references rather than extensive supervised training. Each exemplar is analyzed via PCA-based geometric fitting to estimate axis, radius, length, and straightness, and is augmented with geometrically consistent points when necessary. Representative geometric statistics are then computed to derive calibration parameters controlling neighborhood size, angular consistency, radial deviation, and minimum rebar length. Using these calibrated parameters, a region-growing strategy is applied to segment rebar clusters, with seed selection based on local linearity and iterative growth under spatial and geometric constraints. Cluster geometry is periodically updated to refine axis and radius estimates. A subsequent fill-in step recovers missed but consistent points, and clusters are validated by size, straightness, and length criteria before extracting geometric descriptors for BIM-compatible output.

4 Implementation details

4.1 Dataset preparation

In this study, a simulated approach was first employed to generate volumetric data representing the internal structure, which were stored in the NIfTI (.nii.gz) format. The simulated data were subsequently processed using software provided by GSCAN, through which structural components, including reinforcement and concrete, were identified and encoded in the volumetric representation. The resulting .nii.gz files contain three-dimensional voxel-based data that describe material distributions within the structure.

The NIfTI data are characterized by high dimensionality and volumetric continuity, making them well suited for representing internal structural conditions but less convenient for direct geometric analysis. To facilitate subsequent processing and reconstruction tasks, the volumetric data were therefore converted into point cloud representations, enabling more efficient handling and geometric-based analysis in later stages of the workflow.

The experimental dataset consists of point cloud data representing reinforced concrete elements with irregular rebar layouts. The point clouds were acquired through simulated scanning generation, capturing variations in rebar diameter, curvature, spacing, and overlap. Ground truth geometric information was used only for evaluation purposes and not for training. Figure 2 presents representative reconstruction results obtained using the proposed framework..

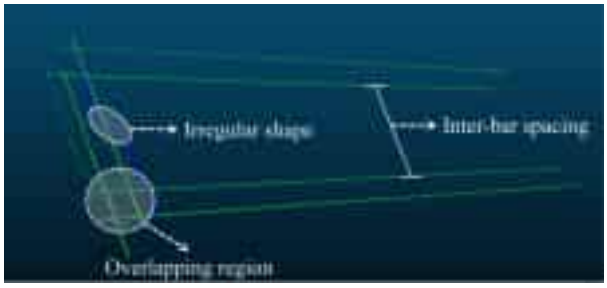

Figure 2. Labeled rebar data for training

4.2 Results of the proposed methods

This subsection presents the results of rebar segmentation from raw point cloud data. The proposed method effectively isolates rebar points from surrounding concrete and noise, even in cases of complex intersections and curved geometries. Quantitative and qualitative results demonstrate stable segmentation performance across different rebar configurations. Figure 3 shows representative examples of challenging rebar layouts, including dense arrangement, local overlap, and irregular spacing.

It is obvious that the segmentation results produced by the proposed AI-enabled few-shot calibrated method. Each reinforcement bar is identified as an individual cluster and visualized using a distinct color, demonstrating the method's ability to properly segment closely spaced rebars within a dense internal reinforcement layout.

As shown in the figure, the proposed approach successfully separates individual rebars even in regions with strong spatial proximity and complex intersections.

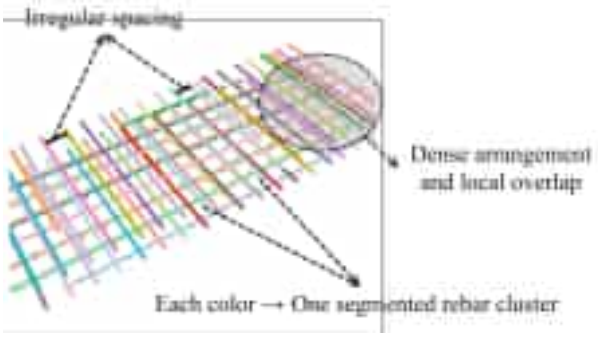

Figure 3. Segmentation results of using the proposed AI-enabled method

Importantly, rebars with irregular geometries and nonlinear connections are also correctly identified as continuous structural elements rather than being fragmented or merged with neighboring bars. This indicates that the geometry-calibrated region growing process effectively preserves rebar continuity while maintaining clear separation between adjacent elements.

Overall, the results confirm that the proposed method can (1) accurately segment individual rebars from complex internal point cloud data and (2) reliably identify connected rebars with irregular shapes, providing structured outputs suitable for downstream applications such as BIM reconstruction, defect detection, and structural condition assessment.

4.3 Comparison with other segmentation methods

This research further compares the proposed method with commonly used instance segmentation algorithms for individual rebar identification, including DBSCAN, cylinder-model fitting, and region growing segmentation.

As shown in Figure 4, DBSCAN detects a large number of rebar instances, with 220 rebars identified. However, the results exhibit severe over-segmentation. Individual rebars are frequently divided into multiple clusters, and the algorithm fails to identify connected rebars with complex or irregular geometries. This behavior is mainly due to DBSCAN's sensitivity to point density and distance thresholds, which limits its robustness in dense reinforcement layouts.

Figure 5 presents the results obtained using cylinder-model fitting, where only 36 rebars are detected. Many rebars are missed due to the strict geometric assumptions of the cylinder model, and connected rebars cannot be correctly identified. This approach is particularly sensitive to incomplete or noisy data and struggles to represent irregular rebar shapes.

As illustrated in Figure 6, region growing segmentation detects 56 rebars but suffers from significant fragmentation, especially for vertical rebars. While region growing partially captures linear structures, it fails to maintain rebar continuity and cannot reliably identify connected rebars, leading to incomplete and fragmented segmentation results.

Overall, the comparison demonstrates that existing instance segmentation methods either over-segment rebars or fail to capture their connectivity and irregular geometry. In contrast, the proposed few-shot calibrated method achieves accurate individual rebar segmentation while preserving connected and irregular rebar structures, highlighting its robustness and suitability for construction-oriented applications.

Figure 4. Segmentation results of using DBSCAN

5 Results and discussion

The experimental results demonstrate clear performance differences between the proposed method and commonly used instance segmentation algorithms for rebar identification, highlighting the challenges of density-based, model-based, and purely geometric approaches when applied to complex internal reinforcement layouts. DBSCAN detects a large number of rebar instances but suffers from severe over-segmentation. Individual rebars are frequently fragmented into multiple clusters, particularly under varying point density or close spatial proximity, preventing reliable identification of connected rebars and irregular geometries. Cylinder-model fitting exhibits the opposite behavior, detecting only a small subset of rebars. The method relies on strong geometric assumptions and is sensitive to incomplete data and deviations

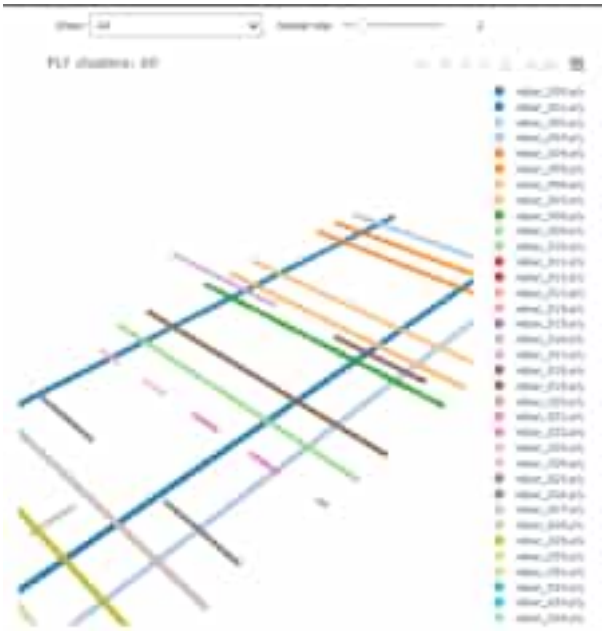

Figure 5. Segmentation results of using cylinder-model fitting

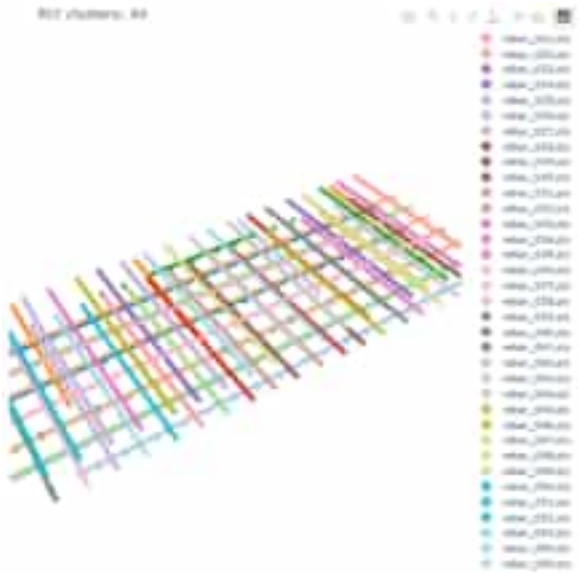

Figure 6. Segmentation results of using the region growing segmentation

from ideal cylindrical shapes, leading to missed rebars, under-segmentation, and incomplete internal structure reconstruction. Region growing achieves moderate detection performance but produces fragmented results, especially for vertical rebars. Although linear features are partially captured, the absence of calibrated geometric constraints prevents reliable identification of continuous and connected rebars. In contrast, the proposed few-shot calibrated method achieves accurate individual rebar segmentation while preserving continuity and connectivity, including irregular rebars embedded in structural components. This capability supports internal reinforcement modeling and downstream applications such as structural condition assessment, defect detection, retrofitting planning, as-built BIM generation, and digital twin development.

Several limitations of this study should be noted. First, standard quantitative instance segmentation metrics (e.g., IoU, precision, recall, and F1-score) were not reported, as no benchmark dataset was available for this evaluation. The current assessment is therefore based on manual observation and qualitative analysis. The current datasets are generated through simulation-based muon tomography, and robustness under real acquisition noise and reconstruction artifacts remains to be validated. Experiments were conducted on a limited range of reinforcement layouts and reconstruction settings; broader tests on varying densities and resolutions will be explored. Finally, while scan-to-BIM conversion is demonstrated, detailed evaluation of geometric parameter extraction and IFC/BIM generation accuracy will be investigated in future work.

6 Conclusions

Reconstructing internal structural elements remains a significant challenge in the construction industry due to the limited accessibility of concealed components. While muon tomography offers a promising non-destructive means of capturing internal structural information, its practical use in construction has been constrained by the complexity of the data and the lack of effective processing methods. Addressing this gap, this paper proposed a few-shot parameter calibration–based framework for the automated segmentation and reconstruction of internal building elements from muon tomography data, with a particular focus on reinforcement bars.

By leveraging a small number of labeled examples to calibrate geometry-driven segmentation, the proposed method generalizes effectively to unseen rebar configurations and reduces reliance on large annotated datasets. Comparative experiments demonstrate that the proposed approach achieves improved accuracy and continuity in rebar identification compared to commonly used segmentation methods. Furthermore, the reconstructed rebars are directly convertible into BIM-ready representations, enabling practical applications such as defect detection, structural condition assessment, retrofitting planning, and digital twin development for existing structures.

7 Acknowledgments

This research is part of the "Muon Tomography for Assessing Bridge Structures" (M-TABS) project, funded by Innovate UK (Project Ref: 10132366). Abstract -

Extrusion-based robotic additive manufacturing for construction-scale fabrication is highly sensitive to process faults such as unstable flow, clogging, and fluctuations in feed supply. Without continuous monitoring, these failures can cause prolonged non-deposition and geometric error. To address this limitation, this work presents a vision-guided supervisory framework that couples nozzle-centric process perception with controller-level intervention on an industrial robot. Visual process feedback is obtained from an eye-in-hand RGB-D camera, whose observations are processed online by an instance-segmentation model to classify extrusion behavior. In parallel, motion and process data are retrieved from the robot controller, establishing a common temporal basis between sensed process state and executed robot motion. Upon detection of persistent extrusion failure, the supervisory layer adjusts a bounded program override to reduce or halt robot motion, thereby constraining air-printing duration and facilitating prompt intervention. A proof-of-concept demonstration on an industrial robotic extrusion platform compares nominal reference prints with an induced pump-off failure event in which extrusion loss is detected online and followed by controller action. The results show a practical route toward process-aware supervision without invasive controller modifications and provide synchronized logs for future learning-based methods.

1 Introduction

Additive manufacturing (AM) is increasingly explored for large-scale construction, yet robust and repeatable printing remains challenging due to the interplay of multiple time-coupled sub-processes [1]. These challenges become more pronounced for rheology-sensitive and non-cementitious feedstocks, where process stability depends strongly on material consistency and environmental conditions [2]. Motivated by reducing embodied emissions of cement-intensive construction, earth-based materials are receiving growing attention as printable alternatives, commonly discussed under the emerging framework of 3D Printed Earth (3DPE) [3, 4]. However, printable mixtures in 3DPE can be highly sensitive to soil composition and moisture content, which affects fresh-state extrudability and build-up performance [5]. Consequently, intermittent flow, clogging, and bonding-related defects can occur during long-duration prints and may remain unnoticed without continuous monitoring [6]. For construction-scale extrusion AM, prior work further highlights that quality assessment should be performed in-process and in-line across multiple scales rather than relying on a single indicator [7].

To overcome the limited availability of practical supervision strategies for extrusion-based robotic printing, this work presents a vision-enabled supervisory loop that detects extrusion state online and triggers controller-side responses to reduce the risk of failing prints. Extending earlier in-process monitoring approaches, this study focuses on integrating near-nozzle RGB-D perception with controller-side intervention in active printing. Robot state variables are streamed from the KUKA KRC4 controller of a KUKA KR210 R3100 via KUKAVarProxy (KVP) and temporally aligned with extrusion-state estimates derived from an eye-in-hand Intel RealSense D405 RGB-D camera. A proof-of-concept experiment demonstrates that detected extrusion-loss events can be followed by adaptive reduction of the program speed override, slowing or pausing motion to enable recovery before major print degradation accumulates. The main contributions are:

- **KVP supervisory interface:** Time-stamped streaming of robot state and read/write access to selected robot variables.
- **Vision-based extrusion monitoring:** Confidence-based extrusion-state detection.
- **Fail-safe intervention policy:** Detect–slow/stop

program-override strategy to mitigate air-printing.

- **Loop-level characterization:** Measurement of detection delay and end-to-end latency (perception → KVP write → override effect) plus qualitative failure-mitigation outcomes.
- **User interface:** Runtime supervisory UI for tuning τ and logging.

As shown in Fig. 1, the experimental platform comprises a pump-fed material supply and a nozzle end-effector mounted on an industrial robot. An eye-in-hand vision sensor observes the nozzle and immediate deposition zone to enable in-process monitoring of extrusion continuity during execution.

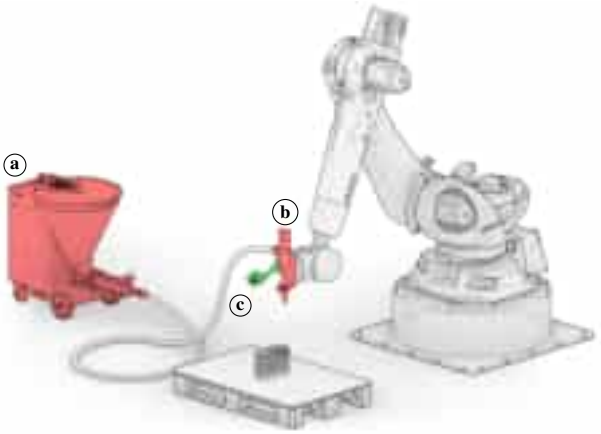

Figure 1. Robotic AM setup: (a) feeder/pump, (b) end-effector/ extruder, (c) eye-in-hand vision sensor.

2 Related work

Large-scale AM has evolved from geometry- and material-centric studies toward integrated pipelines that combine sensing, interpretation, and intervention. This section reviews (1) quality assessment and in-process monitoring for extrusion-based AM and (2) controller interfaces that enable supervisory feedback on industrial robots.

2.1 Quality assessment and in-process monitoring

Quality assessment in extrusion AM can be performed during fabrication (*in-process*) or after completion (*post-process*), and it can be embedded in the production flow (*in-line*) or carried out with separation in time/handling (*at-line/off-line*). In this work, we focus on *in-process, in-line* supervision to enable immediate intervention while the robot program is executing.

Table 1 summarizes the monitoring terms used in this paper. We use *in-process* to denote measurement during fabrication, and *in-line* for sensing integrated into the production flow without interrupting execution.

Table 1. Terminology used in this paper for monitoring and inspection placement.

Term	Description (as used in this work)
In-process	Measurement during fabrication; enables immediate detection/intervention.
Post-process	Inspection after fabrication; verification and documentation.
In-line	Embedded in the production flow; no interruption of execution.
At-/Off-line	Separated from production by handling and/or time delay; delayed feedback.

Extrusion-based AM comprises interdependent subprocesses whose timing and interaction strongly influence print quality, motivating standardized evaluation and monitoring strategies [1]. For construction-scale extrusion, monitoring is frequently framed as a multi-scale problem where no single indicator is sufficient; instead, assessment should cover material delivery, geometric consistency, and early-age behavior [7]. Early demonstrations of measurement-informed correction further indicate that real-time sensing can support corrective actions during deposition [8].

Vision-based monitoring complements geometric inspection by providing spatially resolved observations around the nozzle and deposited bead. Robot-vision methods have been used to support environment-aware printing and adaptive decisions under non-ideal boundary conditions [9]. For earthen extrusion, monitoring is particularly relevant because material variability (e.g., soil composition, moisture) can affect extrudability, build-up, and interlayer bonding [2, 5]. Frameworks for 3DPE emphasize both sustainability motivations and increased process variability introduced by earth-based feedstocks [3, 10].

Beyond monitoring placement, inspection can also be distinguished by *granularity* (e.g., nozzle-centric point/feature cues versus stage-level or post-print verification); in this work, point/feature cues are used to trigger stage-level supervisory intervention (slow-down or stop) during deposition [7].

Commercial desktop fused deposition modeling (FDM) systems further illustrate camera-based failure detection during printing, where detected anomalies can trigger a pause of the build [11, 12, 13].

2.2 Controller interfaces for supervisory feedback in robotic fabrication

Industrial robot-based fabrication typically relies on supervisory feedback rather than low-level closed-loop control: external sensing triggers discrete interventions such as slowing, pausing, or adjusting process parameters. In

construction printing, this trend is reflected in the shift from measurement-only systems toward monitoring-and-action loops where sensing is explicitly coupled to control signals [8, 7].

A practical barrier is the limited and vendor-specific access to controller state and intervention channels. Available interfaces differ in achievable update rates, integration effort, and required controller-side configuration. For KUKA systems, prior work contrasts KVP and the Robot Sensor Interface (RSI), highlighting timing behavior and trade-offs for feedback applications [14]. Lightweight and open solutions are therefore attractive for research prototypes, as they reduce reliance on licensed options and minimize invasive controller modifications.

Building on these insights, the present work implements a vision-enabled *supervisory* loop using KVP: controller state (e.g., axes, tool pose, process-related globals) is streamed and time-aligned with a vision-based extrusion-state estimate, while interventions are applied via program override. This positions KVP as a pragmatic bridge between in-process perception and controller action for extrusion-failure mitigation in robotic 3D printing [14, 7].

3 Methods

System responsibilities are distributed across the robot controller level, KVP-based variable streaming, RGB-D sensing, and a workstation that performs synchronization, inference, dataset recording, and visualization.

3.1 System workflow and architecture

During execution, the workstation acquires and timestamps RGB-D frames of the nozzle region while concurrently polling KRC4 controller variables via KVP, including joint axes, TCP data, and process-related globals such as `$OV_PRO`). Both streams are synchronized, stored in a session-structured dataset, and visualized in a custom interface (Figure 3).

The synchronized observations are subsequently used for extrusion-state classification within a nozzle-centric region of interest (ROI), yielding a binary printing/non-printing signal. Based on this signal, a fail-safe supervisory intervention policy maps sustained extrusion loss to a bounded controller-level action via `$OV_PRO` through KVP, thereby slowing or stopping motion to limit "air-printing" and enable timely recovery.

As shown in Figure 2, the system architecture is organized into a robot controller level and a supervisory level. At the robot controller level, the program executes the print motion while robot state variables are made accessible through KVP. At the supervisory level, an RGB-D camera feed is processed by the detection pipeline to determine the current printing state from the nozzle region. This decision is then mapped to controller action by writing `$OV_PRO` via KVP: printing continues under the nominal override, whereas sustained non-printing triggers a reduced override to slow down or effectively pause robot motion.

3.2 Robotic printing platform and sensing

The experimental setup uses a KUKA KR210 R3100 with an Erratic Extruder MS40 supplied by an Erratic Feeder DM80 through a 5 m hose. To observe deposition at the nozzle, an Intel RealSense D405 short-range RGB-D camera is mounted in an eye-in-hand configuration on the robot flange and oriented toward the nozzle and immediate deposition region (Figure 4). This viewpoint captures bead formation and extrusion continuity during motion.

An external workstation serves as the acquisition and logging node. The workstation is a Windows PC that runs acquisition, synchronization, inference, visualization, and dataset recording. RGB and depth frames are streamed from the D405 with per-frame timestamps, while robot state and selected controller and process variables are ac-

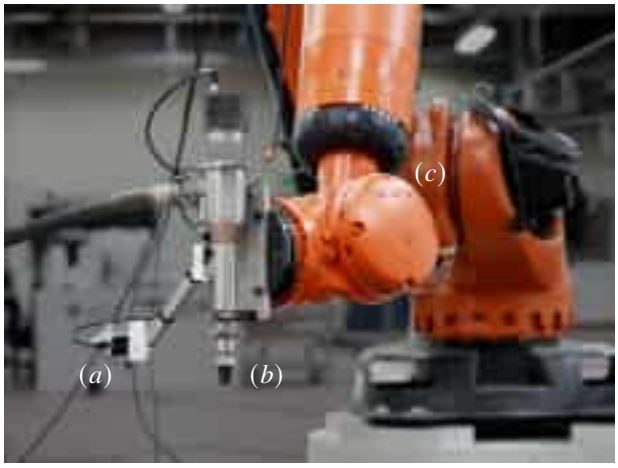

Figure 4. Eye-in-hand nozzle-centric sensing setup: RGB-D sensor (a) mounted to observe nozzle region (b) on the industrial robot (c) for in-process extrusion monitoring.

Table 2. Logged variables, corresponding KUKA controller variable semantics and Description.

Log key	KUKA variable	Description
t_wall	–	Host wall-clock timestamp (Unix s); session reference time.
t_mono	–	Host monotonic time (s); stable for latency measurements.
t_robot	–	KVP interface timestamp associated with each sample.
a1..a6	`$AXIS_ACT.A1..A6`	Actual joint angles (deg).
e1	`$AXIS_ACT.E1`	External axis position (unbounded / "infinite" axis). In this setup, E1 encodes the extruder axis position; its time derivative relates to extrusion rate.
ov_pro	`$OV_PRO`	Program override / global speed scaling (%).
e_rpm	`E_RPM`	Derived extruder speed computed from E1 progression (scaled to RPM for visualization/ monitoring).
e_mod	`EXTR_MOD`	Extrusion modification override (dimensionless scaling factor).

cessed from the KRC4 via KVP (TCP/IP). Both streams are recorded concurrently in a session-structured dataset, enabling timestamp-based alignment of RGB-D observations with robot kinematics and process state. The overall workflow, including sensing, controller streaming, logging, and the integration of extrusion-state detection with program override intervention, is summarized in Figure 2.

3.3 Controller interface via KVP

Controller telemetry and supervisory actuation are implemented via KVP, which exposes external read/write access to selected KRL global variables and KRC4 system variables over TCP/IP during program execution. Unlike low-level motion interfaces, KVP enables lightweight supervisory feedback through discrete controller-level interventions.

During printing, the workstation polls the controller to obtain time-stamped robot state for contextualization and temporal alignment with RGB-D frames. In the current setup, the logged variables include the joint configuration (A1–A6) and the tool state required to interpret nozzle motion; the interface is extensible to additional process signals (e.g., extrusion rpm, extruder command values) depending on the configured KRL globals. All KVP reads are recorded together with local receive timestamps to capture the as-executed motion state observed by the external supervisor.

Supervisory actions are issued through the same channel using the program speed override `$OV_PRO` as the intervention variable. Upon a sustained extrusion-loss decision, the workstation writes a bounded override value to slow down or effectively pause execution. To ensure stable behaviour and to avoid excessive controller traffic, override writes are rate-limited and only updated on state transitions (normal → intervention, intervention → normal). If automatic recovery is enabled, the nominal override value is cached prior to intervention and restored once extrusion is detected again. Overall, KVP provides a practical link between vision-based monitoring and controller-level motion intervention, while keeping the actuation explicit, bounded, and compatible with safety-oriented supervisory control.

3.4 Data synchronization and logging pipeline

All sensing, controller streaming, inference, and dataset logging are executed on a single workstation to ensure a shared time base. The D405 provides synchronized RGB-D frames of the nozzle region, while robot and process variables are polled from the KUKA controller via KVP (KVP) in parallel. The two streams are acquired asynchronously at different rates: KVP samples are queried at an effective update rate of approximately 9.1 Hz (about 110 ms per update), and the camera stream is recorded at 30 fps. To enable consistent multimodal fusion, every sample is timestamped upon arrival at the workstation using (i) a wall-clock timestamp for dataset indexing and (ii) a monotonic timestamp for latency evaluation.

The logger writes a session-structured dataset with three synchronized components: (1) RGB and depth image sequences, (2) a per-frame timestamp table linking frame indices to host and camera time, and (3) a controller-state log containing the KVP samples, like extrusion value `E1` (Table 2). Note that `E1` is an external-axis position signal that increases along the toolpath; the variable `E_RPM` represents a scaled speed estimate derived from the rate of change of `E1`. In post-processing, each camera frame is associated with the temporally nearest KVP sample in host

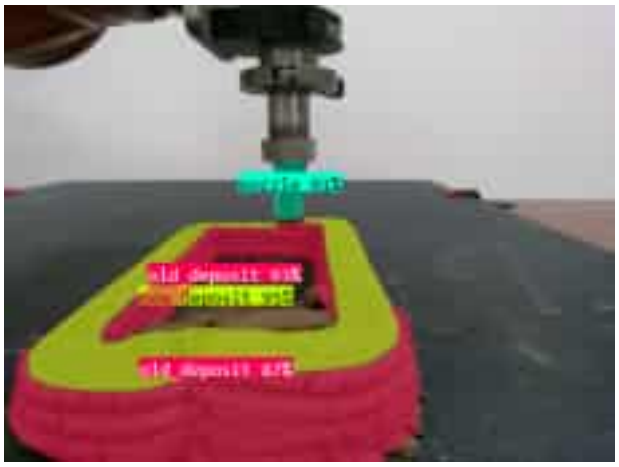

Figure 5. Example YOLOv11 instance segmentation outputs used for extrusion-state inference: nozzle, newly deposited material near the tip (*new_deposit*), and previously deposited layers (*old_deposit*).

time. Associations exceeding a configurable tolerance are optionally rejected to prevent spurious matches under transient delays. This logging design provides time-aligned nozzle observations and robot states for extrusion-state estimation and supervision.

3.5 Vision-based extrusion-state estimation

On top of the logging layer (Section 3.4), a learning-based perception module is trained to detect nozzle-adjacent deposition cues. Recordings were collected under two operating conditions—normal printing and induced extrusion interruption—to capture representative examples of both states. Annotations were managed in Roboflow, and a YOLOv11 instance segmentation model was trained on RGB images to predict three classes: *nozzle*, *new_deposit* (fresh material near the tip), and *old_deposit* (previously deposited layers). Figure 5 shows typical outputs used for subsequent decision logic. In total, 400 images were manually labeled and augmented using geometric and photometric transformations, resulting in 1536 images, which were then split into 92% training, 5% validation, and 2% test data. This setup was used for a fast proof-of-concept validation and to improve robustness under varying conditions, although some augmentation-related correlation risk cannot be fully excluded.

3.6 Supervisory intervention policy

Extrusion supervision is implemented as a rule-based policy that converts vision-derived nozzle-region cues into a controller-level intervention. A YOLOv11 instance-segmentation model predicts instance masks and confidence scores for *nozzle*, *new_deposit*, and *old_deposit* on RGB frames. At runtime, RGB inference is applied to a depth-filtered crop so that evaluation is focused on the near-nozzle working region rather than the wider surroundings. The decision is then restricted to a nozzle-centered ROI beneath the tool, where fresh deposition is expected.

The intervention logic operates on a binary extrusion-state estimate derived from threshold-based ROI evidence for fresh deposition relative to the nozzle tip. To suppress transient misdetections (e.g., brief occlusions or segmentation noise), the decision is filtered using a persistence window τ. In the current experiments, $\tau = 10\,\mathrm{s}$ bounds "air-printing" while reducing nuisance stops; τ can be adjusted at runtime in the developed user interface to match part geometry and acceptable defect tolerance (Fig. 2), trading faster interruption against a higher probability of false stops.

Printing-state decision. From each frame, compact indicators are computed inside the ROI, including (i) nozzle confidence, (ii) the normalized area of *new_deposit* within the ROI, and (iii) a spatial consistency cue that checks whether *new_deposit* occurs in the expected vicinity below the nozzle tip. A *non-printing* state is declared when the nozzle is confidently detected but *new_deposit* evidence remains below threshold or spatially inconsistent with the nozzle tip region.

Temporal buffering. To avoid spurious interventions from transient occlusions and segmentation noise, the decision is temporally filtered using a sustained-evidence criterion. Let $s_t \in \{\text{print}, \text{no-print}\}$ denote the per-frame decision. An intervention is triggered only if s_t = no-print persists for at least τ seconds (here $\tau = 10\,\mathrm{s}$, corresponding to $N = \lceil \tau f \rceil$ frames at frame rate f). This buffering prevents short false negatives from interrupting the process.

Controller intervention via override. When sustained non-printing is detected, the supervisor writes a bounded program speed override to the KUKA controller via KVP using the system variable `$OV_PRO`. Override updates are clamped to valid limits and rate-limited to avoid repeated writes in consecutive cycles. If recovery is enabled, the pre-intervention override value is stored and restored once printing evidence is re-established. Figure 6 illustrates the time-lapse behavior, including ROI evaluation, the printing/non-printing overlay, and the resulting override-based slow-down/stop response under extrusion loss.

4 Experiments and Results

4.1 Baseline vs. induced-fault comparison

To demonstrate the proposed supervisory safety layer, we report a proof-of-concept comparison between (i) a nominal reference run and (ii) an induced extrusion-loss

Figure 6. Time-lapse of the vision-based supervisor during printing, showing the RGB-D decision overlay (printing/not-printing) and tracked nozzle ROI; timestamps (t=00:00–06:40) indicate the evolution over the full run till detected failure and program override intervention.

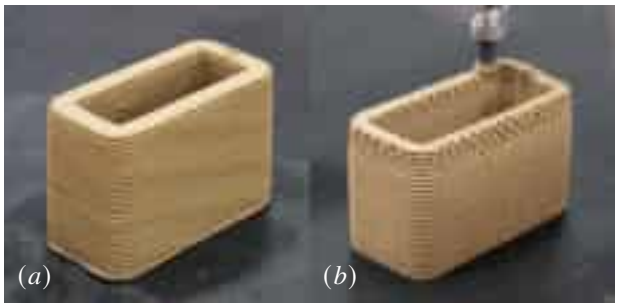

Figure 7. Extrusion-loss comparison: (a) uninterrupted extrusion; (b) induced pump-off event leading to under-extrusion until the supervisor intervenes and stops motion.

Figure 8. Front-view comparison emphasizing deposition quality differences for the same toolpath: (a) baseline deposition; (b) induced pump-off event (poe) leading to under-extrusion with intervention triggered after detected extrusion loss.

run in which the material pump was switched off approximately halfway through execution. The supervisor monitors the nozzle region and, upon sustained non-printing, writes a bounded program-override command via `$OV_PRO` through KVP to reduce motion, thereby limiting continued travel without deposition.

Figure 7 provides geometric context for the failure case. The baseline run (Figure 7a) maintains stable material delivery and produces consistent layer stacking. In the induced-failure run (Figure 7b), turning off the feeder results in progressively under-extruded layers; the final nozzle position indicates where the supervisory loop triggered an override-based stop to prevent further air-printing and to enable recovery actions (e.g., refill or unclogging) before degradation propagates.

While the perspective view highlights the overall geometry, Figure 8 emphasizes the resulting deposition quality. In the baseline case (Figure 8a), bead thickness and layer continuity remain visually consistent. In the failure case (Figure 8b), under-extrusion accumulates over successive layers prior to intervention. Together, the two views illustrate that the proposed supervision can prevent extended motion under extrusion loss, limiting the spatial extent of degraded deposition and supporting timely recovery.

4.2 Runtime performance and response behavior

We evaluate the proposed supervisor in terms of (i) runtime throughput and stability and (ii) override-based intervention behavior under an induced extrusion fault. During live operation, the effective end-to-end processing rate (capture → inference → UI/logging) was approximately 12 fps, below the configured camera capture rate, reflecting workstation compute constraints. Nevertheless, the system operated continuously during the reference and pump-off runs and produced complete, time-stamped logs without dropped-session failures.

In the induced pump-off run, the supervisor triggered a program-override intervention after $\tau = 10\,\mathrm{s}$ of sustained non-printing, reducing motion to limit further travel without deposition.

For the underlying perception module, the YOLOv11 instance segmentation achieved 99.0% precision, 83.9% recall, and 84.3% mAP@50 on the held-out evaluation set. The confusion matrix indicates low class confusion overall, with the dominant errors occurring between *new_deposit* and *old_deposit*, which exhibit similar appearance under the given lighting and surface conditions.

4.3 Validation of the supervisory feedback loop

To complement the proof-of-concept comparison, two small repeated-trial test conditions were evaluated, as summarized in Table 3: a non-stop print test and a stop-test with visible printing degradation. The non-stop test was used to verify that the supervisor does not trigger false interruptions during normal operation, while the stop-test was used to assess whether extrusion loss is detected consistently before visible quality degradation becomes pronounced. Three samples were evaluated per condition as a compact first repeatability check. The results indicate stable behaviour in the non-stop trials and consistent early detection in the stop-tests, supporting the intended role of the loop as an early warning and intervention layer.

Table 3. Repeated-trial timing results for false-interruption screening and early extrusion-loss detection.

Measure	S1	S2	S3
False interruption (non-stop test)	No	No	No
Quality-drop time [s]	26	25	27
YOLO detection time [s]	20	20	20
Lead time [s]	6	5	7

5 Conclusion

5.1 Key contribution and takeaway

This paper presented a vision-enabled supervisory feedback loop for extrusion-based robotic 3D printing that couples in-process perception with controller-level intervention using KVP. An eye-in-hand RGB-D sensor provides nozzle-centric observations, which are converted into an extrusion-state signal and mapped to a bounded intervention through the KUKA program override variable `$OV_PRO`. The loop enables a controller-compatible 'detect, slow/stop' strategy that limits air-printing while preserving lightweight integration with industrial robot controllers.

5.2 Constraints and limitations

This study is a proof of concept with limited experimental scope and fault coverage. All experiments were performed on a single robotic platform using one sensor configuration, and extrusion loss was introduced under controlled conditions; accordingly, generalization to other toolpaths, lighting conditions, and material behaviors remains to be established. Runtime performance was limited by the available computing hardware, resulting in an effective inference rate of approximately 12,fps on a Dell Precision 5680 equipped with an Intel i9-13900H, an RTX 4000 GPU, and 32,GB RAM; this reduces the temporal resolution of the perception stream and may lower sensitivity to brief failure events. While higher inference rates would be desirable for broader deployment, the achieved performance was sufficient for the present proof-of-concept demonstration and offered practical value compared with exclusive reliance on human supervision alone.

The supervisory policy is intentionally conservative, requiring extrusion loss to persist for a configurable time window τ before intervention; this improves robustness against transient occlusions and segmentation noise at the cost of a bounded detection delay. Moreover, the current intervention channel is restricted to program override via `$OV_PRO`, providing reliable slowdown/stop behavior but not yet exploiting additional process actuation variables (e.g., `EXTR_MOD` for increasing/ decreasing extrusion rate) for corrective actions such as extrusion-rate compensation.

5.3 Outlook and scaling path

Future work will expand data collection and evaluation by logging full RGB-D streams, controller variables, and intervention events across a broader set of toolpaths and failure modes. This will support quantitative characterization of loop timing, robustness across operating conditions, and sensitivity to the persistence window τ, as well as refinement of the vision model and decision logic.

Beyond pause/stop interventions, the same controller-access setup can be extended toward *corrective* measures. In particular, future iterations will investigate modulating extrusion commands online (e.g., via `EXTR_MOD`) to compensate short periods of reduced flow, and streaming the executed robot motion state to enable localized path-level recovery, such as re-tracing segments or re-depositing under-extruded layers when deviations are detected. These extensions must be designed in strict compliance with applicable safety regulations and risk assessments: once robot motion is altered autonomously, additional safeguards are required, including bounded interventions, limits on axis travel and rotational speeds, and independent safety mechanisms to prevent harm to personnel or equipment. This positions the presented KVP-enabled supervi-

sor as a scalable foundation for increasingly process-aware robotic extrusion AM.

6 Acknowledgement and Funding

The authors gratefully acknowledge the support of the industry partner ClayTec for providing the base materials used in the additive manufacturing experiments. The authors also acknowledge the financial support provided by the IDEA League Fund, which enabled international exchange and facilitated the collaboration between ETH Zurich and RWTH Aachen University. This work was supported by the German Federal Ministry for Economic Affairs and Energy (Bundesministerium für Wirtschaft und Energie, BMWE) through the Central Innovation Programme for SMEs (Zentrales Innovationsprogramm Mittelstand, ZIM), as part of the research project *ClayX* at RWTH Aachen University.

Abstract –

Safety remains a central challenge in the construction industry, where OSHA standards define most regulatory requirements. Although comprehensive, these standards are dispersed across lengthy documents, making it difficult to locate provisions relevant to specific tasks or safety concerns. This complexity is especially evident in education and training settings, where instructors must interpret regulatory text and learners often lack familiarity with its structure and terminology. Recent advances in generative Artificial Intelligence (AI) offer new opportunities for improving access to technical information, but general-purpose models lack the grounding needed for authoritative regulations. This study presents a Retrieval-Augmented Generation (RAG) platform that provides clause-linked answers based on OSHA construction standards. The platform integrates document preprocessing, semantic retrieval, and citation-aware response generation through a web interface that enables direct inspection of referenced clauses. Automated evaluation using thirty representative safety questions showed strong performance, with average scores of 0.95 for context relevance, 0.99 for factual accuracy, and 0.90 for response relevance. The study contributes a verifiable and regulation-aligned approach for delivering accessible safety guidance, offering an adaptable framework for construction safety education and training.

Construction safety; OSHA; RAG; ISARC

1 Introduction

In 2023, the United States construction industry recorded 1,075 fatal work injuries, which represented nearly one fifth of all occupational deaths nationwide [1]. The consistently high number of fatalities highlights the persistent challenges associated with managing safety in an inherently hazardous sector [2]. Regulatory requirements issued under the Occupational Safety and Health Administration (OSHA) [3] construction standards therefore serve a central role in guiding hazard prevention across activities such as fall protection, scaffolding, electrical installation, excavation, equipment operation, and hazard communication. The standards offer comprehensive coverage of the risks commonly present on construction sites, yet the regulations are distributed across numerous subparts and contain extensive cross-referenced provisions [4]. The scale and organization of this regulatory corpus often make it difficult for workers, engineers, and students to identify the specific clauses relevant to a particular task or condition. Locating applicable requirements within lengthy documents requires substantial manual effort, which can hinder timely decision making and reduce the effectiveness of safety management practices.

Currently, users depend on keyword searches and personal familiarity with the structure of OSHA's construction regulations to locate relevant provisions, a process that often yields partial retrieval and inconsistent interpretation among individuals with limited regulatory experience [5]. The difficulty of identifying applicable clauses is evident across workforce training, onboarding programs, continuing professional development, and university instruction, where learners must connect specific safety questions to authoritative requirements without a clear mechanism for navigating the structure of the standards. Existing digital resources, including OSHA's eTool libraries and CPWR training materials [6, 7], improve access to regulatory information but remain primarily document centered and require substantial manual navigation. The absence of tools that can align user queries with the semantic content of regulatory text limits the role of OSHA standards as a foundation for

accurate, transferable, and instructionally meaningful safety knowledge. These limitations create a pressing need for a system capable of guiding users from practical safety questions to the corresponding OSHA clauses while providing transparent explanations that support both learning and decision making.

Advances in generative AI have created new opportunities for addressing the challenges associated with linking safety questions to relevant regulatory content. Recent developments in large language models have demonstrated strong capabilities in complex question answering, context interpretation, and the generation of instructional explanations, suggesting potential value for safety education and training [8]. Retrieval-Augmented Generation (RAG) has become particularly promising for applications that require the integration of authoritative sources with model-generated responses [9], since retrieved text can anchor explanations in verifiable regulatory clauses. Several studies have applied retrieval-based generative approaches to tasks such as building code interpretation, engineering documentation support, and domain-specific instructional assistance [10]. However, research focused on OSHA construction safety remains limited. Existing efforts rarely incorporate clause-level grounding in OSHA's construction regulations or provide mechanisms that align user queries with specific provisions in a manner suitable for education and training. The limited attention to OSHA-centered generative systems indicates the need for a solution capable of connecting user questions to regulatory clauses while delivering explanations that support accurate, transparent, and instructionally meaningful safety learning.

This study investigates how a retrieval-augmented generative AI framework can support accurate and transparent access to OSHA construction safety regulations through clause-grounded retrieval and explanation. To address this problem, a retrieval-augmented framework was developed to ground generative AI responses in authoritative OSHA construction regulations. The framework integrates document retrieval and controlled response generation to provide clause-level traceability and transparent evidence for each answer. A web-based platform was implemented to operationalize the framework and to present both the generated explanation and the corresponding regulatory text in an accessible interface. The platform was evaluated using automated metrics, including relevance, factual alignment, and citation correctness, to examine the extent to which system responses remain consistent with regulatory content. The results demonstrate that the proposed approach can effectively connect user questions with verifiable OSHA clauses while maintaining transparency in the response generation process.

2 Literature Review

This section reviews the state-of-the-art literature related to generative AI in construction education, which includes technologies in construction education, generative AI in intelligent tutoring, and generative AI in domain-specific education.

2.1 Construction Safety Management

Construction safety management has been widely examined due to the persistently high incidence of injuries and fatalities in the sector. Recent studies emphasize that structured safety management systems and systematic risk assessment play a critical role in reducing incident likelihood. Sadeghi et al. demonstrated that ensemble risk-assessment models can improve the identification of high-risk situations on construction projects [11], while Zhang and Mohandes developed a holistic occupational health and safety framework that links risk control measures to project-level decision making [12]. More recent work has shown that targeted management interventions and safety management measures can have measurable effects on workers' safety behaviors and incident outcomes [13, 14].

OSHA construction standards constitute the primary regulatory foundation governing hazard control in the United States and are frequently cited as the formal basis for site-level safety practices. However, prior research has indicated that regulatory requirements are difficult to explain and apply in practice. Semantic analyses of construction safety knowledge highlight that relevant information is highly fragmented and embedded in complex technical language, which complicates efforts to translate formal requirements into actionable guidance [15, 16]. Studies on construction safety knowledge systems similarly note that safety-related concepts are dispersed across documents and topics, and that workers often rely on local practices and informal guidance rather than directly consulting formal regulations [15]. Although digital resources, such as OSHA e-tools and online training portals, have broadened access to regulatory information, existing platforms still require substantial manual navigation and provide limited semantic support for locating clause-level requirements within lengthy regulatory documents [13].

Challenges related to regulatory comprehension also affect safety education and workforce training. Survey-based studies report that trainees and frontline workers frequently struggle to interpret technical terminology and to connect safety requirements with realistic site scenarios, which constrains the transfer of formal knowledge to field practice [17]. Eye-tracking and experimental training studies further show that limited safety knowledge undermines hazard-identification performance, even when workers have access to visual

examples and instructional materials [18]. The challenges highlight a continuing need for approaches that improve the accessibility and contextual alignment of safety regulations within both education and workforce training.

2.2 Generative AI Applications in Construction

Recent research has begun to explore how generative artificial intelligence can be incorporated into construction management, reflecting the broader digital transformation underway in the sector. Ghimire, Kim, and Acharya (2023) offered an early synthesis of the opportunities and challenges associated with generative AI [19], noting the potential to automate documentation, summarize technical information, and support managerial decision-making. Their analysis also emphasized that the rapid emergence of large language models has created new expectations for access to timely and interpretable information, while simultaneously raising concerns regarding reliability, data governance, and the need for domain-sensitive safeguards in safety-critical applications.

Industry-focused investigations provide complementary evidence regarding the growing relevance of generative AI. Nyqvist et al. (2024) examined how generative AI tools can be aligned with common construction management tasks and reported substantial perceived value in communication support [20], meeting administration, situational awareness, data analysis, and risk monitoring. Their evaluation, conducted through focus group discussions and practitioner surveys, suggests that generative AI can strengthen several routine managerial functions, although its effective use requires structured workflows and mechanisms that prevent excessive dependence on uncontrolled model behavior.

Applications at the project and design levels further illustrate the expanding role of generative AI across construction activities. Recent studies have shown that generative models can accelerate conceptual design, produce alternative layouts, and enhance sustainability assessments when integrated with BIM and digital twin environments, particularly by enabling rapid scenario exploration and reducing material waste [20, 22]. In project management settings, the use of large language models such as ChatGPT has demonstrated potential for automating routine planning descriptions, refining resource allocation, and supporting team coordination [23]. Emerging discussions also highlight generative AI as a candidate technology for advancing safety and sustainability outcomes, particularly by improving planning accuracy and facilitating data-driven decisions [24].

Although these developments indicate accelerating interest, current generative AI applications in construction largely operate as general-purpose assistants. Most systems do not incorporate domain-specific constraints, authoritative regulatory sources, or mechanisms that ensure traceable and verifiable outputs. Prior studies repeatedly point to the need for generative AI systems that can operate within clearly defined domain boundaries and provide transparent reasoning aligned with industry standards. The absence of such capabilities highlights a continuing gap, particularly for safety-critical contexts where the interpretation of formal regulatory requirements must be both accurate and verifiable.

3 System Design

3.1 Overview

The Construction Safety Assistant is implemented as a retrieval-augmented platform that supports OSHA-grounded question answering for construction safety education and training. The system consists of three primary components: OSHA document preprocessing, semantic retrieval, and controlled answer generation, all integrated into a web-based interface. The workflow begins with the preparation of OSHA construction safety documents, which are parsed, segmented, and transformed into an indexed knowledge base to enable efficient semantic search. When a user submits a query through the interface, the system encodes the input and matches it against the indexed corpus. Retrieved OSHA excerpts are then incorporated into a structured prompt for the generative model to ensure grounded and citation-constrained responses. The platform outputs an OSHA-referenced answer along with citation links pointing to the corresponding regulatory documents. Figure 1 presents the system architecture and the end-to-end flow from query submission to retrieval, generation, and citation display. Figure 1 presents the system architecture and the end-to-end workflow from query submission to retrieval, generation, and citation display.

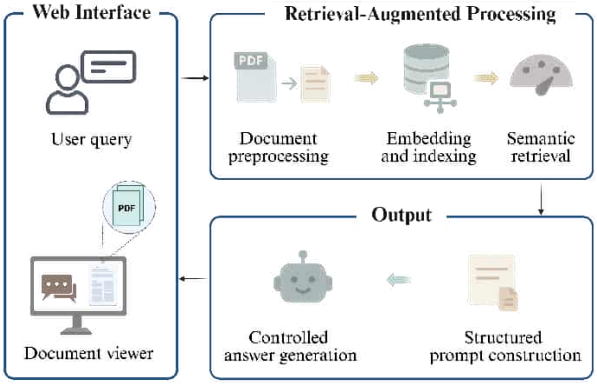

Figure 1. Overview of the construction safety assistant

3.2 OSHA Document Processing

The Construction Safety Assistant is built on OSHA construction safety regulations obtained in PDF format. Each document is converted into machine-readable text through an automated extraction procedure that preserves the regulatory reading order while removing layout artifacts inherent to PDF formatting. Non-informative elements such as headers, footers, page numbers, and residual formatting symbols are removed to ensure that only substantive regulatory content is retained.

After extraction, the regulatory text is segmented into fixed-length fragments to support efficient semantic retrieval. Each fragment is paired with metadata identifying the source OSHA document and its corresponding page index within the original file. These metadata elements enable transparent citation during answer presentation and allow users to inspect the regulatory basis of each response.

The processed fragments are then transformed into vector representations using a pretrained embedding model and stored in an indexed corpus that supports top-k similarity search. This indexing structure allows user queries to be mapped to relevant OSHA content with high precision, forming the foundation for verifiable and document-grounded question answering.

3.3 Retrieval-Augmented Answer Generation

The answer generation process integrates semantic retrieval with controlled natural-language synthesis to produce grounded explanations drawn from OSHA construction safety regulations. When a user submits a question, the system converts the input into a dense semantic representation that supports comparison with the indexed regulatory corpus. Let q denote the user query. The embedding function $f(\cdot)$ maps the query into a vector space as shown in Equation (1):

$$e_q = f(q) \tag{1}$$

This representation allows the system to evaluate conceptual similarity between the user query and the embedded OSHA fragments.

Each OSHA text fragment is represented by a vector e_i, and the semantic similarity between the query and each fragment is computed using cosine similarity. The similarity score is given in Equation (2):

$$Sim(e_q, e_i) = \frac{e_q \cdot e_i}{\| e_q \| \| e_i \|} \tag{2}$$

The retrieved fragments are ranked according to this similarity measure. The system selects the top-k fragments that exhibit the strongest alignment with the query, as expressed in Equation (3):

$$R_k(q) = TopK_{e_i \in E}\ Sim(e_q, e_i) \tag{3}$$

where E denotes the full embedded corpus. Each retrieved fragment includes metadata identifying the source OSHA document and page location, which is preserved throughout the subsequent generation process.

After the relevant fragments are identified, the system constructs a structured prompt that combines the original user query with the retrieved regulatory text. This prompt formulation establishes the context and boundaries within which the generative model operates, limiting the model's responses to material drawn from the retrieved fragments. When the retrieval stage fails to return fragments that meet the predefined relevance threshold, the system activates a fallback mechanism that guides the model to request clarification or to provide a neutral response rather than infer unsupported information. Figure 2 illustrates the structured prompt construction process.

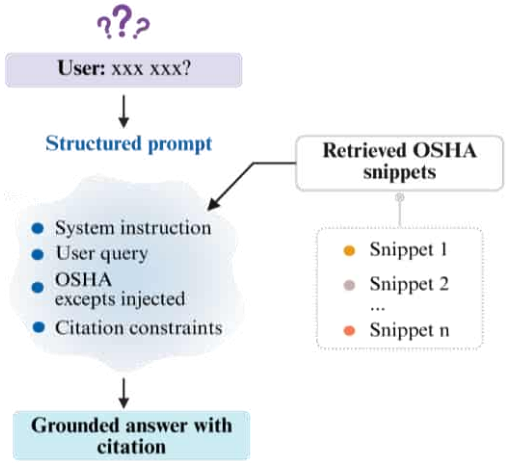

Figure 2. Structured prompt construction process

Using the retrieved content and structured prompt, the generative model synthesizes an answer that restates and interprets the OSHA provisions. Citation metadata is embedded directly into the response and linked to the original OSHA documents, allowing users to inspect the regulatory basis of each statement through the interface. This grounding mechanism supports transparent and verifiable use of OSHA standards in safety education and training.

3.4 Web Interface

Following the retrieval and generation pipeline, the Construction Safety Assistant presents the grounded responses through a web-based interface designed to support transparent review of OSHA regulatory material. The interface provides two coordinated components: a conversational panel for user interaction and a document viewer for inspecting cited OSHA content. In the conversational panel, users submit safety-related questions in natural language. The system's responses appear in the same panel and include embedded citation markers that identify the OSHA document and page from which the supporting content was retrieved. These markers are integrated directly into the response text to

maintain readability while indicating the regulatory source of each referenced statement. Selecting a citation opens the corresponding OSHA PDF page in a side panel, allowing users to review the original regulatory wording without leaving the ongoing interaction.

4 Implementation and Evaluation

4.1 Implementation

The platform is composed of a Python backend and a browser-based frontend. OSHA regulations are stored in PDF format and processed using a text extraction pipeline that removes headers, footers, page numbers, and formatting artifacts. The cleaned text is segmented into fragments of approximately 300 characters, each paired with metadata identifying the source PDF filename and page index.

The processed fragments and metadata are uploaded to Azure Blob Storage, where a Shared Access Signature (SAS) URL is generated for each fragment to provide direct access to its corresponding location within the original PDF. Text embeddings are created using the text-embedding-ada-003 model, and both the embeddings and their metadata are indexed through Azure Cognitive Search to enable vector-based similarity retrieval.

At runtime, the backend receives a user query, computes its embedding, and issues a vector search request to Cognitive Search. The retrieved OSHA fragments and their SAS URLs are assembled into a structured prompt that is sent to a GPT-4o model for grounded answer generation. Citation links are inserted into the output using the stored metadata so that each referenced clause can be opened directly.

Figure 3. Web interface of the platform

The backend exposes REST endpoints for query submission and citation retrieval. The application runs in a cloud environment that supports stateless request–response communication with the frontend, which is implemented using standard web technologies. As illustrated in Figure 3, the web interface allows users to submit queries, view generated responses, and interact with citation links to access the corresponding OSHA PDF pages in an embedded viewer, completing the end-to-end interaction between retrieval, generation, and document-level inspection. When users select a citation in the generated response, the front end loads the associated SAS URL and displays the referenced OSHA PDF page.

4.2 Automated Evaluation Framework

The performance of the platform was assessed using an automated evaluation framework configured with UpTrain [25], which enables systematic comparison between system-generated answers and authoritative OSHA regulatory text. UpTrain provides normalized metric scores between 0 and 1 for each evaluation criterion, supporting large-scale, clause-level assessment without manual scoring. A benchmark set of thirty representative safety questions was constructed to cover major regulatory domains such as fall protection, excavation and trenching, scaffolding, electrical hazards, confined spaces, and personal protective equipment. Each question was paired with a ground-truth citation from the corresponding OSHA construction standard, forming the reference set used in the evaluation. Table 1 summarizes the benchmark questions and their associated regulatory topics.

Table 1 Questions used for automated evaluation

No.	Question	Type
1	What is the minimum width for a scaffold walkway?	What
2	What does OSHA define as a “competent person” in excavation work?	
3	What is the permissible exposure limit (PEL) for noise in construction?	
4	What is the maximum allowable slope for a Type C soil trench?	
5	What class of hard hat offers protection from electrical hazards?	
6	What are the signage requirements near a trenching operation?	
7	What are the minimum illumination levels required in construction tunnels?	
8	What are the minimum spacing requirements for cross braces on	

	scaffolds?	
9	What is the definition of “confined space” in construction?	
10	When is fall protection required for workers on low-slope roofs?	
11	When should a safety harness be inspected?	
12	When should protective systems be installed in excavations?	When
13	How often must trenches be inspected by a competent person?	
14	How often must cranes be inspected?	
15	How should workers be protected from cave-ins during trenching?	
16	How does OSHA define “confined space” in construction?	
17	How do scaffolds and aerial lifts differ in terms of fall protection?	How
18	How should hard hats be worn in construction zones?	
19	How often must safety harnesses be inspected?	
20	Why is eye protection mandatory during welding operations?	
21	Why must hard hats be worn in construction zones?	
22	Why are GFCIs required on construction sites for power tools?	Why
23	Why is ventilation important in welding operations inside a confined space?	
24	Is it acceptable to stack bricks more than 7 feet high without restraint?	
25	Is training required before operating a scissor lift?	Is / Are
26	Is daily site inspection required for all excavation work regardless of depth?	
27	Are reflective vests mandatory for night work near roadways?	
28	Can a scaffold be used if it is partially disassembled?	
29	Can a ladder be used horizontally as a platform?	Can
30	Can a trench shield be used in unstable soil conditions?	

Three quantitative metrics were used to characterize system performance. Context relevance evaluates whether the retrieved OSHA passages correspond to the substantive focus of the user query. Factual accuracy assesses the correctness of statements in the generated answer relative to the regulatory source. Response relevance measures how well the answer addresses the intent of the question in a clear and semantically appropriate manner. In addition to these metrics, a Reference Match check was included to verify that the citation links embedded in the output point to the expected OSHA clauses, ensuring traceability and source transparency.

4.3 Evaluation Results

The automated evaluation produced consistent evidence of strong grounding performance across the selected metrics. The system achieved an average context relevance score of 0.95, indicating that retrieved OSHA passages typically aligned with the substantive focus of the questions. Factual accuracy reached 0.99, reflecting near-perfect agreement between generated statements and the corresponding regulatory clauses. The average response relevance score of 0.90 suggests that the generated answers generally addressed the user intent with appropriate specificity. All citation links passed the Reference Match check without errors. Table 2 summarizes the metric scores for all thirty benchmark questions.

Table 2 Automated evaluation results

No.	Context relevance	Factual accuracy	Response relevance
1	1	1	1
2	1	1	1
3	0.67	1	1
4	1	1	1
5	1	1	1

30	1	1	1
Ave. score	0.95	0.99	0.90

5 Discussion

The evaluation results highlight several characteristics of the system's behavior across different question types and regulatory topics. High factual accuracy reflects the constraint imposed by retrieval-augmented generation, which restricts responses to OSHA source text and minimizes reliance on model priors. Variations in context relevance are largely associated with questions whose answers span multiple regulatory clauses, particularly in areas such as confined spaces and ventilation where relevant information is distributed across several subparagraphs. Lower response relevance in some how and why questions stem from the broader interpretive nature of these items, which may not be fully represented within a single retrieved fragment.

The observed patterns underscore the influence of OSHA's document structure on retrieval performance. Standards that rely on explicit thresholds or enumerated requirements, such as fall protection and scaffolding, align well with fragment-level retrieval and produce consistent grounding results. Sections organized around descriptive or condition-dependent language present additional challenges, as semantically related content may reside in multiple locations. This separation affects the system's ability to assemble a complete context window for procedural or explanatory questions.

Several limitations arise from these characteristics. The retrieval process operates at the level of individual text fragments and does not aggregate related clauses unless they co-occur within the same segment. Citation links reflect the segmentation scheme rather than the full logical scope of a regulation, which may omit adjacent supporting text. Additionally, queries that rely on implicit hazard rationales or multi-step procedures may not fully align with the structure of the underlying standards, reducing the semantic match between the question and the retrieved passage. While the automated evaluation provides a consistent and scalable assessment of system performance, it does not fully capture aspects such as interpretability for practitioners or effectiveness in real-world decision-making contexts.

For future research, improvements to the retrieval process could focus on integrating multi-clause retrieval to better capture regulatory content that is distributed across several sections. Additional refinement of semantic clustering may also help group related provisions into coherent units, improving coverage for questions that require broader contextual grounding. Enhancing query processing with domain-informed expansion represents another opportunity to reduce mismatches between user phrasing and OSHA terminology. Future work will also incorporate expert-based and user-centered evaluation to complement automated assessment and to further examine the usability and practical effectiveness of the system in construction safety contexts.

6 Conclusion

This study developed a retrieval-augmented question-answering system to support construction safety education and training through clause-linked access to OSHA standards. The system integrates document processing, semantic retrieval, and citation-aware answer generation within a web-based interface, enabling users to examine both the generated response and its regulatory source. The findings provide a direct response to the research question by demonstrating that a retrieval-augmented framework can enable accurate, transparent, and clause-level access to OSHA construction safety regulations.

Automated evaluation across thirty representative safety questions showed consistently high factual accuracy and strong performance in relevance and citation correctness, with lower performance primarily observed in questions whose regulatory basis spans multiple sections of the standards. These results indicate that clause-grounded retrieval combined with citation-aware generation can support more reliable access to OSHA regulations by aligning user queries with verifiable regulatory content and preserving transparency in the response process.

The proposed approach provides a practical mechanism for interacting with prescriptive and authoritative documents such as OSHA standards, particularly in contexts where regulatory information is distributed across multiple sections and requires structured access. Future work may focus on improving retrieval coverage and contextual aggregation for complex regulatory queries. In addition, comparative evaluation with existing tools, such as keyword-based search systems and general-purpose language models, will be conducted to further assess the relative performance and practical advantages of the proposed approach. The framework can also be extended to additional regulatory corpora and specialized application contexts.

Abstract -

In recent years, the civil engineering and construction industry has faced a severe shortage of skilled workers due to a declining workforce and the aging of infrastructure. To address this challenge, we have been developing ROS2-TMS for Construction, a cyber-physical system (CPS) platform for earthwork sites that aims to automate earthwork operations using construction machinery. OperaSimVR serves as the cyber component of this CPS platform. It reconstructs earthwork sites in cyberspace, enabling real-time monitoring and remote operation. OperaSimVR has four modes: Standard Mode, Playback Mode, Teleoperation Mode, and Preview Mode. The Preview Mode visualizes the motions of autonomously operating construction machinery several seconds into the future, allowing operators to confirm and assess upcoming actions in advance. This paper presents an overview of OperaSimVR and reports the experimental results of the Preview Mode.

Keywords -

Previewed reality; Automated construction; Cyber-Physical System

1 Introduction

In the construction industry, the number of workers has been steadily declining due to the effects of a decreasing and aging population, as well as a higher incidence of occupational accidents compared with other industries. At the same time, the deterioration of infrastructure built during the period of rapid economic growth has become a serious issue, leading to an increasing demand for civil engineering and construction work. As a result, the shortage of skilled personnel has become increasingly severe.

To address these challenges, we have been developing a cyber-physical system (CPS) platform for earthwork sites, namely ROS2-TMS for Construction, as a system aimed at improving construction efficiency and safety [1]. ROS2-TMS for Construction enables the automatic operation of construction machinery using environmental data acquired from sensors installed in the work environment, thereby realizing the automation of earthwork operations. Furthermore, we have been developing OperaSimVR as the cyber component of the CPS, ROS2-TMS for Construction. OperaSimVR constructs a representation of the real-world earthwork site in a virtual (cyber) space using environmental information obtained from sensors. By immersing themselves in this cyberspace, users (site managers) can observe and monitor the conditions of the earthwork site. In this paper, we present an overview of OperaSimVR and report the experimental results of the Preview Mode.

2 Related work

In the civil engineering and construction industry, initiatives utilizing information technology have also been increasingly promoted. Virtual reality (VR) and augmented reality (AR) technologies are being used in conjunction with BIM (Building Information Modeling) during the design phase and for construction management. BIM is an information-rich building model that integrates a three-dimensional representation of a structure with data required for design, construction, and maintenance, such as material properties, costs, and schedules.

In studies that apply VR during the design phase, BIM is integrated to enable designers to immerse themselves in BIM-generated 3D models and visually verify design details [2]. In research on construction management using AR technology, AR-based management systems have been developed that link with BIM-based construction plans and overlay the designed geometry corresponding to user-specified times or construction stages onto the real

environment. This allows intuitive, on-site comparison between the planned construction process and the current site conditions using devices such as tablets [3].

In addition, studies using AR technologies to compensate for delays during teleoperation have also been actively conducted. Research aimed at mitigating the effects of teleoperation latency by estimating and overlaying the actual robot position includes studies in remote driving, where predictive wheel trajectories are displayed on the operator's head-mounted display (HMD) to improve steering stability degraded by communication delays and insufficient visual information [4]. Similarly, in robot-assisted remote surgery, communication delays between the surgical robot and the remote operator pose significant challenges; therefore, predictive displays based on AR have been proposed for teleoperated surgical robots [5]. However, since these studies primarily focus on compensating for teleoperation delays, they estimate and display the current pose of the robot and do not present future poses.

In environments where robots and humans coexist, such as those involving service robots, it is necessary to prevent collisions between humans and robots. To address this issue, systems have been studied that display a robot's motion several seconds into the future on an AR display, enabling humans to perceive the robot's future trajectory and thereby avoid collisions [6].

In this study, we developed a system that visualizes the future poses of autonomously operating construction machinery to predict collisions in advance at earthwork sites. The novelty of this system lies in its use of AR technology to present future actions to the operator during autonomous operation. Additionally, since it is implemented as part of the construction machinery control system, ROS2-TMS for Construction, both real and virtual construction machines can be operated using the same control commands, making it easy to implement the proposed Previewed Reality.

3 OPERA

OPERA (Open Platform for Earthwork with Robotics and Autonomy) is an open platform being developed by the Public Works Research Institute to standardize control signals for construction machinery and promote the automation of construction equipment [7]. OPERA aims to disseminate automated construction technologies by standardizing construction machinery control signals and adopting ROS/ROS2 as middleware [8]. OPERA includes electronically controlled construction machinery, such as hydraulic excavators and crawler dump trucks, as well as OperaSim, a simulator developed using Unity.

4 ROS2-TMS for Construction

ROS2-TMS for Construction is an automated construction cyber-physical system (CPS) platform developed based on OPERA, an autonomous construction technology framework. ROS2-TMS for Construction executes construction machinery operations based on a given sequence of tasks, using information acquired from sensors installed at the site.

Autonomous construction is performed following the workflow illustrated in Figure 1.

1. Environmental information is collected using sensors installed in the environment and on construction machinery (Measure).

2. Based on the collected environmental information, an earthwork site is reconstructed in real time within cyberspace. The site conditions are then analyzed, and construction machinery operations are planned (Analyze and Plan).

3. Control commands required to execute the planned operations are generated and transmitted to the construction machinery via OPERA (Control).

The architecture of ROS2-TMS for Construction is shown in Figure 2. Each function is modularized, and the system is formed through the coordination and interaction of these modules. To date, we have conducted automation experiments for earthwork operations, including excavation, loading, transportation, and dumping of soil using a hydraulic excavator and a crawler dump truck [9], as well as field deployment experiments for soil improvement construction [10] using ROS2-TMS for Construction.

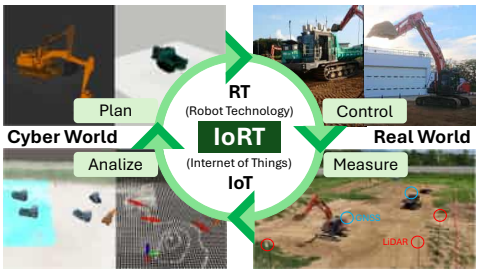

Figure 1. Schematic diagram of ROS2-TMS for Construction

5 OperaSimVR

5.1 Overview of OperaSimVR

OperaSimVR is the cyber component of ROS2-TMS for Construction. It was developed by extending OperaSim,

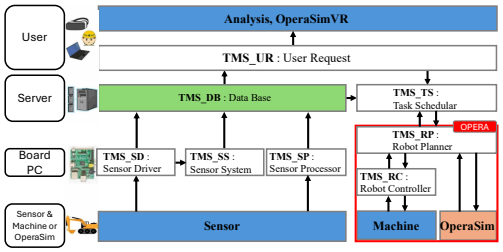

Figure 2. Architecture of ROS2-TMS for Construction

the simulator of OPERA, by adding several new functions in addition to its original simulation capability (Standard Mode). Specifically, visualization (Playback Mode), operation (Teleoperation Mode), and preview (Preview Mode) functionalities were incorporated. By deforming the ground surface of the simulator using terrain data from earthwork sites, OperaSimVR can reproduce earthwork operations such as excavation. In addition, buildings and autonomously operating construction machinery can be modeled, enabling the construction of a cyber representation of an actual earthwork site environment.

Users can immerse themselves in cyberspace by wearing a VR headset, allowing them to walk within the virtual environment, observe the site from a bird's-eye view, or experience views as if seated in the operator's cabin of construction machinery within cyberspace. When a VR headset is not used, the system can be operated via keyboard input through the Unity game view on a PC. Furthermore, real-time 360-degree images of the physical site can be acquired from omnidirectional cameras [11] installed on-site and switched with cyberspace view, enabling users to monitor the actual site conditions.

When using OperaSimVR, a control PC connected to the construction machinery, on which ROS2-TMS for Construction is running, launches the ROS-TCP Endpoint and establishes a connection with the PC used to run OperaSimVR, enabling operation and control through this communication link.

5.2 Standard Mode (OperaSim)

In the Standard Mode of OperaSimVR, the motions of construction machines can be simulated using the OperaSim simulator. OperaSim is the official simulator of OPERA, an autonomous construction technology platform developed by the Public Works Research Institute using Unity and the PhysX and AGX physics engines. In OperaSim, motion commands sent from an operation PC are processed in the same manner as those for actual OPERA-compliant construction machines, including the computation of gravity and friction. When excavation operations are performed, terrain deformation occurs, and soil behaviour can also be simulated.

5.3 Playback Mode

In the Playback Mode, the system acquires the current position information and joint angles transmitted from each construction machine and constructs and visualizes the state of the actual earthwork site within cyberspace. The construction machinery models in cyberspace operate in real time in synchronization with the motions of the corresponding machines in the physical environment. With respect to terrain representation, simulations of excavation operations can be performed in the same manner as in the Standard Mode. The Playback Mode enables remote monitoring of earthwork site conditions without the need to physically enter the site. In addition, it allows construction managers to observe the behaviour of construction machinery during autonomous construction even under conditions with limited visibility, such as nighttime or fog.

5.3.1 Machine location visualization

Position and orientation information are acquired using GNSS and IMU sensors mounted on construction machinery. The obtained position data are represented either in the world geodetic coordinate system (world coordinates) or in a map coordinate system, where the origin is translated to a reference point within the construction site. To visualize these data in cyberspace (Unity), coordinate transformation is required to align the coordinate systems and reference points.

Therefore, OperaSimVR performs internal coordinate transformations to align the reference point in cyberspace with the corresponding reference point of the actual construction site within the virtual construction environment. This process updates the position and orientation of the construction machinery models in cyberspace. Since coordinate systems, reference point locations, and offsets vary depending on the site and the construction machinery, these parameters—including the coordinate system, reference point coordinates, and offsets—can be configured for each site and machine.

As a result, the position and orientation of autonomously operating construction machinery in the physical environment can be visualized in real time within cyberspace.

5.3.2 Machine posture visualization

Joint angle information acquired from sensors such as IMUs mounted on the joints of construction machinery is received by the system. For an excavator, the swing, boom, arm, and bucket are actuated in cyberspace based on the joint angle data obtained from the physical machine. For

a crawler dump truck, the vessel and swing motions are driven according to the joint angle information from the real machine. As a result, the posture of autonomously operating construction machinery in the physical environment can be visualized in real time in cyberspace.

Figure 3 illustrates the visualization, using the Playback Mode of OperaSimVR, of the motions of construction machines autonomously operating with ROS2-TMS for Construction as well as the actual site conditions.

Bird's-eye views of cyberspace Bird's-eye views of real space

Figure 3. Real-time visualization of autonomously operating construction machinery in cyberspace using Playback Mode

5.4 Teleoperation Mode

In the Teleoperation Mode, individual construction machines can be remotely operated from OperaSimVR. According to the "Safety Rules for Automated Construction, Ver. 1.0" established by the Ministry of Land, Infrastructure, Transport and Tourism (MLIT) of Japan, construction sites must be divided into a "manned area," where operations are conducted by manned construction machinery, and an "unmanned area," where operations are performed by automated or remotely operated construction machinery [12] (Figure 4).

When unexpected events occur during autonomous construction and manual intervention is required, the construction machine operating autonomously within the unmanned area must either be stopped and operated by an on-site operator or controlled through remote operation. In such situations, OperaSimVR enables operators to respond by remotely controlling the construction machinery.

The Teleoperation Mode can be used when OperaSimVR is operating in either the Standard Mode or the Playback Mode. During teleoperation, the operator controls the machine while viewing imagery that simulates being seated in the operator's cabin of the construction machinery model in cyberspace. In the Standard Mode, the physical machine in the real environment is not actuated; instead, the operator controls the construction machinery model in cyberspace to simulate its behaviour. In contrast, in the Playback Mode, the operator can directly control the construction machinery in the physical environment.

The operations that can be performed in the Teleoperation Mode are listed below.

- Ground velocity commands (locomotion commands)
  Ground velocity commands are transmitted in response to inputs from a VR controller or a keyboard. In the Standard Mode, motion commands are directly applied to the construction machinery model in cyberspace. In the Playback Mode, the ground velocity command topic is published, and the construction machine in the real world receives the topic and executes the commanded motion. This enables operations such as forward and backward movement and turning.

- Joint angular velocity commands
  Joint angular velocity commands are transmitted in response to inputs from a VR controller or a keyboard. In the Standard Mode, the commands are directly applied to the construction machinery model in cyberspace. In the Playback Mode, the joint angular velocity command topic is published, and the construction machine in real world receives the topic and performs the corresponding motion. In the case of a hydraulic excavator, this allows the operator to control the swing, boom, arm, and bucket.

When the VR controller or keyboard is operated, motion command topics are published, and the physical construction machinery that receives these topics operates in real time. At the same time, the construction machinery model in cyberspace moves in synchronization with the physical machine, enabling the operator to control the real machine while visually monitoring its motion within cyberspace.

Figure 5 illustrates the teleoperation of a crawler dump truck using OperaSimVR. In each subfigure, the upper left shows the cyberspace view observed by the operator during teleoperation, the upper right shows the teleoperation interface in use, the lower left presents a view from the operator's cabin in the physical environment captured for comparison, and the lower left shows the physical site scene recorded for comparison.

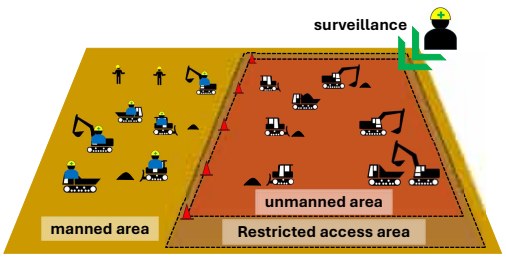

Figure 4. Manned and unmanned areas during autonomous construction [12]

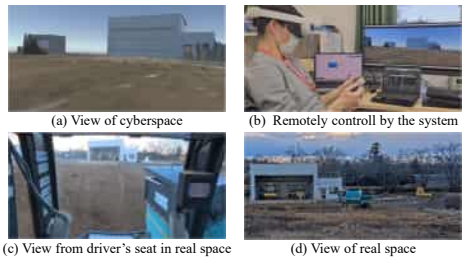

Figure 5. Teleoperation using OperaSimVR

5.5 Preview Mode

In the Preview Mode for autonomous operation, OperaSimVR receives motion plans from autonomously operating construction machinery and visualizes their future motions in cyberspace. According to the "Safety Rules for Automated Construction, Ver. 1.0" established by the Ministry of Land, Infrastructure, Transport and Tourism (MLIT) of Japan, during autonomous construction, "the operating status of automated construction and its surrounding conditions must be confirmed through visual observation, monitors, GNSS-based position information, and other means, and warnings or emergency stop systems must be activated when necessary." However, merely monitoring autonomously operating construction machinery in real time may be insufficient, as collisions or other hazardous events can still occur even if an emergency stop is triggered after a danger is recognized (Figure 6). To address this issue, the Preview Mode of OperaSimVR enables operators to examine future motions of construction machinery in advance, thereby preventing potential collisions before they occur. OPERA-compatible construction machinery performs path planning using Nav2 [13] and motion planning using MoveIt [14] on an onboard PC upon receiving motion commands, and executes motions based on these plans. Before the corresponding motions are executed on the actual construction machinery, the preview function of OperaSimVR visualizes the paths and motion plans generated by Nav2 and MoveIt in cyber space.

5.5.1 Machine future location visualization

The future positions of construction machinery are visualized as follows. First, the planned paths generated by Nav2 for each construction machine are acquired. Since the obtained paths are represented in a map coordinate system based on a reference point within the construction site, the coordinates are transformed into the Unity coordinate system in the same manner as in the Playback Mode.

Next, the current velocity of each construction machine is computed from its current position information. Using this velocity, the distance traveled over a specified future time interval is calculated. The construction machinery model is then displayed at a point along the planned path that is offset from the current position by this computed distance. If the predicted motion reaches the end of the planned path, the model stops at the terminal point. Through this process, the future positions of autonomously operating construction machinery several seconds ahead can be visualized. At present, future rotational motion is not considered; instead, the model orientation is determined based on the current orientation of the construction machinery. In addition, by visualizing the received planned paths in cyberspace, operators can inspect motions further ahead along the trajectory.

5.5.2 Machine future posture visualization

The future motions of the construction machinery are visualized as follows. First, motion plans generated by MoveIt for each construction machine are acquired. These motion plans are represented as a sequence of planned poses at fixed time intervals. From the acquired motion plans, the pose of the construction machinery at an arbitrary future time is extracted, and a model corresponding to the extracted pose is displayed in cyberspace. If the duration of the acquired motion plan is shorter than the specified future time to be visualized, the posture of the construction machinery model is set to the final pose of the motion plan. Through this process, the future posture of autonomously operating construction machinery several seconds ahead can be visualized.

In cyberspace, both a construction machine model that displays the current position and posture in real time and a construction machine model that represents its future motion are visualized. This enables the simultaneous visualization of both the current posture and the future motion within cyberspace.

Figure 8. ZX200

tonomous operation described in Chapter 5.5. Using ROS2-TMS for Construction, the construction machinery was operated autonomously to verify that future motions could be previewed. The experiment was carried out at the DX Field of the Public Works Research Institute using OPERA-compatible construction machines: a crawler dump truck (IC120, KATO Works) (Figure 7) and a hydraulic excavator (ZX200, Hitachi Construction Machinery) (Figure 8).

In this experiment, the construction machinery autonomously performed the following sequence of operations:

- Excavation of a soil pile using the hydraulic excavator
- Loading soil onto the crawler dump truck
- After repeated loading operations, the crawler dump truck traveled to the dumping location
- The crawler dump truck returned to the loading location

During the experiment, video streams were recorded from cameras installed in the environment and from a camera mounted in the operator's cabin of the construction machinery. Using these images, we verified the system behaviour when future motions of construction machines in cyberspace were overlaid onto real images using AR.

In OperaSimVR, one translucent model each of a hydraulic excavator (ZX200) and a crawler dump truck (IC120) was used to visualize the future motions of the construction machines. All models other than these two were made transparent, and the recorded real-world camera images were projected as the background, enabling an AR-style overlay of the construction machine models onto the real images.

A PC running ROS2-TMS for Construction was connected to the physical machines, and the ROS-TCP Endpoint was launched to establish communication with the PC running OperaSimVR.

In the experiment, the future motions three seconds ahead were overlaid and visualized.

6.2 Results

Figure 9 and Figure 10 show images in which the future motions of autonomously operating construction machines in the real environment are overlaid using AR. Figure 9 presents a bird's-eye view, while Figure 10 shows the view from the operator's cabin. The translucent models represent the machines visualizing the future motions of the backhoe and the crawler dump truck, respectively. In Figure 9, the excavator's digging and loading operations was visualized by displaying its posture predicted 3 seconds into the future, allowing the future motions to be confirmed. For the crawler dump truck, no future motion is displayed in images 1–7 because no path plan is generated while the excavator is performing the digging and loading operations. After the loading operation is completed, a path plan is received, and the future motion of the crawler dump truck is visualized.

Figure 10 shows the view from the excavator's operator cabin during the digging and loading operations, where the posture predicted 3 seconds into the future is displayed, enabling confirmation of the future motions.

Figure 11 and Figure 12 show images visualizing both the real-time motion and the motion 3 seconds into the future of autonomously operating construction machines in the real environment, as represented in cyberspace using VR.

Figure 13 shows a graph of the joint angles of the backhoe during the experiment, including the angles predicted by the proposed system, the predicted angles delayed by 3 seconds, and the actual joint angles of the backhoe. Since the visualization begins from the posture 3 seconds after receiving the motion plan, motions that are completed within 3 seconds are not shown in the graph. By comparing the predicted angles delayed by 3 seconds with the actual joint angles of the backhoe, it can be observed that, for all joints, the predicted angles generally agree with the actual joint angles. However, for the boom angle, an overshoot occurs in reality, but it is not visualized because it is not included in the motion plan. In future work, we aim to incorporate the overshoot into the visualization so that it can also be represented.

7 Conclusion

This paper proposes OperaSimVR and introduced the Preview Mode. In the experiments, future motions of autonomously operating construction machines were overlaid and visualized in cyberspace, enabling confirmation of their forthcoming behaviour.

In future work, we aim to utilize the passthrough function of VR headsets to overlay predicted future motions onto real-world images. This will enable supervisors to wear AR/VR goggles outside the unmanned area and visually confirm the future motions of autonomously operating construction machines by superimposing them onto the actual machines. However, the current system does not reflect the rotation of the crawler dump truck when indi-

Figure 9. AR view of autonomously operating construction machinery three seconds in the future

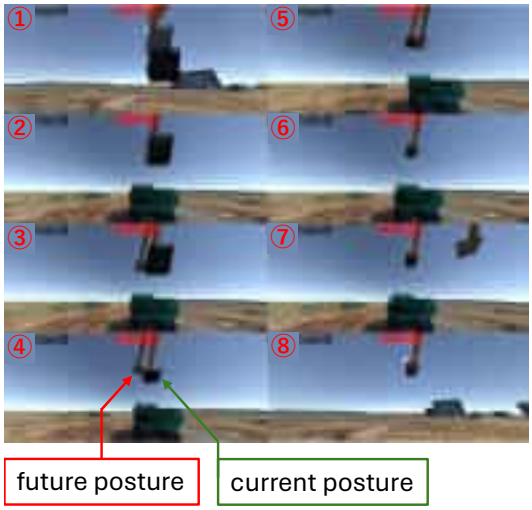

Figure 12. VR view from the cockpit of autonomously operating construction machinery three seconds in the future

cating its future position. Therefore, we plan to implement a method that orients the machinery model along the tangent direction of its path. In addition, we plan to develop a human–machine collaborative framework in which this system enables operators to preview the behaviour of construction machinery in advance. Within this framework, operators can intuitively and seamlessly perceive the predicted future behaviour of the machinery. If any issues are identified, the operator can halt the process; otherwise, the machine will only proceed with the task if no issues are detected. We also plan to add a function that triggers an emergency stop of the construction machine when the model representing its future motion collides with objects such as other construction machine models or structures, thereby preventing collisions. Furthermore, we plan to extend the visualization by adding information such as the final completed shape of earthwork operations.

Abstract –

Non-destructive Testing (NDT) is important for building structure inspection. Ground Penetrating Radar (GPR) is an effective non-destructive testing technique for building inspections, yet the complexity of the radargram data has limited its widespread adoption in engineering practice. This paper presents an approach for reconstructing raw GPR radargrams into 3D point clouds for intuitive visualization and interactive analysis. To evaluate the usability and industry acceptance, this paper conducts a questionnaire survey based on the Technology Acceptance Model (TAM) among 44 industry professionals in Hong Kong. The results indicated that the 3D reconstruction approach received perceived usefulness of 3.26 (Belief that technology improves performance) and perceived ease of use of 3.55 (Belief that technology is easy to use), with the "see-through" function being the most highly regarded. Additional attitude and behavior intention research further confirmed the approach's advantages in terms of intuitiveness and cross-platform compatibility. This paper verified the feasibility and acceptance of reconstructing GPR radargrams into 3D point clouds, which can benefit digital transformation in building inspection.

Ground Penetrating Radar (GPR); Technology Acceptance Model (TAM); 3D reconstruction; Point cloud; Building inspection

1 Introduction

People spend "an average of 87% of their time in enclosed buildings," according to a U.S. national survey [1]. The aging and deterioration of buildings will inevitably lead to a degradation of structural performance, posing a potential threat to residents, public safety, and even cultural heritage buildings. Building inspection is crucial for identifying potential risks and related facility management issues [2, 3].

The verification of internal structures in the past relied on destructive tests, which could leave scars on buildings [4]. Such destructive tests are infeasible for certain types of buildings, such as protected heritage buildings [5]. As a Non-destructive Testing (NDT) method, Ground Penetrating Radar (GPR) has been introduced for subsurface building inspection using electromagnetic signals [6, 7]. GPR can detect subsurface features in as-built buildings and cultural heritage practices [8, 9, 10]. However, a persistent knowledge gap exists between inspectors and the interdisciplinary heritage conservation team, as complex raw radargrams (B-scan/C-scan) are difficult for inspectors to interpret and use in decision-making [4, 11]. Advanced 3D reconstruction is the key to filling the gap in processing the complexity of GPR results, and to enable complex shapes analysis using stereopsis vision [12, 13].

This paper presents a Web AR approach to reconstructing raw GPR radargrams into 3D point clouds (GPR-AR) to overcome subjectivity in conventional interpretations by intuitive, conclusive visual evidence. However, whether this approach can be accepted by industry professionals requires further evaluation and analysis.

The Technology Acceptance Model (TAM) is an information system theory in various fields to interpret and evaluate how users will accept and utilize new technology [2]. TAM clarifies the underlying mechanism of technology adoption by revealing the causal relationships between each external variable and actual system use. The external variables (EVs) encompass external environmental factors that affect potential users; EVs include respondents' backgrounds, technology characteristics, and usage context [14, 15]. The central conceptual component of TAM includes two key constructs, i.e., perceived usefulness (PU) and perceived ease of use (PEOU) [16, 17]. PU refers to the extent to which the respondents believe a particular technology

can enhance their work performance, while PEOU represents the degree to which the respondents believe using this technology is effortless [14].

This paper further presents a TAM-based analysis to assess the acceptance of the proposed GPR-AR. The GPR-AR employed advanced array GPR devices to acquire raw electromagnetic signals and reconstructed them into a 3D point cloud. A TAM-based questionnaire survey targeting professionals was conducted to assess the perceived potential for usability and ease of use. The contribution of this paper is twofold: (i) an intuitive and precise approach to assist the stakeholders in inspecting the building materials; (ii) a high degree of acceptance of reconstructing GPR radargrams into 3D point clouds in the Architecture, Engineering, and Construction (AEC) industry.

2 The 3D Reconstructed GPR in the Web AR (GPR-AR) Approach

2.1 Overview

Fig. 1 shows an overview of the 3D reconstructed GPR presented in the web AR (GPR-AR) approach. It comprises four layers: acquisition, processing, visualization, and interaction. The approach begins with the acquisition layer to collect on-site data. Then, the raw GPR radargram is converted to a 3D point cloud. Next, a 3D reconstruction of GPR scanning results is performed in the processing layer, followed by the visualization layer. The interaction layer provides valuable functions to construction stakeholders and facilitates building inspection.

2.2 Layer-wise technical implementation

The acquisition layer bridges real-world conditions into data. Regarding hardware control, the GPR device's parameters should result in sharp and clear electromagnetic signals. Then, a standard GPR grid scan is carried out to acquire a GPR project data file. Note that GPR data acquisition precedes any processing.

The processing layer generates C-scans and then transforms raw GPR radargrams into 3D point clouds. The Inverse Distance Weighted gridding method is used to convert B-scan data to C-scan data. Besides gridding, cell size, search radius, and moving average are necessary parameters. The spacing between C-scans is set as 0.01m. After the above processing, several C-scan slices can be generated and then passed into the point cloud reconstruction. The outcome point clouds serve for 3D visualization and enable 3D object detection. Each C-scan slice will be converted into a 2D point cloud slice, where the pixel coordinates (x, y) and slice depth (z) are mapped to spatial positions. Rather than RGB colors, the reflection intensity should be labeled at the discretized points. In visualization equalization of GPR-AR, logarithmic and normalization operations lead to define a new index: $RI = (\ln R - \ln R_{\min})/(\ln R_{\max} - \ln R_{\min})$, where R is the reflection intensity, $R_{\min}$ and $R_{\max}$ are the maximum and minimum reflection intensity in all slices. The labeled point cloud slice is finally stacked based on the spatial depth and merged into a structured point cloud.

The third layer visualizes the incoming point cloud in two modalities: isometric 3D and augmented reality (AR). The isometric 3D is convenient for offline visualization and analysis. AR mode aims to map an isometric 3D model for online rendering and visualization.

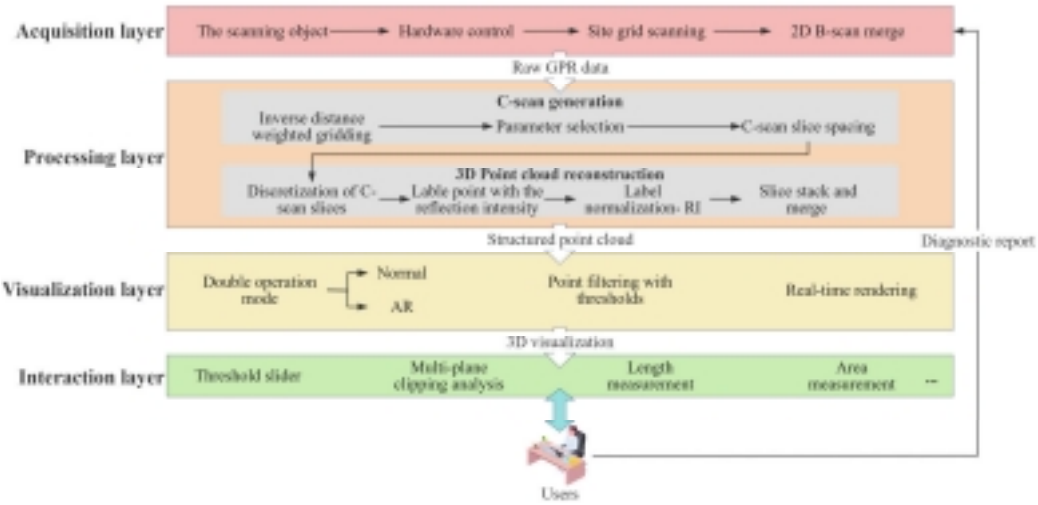

Fig. 1 The technical framework of GPR-AR

User functions in the interaction layer facilitate user operations, as shown in Fig. 2. A sliding filter controls point-level visibility based on the *RI* range. Adequately adjusting the filter hides low-value noises and highlights building elements. The 3D interface adopts adjustable XYZ-axis cutting planes for focused zones. Length and area measurements enable users to efficiently measure spatial data using mouse clicks.

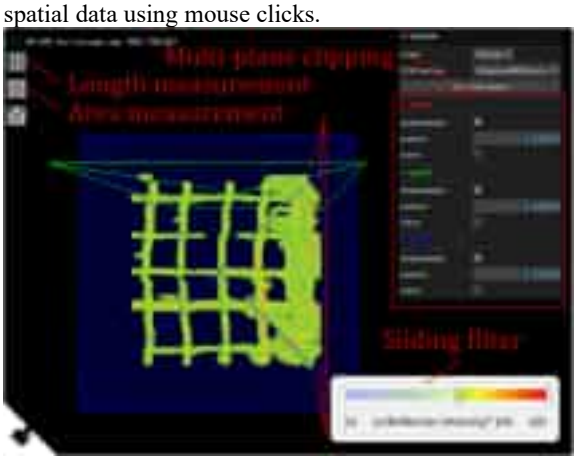

Fig. 2 Interface of the GPR-AR platform

2.3 A demonstration case of reconstruction

Fig. 3 shows a demonstration case of GPR-AR. In this case, a GPR scan was conducted on an aging stair of the MuiWo watchtower in Hong Kong, and the results were processed using GPR-AR. The raw B-scans are isolated and difficult for non-specialists to interpret. In contrast, GPR-AR provides a simple, easy-to-use 3D visualization of results. Using the length measurement function, the spacing between vertical and horizontal rebars was easily measured at 0.17m and 0.16m, respectively. The result was confirmed by the exposed rebar layout in Fig. 3. Two horizontal rebars are detected at a depth of 16 cm, spaced approximately 23 cm apart in the 3D visualization. The user-friendly GPR-AR interface and functions enabled stakeholders to measure and interpret the internal details.

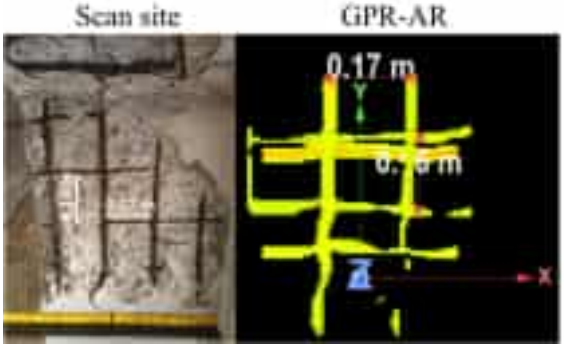

Fig. 3 A demonstration case of GPR-AR

3 Evaluation Using a Questionnaire Survey Based on TAM

3.1 Survey design

A questionnaire survey was designed based on the TAM, as shown in Fig. 4. The respondents were professionals in the AEC industry to reflect the acceptance levels of experts [16, 18, 17]. EVs use respondents' experience and their technology usage context. PU in TAM is measured by evaluating the core functions of the platform, while the overall usability rating measures PEOU. The outcomes of PU and PEOU surveys reflect the respondents' attitudes and behavioral intentions towards use (ABI). This paper employs TAM and designs a structured questionnaire to evaluate the acceptance of the GPR-AR platform among professionals.

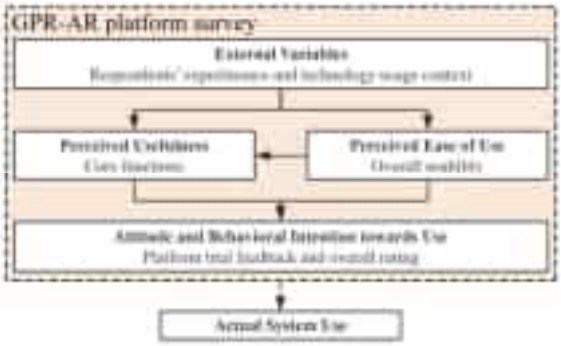

Fig. 4 GPR-AR platform survey based on the TAM [16, 14]

The questionnaire comprises three sections, as listed in Table 1: background information about the respondents, the GPR-AR platform evaluation and open-ended feedback on the GPR-AR platform. Each question corresponds to one specific TAM construct. The questionnaire was electronically distributed to industry professionals after two professional workshops on GPR.

Table 1 The structure of the GPR-AR evaluation questionnaire

Section	Questions	Constructs
Background	Q1 How long have you been working in the AEC industry?	EV
	Q2 How much do you know about GPR?	EV
Evaluation	Q3 How useful do you find GPR technology for building inspection?	PU
	Q4 How intuitive is the "see-through" visualization feature of the GPR-AR platform?	PEOU
	Q5 How useful do you find the length measurement tool in the GPR-AR platform to be for the building inspection?	PU
	Q6 How useful do you find the area measurement tool in the GPR-AR	PU

	platform to be for the building inspection?	
	Q7 How would you rate the ease of use of the GPR platform?	PEOU
	Q8 To what extent can the GPR-AR platform improve the building inspection?	PU
Feedback	Q9 Which aspect of the GPR-AR platform needs the most improvement?	ABI
	Q10 What other suggestions do you have for developing and applying the GPR-AR platform?	ABI

(Note: EV refers to external variables; PU refers to perceived usefulness; PEOU refers to perceived ease of use; ABI refers to attitudes and behavioral intentions towards use)

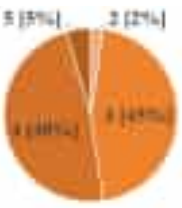
A five-point Likert scale was adopted in the evaluation [3]. Four questions correspond to PU (Q3, 5, 6, 8) to collect respondents' responses, including Not at all helpful = 1, Slightly helpful = 2, Moderately helpful = 3, Very helpful = 4, and Indispensable = 5. For the question corresponding to PEOU (Q4, 7), a five-point Likert scale was also used, where Very difficult = 1, Somewhat difficult = 2, Neutral = 3, Somewhat easy = 4, and Very easy = 5. Notably, although the "see-through" visualization is the prerequisite for platform use, it primarily serves to reduce the burden of data interpretation. Therefore, Q4 was classified as PEOU, which in turn has an indirect impact on PU.

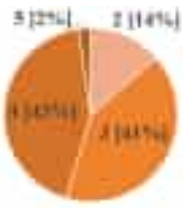
3.2 Data collection

To ensure the accuracy and relevance of the investigation, the target population was limited to active professionals in the fields of construction, safety inspection, and heritage protection in Hong Kong. These professionals, selected from the Hong Kong Institute of Engineers (HKIE, 90.9%) and the Society of Registered Safety Officers (SRSO, 9.1%), were affiliated with contractors, developers, government agencies, and universities. All participants hold a high degree of professional standing and technical expertise. The survey was conducted during industry seminars and workshops from June to July 2025, ensuring that the feedback received was from practitioners familiar with on-site inspection challenges and emerging digital tools.

The collected data was processed into three categories. The data collected in the background section were categorical. The data in Section Evaluation are ordinal (e.g., Indispensable = 5 in the PU-related questions). The data in Section Feedback is open-ended qualitative data. All the ordinal data were analyzed using descriptive statistics to evaluate the GPR-AR platform. Means, variances, and standard deviations were calculated for each question to summarize central tendency and response dispersion.

4 Findings





4.1 Questionnaire survey results

A thorough survey was carried out to evaluate the functions and applications of the GPR-AR platform. Among the 44 respondents, more than 75% have at least 1 year of professional experience in building construction or building safety, with 21 having over 10 years.

For those professional respondents, 45% had no prior knowledge of GPR, while others had only basic awareness (41%) or were familiar with general principles (14%), indicating that GPR is well-known but not widely applied within the construction and safety industry.

The evaluation results of three core functions are listed in Table 2. "See-through visualization" was the most recognized function, with more than half of the respondents finding it very helpful (score ⩾ 4). Length and area measurement are also considered essential

Table 2 Evaluation of core functions on the GPR-AR platform

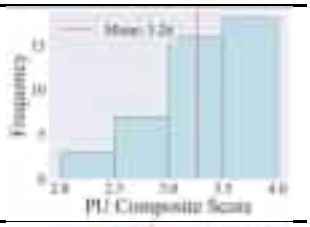
Functions	"See-through" visualization	Length measurement	Area measurement
Construct	PEOU	PU	PU
Mean	3.55	3.30	3.34
Variance	0.38	0.39	0.54
Standard deviation	0.62	0.62	0.74
Distribution			

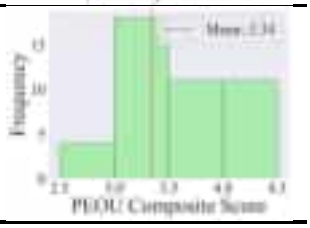
1: Not at all helpful; 2: Slightly helpful; 3: Moderately helpful; 4: Very helpful; 5: Indispensable

functions in engineering practice. Moreover, these industry stakeholders believed that the GPR-AR platform should be improved in several key functions of concern in the industry, including interface design (mentioned by 52%), functional design (50%), and processing speed (26%). Some professionals also suggested that conversion from a 3D scan to a 2D drawing/BIM is needed [19].

4.2 TAM model assessment

Four-item PU and two-item PEOU constructs were created to calculate composite scores (Table 2). The reliability of the PU was tested using Cronbach's alpha value (α), while the internal consistency of PEOU was evaluated through the correlation coefficient between the only two items [20]. For the ordered Likert-scale data, a nonparametric Spearman rank correlation analysis was employed to examine the influence of respondent EVs on platform evaluation [3].





As shown in Table 3, PU demonstrated excellent reliability ($\alpha = 0.803$) based on its four-item scale. The PU composite was 3.26 (mean score of four items), with a distribution indicating a tendency towards higher scores. PEOU only included two items that significantly reduced α (0.434); therefore, an alternative 2-item correlation analysis was applied [21]. The 2-item construct demonstrated acceptable reliability for short scales, as indicated by the Spearman coefficient ($\rho > 0.30$, $p < 0.05$). Consequently, the 2-item composite score was calculated to provide preliminary evidence of internal consistency.

loading and composite reliability (CR). In Table 3, the items demonstrated significance and had factor loadings greater than 0.4 (Q4's was close to 0.4), which can be considered a sufficient variance-explained rate for their construct. CR of PU was greater than 0.7, indicating good aggregation validity; CR of PEOU was within (0.4, 0.7), indicating a moderate but acceptable aggregation effect.

The distributions of PU and PEOU by EVs (professional experience and GPR knowledge level) were elaborated in Fig. 5. PU of GPR-AR by professionals was significantly influenced by their professional background. PU had a "U-shaped relationship" with their professional experience, while PU was positively correlated with the GPR knowledge level. This indicates that GPR-AR is of great value to new practitioners and experienced professionals alike. On the other hand, PEOU was not significantly affected by their GPR knowledge level. This is because ease of use is an objective attribute of a technology, while usefulness is an evaluation that depends on the cognition and needs.

A Spearman correlation matrix was established to analyze the correlations among EV, PEOU, and PU. The correlation between EV and other constructs indicated the extent to which technology has become popularized. The work experience and GPR knowledge in EV were mutually independent. It was found that the correlation between the two items and other assessment variables was insignificant (Table 4). Organizations and stakeholders continue to maintain a conservative attitude, which aligns with the TAM. There was a significant correlation between PU and PEOU ($r = 0.654$), consistent

Table 3 Questionnaire analysis of evaluation items

Construct	Item	Factor Loading	α	CR	Distribution
Perceived usefulness (PU)	Q3	0.357	0.803	0.821	
	Q5	0.894			
	Q6	0.850			
	Q8	0.784			
Perceived ease of use (PEOU)	Q4	0.487	0.434	0.437	
	Q7	0.569			

Confirmatory factor analysis (CFA) assesses whether the measurement model accurately reflects the construct or variable being measured. Content validity was confirmed through classification using TAM. Convergent validity was evaluated by the extracted factor

with a prior TAM study [22]. This positive correlation reflects the interrelationship between PU and PEOU. Especially in the context of emerging technologies, PEOU has a significant impact on PU.

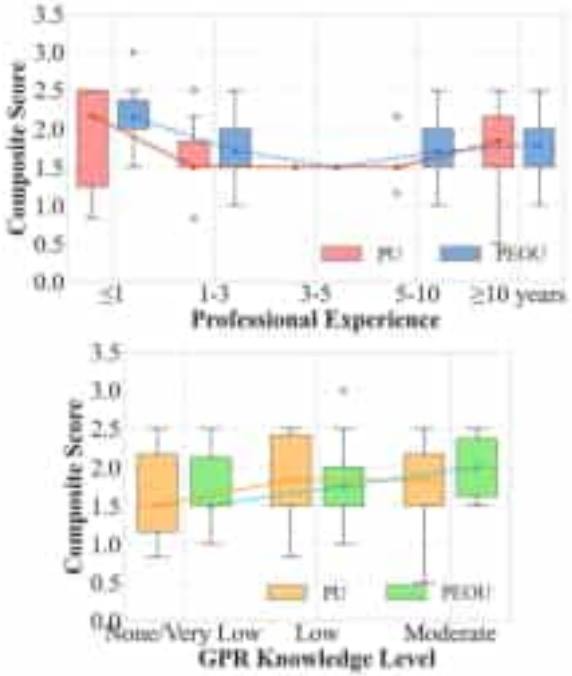


Fig. 5 Distribution of PU and PEOU by EVs

Table 4 Discriminant validity: Spearman correlation and AVE root value

	EV	PU	PEOU
EV	0.927		
PU	-0.077 (p=0.618)*	0.744	
PEOU	-0.165 (p=0.284)*	0.654 (p=0.001)*	0.53

*Values in parentheses represent the significance level, and the diagonal values are $\sqrt{AVE}$

4.3 Attitude and behavior intention from students' feedback

Given the limited practical experience with GPR among professionals in the above survey, it is valuable to gather additional comparative feedback from users with technical awareness. An exploratory study was conducted targeting 70 postgraduates with primary knowledge of GPR. Comparative evaluations and development suggestions for the GPR-AR platform and the mainstream commercial software *Geolitix* were collected. The thematic analysis method was employed to code and categorize the textual data, with a focus on respondents' attitudes and behavior intentions towards the platform. This provides an additional perspective for the TAM study, jointly forming a triangular validation framework for evaluating GPR-AR.

The live poll indicated that students recognized that GPR-AR can improve: (i) 3D presentation of subsurface over 2D sections (93%), (ii) uses for non-destructive testing (81%), and accurate rebar locations/details (76%). We received 15 pieces of feedback comparing GPR-AR with the mainstream GPR processing software *Geolitix*. Generally, it was agreed that GPR-AR has advantages in terms of intuitive 3D visualization, a lightweight user experience, an open-source and free nature, and cross-platform compatibility. However, the feedback also revealed deficiencies in functional depth and data analysis capabilities. It supplemented the ABI of the TAM-based survey and provided a clear direction for the functional optimization of the web AR approach.

5 Discussion and Limitations

5.1 Survey analysis

The questionnaire design in this paper was based on the TAM, aiming to structurally assess the potential application of the GPR-AR platform for building inspection. The survey results indicated that respondents had a high PU, especially in the "see-through" visualization aspect. The PEOU also reached a positive level, indicating that the platform has a strong foundation of user acceptance. Few correlations were identified between EV and the evaluation variables (Table 4), which demonstrates the ease of use of GPR-AR.

Although the Q3 description directly focuses on usability, limited familiarity with GPR and the wording of Q3 hinder respondents from clearly distinguishing between PU and PEOU for an emerging technology, resulting in a relatively low factor loading. Besides, correlated PU and PEOU ($r = 0.654$, $p < 0.001$) in the TAM results in PEOU items inadvertently capturing some of the PU construct [16, 22]. The boundary between "usability" and "ease of use" among these professionals, lacking sufficient experience, may be blurred [23]. Additionally, reliability analysis for PEOU involving a small number of items may limit the accuracy. Future research should adopt a more comprehensive PU and PEOU scale to clarify reliability and validity.

Based on the ABI feedback from students and the results of industry questionnaires, the platform is expected to be systematically enhanced. Expected improvements include optimizing user interface interactions, improving the intuitiveness of operations, and developing advanced analysis functions, such as machine-learning-based rebar recognition and intelligent defect diagnosis [24]. More case studies will also be used to verify engineering usability and ease of use.

In summary, the web AR approach (GPR-AR) has addressed the limitations of interpreting 1D and 2D GPR radargrams in building inspection. The investigation

results regarding the GPR-AR platform indicate that its visualization function effectively leverages augmented reality to make complex GPR data more comprehensible and accessible. This TAM analysis demonstrates that reconstructing raw GPR radargrams into 3D point clouds effectively reduces professional barriers to GPR, making it more accessible to diverse stakeholders.

5.2 Limitations and prospects of GPR-AR

While the TAM-based survey indicates that GPR-AR could contribute to AEC practice, it is limited to directly measuring improvements in inspection. Future research will focus on objective performance metrics using GPR-AR, such as accuracy and time efficiency, to verify perceptions.

Beyond the perceptual scope of this study, several technical challenges should be addressed for the wide adoption of GPR-AR. Firstly, the next phase of research should focus on the precise co-registration of volumetric point clouds between the surface and the subsurface. Secondly, the operation-led trajectory deviations will affect the accuracy of the results. Reducing the influence of operational errors during the analysis process is a research goal for future development. Moreover, the 3D model is currently an intuitive visualization without any annotations or segmentation. Future implementations aim to integrate semantic models and geometric algorithms to achieve a detailed digital twin model [25, 26, 27].

Despite these challenges, GPR-AR holds significant promise for a wide range of applications in the AEC industry. During building inspections, intuitive 3D visualization enables non-professional stakeholders to locate internal rebars and detect defects without destructive tests. In the field of heritage protection, the approach is helpful for conducting subsurface heritage documentation. In addition, the approach's intuitive, easy-to-use nature makes it more convenient for collaborative infrastructure monitoring. These application scenarios demonstrate the great potential of GPR-AR.

6 Conclusion

This paper integrates the reconstruction of Ground Penetrating Radar (GPR) radargrams into 3D point clouds within a web AR platform for building inspection. A questionnaire survey based on the Technology Acceptance Model (TAM) revealed that this integration was well accepted. The scores for perceived usefulness (PU) and perceived ease of use (PEOU) performed well, indicating potential application in engineering practice.

Future work can focus on the following aspects: achieving precise registration of surface and subsurface point clouds, optimizing operation-leading errors, and integrating machine learning algorithms to enable automatic object recognition. This research provides empirical evidence for the digital applications of GPR in building inspections, which align with Hong Kong's smart city development goals and the global digital transformation of the construction industry.

Abstract -

Advances in robotic systems, sensing technologies, and artificial intelligence offer substantial potential to automate construction processes. However, current construction robotics applications are limited to specific tasks in isolated systems, lacking the integration required for coordinated, large-scale robotized construction that is applicable in a wide spectrum of trades. A key challenge is the absence of digital frameworks integrating product information, construction processes, robotic capabilities, and execution feedback across planning, simulation, and on-site operation. This paper presents the concept, principles, and software architecture of the information backbone of robotized construction (IBRC), a unifying framework for planning, simulating, and executing construction projects using coordinated, heterogeneous robotic systems. The IBRC comprises two tightly coupled environments: an offline planning environment and an online execution environment. The planning environment supports successive refinement of product and process information, starting from a building information model (BIM), via a fabrication information model (FIM), to a robot execution model (REM). The refinement is realized through a graph-based product–process representation and rule-based construction recipes, enabling the derivation of atomic construction actions at a granularity suitable for robotic execution. The execution environment builds on the results and supports both simulated and real-world operation. It relies on middleware, such as ROS 2 for real-time robot communication or Apache Kafka for scalable integration with higher-level services. Central orchestration is achieved through behavior-tree-based multi-robot coordination.

Robotized Construction; Information Backbone; Construction Robotics; BIM-based Process Planning; Multi-Robot Coordination; Fabrication Information Model

1 Introduction

Recent advancements in mechatronics, sensor systems, and artificial intelligence have substantially enhanced robotic capabilities, revolutionizing industrial manufacturing and increasing automation across many industries. It is, therefore, not surprising that robotic systems have made significant advancements in construction environments over the past years [1]. However, the robotic automation in construction thus far has been limited to isolated systems and highly specialized processes. Hence, a paradigm shift towards realizing a comprehensive system-of-systems approach is required that facilitates heterogeneous fleets of autonomous and semi-autonomous robotic systems to collaboratively work alongside humans in a well-coordinated manner on-site [2]. Furthermore, to achieve reliable robotized construction, adequate and precise information about the buildings under construction, the construction methods, processes and progress, the position, action, and interaction of robots, as well as the status of the site as a whole, must be available in a coherent digital representation. On the basis of the information, the central coordination of all on-site robotic activities must be established. Today, appropriate information backbones for simulating and executing robotized construction processes do not yet exist. Therefore, this paper proposes the concept of an information backbone of robotized construction (IBRC) that provides these functionalities [3].

The IBRC aims to provide a framework that enables a virtual laboratory environment where new robotized construction methods can be tested and developed. The framework provides fundamental services, such as digital representations of the facility under construction and the involved processes, and, at the same time, provides flexible interfaces to allow the integration of any type of robotic system, sensors, and construction methods. This paper presents the general concepts underlying the IRBC. To this end, rather than describing isolated applications, robotized construction is framed as a two-phase workflow, encompassing (1) the configuration and planning of a largely robotized construction project and (2) its simulation and on-site execution through the orchestration of a fleet of heterogeneous robots across diverse construction tasks.

Regarding (1), the paper defines a digital workflow in

which product and process information are represented as interdependent graph data structures. These graph representations are co-evolved and mutually constrained, enabling the consistent formulation of constructability, sequencing, and system capabilities. Most importantly, the workflow results in a set of atomic, executable actions that can be assigned to robotic systems. Regarding (2), the simulation environments, communication protocols, and interactions with a central coordination system are discussed.

2 State of the art

A crucial aspect of construction robot task and motion planning is the effective use of BIM and construction schedules to generate executable plans. In early work on integrating BIM with robotics, Meschini et al. [4] highlighted the need to link BIM with the Robot Operating System (ROS) [5] to support construction automation. Their study demonstrated scenarios such as precast timber module installation and robotic assistance for elderly care, showing how BIM-based models can be used to evaluate alternative robotization strategies. However, it remained at a high level and did not provide a concrete BIM–ROS integration method. Addressing this limitation, Ibrahim et al. [6] proposed mapping the as-built state of an indoor construction site by generating waypoints in BIM, transforming them into robot navigation coordinates, and performing LiDAR-based mapping during execution.

Similarly, Mantha et al. [7] proposed task allocation and route planning for multiple service robots using simplified 2D building representations, reflecting the broader limitation of insufficient detail in construction schedules. In parallel, CAD-based and geometry-driven frameworks such as compas-fab [8] provide more direct links between design models and robotic task planning, simulation, and execution.

According to the process hierarchy introduced by Everett and Slocum [9], manufacturing-oriented robot process planning operates at the level of elemental motions, whereas construction schedules are typically specified only at the level of coarse-grained activities. This mismatch creates a fundamental gap between the information available in construction plans and the level of detail required for robotic execution. Even with BIM, it is impractical for planners to manually define robot-level tasks at this granularity, and recent approaches [10, 11, 6] have not yet closed this gap.

One of the few approaches addressing this issue is Kim et al. [12], who extend BIM with task-planning information to generate motion-level robot behaviors. Their ROS-based prototype for indoor wall painting includes conversion from IFC to a ROS-compliant world model and integrated localization, navigation, and motion planning.

Related work by Zhu et al. [13, 14, 15] focuses on robotic assembly of prefabricated elements. The smart construction object (SCO) concept assigns state and requirements to components to coordinate multiple robots, and subsequent work enables automatic conversion from IFC to simulation description format (SDF) to create smart building components for simulation.

Despite these advances, most approaches remain restricted to comparatively simple assembly scenarios and lack generality. A comprehensive framework capable of planning and executing diverse robotized construction processes in a coordinated manner is therefore still required.

3 The information backbone: Overall architecture and components

The proposed framework for planning and executing robotized construction projects is organized around an information backbone that integrates product and process representations across planning and execution stages. The backbone provides a consistent data model and set of interfaces through which design information, construction logic, and robotic task specifications are incrementally developed, validated, and executed. While the detailed implementation is described in [16], this section outlines the underlying principles, the overall software architecture, and the interaction between the core components of the IBRC.

At the architectural level, the proposed system consists of two tightly coupled environments:

1. The **planning environment** (“offline” components) that allows for the iterative development of the construction project, starting from the overall building design down to precise instructions for individual robotic systems.
2. The **execution environment** (“online” components) that allows for the steering and coordination of a heterogeneous fleet of robotic systems, implementing the assigned tasks to complete the construction project, while being able to react to unforeseen events. The execution environment is designed to ensure a seamless transition between simulation-based validation and execution in physical environments.

Both environments operate on a shared information backbone that encodes the evolving relationship between the construction product and process, and may employ model-based methods and process simulations.

3.1 Planning environment

The planning module of the IBRC enables the successive and parallel refinement of both the product (= building components) and the process representation. The module

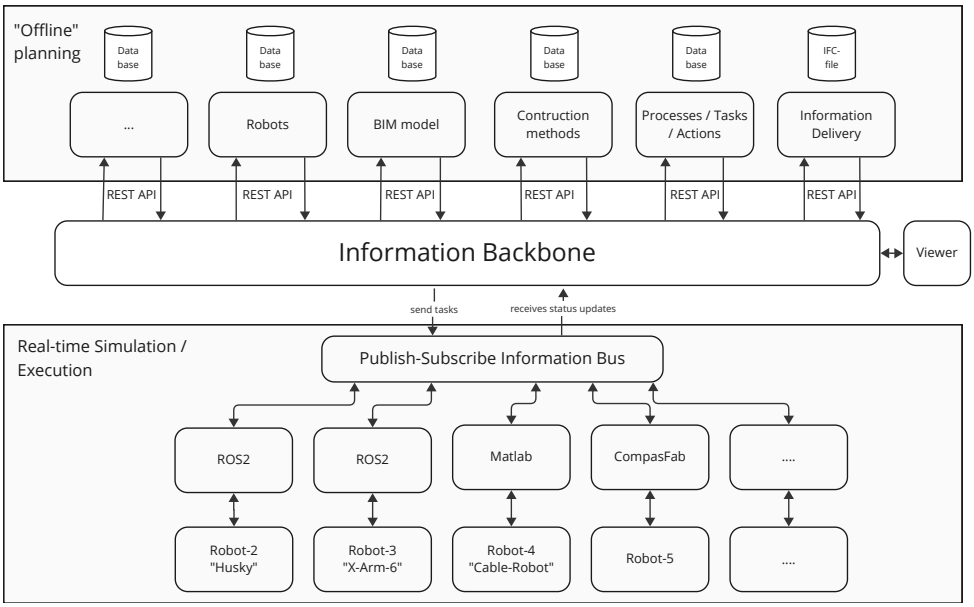

Figure 1. The architecture of the information backbone consists of two major parts: The planning environment and the execution environment

consists of several modules that provide or process data in a service-oriented manner [16].

3.1.1 BIM to FIM to REM: Graph-based refinement of products and processes

The product-process elaboration process is outlined in Fig. 2 and described in detail in [17]. The starting point is a relatively coarse BIM model of the building to be constructed, comparable to an as-designed LOD300 model. The model is represented as a graph that combines two trees, with one tree representing the hierarchical breakdown of the product side and the other representing the hierarchical breakdown of the process side. The process tree is automatically derived from the product graph. Product nodes are linked to the set of process nodes that realize the construction.

By assigning construction methods to individual building components, such as *in-situ concreting, bricklaying,* or *additive manufacturing*, both the product and process graphs are refined. After refinement, the model is referred to as a Fabrication Information Model (FIM) and has a much finer resolution than typical BIM models [18]. FIM contains and represents all atomic – in the sense of indivisible – elements that have to be manipulated for the production of a building element. For example, assigning the construction method *bricklaying* to a wall generates the FIM that contains all individual bricks and the mortar; while assigning the construction method cast-in-situ creates a FIM that represents the concrete, reinforcement, and temporary formwork elements. At the same time, the process graph is further refined and now contains individual activities such as *erect formwork*, *insert reinforcement*, *fill concrete*, and *remove formwork*.

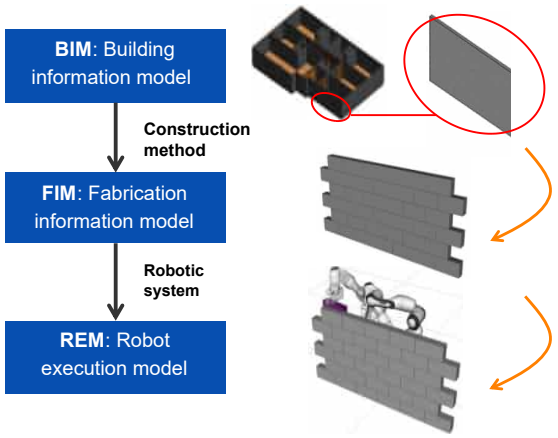

Figure 2. From BIM to FIM to REM

The simultaneous refinement of product and process graph is performed by applying *recipes* that encapsulate the knowledge about specific construction methods [19]. Recipes not only represent the rules for creating sub-nodes for individual process nodes and product nodes, but also define precedence relationships and the required resources (including robots, cranes, construction machines, or human workers). For example, to start "*Fill Concrete*", the activity "*Erect Formwork*" must be completed. For placing formwork and inserting reinforcement, a (robotized) crane is required. The information might later be used e.g. in an event simulation to experiment with the effects that various robot allocation strategies in terms of the amount

and type of robots will have on the overall construction schedule, as well as on construction costs.

The product-process graph is refined down to a level where leaf nodes represent atomic elements (e.g., bucket) and atomic actions (e.g., FillBucket), as shown in Fig. 3. Atomic actions are later transformed into manipulation instructions sent to the individual robotic systems. The instructions are described at a level of abstraction that is executable by robotic systems while omitting low-level motion details, allowing a certain degree of interpretation and thus granting robotic systems the autonomy to plan execution. For example, the *transport formwork* action, sent to a robotized crane, specifies only start and end positions, not the exact crane hook trajectory or jib movement.

This kind of fine-grained information – such as trajectory data or actuator commands needed for a certain manipulation task – is represented by a robot execution model (REM). REMs are created in the next step, and typically reside outside the information backbone, in components closer to robot control. While FIM is robot-type-agnostic, REMs are created for specific robot types and contain all set motion data for the respective robot type to complete a task. REM computation employs robot models (of potentially varying granularities) that might be used to e.g. kinematically compute a simple trajectory or even optimize a motion within a dynamical simulation, considering e.g. collisions, motion time or energy consumption. Accordingly, choosing another robot type for the same manipulation task leads to different motions and thus a different REM. Still, the methods and interfaces for REM computation might be generalized: a BIM-FIM-REM toolchain has been demonstrated to generate a REM model for automated masonry with cable-driven parallel robots [20]. Finding a suitable robot involves robot task allocation (section 3.1.3), but nevertheless, there is feedback from the robotic systems on previous steps, as different robots have different characteristics. For example, robots with higher payloads can place larger brick formats.

The Backbone is accessible mainly through APIs, but also a User Interface, consisting of a modular model viewer and a robot planning viewer. The model viewer offers a visual inspection of the building, status tracking, and enables task planning and execution. The robot planning viewer is used to display simulation results and, during execution, the robot's next planned actions in real-time.

3.1.2 Discrete event simulation

The precedence relationships of the process graph define the general sequence of atomic tasks, but sequence alone does not capture the probabilistic time distribution a specific robot needs for each task. Such knowledge about the overall stochastic distribution is, however, important to plan for the resource-intensive robotic equipment and the equally important supply chain that is required to provide the robotic equipment with the required material.

To determine the stochastic duration of overall robotic work processes on-site, we propose to employ constraint-based discrete event simulation [21, 19]. In these simulations, the duration of a directed graph network of tasks is simulated. Constraints determine when a single task in the network can be started: all preceding tasks in the network need to be finished, all required materials need to be available, and all robotic and non-robotic equipment needs to be available. When all prerequisites are met, the simulation starts a task that executes it for a duration drawn from a specific probability distribution representing the stochastic duration of the atomic task, ideally defined based on empirical data collected from previous construction work. During the duration of a task, all resources are bound and not available for starting other tasks.

A stochastic Monte-Carlo repetition of various individual discrete-event simulations then provides important information to strategically plan the site. Variations in the amount and provision of robotic and non-robotic equipment can provide stochastic durations and costs of specific resource allocations. For each provided resource allocation scenario, simulation results provide information about when specific material resources are required, which, in turn, allows for planning material supply chain aspects for the entire construction site.

3.1.3 Robotic skills and task allocation

To enable the selection of suitable entities, such as robotic systems, construction machinery, or humans, for dedicated construction tasks, a formal method for describing the skills, constraints, and requirements is developed. The *skills* section includes an enumeration of tasks such as *lifting, placing, drilling, demolition*, etc. The *constraints* section includes the maximum load as well as the operational range of the system, among others. The *requirements* section includes the necessary space, supply (electricity, material), and the weight of the system to be considered as loads for the underlying structure.

The formal description of robotic skills, constraints, and requirements forms the basis for multi-robot task allocation. Construction tasks derived from the FIM model are assigned to individual robots capable of performing the task. For example, transport before the assembly of a prefabricated component requires a mobile robot capable of grabbing, lifting, and transporting elements of certain sizes and weights. If multiple robots are qualified, they are ranked by performance factors such as speed, required space, etc. The actual task allocation procedure is based on a free-market allocation approach as proposed by [22].

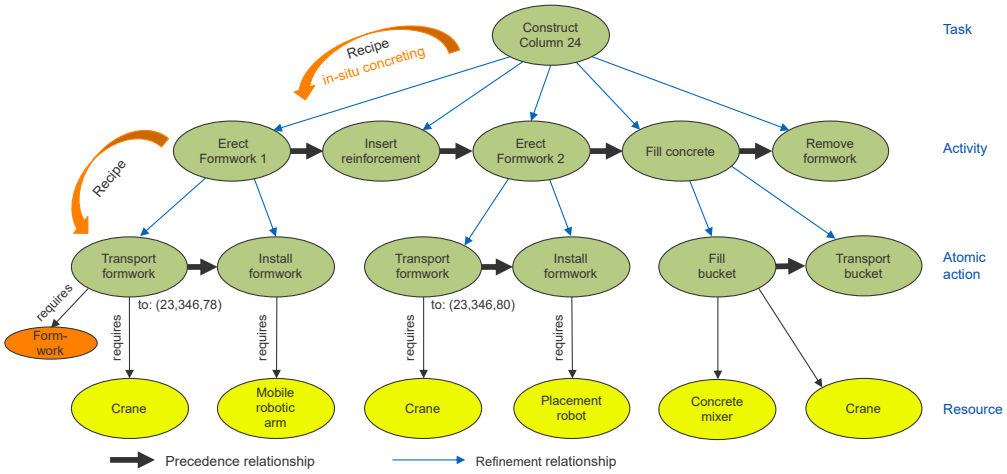

Figure 3. Process graph representing the hierarchical breakdown of the construction processes. The leaf nodes represent instructions for the individual robotic systems.

3.2 Execution environment

The purpose of the second module of the information backbone lies in the execution of the construction processes prepared in the planning environment, primarily involving steering and coordinating the diverse robotic systems. As real-world experimentation is cumbersome and expensive, the proposed approach supports performing robotic simulations with a high level of realism. At the same time, communication protocols are defined to facilitate an easy transition from controlling simulated robots to controlling real robots.

3.2.1 Middleware

Communication between the central coordination module and the robotic systems is handled by middleware, with an implementation using the Robot Operating System 2 (ROS 2) as the primary framework. ROS 2 is a modular, open-source framework for developing, deploying, and operating robotic systems. It provides standardized communication mechanisms, tooling, and abstractions that support distributed, heterogeneous, and real-time-capable robotic applications.

ROS 2 builds on Data Distribution Service (DDS) implementations such as eProsima Fast DDS [1], or Eclipse Cyclone DDS[2], which use the DDS-RTPS wire protocol[3] for message transport over standard network protocols, including UDP and TCP. ROS 2 communication follows a message-oriented paradigm. Data is exchanged through strongly typed messages defined in an interface description language. Messages are published and subscribed via named topics, enabling loosely coupled, asynchronous communication between robot components and processes.

Alternatively, Apache Kafka[4] is available as an additional abstraction layer. While ROS 2 provides a very complete toolset with extensive libraries, computational methods and robot-centric communication, Kafka provides a scalable and fault-tolerant event-streaming that supports integration of external systems such as digital twins, BIM services, or analytics platforms. Bridging ROS topics to Kafka streams allows robot-generated events to be consumed by higher-level coordination and monitoring services, while process-level commands can be reliably disseminated to the robotic fleet. The separation supports heterogeneous system landscapes and enhances scalability without affecting time-critical robot control. Furthermore, Apache Kafka provides an interface to industry-standard bus systems such as EtherCAT. In this context, an interface to MATLAB Simulink is created to enable the simulation of robotic systems outside of the ROS 2 environment.

Exemplarily, this is used for the simulation and control of a cable-driven parallel robot for construction.Due to its size, payload and sensitivity towards stable control frequencies, industrial hard real-time control is required. Accordingly, control is performed on a Simulink target in a Beckhof TwinCAT PLC, while hardware communication is performed via an EtherCAT bus.

3.2.2 Shared model hosting and hierarchical information flow

Beyond communication protocols, the system architecture must define how shared product and process representations are hosted and maintained. In the proposed framework, the BIM and the FIM serve as authoritative,

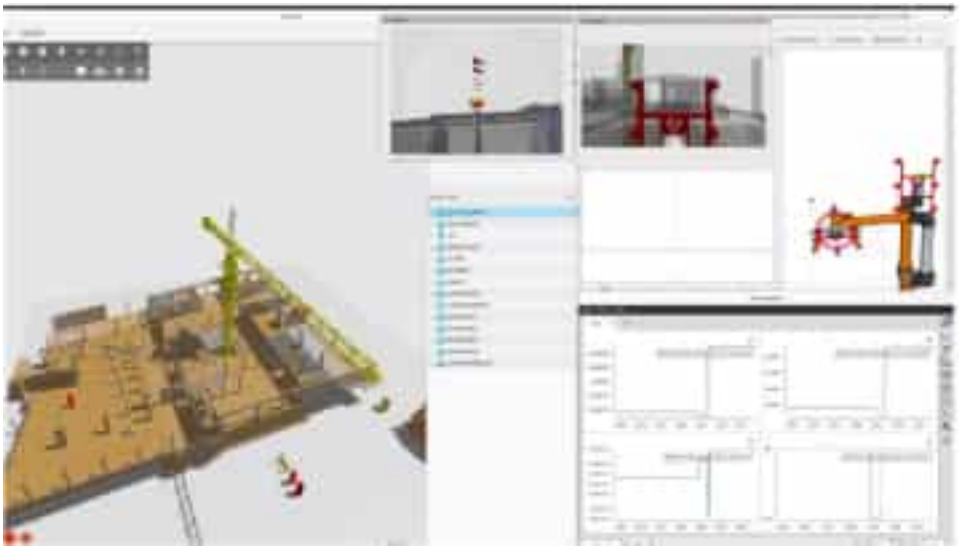

Figure 4. Gazebo is one of the employed simulation environments. Here, the interaction between a robotized crane and a mobile manipulator on a wheeled base is simulated.

global descriptions of the construction state and therefore cannot be treated as local or transient data structures.

Both models are hosted in a cloud environment and are accessible to all distributed agents participating in the construction process, including planning services, simulation components, and robotic execution systems. Shared hosting enables synchronized access to up-to-date product and process information, supporting continuous updates that reflect construction progress, execution outcomes, and detected deviations.

3.2.3 Behavior tree for the central orchestration of the robotic fleet

For executing robotic processes in a coordinated manner, process graphs resulting from the planning environment are transformed into behavior trees (Fig. 5) [17]. Behavior trees are hierarchical, graph-based task control structures for modeling and executing robot behaviors in a modular and reactive manner [23, 24]. The authors decompose complex tasks into reusable nodes, developed in the form of robotic capability subtrees [24], that encapsulate actions, conditions, and control flow, enabling clear separation of decision-making and execution. Due to the scalability, readability, and support for real-time reactivity, behavior trees are widely adopted for robotic task execution and control in both research and industrial applications.

In contrast to controlling individual robotic systems, behavior trees are employed as a centralized coordination mechanism to orchestrate the tasks of an entire heterogeneous robotic fleet. In the IBRC architecture, the leaf nodes of the behavior tree issue messages to the respective robotic systems, enabling coherent and synchronized multi-robot behavior. The messages mirror the level of (process) detail provided by the product-process graph and allocate tasks based on robotic capabilities, leaving a certain freedom of interpretation and degree of independence to the individual robotic systems.

Individual robotic systems may additionally implement local behavior trees for fine-grained control over robotic behavior. In the hierarchical organization of the IBRC, behavior trees do not directly manipulate shared models; instead consume task assignments and constraints derived and report execution results back to the information backbone, enabling closed-loop updates of the global construction state. More details are provided in [17].

3.2.4 Robotic simulation environments

Robotic simulation environments are a central component of the proposed architecture, as construction robots must operate in complex, unstructured, and continuously evolving environments. Reliable interaction with the built environment, human workers, and other robots requires extensive validation of perception, control, and coordination strategies prior to on-site deployment. Simulation therefore provides a controlled setting in which these capabilities can be developed, tested, and refined before being transferred to physical systems.

Within the proposed framework, simulation environments act as first-class execution entities that mirror the physical world within the same software architecture. Simulated robots receive control commands and publish state and sensor data via middleware interfaces, allowing them to function as substitutes for physical robots during planning, validation, and testing (Fig. 4), and enabling seam-

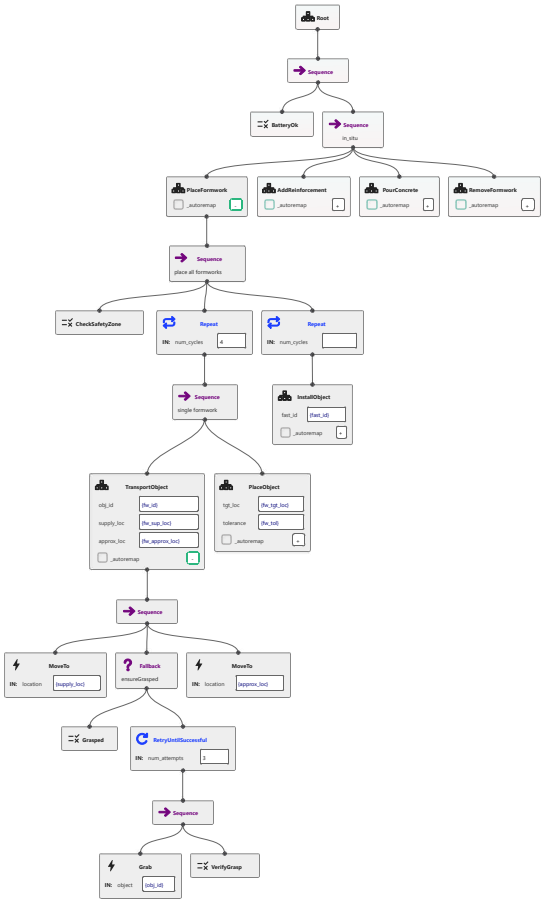

Figure 5. Behavior tree created from the process tree, serving as an executable representation for steering and coordinating the fleet of robotic systems on-site.

less switching between simulated and real execution while preserving identical orchestration and control logic.

Simulation also supports data-driven development workflows. Real-world data acquired through teleoperation, such as camera images, joint states, or encoder readings, can be used to train, calibrate, and refine algorithms that are then evaluated in simulation, which is particularly relevant for construction-specific challenges such as traversing uneven terrain. Core subsystems including controllers, navigation stacks, and SLAM algorithms are therefore developed and validated in simulation prior to deployment. Although simulations cannot fully replicate real-world conditions, noise-aware training and robust algorithm design enable effective transfer to physical robots.

Our framework employs Gazebo, Isaac Sim, and PyBullet as simulation backends, all providing high-fidelity rigid-body physics and tight ROS integration (Fig. 4). Simulation environments are initialized using product and process information from the planning environment. BIM and FIM models are translated into simulator-specific geometry and assets, e.g., SDF entities in Gazebo [25] or NVIDIA-internal formats in Isaac Sim. Robots are instantiated from URDF models provided by the information backbone, allowing the planning layer to remain independent of simulator-specific data structures while supporting multiple simulation platforms. Alternatively, MATLAB Simulink provides powerful tools for modeling construction robots, enabling high-granularity representations of kinematics, dynamics, and physical subsystems such as electronics, pneumatics, and hydraulics.

3.2.5 Human–robot collaboration

Although the proposed framework targets a high degree of robotization, construction remains dependent on human labor and decision-making. Human activities must therefore be explicitly represented in planning and execution, treating the site as a shared workspace where humans and robots perform tasks independently, sequentially, or in close physical interaction.

Human representation is a prerequisite for planning and simulation of collaboration. In simulation, humans can be modeled at different abstraction levels, e.g., kinematic chains, motion-capture trajectories, or avatar-based motion primitives. These models enable analysis of human–robot tasks derived from the process graph and behavior tree, allowing spatial conflicts, interference, and safety-critical situations to be detected before deployment.

Construction activities are classified into robot-only, human-only, and collaborative tasks. Robot-only and human-only tasks can proceed under sequencing constraints, whereas collaborative tasks require coordinated actions. This classification supports task allocation, synchronization, and monitoring across heterogeneous agents.

Coordination is implemented via synchronization constructs embedded in the centralized behavior tree. Robots can wait for human actions, react to changes in human state or position, signal completion, and assist during joint operations. Thus, behavior trees encode both robotic actions and interaction logic for handovers, sequential execution, and parallel work on shared workspaces or workpieces.

Given complementary strengths – robots in repetitive, heavy, and precision-demanding operations; humans in dexterity and situational decision-making – the framework incorporates human-in-the-loop control. Human input can initiate execution, approve transitions, or override robot behavior for supervision and safety.

All human actions and human–robot interactions are reported to the information backbone and integrated into the digital twin, capturing progress, contributions, and interaction states. Simulation further enables validation of collaborative scenarios with respect to safety, efficiency, and usability prior to real-world deployment.

4 Summary

The paper has presented overall concepts, procedures, and the software architecture of the Information Backbone for Robotized Construction. Further details are provided in accompanying papers [16, 17, 25]. The concept has been implemented in a proof-of-concept prototype combining the described modules through a micro-service platform [16]. In the next step, a comprehensive simulation experiment of a close-to-real construction project will be performed to further refine and elaborate the components.

Acknowledgments

Abstract –

Interoperability between industrial and construction digital models remains a persistent challenge, particularly in projects that require the integration of manufacturing machinery within building environments. Manufacturing workflows typically rely on CAD models based on the STEP standard, whereas the Architecture, Engineering, and Construction (AEC) sector adopts BIM methodologies founded on the IFC standard, which integrates geometry with semantic, relational, and contextual information. Although both standards are mature and widely adopted, interoperability remains limited, with the main bottleneck arising from the transformation of industrial CAD models into semantically meaningful BIM representations.

This paper addresses this gap by proposing a lightweight, open-source framework for STEP-to-IFC integration that goes beyond simple geometric conversion. Instead, the framework adapts industrial product logic to satisfy the information requirements of the AEC domain. The proposed procedure reduces assembly complexity by removing unnecessary components, simplifying overly detailed geometries, limiting the number of objects to those strictly required, and enriching them with appropriate semantic properties.

The framework is implemented as a Blender add-on using the Bonsai extension and features an intuitive user interface, making it accessible to practitioners without advanced programming skills. Preliminary results demonstrate its effectiveness in enriching industrial CAD models with BIM-compatible semantics, highlighting its potential for both research and professional applications in complex industrial–building integration scenarios.

1 Introduction

Interoperability between digital models remains one of the most critical challenges in both the Architecture, Engineering, and Construction (AEC) and industrial domains. The manufacturing industry typically relies on Computer-Aided Design (CAD) systems to design machinery, products, and furniture that will be produced by industries. In contrast, the civil sector generally adopts Building Information Modeling (BIM) methodologies, which integrate geometric representations with structured product and semantic information. In the design of industrial or production plants, as well as in certain specialized projects, machinery must be integrated within buildings that are required to accommodate, protect, and support all systems necessary for their operation. Consequently, it is essential for civil engineers to import models into their authoring software that provide comprehensive information necessary for designing buildings, systems, supports, and related infrastructure. By integrating these domains, the design process can be accelerated, achieve higher-quality outcomes, and reduce the likelihood of errors. Such projects are commonly classified as complex, as they are not only complicated, multifaceted, and composed of numerous interconnected components [1], but also characterized by an additional layer of complexity arising from CAD–BIM integration.

Within their respective domains, manufacturing and construction rely on well-established standards for representing three-dimensional and information-rich models: the Standard for the Exchange of Product Data (STEP) format [2] in manufacturing, and the Industry Foundation Classes (IFC) format [3] in construction. Although both standards are based on explicit and formally defined data structures, effective interoperability between the two domains remains limited due to substantial differences in conceptual modeling paradigms, levels of detail, and intended use

cases. Notably, the primary challenge does not lie in data transfer from the civil to the industrial domain (i.e., IFC to STEP), as several tools are available to convert IFC models into simplified STEP geometries, typically renouncing product and semantic data. Instead, the more significant issue concerns the reverse process—from STEP to IFC—because IFC models are required to represent not only geometry but also rich product, relational, and contextual data.

This study proposes a framework that should not be regarded merely as a geometric conversion tool, but rather as a system capable of adapting industrial product logic to the information requirements of the AEC domain based on open-source tools and formats. The proposed approach demonstrates strong potential for application in both academic research and professional practice.

2 Background

As demonstrated in previous work [4], the existing literature on CAD–BIM interoperability between the industrial and AEC domains is limited, with most relevant contributions dating to the 2006–2008 period and lacking alignment with recent standard developments such as STEP AP242 and IFC4.3_ADD2. This situation highlights a clear gap in the current body of knowledge. Moreover, the reviewed studies consistently emphasize the absence of practical, deployable solutions and underscore the urgent need for interoperable, open-source tools capable of mitigating the fragmentation within the AEC sector [5–8].

At present, the most common approaches adopted to compensate for the lack of robust conversion tools include the following practices:

- Importing geometries as meshes, resulting in excessively complex representations that require the manual addition of product properties and relationships. Such meshes are often derived from low-level CAD models [9] that provide only viewable representations, characterized by faceted geometries or "frozen" solids, such as the Stereolithography (STL) format, the Initial Graphics Exchange Specification (IGES), or CATIA Graphics Representation (CGR). Each manual step is prone to error, and the use of highly detailed geometries leads to unnecessarily models.
- Manual redrawing of simplified components across different BIM authoring software, with properties and relationships added manually. This process is time-consuming and highly error-prone.
- Using converters that map all elements to *IfcBuildingElementProxy* or *IfcElementAssembly* entities, which causes semantic degradation, does not address excessive geometric complexity, and generates instances for all parts of a product—including components irrelevant for civil purposes (e.g., screws, bolts, labels). This results in IFC files with an excessive number of objects and redundant information.
- Relying on proprietary ecosystems managing both CAD and BIM environments, which does not resolve data exchange issues with external stakeholders and may conflict with regulatory requirements that mandate open formats, as is often the case in public administration projects. Additionally, large models can cause performance issues, making it difficult to upload and obtain a complete project view.

In summary, current procedures focus primarily on conversion tools without considering the fundamental differences between industrial and civil design logics. Industrial models are typically highly detailed, representing every part of a product to the level required for industrial production. Such models contain a large number of objects (e.g., screws, bolts) and detailed geometries that exceed the information needs of the AEC domain and can significantly compromise BIM performance. In contrast, the AEC sector requires models with a lower level of geometric detail, omitting minor components while preserving overall dimensional information. Moreover, industrial models often lack product properties, requirements, and inter-object relationships, which are typically stored in separate documents or managed via other systems. Conversely, in the IFC format, such data are represented as object properties, enabling professionals to design more efficiently and implement validation procedures to improve quality and save time. Thus, a simple conversion tool is insufficient. What is required is a procedure capable of adapting the logic of industrial products to the information requirements of the AEC domain. An initial attempt to address this challenge was proposed by [4], introducing a framework that leverages open-source technologies to adapt industrial product logic for AEC use. The present work extends this framework, presenting a new version designed to overcome limitations identified in the previous implementation.

3 Materials

A market analysis was conducted to identify open-source tools capable of importing industrial geometries and exporting IFC models suitable for implementing the proposed procedure. This analysis identified two primary candidates: FreeCAD [10] and Blender [11] equipped with the Bonsai extension [12]. Blender and Bonsai were selected due to the availability of documentation and because these tools are specifically developed and widely adopted for civil and BIM-oriented workflows.

Blender does not natively support the direct import of STEP files. To address this limitation, an intermediate exchange format was required that would preserve geometric integrity and structural information. Among the formats supported by Blender, glTF 2.0 (Graphics Library Transmission Format) was selected, as it is an efficient, open, and neutral standard well aligned with Blender's internal architecture. Developed and maintained by the Khronos Group, glTF 2.0 is designed for the efficient transmission and representation of three-dimensional content. It consists of a structured set of files, including a JSON file (.gltf) describing the scene, node hierarchy, materials, cameras, and references to geometry and texture data; one or more binary files (.bin) storing high-density buffered data such as meshes and animations; and image files (.jpg, .png) defining textures associated with materials.

The glTF format was chosen not only for its performance and ability to preserve product hierarchies, but also for its support of custom metadata through the *extras* field. While STEP files typically convey only geometric information and do not include semantic or property data, it is possible to develop a procedure to encode any additional properties associated with industrial components within the *extras* field, thereby enabling their transfer into the BIM environment. The open-source software Mayo [13] was used to convert STEP files into glTF format, which can then be imported into Blender without loss of geometric fidelity.

Blender supports the development of custom add-ons developed in Python, including the creation of tailored user interfaces. This capability enables the implementation of structured and intuitive workflows that are accessible even to users without advanced programming skills. The proposed framework is entirely based on open-source tools, ensuring independence from proprietary software ecosystems and broad accessibility. The overall framework and its operational steps are described in detail in the following section.

4 Framework

4.1 Case study: Paul Scherrer Institut (PSI)

The Paul Scherrer Institut (PSI) is a research center that conducts internationally recognized, cutting-edge research in the natural and engineering sciences. PSI develops, builds, and operates highly complex particle accelerator–based large-scale research facilities, which are made available to both the scientific community and industry. Among its most prominent facilities are the Swiss X-ray Free Electron Laser (SwissFEL) and the Swiss Light Source (SLS) [14].

Due to its extensive building portfolio and the continuous development and upgrading of facilities to incorporate new technologies and enhance its scientific offerings, PSI routinely faces challenges related to the integration of BIM models used for civil design with CAD models employed for the industrial design of its research infrastructure. For clarity, the following sections present a girder from the SLS facility as an illustrative example (Case Study 1, CS1). The framework has also been tested on additional models from the same facility, including a linear accelerator (CS2), a transfer line (CS3), and an undulator (CS4).

4.2 Add-on

The framework is presented step by step in the following sections. The user interface of the Blender add-on developed for this framework is shown in Figure 1 and is available on GitHub [15]. The arrangement of commands in the interface follows the sequential workflow of the procedure, guiding the user through the proper use of the framework. The framework is not limited to the STEP format but is generally applicable to all file formats that can be imported into Blender and that provide a hierarchical decomposition of components.

Figure 1. User interface of the proposed Blender add-on that reflects the methodological workflow

4.2.1 Make meshes unique

This operation is required to prevent unexpected behavior and to ensure the correct execution of the procedure. The command standardizes object names by removing unsupported or problematic characters that could cause ambiguities or errors during script execution. In addition, modeling software often employs multi-user meshes when multiple identical objects are present to reduce memory usage, meaning that a single mesh dataset is stored and referenced by multiple distinct objects. While this strategy is effective for optimizing storage, it can lead to errors when mesh data are accessed programmatically, potentially causing script failures. To avoid such issues, all meshes are made unique so that each object has its own mesh, ensuring that it references independent mesh data. This step is required solely to

guarantee the robustness and reliability of the code and does not affect the geometric outcome of the model.

4.2.2 Select fundamental nodes for IFC conversion

This step aims to adapt the complexity of the hierarchical structure of the imported STEP model to meet the requirements of the AEC domain. Well-structured industrial models often feature deeply nested hierarchies to manage and organize the numerous components that make up a product. This hierarchy is expressed through parent nodes containing multiple child nodes. As shown in Figure 2, when an industrial model is imported into the Scene Container, the hierarchy is displayed using two main types of icons: a triangle icon representing mesh objects and an axes icon representing empty objects. Mesh objects consist of vertices, edges, and polygonal faces, whereas empty objects are void transformation nodes used solely for grouping and manipulating child objects. Typically, empty objects act as parent nodes that contain other empty objects and mesh objects. When a parent node is collapsed in the tree view, the number of its child elements is displayed next to its name, as illustrated in Figure 2.

Figure 2. Hierarchical structure of the imported model in its initial assembly tree

For civil purposes, distinguishing every individual part of an industrial product is generally unnecessary. Instead, the focus is on representing the overall product at an appropriate level of decomposition. Figure 3 illustrates a simplified hierarchy in which only the elements relevant for BIM representation are retained, representing the outcome of the proposed procedure.

Figure 3. Final assembly tree

Accordingly, the user's first task is to select the fundamental nodes that will correspond to independent IFC objects. Within the assembly tree, a fundamental node represents an object that will be converted into an IFC element. If a fundamental node contains other fundamental nodes as children, it corresponds to an *IfcElementAssembly* aggregating multiple IFC elements. Conversely, if a fundamental node is a leaf in the assembly tree, all of its child mesh components are merged into a single object, as this represents the maximum level of decomposition required for civil applications. So, if a leaf fundamental node is an empty object, all mesh objects contained within its hierarchy are merged into a single mesh object.

To perform this operation, the user selects the desired object, chooses the appropriate Level of Detail (Low, Medium, or High) from the corresponding menu, and then presses the *Select nodes for IFC conversion* button. The concept of Level of Detail is discussed in Section 4.2.5. Once the button is pressed, a custom property named *Node for IFC conversion* is created and associated with the selected object. This property states that the node is a *fundamental node* and is essential for the correct functioning of the subsequent processing scripts.

4.2.3 Delete small parts

This step is optional but highly recommended, as it allows the removal of elements that are unnecessary for civil purposes and typically characterized by a high number of vertices, faces, and triangles, such as screws, bolts, and similar components. The command deletes all meshes that do not have the *Node for IFC conversion* property assigned and whose size is below a user-defined threshold. Meshes marked with the *Node for IFC conversion* property are preserved, as some small components—such as plugs, valves, or comparable elements—may still be relevant and required in the IFC model. By defining an appropriate threshold and activating the *Delete parts smaller than* command, the user can efficiently eliminate insignificant elements while retaining those essential for IFC conversion. Figure 4 shows the difference between the initial state and the model after deleting objects smaller than 0.05 × 0.05 × 0.05 m. As reported in Table 2, in the considered case studies, approximately the 61.2% of the total number of objects are removed through this operation.

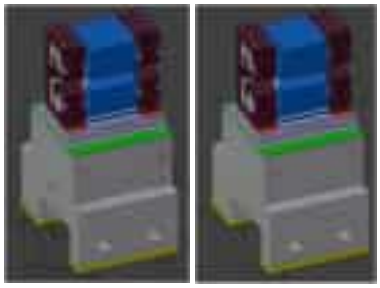

Figure 4. Comparison of the initial state (left) and the girder after removing elements below 0.05 × 0.05 × 0.05 m (right)

4.2.4 Database and ODS printing

For each fundamental node, an OpenDocument Spreadsheet (ODS) file is generated. The ODS format is an open-source spreadsheet standard. The user must specify a directory on their local system where these ODS files will be stored. Each ODS file is named after the corresponding fundamental node, excluding any automatically generated progressive suffixes. In modeling software such as Blender, progressive suffixes (e.g., ASS. AS2B QUAD_DIPOLE.1, ASS. AS2B QUAD_DIPOLE.002) are appended to distinguish objects with identical base names. Since these objects are geometrically and hierarchically identical, generating multiple ODS files with the same content is unnecessary; therefore, a single ODS file is created using only the base name. Each ODS file contains a list of the elements in the hierarchy of the fundamental node after which the file is named. If the fundamental node contains other fundamental nodes as children, as shown in Figure 5, the user is required to define the data for the corresponding IFC objects, including the *IfcClass*, *PredefinedType*, *ObjectType*, and any required property sets (Psets) and properties. If the fundamental node is a leaf node, as illustrated in Figure 6, the user must instead specify data related to the mesh components that will constitute that node. Specifically, for each mesh, the user indicates whether it should be deleted—for example, if it represents an internal or otherwise irrelevant component—or retained. For retained meshes, the user may also specify whether the geometry should be simplified. When geometries are excessively detailed for civil applications, simplification replaces the original mesh with its bounding box, thereby significantly reducing the overall model size.

As illustrated in Figures 5 and 6, the cells requiring user input within the ODS files are highlighted to guide the data-entry process: grey cells must not be filled, dark green cells are mandatory, and light green cells are optional.

Based on the directory specified by the user, the script automatically creates two subfolders—*Completed* and *To be completed*—if they are not already present. For each fundamental node, the script checks whether an ODS file with the corresponding name exists in the *Completed* folder. If no such file is found, a new ODS file is generated in the *To be completed* folder.

After completing the data entry in the ODS files, the user must manually move the files from the *To be completed* folder to the *Completed* folder. This workflow supports the reuse of ODS files across different conversion projects, as multiple models may share identical components—for example, different STEP files of girder models may reference the same *ASS. AS2B QUAD_DIPOLE* magnet, making it unnecessary to compile the corresponding ODS file more than once. By maintaining a single, centralized repository of completed ODS files, redundant data entry is avoided, resulting in improved efficiency and reduced preparation time. In addition, storing manually entered data in a centralized database prevents the need for repeated compilation, which is particularly beneficial in work-in-progress scenarios where the design of industrial products both affects and is affected by the design of the building. This approach enables the procedure to be repeated and updated versions to be shared with minimal or no additional manual effort.

4.2.5 Simplify assembly

Once all parameters have been defined, the geometry can be simplified according to the information specified in the ODS files. For each leaf fundamental node, the system determines the appropriate degree of simplification based on the Level of Detail (LOD) selected by the user. When the LOD is set to *Low*, the script reads the corresponding ODS file, deletes all child mesh components marked for removal by the user, and replaces the geometry of all remaining child components with their respective bounding boxes. When the LOD is set to *Medium*, the script deletes all child components marked for removal and simplifies only those child meshes explicitly flagged for simplification in the ODS file by replacing them with their bounding boxes. When the LOD is set to High, no child mesh components are deleted or simplified. In all cases, the remaining child

Figure 5. ODS file of the fundamental node ASM-30050.12

Figure 6. ODS file of the leaf fundamental node ASS. AS2B SUPER BEND (BS2)

mesh components associated with a fundamental node are merged into their parent node. This process significantly reduces the number of objects in the scene, limiting it to the number of fundamental nodes while preserving the level of geometric abstraction required for the selected LOD. Results of the simplification process for the different LOD levels are shown in Figure 7.

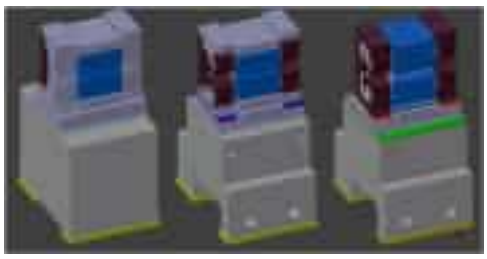

Figure 7. Simplified model outcomes for low (left), medium (center), and high (right) LOD

4.2.6 Compress geometries

To further reduce geometric complexity and file size, the geometries can be optimized using the *Compress geometries* command. This operation merges vertices that are within a defined proximity threshold, removes duplicate vertices, converts triangular faces into quadrilateral faces where possible, deletes vertices and edges not associated with any faces, and enforces geometric planarity. These optimizations reduce the overall complexity of the geometry during IFC export, resulting in significantly lighter IFC files.

4.2.7 IFC conversion

The final step converts the processed geometries into IFC elements using Bonsai capabilities. For each fundamental node, the script reads the IFC attributes and properties defined by the user in the corresponding ODS file and generates the appropriate IFC entities, as shown in Figure 3. Decomposition relationships between parent and child elements are established through *IfcRelAggregates* relationships, thereby explicitly representing the hierarchical structure of the product.

The conversion process is compatible with all IFC versions supported by Bonsai. However, the user must ensure that the selected IFC classes, attributes, and property sets (Psets) are valid for the chosen IFC schema version, as inconsistencies or unsupported definitions may cause the script to fail. For this reason, the use of IFC4 or later versions is recommended. The results of the simplification process at the different LOD levels are presented in Figure 8. Although the geometric level of detail varies, the product data associated with the objects remains unchanged across all representations. As shown, some unexpected behaviour can be observed in the colouring of elements.

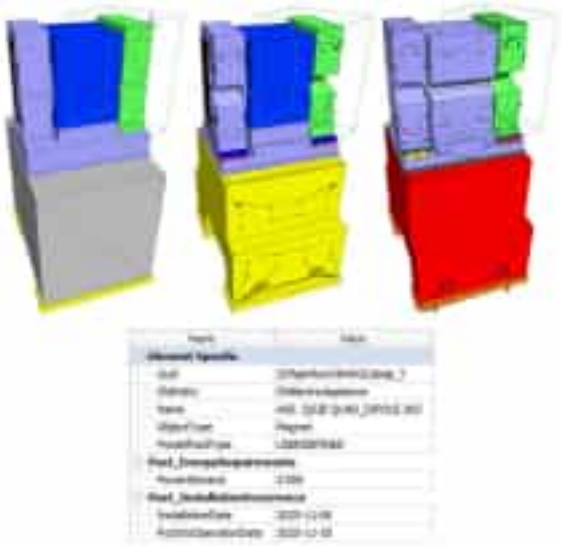

Figure 8. Resulting IFC models viewed in BIMvision [16] with different levels of detail: low (left), medium (center), and high (right). The same magnet selected has the same properties (bottom) in all models

5 Discussion

At the beginning of the present work, the primary objective was to overcome some of the limitations identified in the previous framework [4]. One of the main limitations of that version was the excessive number of rows required to be filled in the spreadsheet. Using the same case study files, the current version of the framework reduced the number of rows to complete by 86% for CS1, 74% for CS2, 81% for CS3, and 82% for CS4, resulting in an average reduction of 81% across all case studies.

However, the most relevant results emerge from the comparison with the original STEP file, which enables a meaningful evaluation of the current status of the tool against other solutions. The first metric of interest is the file size relative to the original STEP model. As shown at Table 1, IFC models generated with a high Level of Detail (LOD) occupy more storage space than the original STEP files. It is important to note that, even at this high LOD, IFC models were processed by removing small elements, as described in Section 4.2.3. This indicates that the same tessellated geometries encoded in IFC require more storage space than when represented in the STEP format. This observation further enhances the significance of the results obtained with lower LODs, which demonstrate encouraging compression ratios and confirm the effectiveness of the proposed approach in reducing model size while maintaining an acceptable level of detail.

Table 1 File size comparison for different case studies, including mean compression percentage

	CS1 [MB]	CS2 [MB]	CS3 [MB]	CS4 [MB]	Mean of %
STEP	12.0	39.8	7.9	314.4	100.0%
IFC high LOD	45.0	140.7	10.9	531.6	258.7 %
IFC medium LOD	4.0	16.5	3.8	147.1	42.4 %
IFC low LOD	0.1	0.8	0.1	0.3	0.9 %

This issue is not solely related to file size. Several systems can handle large IFC files without significant performance loss, making geometric simplification unnecessary. The key factor is instead selecting only the required objects. Some tools convert all STEP entities into *IfcBuildingElementProxy* or *IfcElementAssembly* objects. While this enables geometry import into BIM or civil environments, it is ineffective for product data management. Large numbers of objects without associated product information add complexity while providing only generic classifications. Without linked data, the benefits of the IFC standard are largely lost, reducing the model to a collection of heavy 3D geometries. Table 2 shows the number of objects removed or merged during conversion. The resulting compression rate is encouraging and confirms that the proposed framework effectively adapts an industrial model for civil engineering applications.

Table 2 Object count across process phases for different case studies, including mean compression percentage

	CS1	CS2	CS3	CS4	Mean of %
Initial stage	1633	3729	501	7632	100.0%
Delete small objects [<0.05m]	839	1241	213	2148	38.8%
Simplify geometries	10	325	6	52	2.8%
Convert IFC meshes	6	256	4	43	2.2%

Another key efficiency metric is the workload for both the user and the computational process, as shown in Figure 9. The main factor affecting the total duration is model complexity, measured by the number of objects. On average, processing rates are about 0.58 elements per second for low LOD, 0.63 for medium LOD, and 0.72 for high LOD. As the number of objects increases, both user effort and processing time grow, regardless of the selected LOD. Performance differences between LOD levels mainly reflect the computational cost of handling geometries of varying complexity, and this gap becomes more evident as the number of objects increases.

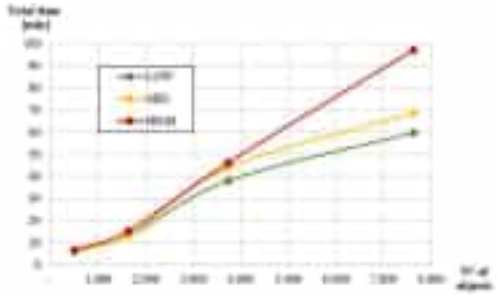

Figure 9. Procedure duration (minutes) relative to the number of objects contained in the STEP model.

5.1 Limitations

A key limitation of the framework is that, despite being designed for general professionals, it remains cumbersome and requires targeted training for effective use. Users must also possess knowledge of the IFC standard to correctly assign properties. Errors can occur during ODS file compilation (e.g., typographical mistakes), highlighting the need for more error-resistant mechanisms such as dropdown menus or predefined inputs. Additionally, manual file transfers introduce further risk of user error.

Another limitation lies in the reliance on STEP files with a specific decomposition logic, assuming a well-structured hierarchy of products and parts. In practice, such files may contain inconsistencies, merged components, or unexpected configurations. Therefore, broader testing on real-world cases is needed to assess robustness and identify improvements for professional use.

5.2 Future works

Future work will address the identified limitations through more extensive testing, providing clearer insights into application time and performance. Enhancements are planned to reduce manual effort, including features to automatically populate the *Node for IFC conversion* property using existing ODS database entries, enabling recognition of previously defined components and streamlining the workflow.

The framework will also be extended to support additional IFC classes, such as *IfcDistributionElement* and *IfcPort*, and to incorporate system management properties. Furthermore, it will be expanded to handle material data that require dedicated IFC classes rather than simple attributes or property sets.

The current need for expertise in IFC and Blender limits scalability and adoption. To mitigate this, a more

user-friendly solution should be developed to assist in selecting IFC classes and properties while reducing direct interaction with Blender. A potential approach is a web-based platform that runs Blender processes in the background, simplifying the workflow and improving accessibility.

6 Conclusion

This work examines the challenges of integrating industrial and civil domains through open standards such as STEP and IFC. Despite relying on mature data models, their differing paradigms and information requirements hinder interoperability, particularly when embedding industrial machinery within building models. The primary bottleneck does not lie in simplifying BIM data for industrial use, but rather in enriching industrial CAD models to satisfy the semantic, relational, and contextual requirements of the BIM environment. To address this gap, the study introduces a lightweight, open-source framework that goes beyond mere geometric translation. The framework demonstrates the feasibility of aligning industrial product logic with AEC information structures. The entire procedure is based on open-source technologies and is implemented as a Blender add-on using the Bonsai extension. Its intuitive user interface makes the workflow accessible even to users without specialized programming skills.

The procedure presented in this paper focuses on reducing the assembly complexity of industrial models by removing unnecessary components, simplifying excessively detailed geometries, reducing the number of objects to those strictly required, and attaching the appropriate semantic properties to them. In addition, mechanisms for storing and reusing manually inserted data are incorporated to minimize repetitive tasks. These strategies are intended to make the framework suitable for professional use by reducing manual effort and saving time during the conversion process. Preliminary results indicate the effectiveness of the proposed approach in adapting industrial product logic to AEC requirements.

Abstract

In structural health monitoring (SHM) systems, sensor signals are often affected by multiple external load effects that are strongly coupled across different frequency bands, posing significant challenges for accurate signal interpretation. To address this issue, this paper proposes a two-stage blind source separation method aimed at effectively decoupling sensor signals across multiple frequency ranges. In the first stage, a deep kernel regression (DKR) model integrating a long short-term memory (LSTM) network with Gaussian process regression (GPR) is developed. By adaptively learning the complex mapping between time-varying environmental factors and kernel hyperparameters, the model enables accurate prediction and removal of low-frequency temperature-induced strain components. In the second stage, wavelet multiresolution analysis (WMRA) is applied to the residual signal. Through optimized selection of the wavelet basis and key parameters, the mid-frequency quasi-static vehicle-induced response and high-frequency signal components are effectively separated. The proposed method is validated using 227 days of monitoring data collected from a real long-span bridge. The results demonstrate that the proposed approach can progressively extract signal components with clear physical interpretations from the original mixed signals. The separated vehicle-induced responses exhibit smooth curves consistent with mechanical principles, while time-frequency analysis confirms the effective suppression of high-frequency interference. Overall, the proposed method provides an effective tool for fine-grained signal decomposition in structural health monitoring, significantly improving the accuracy and reliability of load effect separation, and shows strong potential for engineering applications.

Structural Health Monitoring, Sensor Signal Processing, Blind Source Separation, Deep Kernel Regression, Wavelet Multiresolution Analysis, Gaussian Process Regression

1 Introduction

For a health monitoring system of a bridge or building structure, sensor measurements contain crucial information about the structural load-bearing condition and constitute one of the most critical components of the monitoring system [1]. However, sensor signals result from the combined action of multiple external loads. For effective condition assessment and damage early warning, it is necessary to precisely decompose sensor data to isolate effects caused by different load types. To better characterize structural response components, the field of structural health monitoring has developed a series of solutions to eliminate or reduce the influence of interfering responses and separate the desired structural response for health state evaluation. Typically, researchers categorize the information in the total structural response of a bridge into three parts: i) high-frequency components dominated by vibration effects; ii) long-term, low-frequency components induced by factors like temperature; and iii) vehicle-induced quasi-static effects, which lie between the two in frequency. To perform refined signal analysis, blind source separation of measured signals is required.

In theory, modern signal processing methods can separate effects caused by temperature variation, vehicle loads, and noise based on their distinct frequency characteristics. For example, previous studies have leveraged temperature-induced strain for bridge condition assessment [2] and developed automatic uncoupling methods to isolate vehicle- and temperature-induced strains [3]. Subsequent signal reconstruction

algorithms can then recover the original distributed effects. However, signals in different frequency bands often exhibit substantial frequency disparities, making direct decomposition using a single unified framework challenging. For instance, while high-frequency signals can be decomposed using time-frequency methods, these approaches struggle with low-frequency components like diurnal (24-hour period) temperature-induced effects [4]. To address this issue, the optimal strategy is to design tailored blind source separation algorithms according to the characteristics of each signal component. Therefore, this paper proposes a two-stage sensor signal blind source separation algorithm that integrates deep kernel regression and wavelet transform.

The algorithm first constructs a deep kernel regression-based time-series prediction model to extract the temperature-induced component from the signal [5]. This model employs a sequential feature extraction module and a non-sequential feature fusion module, utilizing multi-source, multi-format historical and real-time data to predict the kernel parameters of a Gaussian Process Regression model. Using these predicted parameters, the model forecasts the low-frequency thermal response. Subsequently, the residual signal is processed using wavelet multiresolution analysis to separate the mid-frequency vehicle-induced response from the remaining high-frequency components. Through this proposed dual-stage signal decomposition approach, efficient sensor signal processing is achieved.

This study presents three principal contributions: (1) a novel two-stage framework that decouples temperature-induced (low-frequency) and vehicle-induced (high-frequency) strain components using Deep Kernel Regression (DKR) and Wavelet Multiresolution Analysis (WMRA), respectively; (2) the DKR model synergistically integrates deep learning adaptability with Gaussian process uncertainty quantification and physical interpretability—overcoming limitations of ARIMA in nonlinear thermal dynamics and LSTM in confidence estimation; and (3) WMRA ensures mathematically rigorous, adaptive time-frequency decomposition robust to mode-mixing artifacts of empirical mode decomposition variants, enabling precise isolation of transient vehicle responses. Collectively, this physics-informed, uncertainty-aware methodology advances structural health monitoring through interpretable, reliable multi-component strain separation.

2 Data Acquisition and Preprocessing

2.1 Raw Data Collection

The raw data is derived from the health monitoring system of a long-span suspension bridge in Hebei Province, China. The monitoring system installed four strain sensors on the bottom surface at the mid-span and the three-quarter span of the bridge's main span respectively. In addition, a temperature sensor was mounted at the pylon to detect the environmental conditions. Therefore, a total of nine sensors were used for data collection in this task, including eight strain sensors and one temperature sensor, as shown in Figure 2. All sensors had a sampling frequency of 200 Hz, and the final dataset included all available data collected over 227 days from February 22 to October 6, 2022.

Figure 2. Layout of strain sensors and temperature sensors

2.2 Offline Extraction of Temperature-Induced Strain

Since the low-frequency signal processing in the proposed two-stage method relies on a data-driven approach, data preprocessing is required to construct the dataset for deep kernel regression. The raw strain data contain outliers caused by heavy vehicle loads. To robustly extract temperature-induced strain components, the robust locally weighted scatterplot smoothing (RLOESS) algorithm is adopted [6].

RLOESS minimizes the influence of outliers by iteratively adjusting data point weights. Its core steps include neighborhood selection, weight calculation, weighted quadratic polynomial regression, and smoothed value estimation. Using this method, temperature-induced strain data over the entire 227-day monitoring period were successfully extracted.".

3 Stage I: Deep Kernel Regression Model for Low-Frequency Signal Extraction

To address the challenges of predicting temperature-induced strain in complex structures, a deep kernel regression (DKR) model is proposed. This model integrates a long short-term memory (LSTM) [7] network with Gaussian process regression (GPR) [8], enabling deep learning–based estimation of GPR kernel hyperparameters that vary with environmental conditions. This approach overcomes the limitation of conventional GPR models that rely on fixed kernel parameters, while combining the feature learning capability of deep learning with the interpretability and uncertainty quantification advantages of Bayesian methods. A detailed discussion of this algorithm can be found by Xu and Liu's work [9].

3.1 Gaussian Process Regression-based Time Series Forecasting

Compared to other methods, GPR has three critical advantages: (i) GPR provides a full Bayesian framework that quantifies prediction uncertainty via posterior variance—a non-negotiable requirement in structural health monitoring where safety-critical decisions depend on confidence intervals; (ii) The kernel function explicitly encodes prior physical knowledge (e.g., periodic temperature effects through the Periodic kernel), enhancing model interpretability and alignment with engineering principles; (iii) Unlike black-box models, GPR offers transparent hyperparameter interpretation (e.g., length-scale parameters directly reflect signal smoothness and periodicity), facilitating domain expert validation.

GPR is a non-parametric Bayesian regression method. For an input time series $X = \{x_1, x_2, ..., x_N\}$ and its corresponding temperature-induced component output $Y = \{y_1, y_2, ..., y_N\}$, GPR assumes the target function $f(x)$ follows a Gaussian process prior: $f(x) \sim GP(m(x), k(x, x'))$, where $m(x)$ is the mean function and $k(x, x')$ is the kernel (covariance) function. Given training data (X, y), the posterior distribution of the predicted values f^* at test points X^* remains Gaussian, with mean μ^* and variance Σ^* given by Equations (1) and (2), respectively.

$$\mu^* = K(X^*, X)[K(X, X) + \sigma_n^2 I]^{-1} y \tag{1}$$

$$\Sigma^* = K(X^*, X^*) - K(X^*, X)[K(X, X) + \sigma_n^2 I]^{-1} K(X, X^*) + \sigma_n^2 I \tag{2}$$

To capture the composite characteristics of short-term monotonicity and long-term periodicity in temperature-induced strain data, a combined kernel function is chosen as the product of a Radial Basis Function (RBF) kernel (which is suitable for modeling gradual temperature-induced drift) and a Periodic kernel (which encodes repeating temperature-induced patterns). This combined kernel contains three hyperparameters $\Theta = (\Theta_1, \Theta_2, \Theta_3)$, controlling the function's rate of change, period length, and weight, respectively, as shown in Equation (3):

$$\begin{aligned} K(\Theta_1, \Theta_2, \Theta_3) &= \Psi\left[k_{RBF}(x_i, x_j), k_{Periodic}(x_i, x_j)\right] \\ &= \left[exp\left(-\frac{\|x_i - x_j\|^2}{2\Theta_1^2}\right)\right]^{\Theta_3} \left[\left(-\frac{2\,sin^2\left(\frac{\pi}{p}\|x_i - x_j\|\right)}{\Theta_2^2}\right)\right]^{1-\Theta_3} \end{aligned} \tag{3}$$

As hyperparameters significantly impact prediction results in GPR-based time series tasks, they must be dynamically adjusted based on the data.

3.2 Forecasting Framework

Based on the constructed dataset and environmental variables, a hybrid deep learning–Bayesian regression framework is developed:

1. **Sequential feature extraction:** An LSTM network is used to extract temporal features from historical temperature-induced strain data.
2. **Non-sequential feature fusion:** Fully connected layers integrate LSTM features with key environmental variables, including date, time, and temperature.

3. **Deep kernel regression:** The fused features are used to predict GPR kernel hyperparameters via a deep learning module, followed by real-time temperature-induced strain prediction using the parameterized GPR model.
4. **Model training:** The entire framework is trained by maximizing the marginal likelihood of the training dataset.

The algorithmic framework of this model based on deep kernel regression is shown in Figure 3.

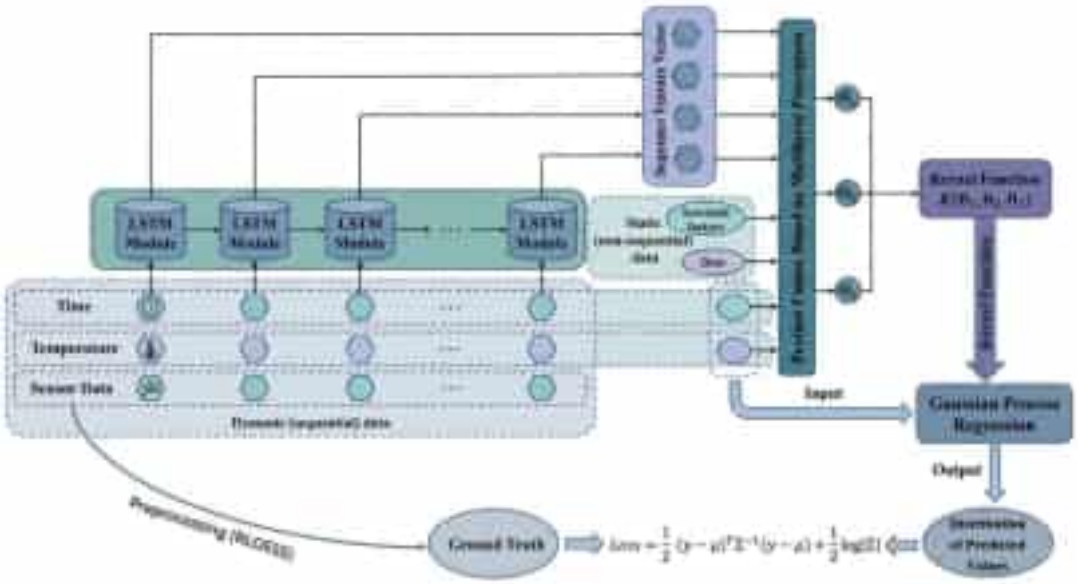

Figure 3. Framework of the deep kernel regression method

3.3 Forecasting Framework

The training objective is to find the optimal hyperparameters Θ_{opt} that maximize the probability of the true strain values under the predictive distribution. The loss function is defined as the negative log marginal likelihood, as shown in Equation (4):

$$\mathcal{L} = \frac{1}{2}(y-\mu)^T\Sigma^{-1}(y-\mu) + \frac{1}{2}\log\ |\Sigma| \qquad (4)$$

This loss function consists of two terms: the first is a weighted prediction error, and the second relates to prediction uncertainty (determinant of the covariance matrix). Optimising this loss function not only drives predictions closer to true values but also constrains output uncertainty, enhancing model robustness.

4 Stage II: Wavelet Multiresolution Analysis for High-Frequency Signal Separation

After successfully extracting the low-frequency temperature-induced components in Stage I, the residual signal still contains mixed mid- to high-frequency components, primarily consisting of vehicle-induced quasi-static effects and vibration-related noise. To address this, Stage II employs Wavelet Multiresolution Analysis (WMRA) for further signal decomposition [10]. This stage focuses on separating the vehicle-induced quasi-static response (mid-frequency) from high-frequency noise and vibrations. Unlike conventional filtering techniques, WMRA provides localized time-frequency characterization, making it particularly suitable for processing non-stationary signals under varying operational conditions. This section details the theoretical foundations, parameter selection strategies, and implementation procedures of the WMRA-based separation framework.

4.1 Wavelet Transform and Multiresolution Analysis

Following the extraction of low-frequency thermal signals in the first stage, and considering the significant frequency differences between vibration-induced high-frequency effects and vehicle-induced quasi-static responses, this section employs Wavelet Multiresolution Analysis (WMRA) for signal separation. Wavelet transform possesses time-frequency localization capabilities, enabling effective separation of signal components with different frequencies.

Wavelet transform overcomes the lack of temporal locality in Fourier transform. For a function $f(t)$, its continuous wavelet transform is defined as

$$W_f(a,b) = \langle f, \psi_{a,b} \rangle = |a|^{-1/2} \int_R f(t) \psi \left(\frac{t-b}{a} \right) \mathrm{d}t \quad (5)$$

where $\psi_{a,b}(t)$ is the wavelet basis derived from the mother wavelet $\psi(t)$ through scaling factor a and translation factor b. For discrete signals, the discrete wavelet transform is used:

$$\psi_{j,k}(t) = a_0^{-j/2} \psi \left(\frac{t - k a_0^j b_0}{a_0^j} \right) = a_0^{-j/2} \psi \left(a_0^{-j} t - k b_0 \right) \quad (6)$$

Multiresolution Analysis (MRA) is central to discrete wavelet transform, approximating the signal space $L^2(R)$ through a series of nested subspaces $\{V_j\}$ that satisfy conditions of monotonicity, approximation, scaling, and translation invariance [11, 12]. The signal can be decomposed layer by layer into low-frequency approximation (A_j) and high-frequency detail (D_j) components, as illustrated in Figure 4.

Figure 4. Signal decomposition method based on wavelet multi-resolution analysis

4.2 Selection of Key Parameters

Many wavelet functions exist with differing properties, leading to varied separation results for structural monitoring data. Therefore, targeted analysis of wavelet function characteristics is crucial for selecting an appropriate function. Generally, the following aspects guide the selection of wavelet functions and parameters:

1. **Wavelet Function Selection:** The choice depends on properties such as support length, orthogonality, vanishing moments, and symmetry. Commonly used wavelets include Daubechies (dbN) and Symlets (symN). Selection follows the principle of self-similarity, considers discriminant functions and support length, and balances properties based on signal characteristics.
2. **Decomposition Level Determination:** The number of decomposition levels n is determined by the signal sampling frequency f_n and the upper-frequency limit f_m of the target component to be separated. Too few levels lead to insufficient separation; too many may lose information and increase computational load.
3. **Thresholding:** To eliminate noise and irrelevant high-frequency components, thresholding is applied to the decomposed high-frequency coefficients. Common threshold functions include:

a. Hard Thresholding: Coefficients with absolute values greater than the threshold λ are retained; others are set to zero. This preserves local signal features but may cause reconstruction oscillations.

b. Soft Thresholding: Coefficients with absolute values greater than λ are shrunk towards zero (subtracting λ). This yields smoother reconstructed signals but may blur edge information. Soft thresholding is more widely used in practice.

4.3 Signal Separation and Denoising Procedure

Assuming the observed noisy signal model is $s(t) = f(t) + e(t)$, where $f(t)$ is the effective signal and $e(t)$ is noise (typically assumed to be Gaussian white noise), the objective of wavelet-based signal separation/denoising is to suppress noise while preserving or separating target frequency components (e.g., live load effects). The basic procedure is as follows:

1. **Decomposition:** Select an appropriate wavelet function and decomposition level, and perform discrete wavelet decomposition on signal $s(t)$ to obtain low-frequency approximation coefficients and high-frequency detail coefficients at each level.
2. **Thresholding:** Apply the selected threshold function to the high-frequency detail coefficients to suppress noise and irrelevant high-frequency components.
3. **Reconstruction:** Perform inverse wavelet transform using the processed coefficients (including low-frequency coefficients and thresholded high-frequency coefficients) to reconstruct the separated or denoised signal.

For the bridge monitoring data processing task in this paper, the key wavelet analysis parameters are selected as follows: The Daubechies wavelet (db4) is chosen due to its compact support and orthogonality, which provide good time-frequency localization suitable for analyzing non-stationary strain signals. Its appropriate number of vanishing moments (4) effectively extracts high-frequency transient components while smoothing low-frequency trends, and it offers high computational efficiency.

The decomposition level is determined to be 7. Based on a 200 Hz sampling frequency and signal characteristics, a 7-level decomposition finely divides the frequency bands. Empirical verification shows that 7 levels achieve an optimal balance between separation effectiveness and computational complexity. Soft thresholding is employed because its coefficient shrinkage enables smoother processing, avoiding potential signal discontinuities (Gibbs phenomenon)

associated with hard thresholding, making it more suitable for subsequent analysis of slowly varying components.

In summary, for this stage, the algorithm uses the db4 wavelet for 7-level decomposition, applies soft thresholding to detail coefficients D1-D7, and reconstructs the signal to obtain high-frequency vibration signals and mid-frequency vehicle-induced signals. This method effectively separates load effects of different frequencies.

5 Algorithm Training and Testing

5.1 Deep Kernel Regression Model Training and Testing

The processed 227 days of temperature-induced strain data for each strain gauge were segmented into 1093 data sequences of 300-minute length. Data from 8 sensors resulted in a total of 8744 sequences. The dataset was split into training, validation, and test sets with a 70%/15%/15% ratio. Model hyperparameters were optimised based on the trained model's performance on the validation set. After obtaining the optimal model, its performance was evaluated by comparing it with classical algorithms (AR, ARIMA) [13] and deep learning algorithms (RNN [14], GRU [15], LSTM [7]) on the same test set. The prediction results of various methods on the test set are shown in Figure 5.

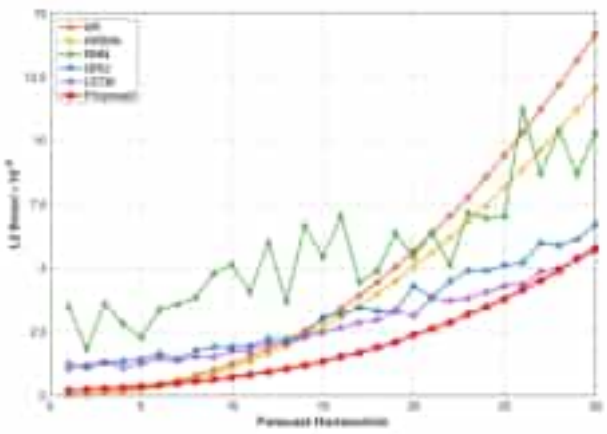

Figure 5. Error over time

Overall, traditional algorithms (AR/ARIMA) exhibited smaller errors and smoother prediction trends in the initial prediction period (approximately the first 5 minutes), aligning with the minor fluctuation characteristics of temperature-induced strain. However, as the prediction horizon increased, errors grew significantly, deviating from true values, indicating their poor adaptability for long-term prediction. Deep learning algorithms (RNN/GRU/LSTM) generally followed the actual trend, but predicted values showed substantial volatility and instability, significantly differing from the actual slowly varying state of temperature-induced strain.

Testing demonstrates that the proposed model maintains the interpretability and output stability of Bayesian methods while achieving superior medium-to-long-term prediction accuracy compared to the benchmark algorithms. Furthermore, the model framework exhibits good extensibility, allowing for the incorporation of additional sensor information to further enhance predictive performance.

5.2 Wavelet Multiresolution Analysis Algorithm Testing

To validate the proposed second-stage signal separation method, a segment of measured strain data was selected for testing. First, the Deep Kernel Regression (DKR) algorithm proposed in Section 3 was applied to extract the low-frequency temperature-induced strain. The original data were then subtracted by this thermal component to obtain strain data with temperature effects removed.

The signal after temperature effect removal still contained noticeable noise and high-frequency vibration induced by vehicle-bridge coupling. To further extract the vehicle-induced quasi-static effect, a 6,000-sample data segment (corresponding to 30s) containing a vehicle crossing event was selected, and wavelet multiresolution analysis was applied for high-frequency separation. After signal reconstruction, the vehicle-induced quasi-static effect was obtained, as shown in Figure 6. The smoothness of the reconstructed signal was significantly improved. The signal shapes from all four sensors were similar, each presenting a unimodal smooth curve consistent with the theoretical bridge influence line. This verifies that the separation method effectively extracts the quasi-static response induced by vehicle loads while suppressing high-frequency noise and vibration.

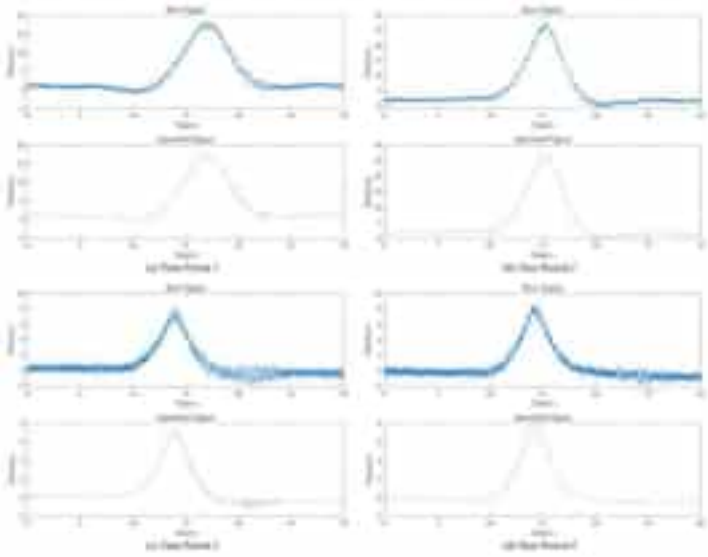

Figure 6. Signal Decomposition Method Based on Wavelet Multi-Resolution Analysis

To further analyse the separation effectiveness, wavelet time-frequency diagrams of the signal before and after high-frequency separation were compared (Figure 7). It can be observed that before separation (Raw), the time-frequency diagram contained numerous scattered energy points in the high-frequency region, primarily originating from sensor noise and vehicle-bridge coupling high-frequency vibrations. After separation (Denoised), the energy distribution of high-frequency components almost completely disappeared, with the time-frequency diagram concentrated in the low-frequency region. Time-frequency analysis indicates that the proposed method effectively filters high-frequency components from the signal and successfully extracts the low-frequency-dominated physical response of vehicle-induced quasi-static effects, validating the effectiveness of the signal separation algorithm. Combining the demarcated algorithm with some existing vehicle perception algorithms enables the refined research on vehicle-bridge correlation [16-19].

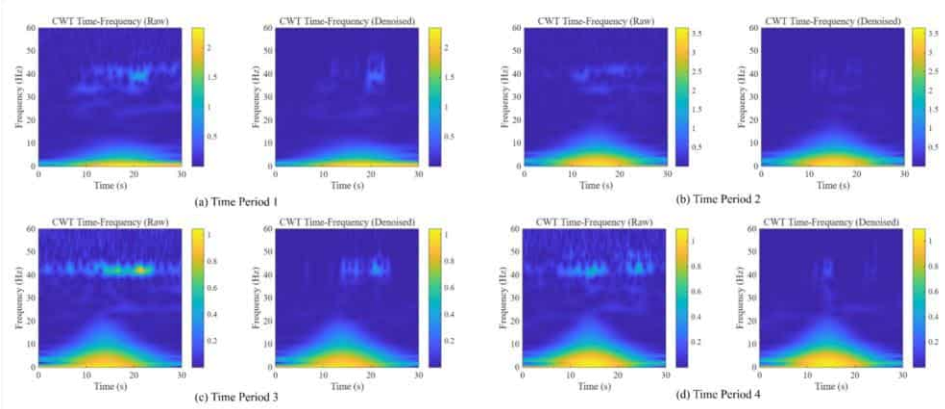

Figure 7. Wavelet time-frequency diagrams of strain before and after high-frequency signal separation

6 Conclusion

This paper addresses the challenge of mixed multi-source signals in bridge health monitoring by proposing an innovative two-stage blind source separation method. Employing a staged processing strategy, it integrates deep kernel regression with wavelet multiresolution analysis, effectively tackling the difficulty traditional methods face in simultaneously handling signal components with large frequency disparities.

In the first stage, we constructed an adaptive model based on deep kernel regression. By fusing the sequential feature extraction capability of LSTM networks with the probabilistic framework advantages of GPR, precise separation of temperature-induced effects was achieved. This model dynamically adjusts kernel parameters based on environmental factors, demonstrating performance superior to traditional methods in medium-to-long-term

prediction. In the second stage, we optimized the wavelet multiresolution analysis method, determining parameter configurations suitable for bridge monitoring signals. This method effectively separated vehicle-induced quasi-static effects from high-frequency vibration and noise, reconstructing smooth response curves that align with theoretical expectations.

Experimental validation based on 227 days of measured data demonstrates that the proposed two-stage method can clearly separate three types of physical effect components from complex raw signals: low-frequency thermal trends, mid-frequency vehicle-induced responses, and high-frequency noise. This method provides an approach to decouple components induced by highly random human activities from infrastructure responses [20] and an effective solution for the fine-grained processing of bridge health monitoring data.

Construction Site Layout Monitoring Using Instance Segmentation

Vimal Bharathi and Jochen Teizer

Department of Civil and Mechanical Engineering, Technical University of Denmark
vvebh@dtu.dk, teizerj@dtu.dk

Abstract

Construction sites are complex and dynamic work environments with frequent changes in layout due to material handling and a diverse workforce presence, necessitating adaptable safety measures. Falls from height remain the primary cause of fatalities in construction, particularly impacting small firms with limited resources. Conventional manual construction site layout inspections are subjective, relative infrequent, and difficult to scale, often resulting in noncompliance with fall protection standards. This paper introduces an automated, geo-aware monitoring system that leverages high-resolution orthomosaic images from consumer drones and a novel Adaptive Multi-Scale DETR (AMS-DETR) model for panoptic segmentation. AMS-DETR enhances traditional DETR performance through dynamic query generation and multi-scale attention yielding lower inference time and segmentation Quality. This approach enables proactive, AI-driven site monitoring, improves regulatory adherence, and offers scalable safety management suitable for resource-constrained projects, advancing intelligent construction safety practices.

Keywords –
DETR, instance segmentation, orthomosaic images, site layout monitoring, unmanned aerial vehicle.

1 Introduction

Construction sites are among the most variable work environments, where complex operations lead to frequent shifts in personnel, materials, and equipment [1]. This constant change poses major challenges in keeping safety measures current and aligned with standards. Unlike stable factory settings, construction sites evolve daily through stages like excavation, framing, and finishing, requiring quick setup of temporary protections such as guardrails to address fall risks at heights over 1.8 m [2]. In 2023, falls caused 421 deaths (39.2% of all U.S. construction fatalities, totaling 1,075) [3], alongside more than 20,000 nonfatal fall-related cases annually [4]; and over 70% of fatal falls happened at companies with fewer than 11 employees, highlighting gaps in monitoring for smaller operations. On a global scale, the International Labor Organization projects over 60,000 construction deaths yearly, with falls responsible for 30–50%, varying by region due to differences in regulations and site conditions [5]. These trends reveal a key problem: even with clear rules (e.g., OSHA's 1.07 m guardrail requirements), unexpected removal of safety gear—due to task demands, worker fatigue, or weather issues quickly makes plans outdated, and over 70% of violations involve absent or incorrectly placed barriers.

As a result, regular compliance checks are essential, but current manual methods using checklists and measurements by safety staff are reactive, subject to human error, and limited by site size and access difficulties. Research shows that up to 65% of fall incidents arise from gaps missed during routine (e.g., weekly) checks [6], worsened by emerging threats like proximity issues: for instance, cranes within 2 m of walkways (violating ANSI Z359.2 buffers) or unguarded gaps between paths and pits, which can significantly increase the risk of secondary impacts [7].

Tools like digital twins, remote sensing, and AI can transform the above issues with real-time tracking that could spot issues early, link to evolving 4D-BIM models for predictions, and fit into standard workflows. However, past efforts are often isolated for example, 2D image detectors miss depth details, while basic Orthomosaic classifiers overlook the fine distinctions needed for tracking specific "things" (e.g., individual guardrail sections) versus backgrounds ("stuff" like debris floors) limiting geospatial tracking and risk calculations [8].

This paper addresses these limitations by proposing a location-aware monitoring pipeline. It integrates high-resolution orthomosaic maps generated from overhead imagery captured by DJI Mini 4 Pro drone and processed via photogrammetry with an advanced Adaptive Multi-Scale DETR (AMS-DETR) model for instance segmentation of safety features (e.g., guardrails, Safety poles, etc.) and site elements (e.g., cranes, excavations, steel plates, etc.). AMS-DETR overcomes key DETR

limitations, including rigid queries, scale mismatches, and boundary inaccuracies, through adaptive query generation and multi-level attention mechanism, delivering higher segmentation quality while enabling real-time inference.

It enables the generation of predictive compliance scores and interactive hazard visualizations within a user-friendly SafeBIM platform [36]. The proposed framework provides a scalable, proactive approach to AI-supported safety oversight on highly dynamic construction sites, with strong potential to enhance fall prevention, regulatory compliance, and overall site management practices.

2 Background

Construction sites present unique challenges for safety monitoring due to their dynamic nature, with frequent changes in layout, equipment, and personnel that heighten risks such as falls from height. Traditional manual inspections are inadequate for real-time compliance, prompting the adoption of AI-driven technologies like Unmanned Aerial Vehicles (UAV), deep learning for image segmentation, and Building Information Modeling (BIM) integration. This section reviews existing DEtection TRansformer (DETR) models for segmentation a critical tool for analyzing site images and related work on AI-based site layout monitoring, highlighting gaps addressed by our proposed Adaptive Multi-Scale DETR (AMS-DETR) framework.

2.1 Existing DETR Models for Panoptic Segmentation

The DETR family has revolutionized object detection by formulating it as a set prediction task using transformer architectures, bypassing traditional components like non-maximum suppression [9]. Rooted in the original transformer model [10], DETR variants have been adapted for panoptic segmentation, which combines instance segmentation of "things" with semantic segmentation of "stuff" [11]. This is essential for processing drone-generated orthomosaic images in construction, where variability in scale, occlusion, and object density demands robust, real-time performance.

Despite advancements, DETR models exhibit persistent limitations in segmentation tasks, including slow convergence, inefficient attention, poor multi-scale handling, and query mismatches. The base transformer [10] lacks spatial hierarchies, leading to high computational costs ($O(n^2)$ complexity) and memory issues for high-resolution images (>1024×1024 pixels), impeding edge-device deployment. DETR [9] introduces fixed queries and bipartite matching for end-to-end detection but requires 300–500 epochs for convergence and struggles with small or occluded objects; panoptic extensions [12] add mask heads, yielding Panoptic Quality ≈43.4 on COCO due to heuristic merging errors.

Deformable DETR [13] sparsifies attention for faster training and better small-object detection but fails in boundary accuracy for crowded scenes and incurs latency from convolutional decoders. DAB-DETR [14] uses dynamic anchors for density adaptation but limits query flexibility, causing over/under-prediction in sparse/dense layouts. DN-DETR [15] employs denoising for quicker convergence but generalizes poorly to sparse scenes and multi-modal data. Lite-DETR [16] prioritizes lightweight design but sacrifices accuracy on textures and small objects. RT-DETR [17] achieves real-time speeds with intra-scale attention but trades PQ for efficiency.

Common flaws include inefficiency (>100 ms inference), mask inaccuracies, fixed queries and weak multi-scale adaptation. Our AMS-DETR mitigates these through adaptive query generation (dynamic counts for crowded and less crowded images) and hierarchical multi-scale attention, achieving higher segmentation quality and less inference time for construction orthomosaic images.

2.2 Site Layout Monitoring via Image Segmentation

Recent studies have advanced site layout monitoring by integrating UAV, AI segmentation, and BIM to enable real-time hazard detection and compliance in dynamic environments. Drone-based photogrammetry generates orthomosaic images for scalable analysis, surpassing manual methods prone to errors in large sites.

Tárrago Garay et al. [18] fused drone point clouds with 4D-BIM for progress/deviation detection (70% reduced verification), supporting unguarded edge identification but without AI segmentation. Han et al. [19] used SAM-based panoramic segmentation for indoor layout, highlighting adaptive segmentation value but limited to indoors. Akinsemoyin et al. [20] applied Faster R-CNN on UAV imagery for hardhat/activity detection, enabling machinery-proximity rerouting but instance-only. Alexandre et al. [21] combined AI-drones with LiDAR for anomaly/progress tracking, focusing on compliance without panoptic depth. Recent YOLOv8-seg improvements have advanced construction site monitoring Bhai et al. [37], offering good real-time performance on standard images. However, they face challenges with extreme scale variations and global context in large orthomosaics. Our method addresses these via adaptive queries and hierarchical multi-scale attention, enabling superior generalization for drone-based orthomosaic analysis.

In recent studies Hong and Teizer [22] introduced RAM module in DTCS, integrating SafeBIM rule-checking with RTK-GNSS trajectories for real-time

struck-by hazard detection, proximity analysis, and dynamic walkway optimization, though sensor-based rather than vision-segmentation. Pfitzner et al. [23] developed KG-enhanced CV (YOLOv8x + GNN) for concrete pouring progress, linking BIM volumes to site images via spatial-temporal graphs for bottleneck identification, but activity-specific without broad safety. Pfitzner et al. [24] proposed grid-based spatial complexity analysis with ViTPoseActivity and BIM projection for rebar duration prediction, enabling localized productivity insights but focused on labor efficiency over fall hazards.

These approaches show progress in BIM-CV fusion and real-time tracking but rely on isolated detectors, lack unified instance segmentation for multi-scale features in orthomosaics, or require extra sensors, limiting geospatial risk mapping (e.g., precise guardrail/pathway buffers).Our AMS-DETR framework advances by delivering real-time instance segmentation of drone orthomosaics (guardrails, cranes, edges, pathways) with geo-spatial information for real time 4D-BIM comparison for the onsite safety Managers.

3 Methodology

To address persistent limitations in existing DETR-based instance segmentation models particularly fixed query cardinality and inefficient multi-scale feature fusion we propose an Adaptive Multi-Scale extension to the SOLQ network (AMS-DETR) for real-time analysis of high-resolution construction orthomosaic images. Building upon SOLQ's end-to-end query-based instance segmentation formulation [25], the proposed approach integrates adaptive query modulation and scale-aware hierarchical attention to improve robustness across highly variable construction scenes. Unlike earlier DETR variants that rely on a fixed number of object queries (e.g., 100 queries in [9, 17]) or convolution-heavy mask heads [26], AMS-DETR preserves SOLQ's fully transformer-based decoding while enabling dynamic allocation of representational capacity based on scene complexity. This design is particularly suited for drone-based site monitoring, where images range from sparse excavation zones to dense equipment clusters within the same orthomosaic images.

The novelty of AMS-DETR lies in its targeted architectural extensions to the SOLQ framework rather than introducing a new segmentation paradigm. Similarly, approaches such as [27] focus on global mask transformers but introduce redundant memory paths that scale poorly in occluded, high-resolution scenes. In contrast, the proposed method augments SOLQ with complexity-driven query adaptation and hierarchical multi-scale attention, allowing the decoder to adjust both the number and scale sensitivity of active queries without introducing heuristic post-processing or convolutional bottlenecks. These additions improve instance separation and boundary accuracy for small and overlapping objects, yielding measurable gains over baseline SOLQ and Mask DINO [26], while maintaining sub-50 ms inference on 1024×1024 inputs. AMS-SOLQ further reduces memory consumption by approximately 40%, making it suitable for edge deployment in construction site monitoring scenarios.

3.1 Adaptive Query Mechanism

DETR-based instance segmentation models employ a fixed number of object queries (e.g., 100 learnable embeddings in DETR [9] and DAB-DETR [14]), which leads to inefficiencies when processing scenes with large variations in object density. In construction orthomosaic imagery, this manifests as missed detections in densely

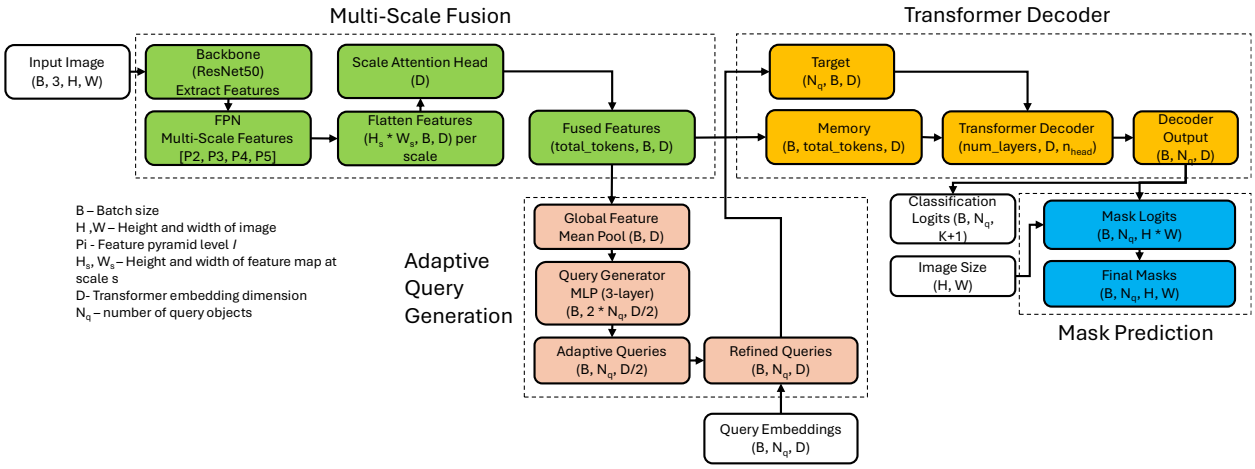

Figure 1: AMSDETR network architecture

populated regions (e.g., clustered equipment) and redundant predictions in sparse areas (e.g., open work zones), as also observed in Co-DETR [28] and RT-DETR [17].

To address this limitation within the SOLQ framework, AMS-DETR introduces an adaptive query mechanism that dynamically modulates the effective number of queries based on scene complexity. Encoder feature maps are globally aggregated and passed through a lightweight multi-layer perceptron (MLP) to estimate image complexity using normalized feature entropy:

$$H(I) = -\sum_i pi \, log \, pi \quad (1)$$

Where p_i represents normalized activation responses. The number of active queries is then determined as:

$$N *= clip(N0 + \alpha H(I), Nmin, Nmax) \quad (2)$$

With N_0=150 base queries and N_{max}=300. Queries beyond N^* are progressively suppressed during decoding using sigmoid-gated residual refinement to ensure stable optimization.

Unlike prior approaches that rely on fixed query sets [9], [14], the proposed mechanism allows the SOLQ decoder to allocate representational capacity in proportion to scene complexity, improving instance separation in crowded regions while preventing over-prediction in sparse layouts. This adaptive strategy enhances matching efficiency and reduces query redundancy without introducing heuristic filtering or post-processing. Empirically, the mechanism improves recall for small and overlapping objects compared to DAB-DETR [14] and Co-DETR [28], while maintaining real-time inference performance comparable to RT-DETR [17].

3.2 Multi-Scale Hierarchical Attention

DETR-based models exhibit limited robustness to scale variation due to rigid global attention mechanisms in DETR [9] or insufficient cross-scale fusion in Deformable DETR [13], leading to degraded performance for small objects and occluded instances in high-density construction scenes. This limitation exists mainly in large orthomosaic images, where objects span multiple orders of magnitude in spatial scale.

To address this, AMS-DETR augments the SOLQ feature encoding stage that combines deformable attention [13], [17] with global context-guided scale aggregation inspired by GM-DETR [29]. Feature maps extracted from a multi-scale backbone (e.g., ResNet-50) at strides $s \in \{8,16,32\}$ are processed in parallel and fused through scale-aware attention.

Each scale is first projected using a lightweight 1×1convolution to obtain scale-specific embeddings. A global context vector q, obtained via global feature aggregation, is then used to compute adaptive attention weights across scales. Specifically, for each scale s, a scale attention weight $\alpha_s$is computed as:

$$\alpha_s = Softmax\left(\frac{\mathrm{QK_s}}{\sqrt{d}}\right) \quad (3)$$

where $\mathrm{k}_s$denotes the pooled key embedding of scale s, and $d$is the embedding dimension. The final scale-aware representation is obtained via a weighted aggregation of scale-specific features:

$$F = \sum_s \alpha_s \mathrm{V}_s \quad (4)$$

with $\mathrm{V}_s$denoting the projected feature map at scale s. This formulation enables the encoder to dynamically emphasize high-resolution features for small objects (e.g., safety posts) and lower-resolution features for larger structures (e.g., work zones), thereby improving instance localization across a wide range of object scales.

Overall, the proposed hierarchical attention improves small-object recall and occlusion robustness compared to standard DETR [9] and Deformable DETR [13], while maintaining efficient inference through sparsified attention similar to RT-DETR [17]. Compared to convolution-heavy multi-scale fusion approaches such as Mask DINO [26], the proposed method achieves improved boundary precision without introducing high-resolution bottlenecks, making it suitable for real-time orthomosaic analysis.

4 Training Dataset

The data set used for this paper was collected weekly over a period of 1 year using DJI Mini 4 Pro. The data was collected in a time-series using manual path planning. The images collected per flight are processed into Orthomosaic images using Agisoft Metashape Pro [30] which can be seen in Figure 3. This resulted in approximately 45 Orthoimages with a resolution of approx. 14.000 x 14.000 pixels which was then split into 1024x1024 pixels and processed for training. The objects in the images were labelled using LabelMe software.

The labeled classes in Figure 2 were selected based on their direct relevance to fall-from-height hazards and site layout compliance monitoring, as guided by OSHA [2] and ANSI [7] standards. Key safety elements include guardrails, poles, and excavations (to detect unguarded edges), while site elements such as cranes, steel plates, and work areas support geospatial risk analysis (e.g., proximity to pathways) and integration with 4D-BIM models. These classes represent the most frequent and critical objects observed across the one-year dataset.

The resulting dataset contains approximately 1500 images which are filled with objects used for this work after filtering out the images that do not contain any objects. The dataset is split into 80% training and 20% validation data.

Figure 2: Labelled objects used for this work to monitor the construction site layout activity.

Figure 3: Cropped orthoimages from drone flights.

5 Results

Performance is evaluated using standard COCO-style Average Precision (AP) metrics. Bounding box AP and mask AP are reported at IoU thresholds from 0.5 to 0.95 (AP@0.5:0.95), following common practice in instance segmentation benchmarks. The performance of our model during training can be seen in the Table 1.

The overall Box AP and Mask AP are primarily affected by the relatively low performance on smaller object classes such as safety poles, cranes, and certain equipment categories. These objects occupy fewer pixels in high-resolution orthomosaic images and often appear with limited visual detail, making them more difficult for the model to detect and segment accurately.

Per-class results in Table 2 confirm that larger and well-defined objects (e.g., office containers, rollers, storage containers) achieve high AP scores, while smaller or thin-structured objects (e.g., safety poles) exhibit significantly lower performance. This imbalance explains the gap between overall metrics and the strong qualitative segmentation results observed for larger and safety-critical structures in Figure 5.

This shows that the instance segmentation over a large orthoimages of approx. 14000x14000 pixels has proved to be a fruitful way for monitoring site layout of construction site. The images also show the number of instances of each object at the bottom right. The training metrics can be seen in Figure 4 which shows the Box loss

Table 1: Performance metrics.

Model	Epochs	Box AP (0.50:0.95)	Mask AP (0.50:0.95)
AMS-DETR	140	0.54	0.42
SOLQ	170	0.42	0.29

Table 2: Per-Class AP

Class	Box AP (0.5:0.95)	Mask AP (0.5:0.95)
Articulated truck	0.54	0.47
Crane	0.37	0.29
Fence	0.61	0.41
Gate	0.45	0.23
Hydraulic excavator	0.57	0.39
Office container	0.89	0.79
Protective barrier	0.54	0.49
Roller	0.90	0.90
Safety pole	0.34	0.27
Stairs	0.68	0.58
Steel plates	0.38	0.36
Storage container	0.77	0.71
Work area	0.76	0.74

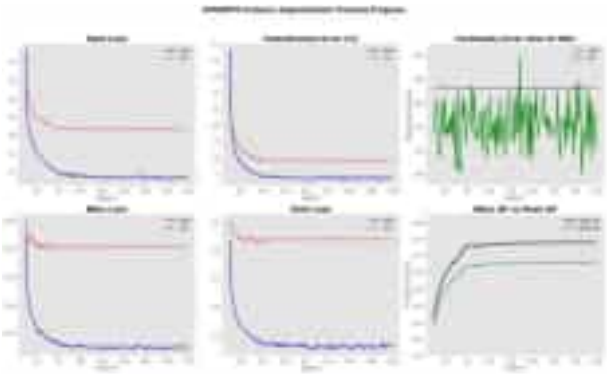

Figure 4: Training metrics.

and GIoU loss along with the BBox AP and Mask AP. The classes that most significantly affect the overall metrics are small-scale and thin-structured objects, particularly safety poles and similar site elements. Due to their limited spatial footprint in large orthomosaic images (~14,000 × 14,000 pixels), these objects are harder to localize and segment precisely, leading to lower AP values and a disproportionate impact on the aggregated performance metrics.

6 Limitations and Conclusion

The results demonstrate the efficacy of the proposed AMS-DETR model in addressing the challenges of real-time instance segmentation for construction site orthomosaic images, particularly in dynamic environments where fall hazards evolve rapidly. As shown in Table 1, the model's performance metrics highlight significant improvements in segmentation quality and inference time compared to baseline DETR variant. This mechanism dynamically adjusts query counts based on scene entropy (as quantified in the methodology), enabling the model to efficiently process sparse scenes (e.g., isolated excavations) without redundant predictions and dense clusters (e.g., equipment-crowded zones) without under-detection.

Figure 4 training metrics further illustrate the model's convergence advantages: the box loss and generalized IoU (GIoU) loss stabilize within 70–100 epochs, faster than traditional DETR [9] or Deformable DETR [13], Mask AP improvements are evident in Figure 5, where boundary precision is maintained even in crowded predictions, with a confidence threshold of 80% effectively filtering noise while preserving accurate instance separation. However, the overall metrics are impacted by challenges in detecting and segmenting small-scale objects, such as safety poles and certain equipment instances. These objects often occupy very few pixels in orthomosaic images and may suffer from low contrast, occlusion, or scale variation, making them difficult for transformer-based models to capture effectively. This limitation is consistent with known challenges in instance segmentation, where small objects contribute disproportionately to performance degradation despite accurate detection of larger structures which align with observations in related works [23, 24], where knowledge graph enhancements or grid-based analyses mitigate similar issues in activity-specific segmentation, suggesting potential synergies for future iterations. This observation highlights a known limitation of transformer-based detectors in high-resolution imagery, where small-object representation and feature resolution remain critical bottlenecks despite improvements in multi-scale attention.

Figure 5: Full ortho instance segmentation for construction site layout status on 2025-05-17.

Practically, the full orthomosaic instance segmentation in Figure 5 exemplifies the system's geospatial utility by geo-aligning segmented features with 4D-BIM models, deviations (e.g., unguarded edges <10 cm from pathways) can be detected with cm-level accuracy, facilitating Voronoi-based risk heatmaps and proximity analyses (e.g., cranes within 2 m of walkways) which is part of the future works. This proactive capability surpasses reactive manual inspections [6], offering scalable compliance monitoring for small firms. Integration with the SafeBIM platform [36] enables interactive visualizations, such as predictive compliance scores derived from temporal changes across the 1-year dataset, empowering site managers to prioritize interventions and reduce secondary risks.

Despite these strengths there are certain limitations. The dataset, while comprehensive (1500 labelled images from 45 orthomosaics), is site-specific and collected via manual drone paths, potentially introducing biases in viewpoint and weather conditions. Model inference, though real-time (<50 ms/frame), may degrade on ultra-high-resolution inputs without further optimization, and the reliance on LabelMe for annotations could amplify human error in ambiguous regions like "work areas." Compared to sensor-fusion approaches [22, 31] our vision-only pipeline is cost-effective but lacks depth cues, limiting 3D hazard assessment. Future work could incorporate multimodal data (e.g., LiDAR) or advanced refinements like diffusion-based boundary sharpening [32] to enhance amorphous class handling. Additionally, expanding the dataset with diverse global sites could improve generalization, aligning with ILO's call for region-specific safety adaptations [5].

Furthermore, aligning construction site layout monitoring using instance segmentation and using it in a Digital Twin for Construction Safety (DTCS) framework has potential for practitioners to detect and track relevant progress while comparing as-performed vs. as-planned status effortlessly [33-36]. Providing previously not available information in safety meetings (e.g., toolbox and safety planning or review meetings) adds value to select and apply the best control measures.

Abstract

Identifying construction equipment activity states is essential for understanding and optimizing earthmoving operations. Trajectory data can be used to infer semantic equipment activities, while it often leads to inconsistent results when simple rule-based methods are applied. This paper presents a trajectory-based activity recognition approach using finite-state machines (FSMs) for earthmoving operations. The method combines kinematic features from Real-Time Kinematic Global Navigation Satellite Systems (RTK-GNSS) trajectories with spatial constraints and predecessor rules to infer activity states of excavators and dump trucks. A real-world earthmoving case study demonstrates that the proposed FSM-based approach captures cyclic operational patterns. The identified activity states provide a reliable basis for downstream operational analysis and simulation, supporting data-driven construction productivity and emission management.

Keywords

Trajectory tracking; Earthmoving operations; Finite-state machine; Activity recognition; RTK-GNSS; Construction automation

1 Introduction

Earthmoving operations are fundamental to infrastructure and building construction, characterized by repetitive and cyclic interactions among heavy construction equipment, such as excavators and dump trucks. The performance of these operations is strongly influenced by how equipment activities are coordinated over time and space. As a result, accurate identification of equipment activity states is required for analyzing productivity, utilization, and operational inefficiencies in earthmoving processes, and for supporting downstream applications such as simulation-based planning and performance assessment. Effective site management requires continuous monitoring of productivity metrics, such as cycle times and utilization rates, to identify bottlenecks [1,2].

Recent advances in Real-Time Kinematic Global Navigation Satellite Systems (RTK-GNSS) have enabled the continuous collection of high-precision trajectory data from construction equipment [3,4]. Such data provides detailed information to infer equipment movement patterns and interactions on site. However, raw trajectory data do not directly represent semantic activity states of equipment, such as *Load*, *Haul*, *Dump*, *Idle*, or *Wait* for dump trucks. Simple rule-based approaches that rely solely on speed or position thresholds often suffer from noisy state transitions and spatiotemporal inconsistencies, especially in congested and dynamic construction environments [5].

To address these challenges, various activity recognition methods have been explored, including rule-based logic, machine learning models, and vision-based approaches [6,7]. While data-driven methods can achieve high classification accuracy, they typically require large labeled datasets and lack interpretability, which limits their practical deployment on construction sites. In contrast, finite-state machines (FSMs) provide an interpretable and structured way to model cyclic equipment operations by explicitly encoding allowable states and transitions. An FSM is a computational model that represents a system as a set of discrete states and allowable transitions between them. By incorporating predecessor constraints, FSMs improve temporal consistency and robustness in activity recognition for construction equipment [5]. In the context of earthmoving operations, FSMs are well suited to describe repetitive operational cycles, where equipment typically transitions through sequential states such as loading, hauling, dumping, and returning.

This paper presents a trajectory-based activity recognition method for earthmoving operations using FSMs. The proposed approach integrates kinematic features derived from RTK-GNSS trajectories with spatial context and predecessor rules to infer temporally consistent activity states of excavators and dump trucks. The identified activity states directly support operation-level analysis and simulation-based applications, enabling data-driven evaluation of earthmoving performance under real-world site conditions.

2 Related Work

Existing research on construction equipment monitoring has primarily focused on collecting and analyzing sensory data to characterize on-site movement and utilization. While trajectory data offers rich insights into the spatiotemporal patterns of construction equipment, effective operational analysis requires the capability to translate raw motion into meaningful activity states [8]. Consequently, this section reviews the literature across two aspects: trajectory-based monitoring of earthmoving operations and activity recognition methods for inferring semantic states.

2.1 Trajectory-based Earthmoving Operation Monitoring

Tracking construction equipment using Global Positioning System (GPS) has been widely investigated to support productivity analysis and operational monitoring. GPS-based systems are extensively applied to capture the spatiotemporal movement of earthmoving equipment, enabling the inference of critical operational patterns, such as cycle times, travel distances, and equipment utilization [9,10]. With the advent of RTK-GNSS, the positioning accuracy of these systems has improved significantly, making trajectory data increasingly suitable for detailed analysis of equipment behavior on construction sites [4].

Recent studies have further explored data-driven and machine learning–based approaches to extract higher-level semantic information from equipment trajectories and sensor data. By leveraging supervised learning, probabilistic models, or deep learning techniques, these methods aim to recognize equipment activities or operational states [10,11], which have demonstrated promising classification accuracy under controlled conditions and highlight the potential of learning-based models for capturing complex motion patterns.

However, inferring detailed equipment activities solely from trajectory data remains challenging. Several studies have attempted to identify activities using speed thresholds or proximity-based rules. While these rule-based methods are computationally efficient and easy to implement, they lack robustness in complex scenarios.

In congested and dynamic construction environments, equipment frequently operates at low speeds, performs short repositioning movements, or temporarily pauses within active zones due to traffic or delays. Consequently, purely kinematic-based approaches often struggle to distinguish between functionally distinct states, leading to noisy state transitions and misclassification. These limitations highlight the critical need for activity recognition methods that account for the cyclic and sequential logic of earthmoving operations, rather than relying exclusively on instantaneous spatial or kinematic threshold rules.

2.2 Activity Recognition Approaches for Construction Equipment

Automated activity recognition serves as the analytical core for evaluating construction productivity and emissions. By analyzing spatiotemporal data, researchers can infer operational patterns at a high level, such as cycle times, haul distances, and overall equipment utilization rates. The integration of high-precision RTK-GNSS has further refined this capability, allowing for the detection of subtle changes based on positioning data.

Armin et al. [11] categorized existing approaches of equipment activity recognition based on their input data sources, including vision-based, audio-based, and motion-based methods. Vision-based approaches rely on camera data and have demonstrated high accuracy, but are sensitive to lighting conditions, occlusions, and site complexity. Audio-based methods utilize acoustic signals and can be cost-effective, but their performance may vary depending on environmental noise. Motion-based approaches, which use trajectory and kinematic data from sensors (e.g., GPS, IMU, or UWB), are more robust to environmental conditions and are well suited for large-scale outdoor construction sites.

However, they require effective modeling of temporal dynamics to infer meaningful activity states from raw motion data. Translating raw kinematic data into semantic activity states remains a complex challenge. Existing methodologies can be broadly categorized into heuristic rule-based approaches [12], classical machine learning methods (e.g., Support Vector Machines [13, 14], Random Forests [15]), and deep learning models (e.g., LSTM [16], CNN [17]). Heuristic rule-based methods infer activities using predefined heuristics, such as speed thresholds or geofence-based proximity rules. These methods are favored for their low computational cost and ease of deployment. But they often lack flexibility in handling complex and irregular operational patterns. In contrast, classical machine learning methods can learn complex patterns from multi-sensor data (e.g., fusing location data with accelerometers), aiming to improve classification accuracy for complex maneuvers [6, 11]. While they improve classification performance over purely heuristic approaches, they typically rely on carefully designed features and overlook temporal dependencies. Deep learning models further enhance classification capability by learning features directly from raw or minimally processed data. However, these methods require substantial labeled data and often lack interpretability, which limits their practical deployment in construction environments.

All these methods have inherent limitations in dynamic site environments. Machine learning models

often suffer from overfitting and lack explainability. On the other hand, purely rule-based approaches are often too rigid. In congested sites, equipment frequently exhibits irregular movement patterns, such as creeping at low speeds due to traffic or performing short repositioning maneuvers, which do not align with static kinematic thresholds. This underscores the necessity for a method that explicitly accounts for the cyclic, sequential nature of earthmoving operations.

In this context, FSM-based approach can be viewed as a structured modeling framework within motion-based methods, explicitly incorporating state-transition logic to improve temporal consistency while maintaining interpretability. Compared with rule-based methods that rely on isolated heuristics, FSM-based approaches explicitly model temporal state transitions for more consistent activity interpretation, while remaining more interpretable and data-efficient than machine learning-based methods.

3 Methods

This section describes the proposed trajectory-based activity recognition method for earthmoving operations. The method integrates RTK-GNSS trajectory data with FSM to infer temporally consistent equipment activity states. The overall workflow consists of trajectory preprocessing, FSM-based state modeling, rule-based candidate state detection, and activity timeline generation. Figure 1 illustrates the overall workflow of the proposed trajectory-based FSM approach for equipment activity recognition.

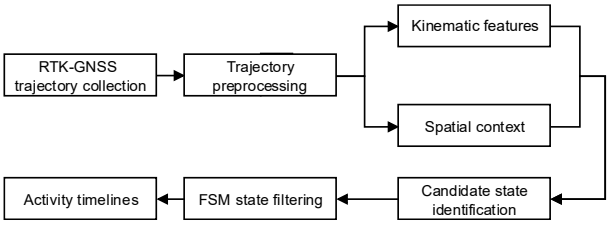

Figure 1. Overview of the trajectory-based FSM workflow for equipment activity recognition in earthmoving operations.

3.1 Trajectory Data Acquisition and Preprocessing

To capture the precise movement patterns of the fleet, equipment trajectories are collected using RTK-GNSS sensors mounted on excavators and dump trucks. These sensors record positioning data, including latitude, longitude, and heading, at a frequency of 1 Hz. Since raw coordinates lack operational context, they are transformed into a site-aligned local coordinate system that matches the digital site layout. This alignment enables the system to perform spatial reasoning, automatically determining whether a machine is located within specific operational zones such as excavation pits, loading points, dumping areas, or haul roads.

From the processed trajectories, two fundamental kinematic features are derived to describe equipment behavior: translational speed and rotational velocity. Translational speed is primarily used to distinguish between stationary states (e.g., *Load*, *Idle*) and mobile states (e.g., *Haul*, *Return*). Meanwhile, rotational velocity, calculated from the change in heading, is a critical indicator for identifying excavator cycles, as these machines frequently rotate their upper structure while the tracks remain static during digging and swinging operations.

However, raw field data inevitably contains noise due to signal multipath effects or temporary obstructions. To prevent the activity recognition model from reacting to these false fluctuations, a temporal smoothing filter is applied to the kinematic data streams. This preprocessing step reduces short-term jitter and satellite signal drift, ensuring that the inputs for the FSM are stable and reliable.

3.2 FSM Design for Earthmoving Equipment

To capture the cyclic workflows of earthmoving operations, separate FSMs are designed for excavators and dump trucks, as illustrated in Figure 2. The state identification integrates instantaneous kinematic features with spatial context. Candidate states are first proposed based on speed and heading, then validated against the equipment's location within defined operational zones (e.g., loading or dumping areas).

For dump trucks, the FSM defines states such as *Load, Haul, Dump, Return,* and *Wait*. Transitions are triggered by specific thresholds, for example, speeds above 2.0 m/s indicate driving modes, while low speeds in specific zones indicate service or queuing. For excavators, the *Excavating* state is distinctively identified by low translational speed ($v < 0.5\ m/s$) combined with high rotational velocity ($\omega > 5\ °/s$).

The FSM enforces predecessor logic to maintain temporal consistency. By explicitly coding allowable transition sequences, such as preventing a truck from entering *Load* without a preceding *Return* state, the system effectively filters out unrealistic state switches caused by signal noise or short interruptions, ensuring robust activity recognition.

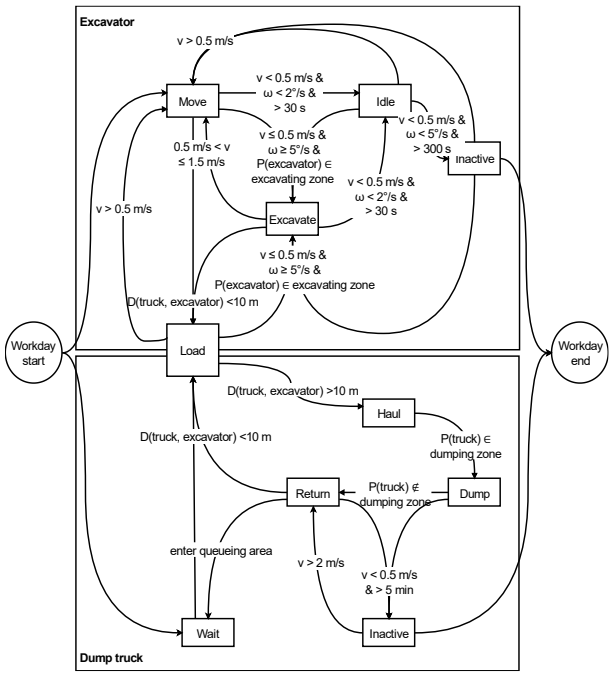

Figure 2. Finite-state machine for excavator and dump truck activity recognition. States (rectangles) and transitions (arrows) are determined by kinematic, spatial, and temporal conditions derived from RTK-GNSS trajectories.

3.3 Rule-based Candidate State Identification

At each discrete time step, candidate activity states are preliminarily identified by evaluating instantaneous kinematic features against predefined thresholds. The primary differentiator is translational speed (v), which serves to classify equipment behavior into stationary, low-speed maneuvering, or high-speed hauling modes. For instance, a speed threshold of 0.5 m/s is selected to distinguish productive stationary activities, such as *Load* and *Dump*, from active transport, while speeds exceeding 2.0 m/s generally indicate a driving state. However, kinematic data alone is often insufficient to determine a stationary state; for example, a truck stops due to traffic looks identical to one stopping for loading. Therefore, spatial constraints are applied as a necessary secondary filter to resolve these ambiguities.

For dump trucks, the identification logic relies heavily on geofenced operational zones to interpret low-speed behaviors. Specifically, a low-speed condition ($v < 0.5\ m/s$) is mapped to a specific activity based on the equipment's containment within defined areas: if the truck is located within an excavator's loading radius (10 m), the state is identified as *Load*; if it is within a designated dumping zone, it is labeled as *Dump*; and if positioned in a queueing area, it is classified as *Wait*. Conversely, high-speed driving periods are categorized into *Haul* or *Return* depending on the truck's position within the haul corridors and its direction of travel relative to the excavation zones. The detailed rule set for dump trucks is summarized in Table 1.

Table 1. State identification rules for dump trucks.

State	Kinematic condition	Spatial condition	Predecessor
Load	v ≤ 0.5 m/s	Distance to excavator ≤ 10 m	*Wait*, *Return*
Dump	v ≤ 0.5 m/s	Within dumping zone	*Haul*
Haul	v ≥ 2.0 m/s	Along haul corridor	*Load*
Return	v ≥ 2.0 m/s	Along return corridor	*Dump*
Wait	v < 0.5 m/s	Within queue area	Duration ≥ 30 s
Inactive	v < 0.2 m/s	Anywhere	Duration ≥ 300 s

Excavators require a more complex rule set due to their stationary working nature, where the chassis remains fixed while the upper structure performs the work. Consequently, rotational velocity becomes a critical indicator alongside translational speed. A combination of low translational speed ($(v < 0.5\ m/s)$ and significant upper-structure rotation ($\omega > 5\ °/s$) within the excavation zone is defined as the *Excavate* state. When it is in close proximity to a dump truck, it is reclassified as *Load*. Repositioning movements are captured when the translational speed falls between 0.5 and 1.5 m/s. Finally, prolonged periods of low motion, both in translation and rotation, are categorized as *Idling* or *Inactive* based on specific duration thresholds, as detailed in Table 2.

The threshold values used in the rule-based candidate state identification were determined based on a combination of domain knowledge, exploratory analysis of the collected trajectory data, and iterative calibration. Specifically, speed thresholds were selected to distinguish between stationary, low-speed maneuvering, and active hauling states observed in the dataset. The rotational velocity threshold reflects typical excavator swing behavior during excavation. The spatial threshold (e.g., 10 m radius) corresponds to practical interaction distances between excavators and dump trucks on site. Duration thresholds were introduced to differentiate short-term pauses from prolonged inactivity.

These parameters can be iteratively refined to ensure temporally consistent activity transitions while avoiding excessive sensitivity to noise in the trajectory data. In practice, moderate variations in these thresholds were found to have limited impact on the overall cyclic activity patterns. These rules generate a set of candidate states that represent plausible equipment activities at each timestep but may still contain short-term inconsistencies.

Table 2. State identification rules for excavators.

State	Kinematic condition	Spatial condition	Predecessor
Load	$v \leq 0.5$ m/s	Distance to truck ≤ 10 m	*Move, Excavate*
Excavate	$v \leq 0.5$ m/s $\omega > 5°$ /s	Within excavating zone	*Move, Load*
Move	$0.5 < v \leq 1.5$ m/s	Anywhere	*Excavate, Load*
Idle	$v \leq 0.5$ m/s $\omega \leq 2°$ /s	Anywhere	Duration > 30 s
Inactive	$v \leq 0.5$ m/s $\omega \leq 2°$ /s	Anywhere	Duration > 300 s

3.4 FSM-Based State Filtering and Activity Timeline Generation

The candidate states are filtered through the FSM transition rules to ensure temporal consistency. Only transitions that are allowed by the FSM are accepted, while invalid transitions are rejected or delayed until valid conditions are satisfied. This process prevents rapid switching between states caused by measurement noise, brief pauses, or short repositioning movements.

The final output of the method is a continuous activity timeline for each equipment unit, describing the sequence and duration of operational states over time. These timelines capture the cyclic structure of earthmoving operations and enable quantitative analysis of duty cycles, utilization, queueing behavior, and non-productive time.

The proposed FSM-based trajectory-driven method provides an interpretable solution for equipment activity recognition in earthmoving operations. By combining kinematic features, spatial context, and FSM-based temporal constraints, the method connects raw trajectory data and semantic operational states. The resulting activity timelines can be directly integrated into downstream applications, such as performance analysis and simulation of earthmoving operations.

4 Case Study and Results

The proposed trajectory-based activity recognition method was evaluated using data collected from a real-world earthmoving operation. The case study involves excavation and hauling activities carried out on an active construction site, where multiple excavators and dump trucks operated simultaneously within a confined workspace.

The study area includes predefined operational zones such as excavation areas, loading zones, dumping areas, haul corridors, return paths, and queueing areas. These zones were derived from the site layout and used to provide spatial context for activity recognition. Trajectory data from one representative workday were selected for analysis to capture typical operational patterns while avoiding interruptions caused by weather or major schedule changes. Figure 3 illustrates the spatial distribution of tracked equipment trajectories overlaid on the site layout and orthophoto.

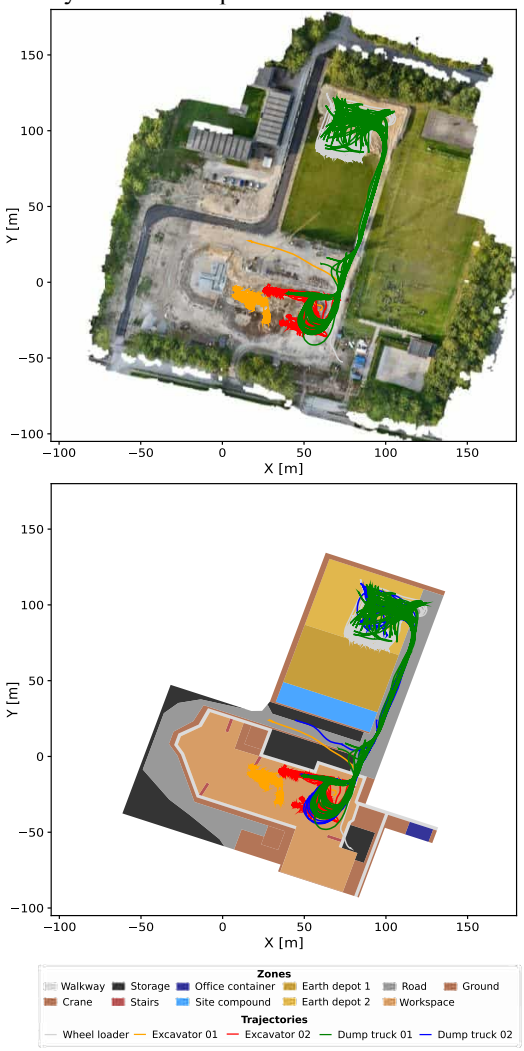

Figure 3. Trajectories of tracked equipment against the 2D site layout (upper image) and orthophoto (lower image) for one workday.

To distinguish the semantic activities visually, Figure 4 shows the typical dumper duty cycle observed from on-site drone images, illustrating the dump trucks' states of *Load*, *Haul*, *Dump*, *Return*, and *Wait* that the algorithm aims to identify.

Figure 4. Observed dump truck duty cycle: (a) Load, (b) Haul, (c) Dump, (d) Return, and (e) Wait.

4.1 Activity Recognition Results

The FSM-based activity recognition method was applied to the processed RTK-GNSS trajectories to infer equipment activity states over time. For each excavator and dump truck, the method generated a continuous activity timeline describing the sequence and duration of operational states. Figure 5 presents the identified activity timelines for the tracked equipment on the selected workday. The results show clear cyclic patterns consistent with typical earthmoving operations, dump trucks alternate between loading at the excavation area, hauling material to the dumping location, dumping, and returning to the excavation site. Compared with simple rule-based classification, the FSM-based approach produces temporally consistent state sequences without rapid fluctuations. Short interruptions, low-speed maneuvers, and brief pauses within operational zones are effectively filtered out by the FSM transition logic.

To quantitatively validate the FSM method, we established a rigorous second-by-second ground truth by manually annotating one hours of synchronized video footage as the upper diagram shown in Figure 5, where two dumpers worked in parallel.

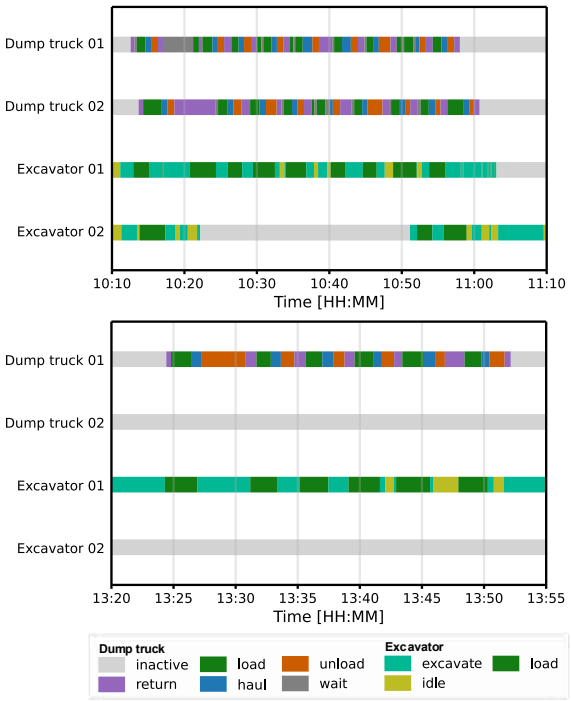

Figure 5. Timeline of identified working stages of the excavators and trucks on one selected working day.

To account for these natural phase shifts without unfairly penalizing the model, we evaluated the recognition accuracy using a standard point-by-point metric with a ± 10-second temporal tolerance window. As detailed in Table 3, the FSM approach demonstrates exceptional reliability for key duty cycle activities. It achieved a satisfying Recall and an outstanding F1-Score of 1.00 for Unload, combined with a high Precision of 0.90 for Haul. The high performance for Unload is mainly due to its clear spatial constraint, as it is defined within a fixed dumping zone. In contrast, other activities depend more on the relative positioning and interactions with excavators, and are more susceptible to interference from surrounding equipment, which introduces ambiguity and leads to comparatively lower performance.

Table 3. Quantitative evaluation of FSM-based activity recognition for dumpers against manual annotation.

Activity	Precision	Recall	F1-Score
Load	1.00	0.39	0.56
Haul	0.90	0.51	0.66
Unload	1.00	1.00	1.00
Return	0.61	0.95	0.74
Wait	0.56	0.59	0.58

4.2 Analysis of Operational Patterns

The extracted activity timelines enable quantitative analysis of equipment duty cycles and interaction patterns. For dump trucks, a substantial portion of non-productive time is associated with waiting and idling near the excavation area, reflecting queue formation when multiple trucks compete for limited excavator capacity. These queueing periods can be distinguished from active loading and hauling states due to the integration of spatial constraints and predecessor logic in the FSM.

For excavators, the activity timelines reveal dominant *Excavate* and *Load* states, with idling primarily occurring during periods of truck unavailability or short operational interruptions. The temporal alignment between excavator *Load* states and truck *Load* states further confirms the consistency of the identified interactions between equipment units.

For this specific analysis, the study focuses on the utilization rate of the dump trucks because the on-site excavators were intermittently tasked with loading external trucks, which introduces variability to the excavator's operation independent of the tracked trucks. Table 4 summarizes the observed work statistics for the selected workday. It presents the total duration and percentage of "Work" (active states: Load, Haul, Dump, Return) vs. "Idle" (Wait) for the monitored equipment.

Table 4. Summary of working cycles of two trucks on one selected workday.

Machine	Work (min)	Idle (min)	Utilization (%)
Truck 01	238.16	11.67	95.33
Truck 02	114.45	29.10	79.73

Overall, the case study confirms that the trajectory-based FSM approach can robustly infer meaningful activity states from RTK-GNSS data under realistic site conditions. The resulting activity timelines provide a representation of earthmoving operations, forming a reliable foundation for future applications such as performance analysis and bottleneck identification.

5 Discussion

This study demonstrates that the FSM-based approach provides an effective and interpretable approach for recognizing equipment activity states from RTK-GNSS trajectory data in earthmoving operations. As evidenced by our quantitative validation against a second-by-second manual ground truth, the algorithm reliably captures critical operational cycles, achieving perfect recall for unloading events and high precision (0.90) for hauling. Compared with simple rule-based methods that rely solely on instantaneous thresholds, the FSM-based approach introduces temporal memory through predecessor constraints. This logic significantly reduces unrealistic state oscillations caused by GPS signal noise, short interruptions, or low-speed maneuvering. Furthermore, unlike data-driven classification models (e.g., neural networks), the FSM logic does not require substantial labeled training datasets and remains transparent to domain experts, allowing for easier debugging and adaptation to different site layouts.

Beyond activity recognition, the generated timelines provide critical insights into fleet performance. The case study revealed that operational inefficiencies can be quantified. As observed in the results, the overlap of truck waiting times highlights a temporary resource imbalance between the excavator's loading capacity and the truck fleet's arrival rate. By visualizing these hidden non-productive times, the proposed framework allows site managers to move from reactive observations to proactive resource leveling, for instance, by adjusting the number of trucks to reduce idling.

Several limitations should be acknowledged. First, the method relies on predefined spatial zones and threshold parameters, which currently require site-specific tuning based on the site layout. Second, equipment performing side tasks or operating outside predefined workflows may lead to temporary misclassification. These limitations could be addressed by incorporating additional sensing modalities to provide complementary information [7, 18]. Nevertheless, the current approach achieves a practical balance between robustness, interpretability, and deployment effort for outdoor earthmoving environments.

6 Conclusions

This paper presented a robust trajectory-based activity recognition method for earthmoving operations using finite-state machines. By integrating RTK-GNSS trajectory data with kinematic features, spatial context, and predecessor constraints, the proposed method infers temporally consistent activity states of excavators and dump trucks. Validation in a real-world tunnel construction project demonstrated that the method effectively captures cyclic operational patterns and produces interpretable activity timelines under realistic site conditions.

The contributions of this study extend beyond algorithm development. By transforming raw position data into semantic operational metrics, the framework provides a reliable foundation for Digital Twin applications. It enables project managers to pinpoint bottlenecks in near real-time and make informed decisions regarding process optimization.

Future research will focus on automating the

generation of site maps and geofences to reduce manual setup time. Additionally, we aim to integrate the output of this productivity analysis into real-time simulation models to predict future project performance and enable proactive schedule adjustments.

Abstract

In many urban areas, under-bridge spaces have become common gathering spots for older adults, offering venues for leisure, social interaction, and physical activity. Various policies and community initiatives have been introduced to improve the quality and usability of these spaces. However, efficiently and automatically assessing the elder-friendliness of such environments remains an open challenge, particularly for supporting data-informed spatial design and policy decisions. To this end, this study proposes a Care-Centered Vision–Language (CC-VLM) framework with three contributions: (i) Develop a care-theory-centered evaluation metric model, using this as the basis for subsequent labeling and assessment; (ii) Design a multi-elder-agent workflow for automatically generating labels to solve the problem of data scarcity from older adults; and (iii) Build a XGboost-based classification model for automated under-bridge spaces scene assessment. The proposed framework is applied to 5 under-bridge spaces in Hong Kong. Experimental results demonstrate an accuracy of 65.5% and a recall rate of 71.4%. This framework offers a scalable and interpretable approach to support the inclusive and age-friendly transformation of overlooked urban spaces.

Care Theory; Older Adults; VLM; Under-Bridge;

1 Introduction

Globally, under-bridge spaces in high-density cities have emerged as vital gathering spots for older adults, providing venues for leisure, social interaction, and physical activity. Many regions face a pressing contradiction: a growing and aging population drives sustained demand for public recreational spaces, while existing provision remains insufficient and is projected to fall further behind. For instance, Hong Kong—representative of such high-density urban contexts—has seen its elderly population proportion projected to rise from 18.4% in 2029 to 36.3% in 2064, alongside a long-standing shortfall in per capita open space (failing to meet its own 2m ²standard since 2008) [1-3]. The current use of under-bridge spaces is subject to government regulations [4] that limit permissible uses. However, official policy exhibits a duality of control and activation: while protecting safety, traffic, environmental, and structural concerns, it also actively encourages greening, beautification, and adaptive reuse. Notable examples include the "Fly the Flyover Operation," organised by the Development Bureau's Energising Kowloon East Office [5] and statements in the Official Record of Proceedings from the Legislative Council [6]. This situation indicates the value of utilizing remaining urban spaces, such as under-bridge areas. But because they are so numerous, automated assessment tools become particularly important.

Existing research on evaluating urban spaces has followed two main paradigms: qualitative approaches and quantitative data-driven methods. Qualitative studies provide rich contextual insights into user experiences, urban space design theory, and elderly-specific needs, emphasising Inclusive, Pleasurable, Safe, Comfortable, and Meaningful Activities [7]. There are numerous qualitative assessment tools for public space quality, among which the UN-Habitat and the Good Public Space Index (GPSI) are considered the most comprehensive; most of these tools rely on on-site observation, questionnaire surveys, and site visits [8]. Those methods are subjective, labour-intensive, and limited in scale, and these drawbacks are amplified when studying older adults due to their physical, cognitive, and

communication challenges. Quantitative methods, largely enabled by street-view imagery and computer vision, can partially compensate for the shortcomings of qualitative research. Common quantitative methods employ semantic segmentation (e.g., PSPNet, SegNet, Swin Transformer) to extract features, such as using a transformer-based framework for urban physical disorder detection [9]. Quantitative methods also include using statistical analysis, machine learning, or deep learning to predict some socioeconomic profiles, like using the spatial distribution of notable urban features identified through the street view images to predict poverty status, crime, and health behaviour [10]. However, these quantitative studies typically require extremely large sample sizes—often involving datasets with over a million street-view images sourced from platforms like Google Street View or Baidu Maps [9, 10]. Such data demands pose significant barriers for niche, overlooked spaces like under-bridges, where imagery is sparse, site-specific, and difficult to collect at scale due to accessibility constraints, variable lighting, and limited coverage in mapping services. Furthermore, the qualitative method cannot elicit people's subjective perceptions of space. Although qualitative analysis can achieve this, its limitations have been discussed previously.

Vision-Language Models (VLMs) represent a paradigm shift in multimodal AI. By jointly encoding images and text through aligned embeddings (typically involving an image encoder, text encoder, fusion mechanism, and generative language component), VLMs enable advanced tasks such as image captioning, visual question answering (VQA), and zero/few-shot reasoning on novel concepts [11, 12]. VLMs can provide language-guided interpretability. VLMs can also serve as simulated "elderly agents" through targeted prompting, automating subjective evaluations from an older adult's perspective and mitigating the inherent drawbacks of qualitative methods noted earlier. Recent applications show the effectiveness of VLMs in urban scene recognition and street-view analytics. Systematic reviews emphasize VLMs' role in assessing street-level perceptions, including safety, walkability, greenery, and socioeconomic indicators from imagery sources like Google Street View [13]. The spatial reasoning of VLM can be further enhanced by tuning particularly for challenging tasks involving negation or counterfactuals [14]. In addition, VLM can be integrated with broader frameworks for urban renewal diagnostics, combining perceptual scoring with spatial autocorrelation to inform planning decisions [15]. However, off-the-shelf VLMs are not directly suited to evaluating elderly suitability in under-bridge spaces. Pre-training datasets under-represent neglected residual areas, leading to inconsistent performance on atypical layouts and fine details [13, 14]. General-purpose VLMs also lack grounding in elderly-specific care concepts and remain largely vision-centric, with limited handling of specific factors critical for older adults.

This paper, therefore, proposes a Care-Centered Vision–Language Model (CC-VLM) for comprehensive, interpretable, scalable, and elderly-specific assessment of under-bridge spaces. Three sub-objectives are:

1. Develop a care-theory-centered evaluation metric model through a literature review on care and urban design theory, combined with on-site observation, to provide theoretical grounding and a novel perspective on under-bridge spaces assessment.

2. Design a multi-elder-agent workflow to automatically generate diverse visual labels from an elderly perspective, aiming to reflect older adults' perception of the environment. This can overcome subjectivity and labour intensity, particularly acute when elderly participants face physical, cognitive, or communication barriers.

3. Build an XGboost-based classification model for automated scene assessment, integrating care-theory metrics and multi-elder-agent labels to deliver quantitative elderly-friendliness scores and explanations.

2 Methodology

CC-VLM consists of three stages:

(1) Care-Theory-Centered Evaluation Metric Development and Feature Extraction. A hierarchical indicator system is built from care ethics literature and field observation, yielding 27 measurable spatial indicators grouped into three layers (Physical Shelter, Psychological Belonging, Social Activity). Then, a Detectron2 model with a ResNet-101-FPN backbone pre-trained on COCO will be established to perform Panoptic segmentation. According to the Evaluation Metric, Custom class merging and post-processing yield pixel-level ratios, instance densities, and morphological metrics for the 27 indicators.

(2) Multi-Elder-Agent Scoring and Demographic Weighting. Based on the metric developed in step 1, four distinct elderly personas (differing in age, mobility, and sensory profile) are simulated via structured prompts to MiniCPM. Each agent scores the three care layers on a 1–100 scale. Final image scores are computed as a weighted average based on Hong Kong's official elderly age distribution, yielding a continuous elderly-friendliness score.

(3) Assessment Model Building and Interpretation. The extracted features and weighted scores are used to train an XGBoost binary classifier. The CC-VLM framework is shown in Figure 1.

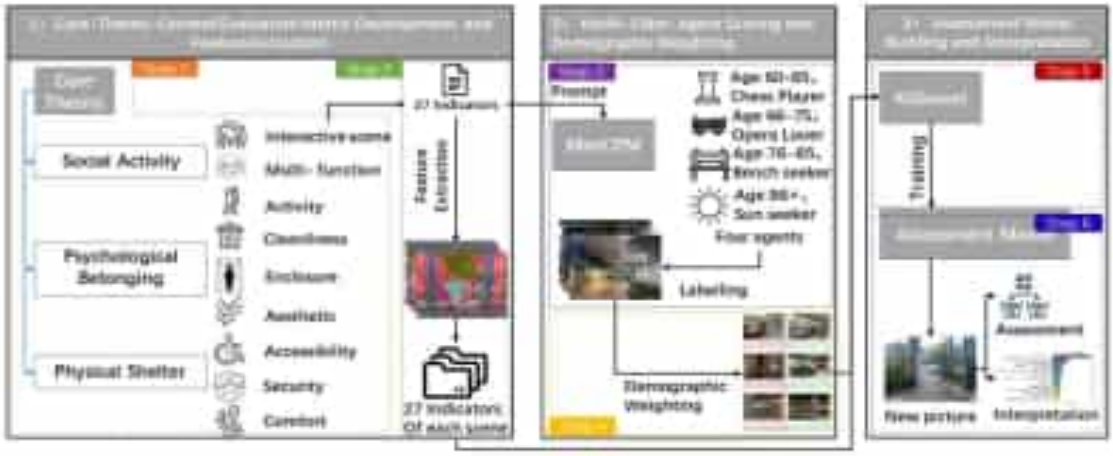

Figure 1. CC-VLM framework.

2.1 Care-Theory-Centered Evaluation Metric Development and Feature Extraction

2.1.1 Care-Theory-Centered Evaluation Metric Development

To address the limitations of existing public space evaluation tools, this study constructs a dedicated Care-Theory-Centered Evaluation Metric through theoretical and methodological synthesis. Drawing on the care ethics in urban contexts, the framework integrates three progressive phases: (1) political ethics, rooted in foundational manifestos emphasizing interdependence and universal care as a societal organizing principle [16]. (2) empirical studies, informed by care infrastructures in high-density cities, such as Boston's labor-focused activations and relational interventions [17], framework for a revised approach to intergenerational public space design, pocket park in Los Angeles [18]. and (3) design practice, exemplified by relational and caring city models in London that translate ethics into actionable placemaking [19]. This evolutionary trajectory is complemented by established urban design standards, including environmental psychology principles, WHO Age-Friendly Cities guidelines, and Hong Kong-specific urban design directives, which collectively emphasize multidimensional human needs in public realms [7, 8]. The structure of the metric is shown in Table 1.

2.1.2 Feature Extraction

This step contains two parts that transform raw street-view images into quantifiable indicators.

Part 1: Visual Analysis Leverages Detectron2's panoptic segmentation model with a ResNet-101 Feature Pyramid Network (FPN) backbone ShuffleNet), ResNet demonstrated superior overall performance [20]. Besides, it can also cover common item categories.

Table 1. Care-Theory-Centered Evaluation Metric

Primary	Secondary	Tertiary
Physical Shelter	Comfort	Seat, Green rate, Microclimate.
	Security	Physical disorder, Visual transparency, Safety protection facilities.
	Accessibility	Accessible space, Accessibility facilities, pedestrian paths.
Psychological Belonging	Aesthetic experience	Disorderliness, Color richness, Green rate,
	Enclosure sense	semi-enclosed spaces, Visibility of sky, Boundary closure.
	Cleanliness	Garbage coverage rate, Cleanliness, Ground pavement.
Social Activity	Activity Support	Activity space area, Social furniture, Pedestrian activity.
	Multiple function	Convenience facilities, Non-motorized Transport, Convenience of Access.
	Interactive scene	Recreational facilities, Stay friendliness, Openness of Public Spaces.

Part 2: Logical Extension Transform visual outputs into the indicators through systematic post-processing and mapping. Three kinds of representative indicators across distinct calculation categories are as follows:

Greenery Coverage Rate (turn pixel data into ratio indicators). This indicator reflects the proportion of vegetation in spaces and serves as a core metric for evaluating ecological comfort for older adults. Its calculation formula is shown as equation 1:

$$G = 100 \times \frac{M_{tree} \cup M_{grass}}{N} \quad (1)$$

Where $M_{tree} \cup M_{grass}$ represents the total pixel count of the merged "tree " and "grass " categories in the panoptic segmentation mask. N represents the total pixel count of the image.

Bench Density (turn count into density indicators). This indicator measures the supply of elderly-friendly resting facilities. It can be shown as equation 2:

$$P = 100 \times \frac{count(bench)}{A}, A = N \times 0.01^2 \quad (2)$$

Where P represents the bench density in the space per 100 m^2; $count(bench)$ represents the total instance count of the "bench" category in the panoptic segmentation result. A is physical area of space. 0.01 is the conversion coefficient from pixel to meter.

Semi-Enclosed Space Quantity (turn spatial features into morphological indicators). This indicator characterizes the scale of enclosed local areas in under-bridge spaces. It can be shown as equation 3:

$$E = num\{S | S \geq ENCLOSED_AREA_THRESH\} \quad (3)$$

Where E is the number of semi-enclosed spaces. S is the area of a single enclosed region in the under-bridge space. $ENCLOSED_AREA_THRESH$ is the area threshold for defining a semi-enclosed space and was set to 1.5 m^2. According to field surveys, enclosed areas smaller than 1.5 m^2 are mostly structural gaps with no actual rest value, so this threshold filters invalid regions. OpenCV is used as the core computer vision tool, it extracts the outer contours of discrete spatial regions and computes the pixel area of each region.

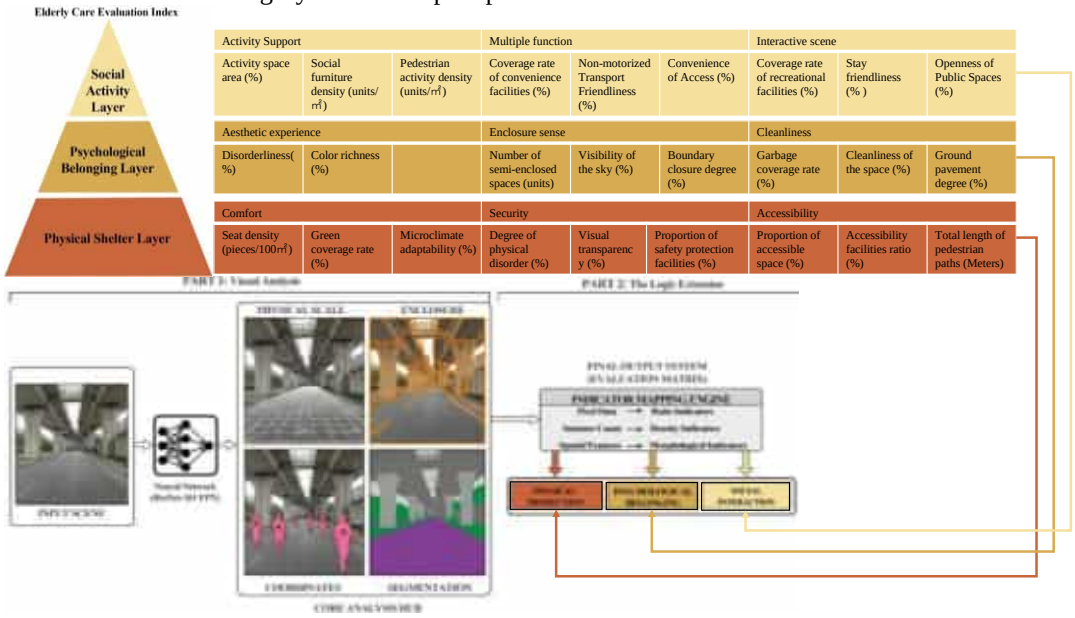

Figure 2. Feature extraction based on care-theory-centered evaluation metric

2.2 Multi-Elderly-Agent Scoring and Demographic Weighting

Existing research has realized task splitting and collaborative execution of BIM spatial queries through an LLM-based agent framework [21]. Drawing on this idea, this study designs multi-elderly agents to simulate the subjective evaluation perspectives of elderly groups.

This step addresses the subjectivity and small-scale limitations of traditional qualitative evaluations by simulating diverse elderly perspectives through AI agents and ensuring that scores reflect the needs of the target population via demographic weighting.

2.2.1 Design of Multi-Elderly Agents

To comprehensively cover the heterogeneous needs of older adults across different age groups and physical conditions, 4 elderly agents were designed through a prompt engineering approach.

Prompt Engineering: Each persona receives a structured prompt template, assigned a realistic background and key concerns derived from care theory, to ensure the agents' evaluations mirrored real-world elderly needs:

'You are a [age]-year-old elderly person with [mobility/sensory profile]. Evaluate the attached under-bridge space image from your perspective according to

three dimensions: (1) Physical Shelter (accessibility, safety, comfort), (2) Psychological Belonging (aesthetics, enclosure, cleanliness), (3) Social Activity (activity support, functional diversity, interaction affordance). Provide three scores from 1–100.'

Model Deployment and Optimization: The MiniCPM model was adopted for agent reasoning, optimized for batch processing with 8-bit NF4 quantization and image resizing to balance efficiency and accuracy. Each agent processed 302 images, generating three-dimensional scores and an average score per image.

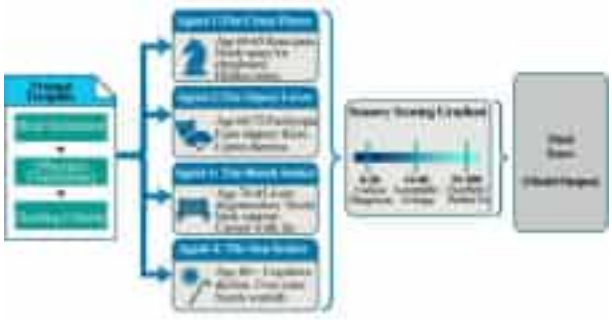

Figure 3. Multi-Elderly-Agent Scoring Framework.

2.2.2 Demographic Weighting

To reflect the actual age structure of Hong Kong's elderly population, weighted aggregation was performed on the four agents' total scores. The weighted total score for each under-bridge space was calculated as equation 4:

$$Weighted\ Score = \sum_{i=1}^{4} (S_i \times W_i) \quad (4)$$

In which S_i is the average total score of the i-th elderly agent, and W_i is the corresponding demographic weight. According to the statistics from the Census and Statistics Department of Hong Kong, the age structure of the elderly population in Hong Kong is shown in Table 2.

Table 2. The age structure of the elderly population in Hong Kong

Ages	Ratio (%)
60-65	26
66-75	43.7
76-85	19.8
Above 85	10.5

2.3 XGboost-Based Classification Model And Model Performance Analysis

This section integrates objective spatial features and demographic-weighted elderly satisfaction scores to construct a robust, interpretable, and scalable automated assessment model. The core goal is to learn the mapping relationship between under-bridge space attributes and elderly-friendly degrees, while providing data-driven decision support for age-friendly urban design or renewal.

As shown in equation 5, given the input feature matrix $\mathbf{X} \in \mathbb{R}^{n \times m}$ (where $n = 302$, the number of under-bridge image samples, $m = 27$, the quantifiable spatial indicators) and the demographic-weighted satisfaction score $S_\omega \in [1, 100]$ for each sample, the task is formulated as a binary classification problem to predict elderly satisfaction levels. The binary label y_i is defined using a calibrated threshold $\tau = 68$ (the average score determined by elderly agent). Similar urban application employs XGBoost on street-view features to predict public-space vitality scores and then reference the dataset mean to derive high or low classifications for age-inclusive urban design interventions [23].

$$y_i = \begin{cases} 0, S_{\omega,i} < \tau (Low\ Elderly - Care) \\ 1, S_{\omega,i} \geq \tau\ (Low\ Elderly - Care) \end{cases} \quad (5)$$

2.3.1 Model Selection and Building

Extreme Gradient Boosting (XGBoost) is selected as the base model due to its superior performance in handling high-dimensional tabular data, nonlinear feature interactions, and class imbalance. Its regularized objective function balances fitting capability and generalization. It can be expressed as equation 6.

$$L(\varphi) = \sum_{i=1}^{n} l(y_i, \hat{y}_i) + \sum_{k=1}^{K} \Omega(f_k) \quad (6)$$

Where $\sum_{i=1}^{n} \boldsymbol{l(y_i, \hat{y}_i)}$ stands for the empirical loss of the predicting model. It measures the prediction error between the model's output ($\hat{y}_i$, for under-bridge space samples) and the true binary label (y_i, 0=low elderly-care, 1=high elderly-care), using logistic loss to fit the binary classification task. $\sum_{k=1}^{K} \boldsymbol{\Omega(f_k)}$ stands for regularization loss.

When constructing the model, we encountered three other issues: (1) Class imbalance in labeled samples, (2) Noise sensitivity of spatial features due to diverse under-bridge layouts, and (3) Need for interpretable predictions to guide urban planning decisions. So we added four interconnected modules: (1) Feature preprocessing with outlier-resilient normalization; (2) Dual-stage data augmentation for class imbalance mitigation; (3) Bayesian optimized hyperparameter tuning; (4) Interpretability enhancement.

1. Feature preprocessing with outlier-resilient normalization. To mitigate the impact of outliers in spatial feature measurements, we employ RobustScaler for normalization to ensure stability. It is expressed as equation 7.

$$X_{ij}^{scaled} = \frac{X_{ij} - median(X_j)}{IQR(X_j)} \quad (7)$$

Where $\mathrm{IQR}(X_j) = Q_3(X_j) - Q1(X_j)$ (25th and 75th percentiles of feature j).

2. Dual-stage data augmentation for class imbalance mitigation. To address class imbalance without distorting feature semantics, we propose a dual-stage augmentation strategy, including SMOTE Oversampling and Gaussian Noise Augmentation.

3. Given the dataset imbalance and the high-stakes urban renewal context in Hong Kong, the model is optimized using a weighted multi-metric score via Optuna. This process can be expressed as equation 8.

$$\text{Score} = 0.45\text{Acc} + 0.30\text{F1} + 0.125\text{Prec} + 0.125\text{Rec} \quad (8)$$

Where equation 9

$$\text{ACC} = \frac{TP+TN}{TP+TN+FP+FN}, \quad (9)$$

is the correctness of the model. It assesses overall classification correctness, weighted most heavily. Because bridges, as basic city infrastructure, are very difficult to change or renew. A high accuracy ensures the model's baseline credibility and avoids resource misallocation. Equation 10

$$\text{F1} = 2 \times \frac{Prec \times Rec}{Prec + Rec} \quad (10)$$

Serves as the primary balance metric for our imbalanced dataset. F1 mitigates the accuracy bias toward the majority class, ensuring that the model neither over-misses high-potential regions nor over-labels low-quality regions. Equation 11

$$\text{Prec} = \frac{TP}{TP + FP} \quad (11)$$

Measures the reliability of "high elderly-friendliness" predictions. A high precision avoids unnecessary renovation costs, for misclassifying a low-friendly space would waste urban renewal budgets. Equation 12

$$\text{Rec} = \frac{TP}{TP + FN} \quad (12)$$

Evaluate the ability to identify all high-potential spaces. A high recall rate can prevent missed opportunities for optimization; failing to detect spaces with high potential will result in neglecting available space for the elderly in underutilized urban areas.

To further enhance model robustness and reduce generalization error, we construct a 9-model soft-voting ensemble based on the Bayesian-optimized parameter set.

4. To bridge the gap between model predictions and urban planning practice, we integrate complementary interpretability tool, Gain-Based Feature Importance, to quantify the contribution of each spatial indicator by cumulative loss reduction during tree splitting. This process can be expressed as equation 13.

$$Gain_j = \frac{\sum_{k=1}^{K} Gain_{jk}}{\sum_{l=1}^{m}\sum_{k=1}^{K} Gain_{lk}} \quad (13)$$

Where $Gain_{jk}$ represents the loss reduction from splitting feature j in tree k. The numerator $\sum_{k=1}^{K} Gain_{jk}$ accumulates the total loss reduction contributed by indicator j across all K decision trees in the XGBoost ensemble; the denominator $\sum_{l=1}^{m}\sum_{k=1}^{K} Gain_{lk}$ sums the total loss reductions of all m spatial indicators, ensuring $0 \ll Gain_j \ll 1$ and $\sum_{j=1}^{m} Gain_{jk} = 1$. Then we select the top 15 indicators with the largest normalized importance scores.

3 Proof of Concept

3.1 Experiment Environment

For the selection of the survey sites for the underpass space in Hong Kong, five research sites were selected, namely: Tsuen Wan-MTR Station Flyover, Sham Shui Po-Tung Chau Street Flyover, Tai Po-Tung Lo Wan Road Flyover, Causeway Bay-Canal Road East, To Kwa Wan- Flyover. Their locations are shown in Figure 4.

The Experiments were conducted on a high-performance computing server equipped with dual NVIDIA GeForce RTX 3090 GPUs (each with 24 GB GDDR6X memory, totaling 48 GB VRAM), an Intel Xeon Gold 6248R CPU @ 3.00 GHz (24 cores/48 threads), 256 GB DDR4 RAM, and 2 TB NVMe SSD storage. The operating model Ubuntu 22.04 LTS, with CUDA 12.1 and cuDNN 8.9 installed for GPU acceleration. All codes were implemented in Python 3.10.

Figure 4. Map of the locations for on-site research.

3.2 Results of CC-VLM

As shown in Figure 5, high scoring samples are more likely from spaces with high green coverage rates, complete resting facilities, and moderate social vitality. These attributes align with the core needs of older adults emphasized in care theory and in on-site observations. In contrast, low-scoring samples are mostly concentrated in spaces characterized by inadequate safety facilities, high garbage coverage rates, and limited semi-enclosed spaces.

Figure 5. Multi-Elderly-Agent Scoring example.

3.3 Results Evaluation

To assess the performance of the classification model, we employ a set of metrics, including accuracy, recall, F1 Score, area under the receiver operating characteristic curve. These indicators are selected for their ability to provide a balanced evaluation. Besides, these metrics are consistent with the research objective, as they not only quantify predictive efficacy but also emphasizing sensitivity to adverse conditions. For instance, high recall ensures that the model reliably flags spaces requiring intervention, supporting equitable transformations of overlooked urban areas for aging populations. Baselines for these indicators are established relative to random guessing and prior benchmarks in analogous street-view-based urban analytics. For binary classifier, random performance yields accuracy, F1 and AUC-ROC are all of 0.5. When comparing with similar study, Hu et al. reported 79.9% accuracy and 75.51% mean average precision in urban physical disorder detection [9]. In our experiments, recall and AUC-ROC values exceeding 0.7 and 0.6 respectively are considered adequate. As shown in Table 3, overall performance metrics confirm balanced yet modest results across standard measures.

Table 3. Binary Classification Model Performance Metrics

Indicator Name	Score
AUC	0.615
Recall	0.714
Precision	0.536
F1-Score	0.612
Accuracy	0.655

As shown in Figure 6, the model demonstrated moderate discriminative ability, with an Area Under the ROC Curve (AUC) of 0.615. This AUC value, while above random chance, reflects the limited variability in the 302-image dataset, indicating potential for improvement with expanded data or refined features.

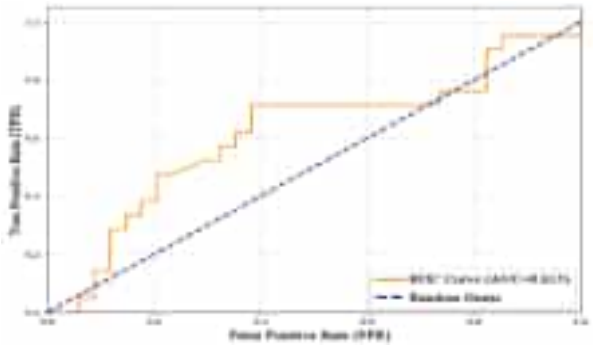

Figure 6. ROC Curve.

As shown in Figure 7, feature importance rankings offer interpretable insights directly tied to the care theory. Indicators from the Physical Shelter Layer predominated, led by green coverage rate and facility completeness, emphasizing greenery and basic infrastructure as primary drivers of elderly satisfaction. Psychological Belonging Layer features ranked prominently, supporting the influence of emotional comfort. Social Activity Layer metrics also contributed substantially.

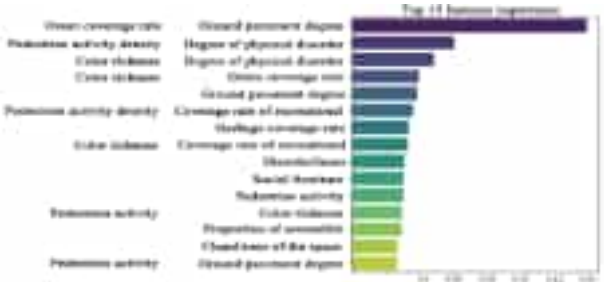

Figure 7. The importance of the top 15 features.

4 Conclusion

This study addresses the critical challenge of efficiently assessing urban under-bridge spaces. By proposing the CC-VLM framework, we achieve three core objectives: (1) a theory-grounded hierarchical metric model synthesizing care ethics into practice; (2) an automated workflow that simulates diverse elderly perspectives to generate subjective visual labels; and (3) a multi-model-enhanced VLM integrated with XGBoost for scene assessment and prediction. Experimental results validate the framework's effectiveness, confirming that greenery, facility completeness, and activity density are dominant drivers.

Limitations include modest predictive performance due to the small dataset size, overreliance on visual imagery alone, and reliance on simulated agents. In particular, the XGBoost classifier is trained using scores generated by the VLM agents as target labels, therefore it is not directly reflecting real-world elderly experiences.

Future work could expand to larger datasets, integrate more data from real older adults, and incorporate multi-modal environmental sensors for evaluations.

Abstract

Construction and demolition waste (CDW) sorting is increasingly being automated using robotics and AI to improve safety, efficiency, and material recovery. However, developing and validating perception and control algorithms directly on physical conveyor systems is costly, time consuming, and difficult to reproduce due to variability in object layouts and operating conditions. The lack of scalable and repeatable benchmarking environments limits rapid experimentation and fair comparison of alternative approaches. This paper presents a digital twin (DT) simulation framework for conveyor-based CDW sorting that enables systematic and data-driven evaluation of robotic strategies. The proposed system integrates three main components: an RGB annotation-driven mesh generation pipeline that converts real waste images into 3D object assets, a Unity based physics simulation that models the conveyor and robotic workspace, and a ROS 2 communication layer that enables real time interaction with external perception and control modules. The generated meshes preserve object footprint and spatial relationships while remaining computationally efficient, allowing realistic cluttered scenes to be reproduced automatically. The framework also provides structured ground truth and event-based signals to support quantitative evaluation. Experimental results show that mesh generation requires approximately 24 ms per image and 5.3 ms per object, while the simulation maintains stable real time performance at around 46–47 frames per second across varying conveyor speeds. These results indicate that the platform is suitable for large scale experimentation. The proposed DT offers a practical and extensible testbed for developing, benchmarking, and transferring robotic waste sorting algorithms from simulation to real world deployment.

Digital Twin; Robotics; Construction and Demolition Wastes; ROS 2

1 Introduction

Construction and demolition waste (CDW) represents a large proportion of global solid waste and poses significant environmental and economic challenges due to its volume and heterogeneity. Automated robotic systems have the potential to improve CDW sorting efficiency by reducing manual labour, increasing material recovery, and supporting circular economy goals. However, the irregular shapes of waste objects, high inter-class variability, and dynamic conveyor conditions make perception, manipulation, and control particularly challenging for robotic systems [1].

Digital twin (DT) technologies have recently emerged as a promising approach for accelerating development and testing of robotic systems in simulation before real world deployment. A DT refers to a virtual representation of a physical system that enables real time communication and interaction between the digital model and its physical counterpart, supporting design, optimisation, and testing tasks without the cost and risk associated with physical experimentation [2]. In robotics, DT platforms integrated with robotic middleware such as the Robot Operating System (ROS) enable evaluation of perception, planning, and control algorithms in controlled environments.

Despite these advances, most existing DT frameworks target structured industrial tasks or generic manipulation scenarios. In contrast, CDW sorting requires handling irregular objects, cluttered conveyor streams, and variable spatial layouts derived from real waste scenes. Existing research on robotic waste sorting largely focuses on object detection and classification,

with limited infrastructure for reproducible evaluation of complete perception-to-action pipelines.

This paper presents a data-driven DT framework for conveyor-based CDW sorting that integrates ROS 2 with Unity and generates simulation assets from annotated RGB waste images. The framework enables realistic reproducible scene generation, object state publishing, and event-based evaluation within a controllable environment. The contributions of this work are threefold: (i) an automated pipeline for generating 3D mesh assets from annotated RGB images of CDW while preserving object footprint, spatial layout, and key geometric attributes relevant for simulation, (ii) a synchronised Unity–ROS 2 DT environment capable of representing conveyor-based CDW sorting scenarios with dynamically generated waste streams derived from real images, and (iii) a configurable benchmarking framework including scenario definitions and performance metrics that enable systematic evaluation of sorting systems in simulation under varying object layouts and conveyor operating conditions.

2 Related Work

2.1 DTs and Simulation Environments for Robotics

DTs are increasingly used for developing and validating robotic systems, enabling safe, repeatable experimentation and rapid iteration of perception, planning, and control algorithms. In construction and built environment applications, recent reviews highlight rapid growth in DT research while identifying challenges in interoperability, real time data integration, and scalable cyber physical architectures that combine sensing, simulation, and decision making [3].

Within robotics, Unity is increasingly adopted as a practical simulation platform due to its high-quality visualisation, flexible scene design, and interactive modelling capabilities. It is commonly integrated with ROS or ROS 2 to connect virtual scenes with external robotic software. Prior work has demonstrated Unity-based DT pipelines and evaluated aspects such as communication latency, synchronisation, and real time interaction [2]. Comparative studies with robotics focused simulators such as Gazebo indicate that Unity supports rapid scene prototyping and visual realism, while Gazebo provides tighter native ROS integration and physics modelling depending on the application [4].

Researchers have also explored more extensible simulation architectures that combine Unity with external computation or messaging layers to support collaborative experiments and modular system design. For example, multi-user simulation environments with Unity-MATLAB bridge have been proposed to enable colloborative experiments and evaluate alternative communication mechanisms [5]. Similarly, DT-driven control platforms have been developed in which Unity-based visual environments interact with industrial robot controllers through bidirectional state and command synchronisation [6]. These studies demonstrate that the DT frameworks can significantly reduce system integration effort and accelerate the development of robotic applications.

However, most existing DT platforms are designed for structured industrial tasks or general manipulation scenarios. They rarely consider domain specific challenges such as conveyor-based handling of irregular waste objects, cluttered object streams, and dynamically generated scenes derived from real observations. As a result, current DT environments provide limited support for benchmarking robotic sorting algorithms under realistic CDW conditions.

2.2 Robotic and AI for CDW Sorting

Robotic sorting has been widely investigated as a means of improving recycling efficiency and reducing manual labour in hazardous and labour-intensive environments. Despite these advances, automated waste sorting remains challenging because CDW streams typically contain cluttered scenes, irregular object shapes, and significant material variability, requiring robust perception and decision making capabilities [1]. Recent research in CDW automation has primarily focused on vision-based detection and classification methods. Advances in deep learning have enabled improved recognition and segmentation of waste categories, supporting automated material recovery systems. They also highlight important practical considerations for real world deployment, including distributed processing between edge and cloud systems and coordination between multiple robotic units in large facilities [7].

Several works have extended these perception capabilities by integrating object detection with robotic manipulation. In such systems, detected objects are localised and then handled using robot kinematic control to perform pick and place or transfer operations [8]. At the same time, sensitivity analyses and field studies emphasise that real world viability depends not only on recognition accuracy, but also on consistent operation under varying throughput, conveyor speeds, and labour or operational constraints [9].

These observations indicate that evaluation of robotic sorting system must consider the full perception-to-action workflow rather than isolated algorithmic components. However, most existing studies validate their approaches using limited experimental setups or fixed test scenarios. Infrastructure that enables controlled, repeatable, and configurable benchmarking of sorting strategies remains relatively limited.

2.3 Data-driven Geometry Generation for Simulation Assets

Realistic simulation environments require representative object geometry to accurately reflect real world operating conditions. In many robotic applications, the quality of object models strongly influences the validity of experimental results, particularly when evaluating perception and manipulation strategies. Manually modelling large numbers of irregular objects is time consuming and often impractical, motivating the development of automated asset generation methods.

In the computer vision community, significant research has focused on reconstructing 3D structure from a single RGB image. These approaches include methods that predict depth maps, point clouds, or mesh representations directly from image features. Survey studies highlight the diversity of reconstruction techniques as well as the inherent difficulties caused by ambiguity, occlusion, and incomplete observations [10]. Although such learning-based methods can produce detailed geometry, they are computationally demanding and may not generalise well to the diverse and irregular shapes commonly found in CDW streams.

Consequently, many robotics and DT simulations instead rely on predefined CAD models or manually curated asset libraries. Although these assets are suitable for structured industrial components, they do not capture the variability and randomness observed in real waste streams. Existing Unity-ROS DT setups have been used to simulate manipulation tasks, but they typically assume that object models are known in advance rather than derived directly from real images [11].

As a result, current approaches either focus on high fidelity reconstruction for visual realism or depend on handcrafted object libraries. Neither direction adequately supports lightweight and scalable geometry generation that can rapidly create large numbers of representative assets for benchmarking cluttered waste sorting scenarios.

2.4 Research Gap and Positioning of This Work

The literature highlights three complementary research directions; DT frameworks for robotic simulation, AI-based perception and manipulation methods for waste sorting, and data-driven approaches for generating 3D geometry from images. However, these areas remain largely disconnected in the context of conveyor-based CDW sorting. Existing DT platforms provide general simulation capabilities but rarely incorporate data-driven scene generation from real waste observations. Meanwhile, robotic CDW sorting research primarily focuses on perception or manipulation algorithms without providing infrastructure for systematic benchmarking under controlled conditions. In parallel, RGB-based 3D reconstruction methods aim for detailed geometry recovery but are often computationally demanding and unsuitable for rapid asset generation.

Consequently, there remains a gap between realistic scene modelling and practical benchmarking environment for evaluating robotic sorting systems. To address this gap, this work proposes a data-driven DT framework that integrates RGB annotation-based mesh generation with a synchronised Unity-ROS 2 simulation environment tailored to conveyor-based CDW sorting scenario. The framework enables automatic generation of realistic cluttered scenes, controlled scenario definition, and event-based performance evaluation, providing a reproducible platform for benchmarking robotic sorting strategies.

3 System Architecture

This section presents the architecture of the proposed DT framework for conveyor-based CDW sorting. The system integrates an RGB driven mesh generation module, a Unity-based simulation environment, and a ROS 2 communication layer. Together, these components enable controllable scenario generation and real time interaction with external robotic software, allowing perception, planning, and control algorithms to be evaluated in a consistent and repeatable environment.

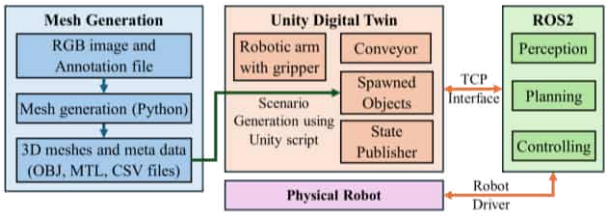

Figure 1. Overall system architecture and data flow between modules.

3.1 Overall Framework

Figure 1 illustrates the architecture of the proposed DT system, which comprises four components: an offline mesh generation module, a Unity based simulation environment, a ROS 2 coordination layer, and an optional physical robot interface. These components are loosely coupled so that scenario generation and simulation remain independent from external control algorithms. The mesh generation module converts annotated RGB images into lightweight 3D mesh proxies. Object boundaries extracted from polygon annotations are exported as OBJ files together with metadata describing class, dimensions, orientation, centroid, and estimated mass. The generated assets are stored locally and imported into Unity for conveyor sorting scene creation.

The Unity environment includes a conveyor, a simulated robot arm, and dynamically spawned waste

objects positioned according to the source image layout using metric scaling. Communication between Unity and ROS 2 is achieved via a TCP interface that supports bidirectional data exchange. Unity publishes object states and scene variables, while ROS 2 nodes provide control inputs such as belt speed and task priorities. This architecture allows the same interfaces to be used in both simulation and physical robotic system.

3.2 Mesh Generation

The mesh generation module converts annotated RGB images into lightweight 3D object assets used to instantiate realistic waste scenes in the Unity DT. Instead of reconstructing exact geometry, the goal is to generate physically plausible mesh proxies that preserve object footprint, class identity, spatial layout, and key geometric attributes required for benchmarking. The overall pipeline is illustrated in Figure 2. The dataset used for asset generation consists of 800 RGB images from a public dataset, containing approximately 1077 concrete, 1146 brick, 1655 wood, and 931 rubber objects [12]. Polygon-based instance annotations compatible with the YOLO format were generated in previous work and reused here to extract object boundaries.

For each image, segmentation annotations are read to obtain polygon boundaries of individual objects. Polygon vertices are converted from image coordinates to metric units using a scale derived from the conveyor belt width, preserving relative spacing in the simulation. Each footprint is then extruded vertically to form a closed triangular mesh, with the height sampled from class specific ranges to introduce realistic thickness variation. The resulting mesh is centred at its centroid to simplify spawning within Unity.

Algorithm 1. RGB annotation-based mesh and metadata generation

Input: RGB image, polygon annotation file, belt width, class height ranges, material densities

Output: Mesh files and metadata for all objects in the image

1. Compute pixel to metric scale from belt width and image width
2. Load polygon annotations and convert to pixel coordinates
3. Remove objects that are truncated near image boundaries
4. For each polygon instance do
   a. Convert polygon vertices to metric coordinates
   b. Estimate geometric properties including area, centroid, and orientation
   c. Sample extrusion height from the class specific height range
   d. Triangulate polygon and extrude to generate a closed mesh
   e. Compute volume and derived mass using material density
   f. Shift mesh so centroid becomes local origin
   g. Export mesh as OBJ and MTL files with unit and axis conversion
   h. Save metadata including class label, centroid position, dimensions, orientation, area, volume, height, and estimated weight
5. Save all object records to a scene level CSV file

Figure 2. Algorithm used for mesh generation.

Most waste objects exhibit approximately convex shapes, while rubber fragments frequently contain concave boundaries. To support both cases, polygon triangulation is performed using an ear-clipping algorithm capable of generating stable meshes from arbitrary simple polygons. Basic geometric validation steps are also applied during preprocessing, including polygon orientation correction and triangulation checks, ensuring robust mesh generation even when annotations contain irregular vertex distributions or minor noise.

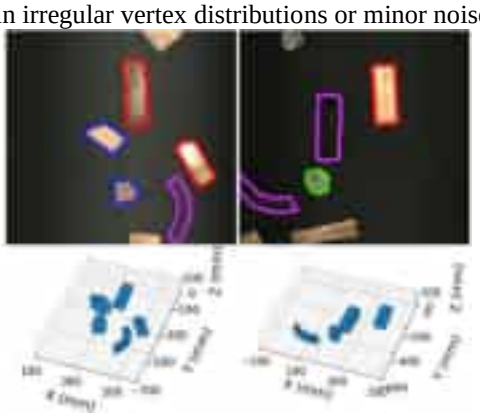

Figure 3. Example of RGB driven mesh generation. Top row shows the annotated RGB image with polygon boundaries and class labels. Bottom row shows the generated 3D meshes obtained by polygon extrusion and metric scaling

For compatibility with Unity, vertices are converted to metres and aligned with the simulation coordinate convention before export. The final assets are saved as OBJ and MTL files, together with a CSV file storing object metadata such as class, position, dimensions, orientation, and estimated mass. This automated process enables rapid and repeatable generation of simulation scenes without manual modelling. Figure 3 shows examples of the generated meshes alongside their annotated RGB images, demonstrating that the resulting assets preserve object layout while providing efficient volumetric representations for physics-based simulation.

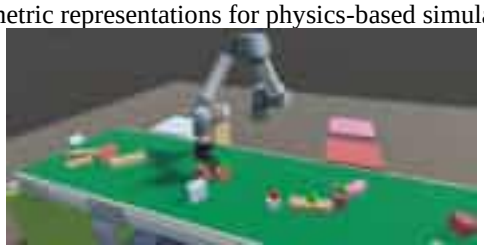

Figure 4. Unity based conveyor DT with dynamically spawned waste objects generated from RGB annotations. The environment includes the conveyor, simulated robot arm, and physics-based object interactions.

3.3 Conveyor DT in Unity

Unity serves as the DT of the physical conveyor sorting system, providing a controllable and repeatable environment for testing perception and decision making algorithms. The scene includes a conveyor belt, a simulated robotic arm with a gripper, and dynamically spawned waste objects generated by the mesh pipeline.

Unity is adopted for its flexible scene configuration, real time rendering, and built in physics capabilities.

At the start of each simulation episode, mesh assets and their metadata are loaded and used to spawn objects on the conveyor as shown in **Error! Reference source not found.**. Object attributes such as class, centroid, dimensions, and orientation are applied to preserving the relative layout of objects through metric scaling, enabling realistic cluttered scenes to be reproduced without manual placement.

Conveyor motion is simulated within Unity, while belt speed is controlled externally through ROS 2 commands and can include smooth variations to emulate realistic operating conditions. The environment continuously publishes object states and receives control inputs, allowing Unity to function as an interactive and measurable testbed for benchmarking rather than a passive visualisation tool.

3.4 ROS2 Interface and Topics

ROS 2 acts as the coordination layer linking the Unity DT with external perception, planning, and control modules. Data exchange is performed through ROS 2 topics via a TCP based interface, enabling bidirectional real time communication between the simulation and higher-level algorithms.

Figure 5. Main ROS 2 topics used for bidirectional communication between Unity and external modules. Arrows indicate data flow direction between Unity and ROS 2.

During operation, Unity publishes object states and global variables such as conveyor speed, while external nodes subscribe to this information for tracking, scheduling, and decision making. Control commands from ROS 2 are then sent back to Unity to influence the simulation, allowing the DT to operate as an interactive and modular experimental platform. Figure 5 summarises the main topics used in the current implementation, providing the necessary state and control information while maintaining a lightweight interface suitable for real time operation.

3.5 Event Detection via Colliders

To enable quantitative evaluation, the Unity DT uses physics-based colliders to automatically detect interaction events during simulation. Instead of relying on visual inspection, these triggers generate discrete signals for contacts, workspace transitions, and object removal, which are published to ROS 2 for real time monitoring and analysis. In addition, a collider at the tool centre point (TCP) is used to approximate grasp interaction, enabling evaluation of picking alignment without explicitly simulating detailed gripping physics.

Four types of colliders are used. Triggers attached to the gripper fingers detect contact with waste objects. A TCP collider provides a simplified representation of grasp interaction. Boundary colliders define the active conveyor workspace and record object entry and exit events. An additional trigger below the belt detects fallen objects and removes them from the scene to maintain stable simulation performance.

All events are transmitted through ROS 2 topics, allowing external nodes to compute statistics such as processed counts, missed interactions, and failures. This enables the DT to function as a measurable and repeatable benchmarking testbed.

4 Scenario Generation and Benchmarking Metrics

The proposed DT functions as both a simulation environment and a benchmarking platform for evaluating perception, scheduling, and manipulation strategies. It enables controlled experimentation through automatic scenario generation, structured ground truth, and quantitative performance metrics, supporting repeatable and fair comparison of algorithms under varying conveyor conditions.

4.1 Scenario Randomisation

To reflect real world variability and avoid overfitting to fixed layouts, the DT supports automatic randomisation of scene parameters at the start of each simulation episode. Randomisation is applied at both object and system levels. At the object level, scenes are generated by selecting mesh assets from different annotated RGB images and spawning them using their recorded spatial layout. Parameters such as extrusion height and material thickness are sampled within predefined ranges to introduce realistic variations in volume and mass while preserving object footprints.

At the system level, conveyor dynamics are varied by adjusting belt speed and adding smooth stochastic perturbations. Additional factors, including object ordering, spawn timing, and scene density, further diversify operating conditions. Because scenarios are generated programmatically, large numbers of repeatable test cases can be created efficiently, enabling statistical evaluation across multiple runs and reducing bias from

fixed layouts.

4.2 Available Ground Truth

A key advantage of the DT is the availability of precise ground truth information for every object and event in the scene. Unlike physical experiments, where sensing noise and occlusion may limit measurement accuracy, the simulation environment provides direct access to exact geometric and state variables.

For each object spawned, the system maintains attributes including class label, centroid position, orientation, footprint dimensions, area, volume, height, and estimated mass. During runtime, Unity continuously publishes object poses and scene states to ROS 2, enabling external algorithms to access accurate and synchronised measurements. In addition, collider-based triggers generate event signals such as object contact, workspace entry or exit, and object removal.

This comprehensive ground truth supports detailed analysis of algorithm behaviour, debugging, and objective evaluation of success and failure conditions without manual annotation.

4.3 Evaluation Metrics

The DT facilitates quantitative assessment of sorting and manipulation strategies through measurable metrics derived from ground truth and event signals. These metrics can be computed online via ROS 2 nodes or offline from logged data.

Typical indicators include the number of processed objects, task completion rate, and the proportion of correctly selected or prioritised targets. Timing related metrics such as processing time per object and throughput are obtained from timestamps associated with entry and exit events. Contact and removal signals enable detection of failed interactions, such as missed picks or unintended collisions. Example metrics are defined as

$$\text{Throughput} = n_{success} / T \quad (1)$$

$$\text{Success rate} = n_{success} / N \quad (2)$$

$$\text{Miss rate} = (N - n_{success}) / N \quad (3)$$

where $n_{success}$ denotes the number of successfully handled objects, T is the total time, and N is the total number of objects. As these measures are computed directly from ground truth rather than sensor estimates, they provide consistent and repeatable benchmarks across different algorithms and experimental settings.

Overall, the combination of automated scenario generation, structured ground truth, and quantitative metrics enables the framework to function as a controlled testbed for developing and comparing robotic sorting strategies prior to deployment on physical hardware.

5 Experimental Demonstration and Evaluation Workflow

This section presents system-level demonstrations to validate the computational efficiency and runtime stability of the proposed DT framework. The focus is not on evaluating specific picking strategies, but on confirming that the mesh generation pipeline and Unity-based simulation operate in real time and support large scale experimentation under varying conveyor conditions.

5.1 Asset Generation Performance

The computational cost of the mesh generation stage was evaluated to assess the feasibility of creating simulation assets directly from annotated RGB images. For each image, the pipeline extracts polygon instances, constructs extruded meshes, computes geometric descriptors, and exports mesh and metadata files without manual intervention.

Across multiple images, the average processing time was approximately 24 ms per image. At the object level, average mesh construction time was 5.3 ms per instance. These results indicate that multiple objects can be generated within a few milliseconds, enabling rapid batch creation of large numbers of simulation scenarios. The low computational overhead demonstrates that the proposed RGB driven geometry generation approach is efficient and scalable, making it practical for repeated asset generation during experimentation.

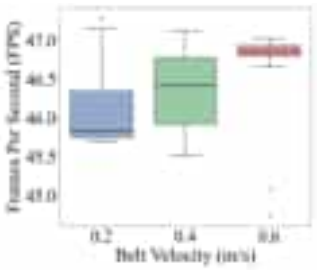

Figure 6. Variation of FPS for three different conveyor speeds measured for 1 minute.

5.2 Simulation Stability and Throughput

The runtime performance of the Unity-based DT was evaluated under cluttered scenes and varying conveyor speeds. Generated mesh assets were dynamically spawned using recorded spatial layout, resulting in multiple interacting objects on the conveyor.

Across tested speeds of 0.2 m/s, 0.4 m/s, and 0.6 m/s, the simulation maintained stable frame rates of approximately 46-47 frames per second (FPS), as shown in Figure 6. Only minor fluctuations were observed, with no noticeable degradation at higher belt velocities. This confirms that the lightweight mesh representation and physics configuration impose minimal computational

overhead and enable real time execution on a standard desktop workstation. Communication performance was also evaluated, showing stable round-trip latency over time with an average round-trip time of approximately 100 ms between Unity and ROS 2. This indicates that the system supports reliable real time interaction for control and state feedback.

To emulate realistic operating conditions, conveyor velocity can be modulated with smooth stochastic variations around a nominal speed. Figure 7 shows an example profile with a base speed of 0.2 m/s and small perturbations. This variability enables testing of perception and scheduling algorithms under non constant motion while maintaining stable simulation performance. Overall, these results demonstrate that DT supports efficient asset generation, stable real time simulation, and reliable communication, providing a practical foundation for large scale benchmarking of robotic sorting strategies.

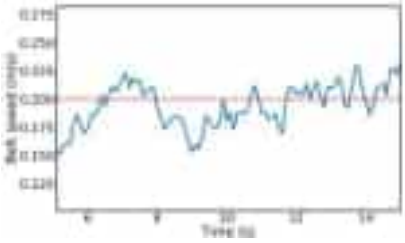

Figure 7. Example belt velocity profile generated from ROS2 side with a base speed of 0.2m/s.

5.3 Evaluation Workflow and Impact of Mesh Approximation

To illustrate how the proposed DT supports benchmarking of robotic sorting systems, a simplified picking experiment was conducted using a velocity feed-forward and feedback-based controller. The objective is not to evaluate the controller itself, but to demonstrate the interaction between perception, control, and the DT, and how performance metrics are computed.

In this framework, detailed physics-based gripping is not simulated. Instead, grasp interaction is approximated using colliders attached to the gripper fingers and tool centre point (TCP). A pick is considered successful when the gripper aligns on opposing sides of an object and the TCP overlaps the object region for a short dwell period ($\approx$0.6 s) before moving to the sorting bin. Based on these events, metrics such as throughput, success rate, and miss rate can be computed using n_success as defined in Equations (1)–(3). To further demonstrate the evaluation workflow, tracking performance was measured by recording the time required for the end-effector to align with a moving target such that the positional error falls below 4 mm. Across multiple trials, an average tracking time of approximately 2.3 s was observed. This result indicates that DT enables consistent evaluation of perception-to-action behaviour under dynamic conveyor conditions.

Under this evaluation, the influence of mesh approximation primarily relates to object footprint, centroid location, and effective grasp width. As meshes are generated directly from annotated polygon boundaries, these planar characteristics are preserved. While fine-scale surface details and complex concavities are not explicitly modelled, their impact is limited for the system-level interaction criteria used in benchmarking.

The mesh generation pipeline is also robust to minor annotation noise. Variations in polygon vertices mainly affect local contour smoothness without significantly altering object footprint or layout. Geometric validation steps, including orientation correction and triangulation checks, ensure stable mesh construction from imperfect annotations. Consequently, the DT is designed for system-level evaluation of perception-to-action behaviour, object localisation, and motion alignment rather than detailed contact dynamics. The use of lightweight proxy meshes enables efficient generation of diverse CDW objects while maintaining sufficient geometric fidelity for reproducible benchmarking.

6 Discussion and Future Integration

The proposed DT framework provides a practical approach for bridging real world waste observations with controllable simulation-based experimentation. By combining RGB driven mesh generation, a Unity-based physics environment, and ROS 2 integration, the system enables repeatable and instrumented evaluation of robotic sorting strategies. Automatic conversion of annotated images into 3D assets eliminates the need for manual modelling and supports rapid generation of diverse scenarios. Together with structured ground truth and event signals, this enables systematic benchmarking that is difficult to achieve in physical experiments.

A key strength of the framework lies in its modular architecture. Asset generation, simulation, and control components are loosely coupled, allowing independent modification of perception, planning, or control modules without altering the environment. This reduces development time and enables fair comparison of alternative approaches under consistent conditions and supports large scale experimentation across varying object layouts, densities, and conveyor dynamics.

Despite these advantages, several limitations remain. The generated meshes are simplified geometric proxies based on polygon extrusion and do not capture fine scale surface details or complex material properties. While this is sufficient for system-level evaluation of perception, localisation, and motion planning, it may limit applicability for detailed grasp contact modelling. In addition, simulation physics cannot fully represent real

world effects such as friction variability or deformability. Therefore, results obtained in the DT should be interpreted as indicative of system-level performance rather than exact predictions of real world behaviour.

Future work will focus on integrating the framework with physical robotic systems and perception pipelines. As both simulated and real setups share the same ROS 2 interfaces, control algorithms developed and tested in the DT can be transferred to the physical robot with minimal modification. Planned extensions include camera-based detection and tracking, implementing grasp planning and scheduling strategies, and conducting closed loop picking experiments on the conveyor. Additional improvements will explore more advanced geometry modelling, domain randomisation of physical parameters, and expansion of the asset library using larger and more diverse datasets.

Overall, the framework provides a scalable foundation for iterative development of AI-driven robotic sorting systems. By enabling safe, repeatable, and data rich experimentation in simulation prior to hardware deployment, the DT reduces integration risk and accelerates the pathway from algorithm design to real world application.

7 Conclusions

This paper presented a DT simulation framework for conveyor-based CDW sorting that integrates RGB driven mesh generation, a Unity-based physics environment, and a ROS 2 communication layer. The system automatically converts annotated RGB images into 3D mesh assets to generate realistic and repeatable sorting scenarios. By coupling data-driven asset generation with real time interaction and structured ground truth, the framework enables systematic benchmarking of perception, scheduling, and manipulation strategies without the cost and risk of physical experimentation. Experimental results confirmed that the mesh generation pipeline operates efficiently, requiring only milliseconds per object, while the Unity simulation maintains stable real time performance across varying conveyor speeds. The framework also supports the evaluation of perception-to-action behaviour and motion alignment under dynamic conditions. Although the meshes are simplified geometric proxies, they preserve key planar characteristics required for benchmarking and are sufficient for system-level evaluation. The modular design supports integration with ROS 2 based algorithms and future deployment on physical robotic platforms, providing a practical and extensible testbed that facilitates rapid development and evaluation of AI-enabled robotic waste sorting systems.

Abstract

Building Information Modeling (BIM) has become a central platform for digital building representation; however, the creation and manipulation of BIM models remain largely manual, and accessible primarily to domain experts. At the same time, architectural information is still commonly produced in 2D drawing formats, creating inefficiencies in translating design intent into semantically rich 3D BIM models. Recent advances in large language models (LLMs) offer new possibilities for natural language–based interaction with complex digital systems, yet their integration with BIM for automated and scalable building modeling is still limited. This research addresses this gap by proposing an automated framework that integrates LLMs with BIM systems to support the transformation of 2D architectural drawings into parametric model generation and manipulation. The framework's capability is demonstrated by using a single-floor architectural plan as input; the system enables the scalable generation of multi-storey buildings. The results indicate that LLM-assisted BIM workflows can significantly reduce manual modeling effort and improve efficiency, while remaining computationally tractable for generating multi-storey buildings. This study demonstrates the potential of LLM–BIM integration as a foundation for more intuitive, efficient, and scalable building modeling workflows.

1 Introduction

Building Information Modeling (BIM) has become a foundational technology for digital building representation and management across the architecture, engineering, and construction (AEC) industry. It is widely regarded as an intelligent, three-dimensional, model-centric process that enables the comprehensive integration of geometric and semantic information across the entire building lifecycle**[1].** By integrating geometric, semantic, and relational information within a unified digital environment, BIM supports improved design coordination, construction planning, and lifecycle management of built assets. As such, BIM has been widely adopted as a central platform for advancing digital transformation in the built environment.

Despite its widespread adoption, the creation and manipulation of BIM models remain largely dependent on manual operations performed within specialized authoring tools. Furthermore, heavily reliant on 2D CAD formats for design communication [2], these processes are time-consuming, require significant domain expertise, and familiarity with software-specific modeling paradigms. Consequently, BIM authoring remains time-consuming, error-prone, and inaccessible to non-expert stakeholders, particularly during the early design stages, where rapid exploration and iteration are crucial.

At the same time, architectural information is still predominantly produced and communicated through two-dimensional (2D) drawings, such as floor plans, sections, and elevations. While these representations effectively convey design intent, they lack the explicit semantic structure and parametric relationships required for downstream BIM-based analysis and automation**[2].** The persistent reliance on 2D documentation creates a disconnect between early-stage design practices and BIM-centric workflows.

Large Language Models (LLMs) provide an opportunity, and a recent review highlights that LLMs in the construction sector demonstrate their high potential, with median accuracies of 89% for building information detection and 91% for auxiliary modeling automation [3]. While earlier studies leveraged LLMs primarily for building information detection[3] and querying 3D spatial relationships through tree-based indexing [4], the contemporary landscape is increasingly defined by generative workflows. Notably, the workflow proposed by[2] orchestrates a multi-agent system to transform abstract textual instructions into imperative Python code for BIM authoring software APIs, enabling the creation

of natively editable models with internal layouts and semantic metadata. Parallel efforts have integrated conversational AI with Visual Programming Languages (VPLs), such as Grasshopper, to allow designers to iterate on forms and materials through natural-language prompts[5][6]. Similarly, [7] proposed the integration of LangGraph and LLM to generate BIM models, and the LSVR-SE workflow demonstrates text-to-BIM conversion for generating compliant Industry Foundation Classes (IFC) files directly from language commands[8].

However, as the field matures, there remains a valuable opportunity to refine the workflows at the technical grounding and orchestration of these generative processes. Existing workflows primarily excel at engaging natural language as input; they often rely on abstract linguistic prompts that may lack the inherent geometric precision and structured data found in existing technical documentation. Furthermore, recent studies indicate that agent-based BIM interactions can remain fragmented, often requiring repetitive re-implementation of core capabilities across different proprietary APIs[9]. This study seeks to build a workflow integrating LLM and BIM to generate BIM models, taking 2D DXF architectural drawings, which provide necessary geometric constraints for professional-grade modelling. Central to this approach is the adoption of the Model Context Protocol (MCP). By utilizing MCP to orchestrate a staged transformation pipeline, this study enables the systematic parsing of 2D primitives and their translation into semantically rich, multi-storey IFC models. The proposed workflow provides an interoperable foundation that moves beyond single-story constraints, offering a scalable bridge between traditional 2D documentation and automated 3D parametric modelling and manipulation.

This research study aims to develop a necessary technical proof-of-concept of a workflow that integrates LLMs with BIM systems to transform the 2D architectural drawings into parametric models. By focusing on the technical feasibility of the proposed integrated workflow, the research study establishes a scalable baseline for automating complex BIM authoring tasks. The proposed framework enables natural language–driven building generation and manipulation, with a specific emphasis on achieving scalability in multi-storey building modeling.

2 Methodology

This study proposes a unified framework integrating LLM with a parametric model from a 2D architectural floor plan. The LLM-driven pipeline for converting two-dimensional DXF architectural drawings into a semantically enriched three-dimensional IFC Building Information Model consists of the LLM orchestrating four core tools: Parse DXF, detect room, Generate IFC, and Create multi-storey building, as shown in Figure 1. Each of these core tools consists of sub-tools such as Read DXF file, followed by Detecting units, normalizing coordinates, and extracting elements, forming a tool Parse DXF as shown in Figure 2.

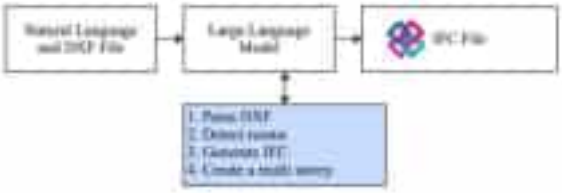

Figure 1. Overview of LLM-driven BIM to automate 2D floor plans into BIM Models

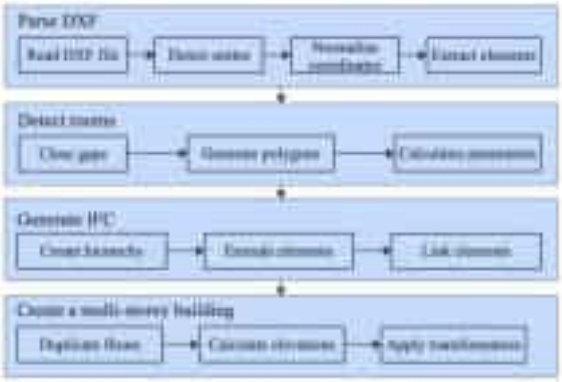

Figure 2. A Detailed Workflow for Generating Multi-Storey BIM Models from DXF Floor Plans

2.1 Parse DXF

This is the first tool that LLM executes in the stack of 4 tools in sequence. In the Parse DXF, the provided DXF file by the user is read with “ezdxf.readfile()” to access the header and model space. Units are detected from $INSUNITS and scaled via “get_dxf_unit_scale()” to millimeters. Layers are mapped using a configurable alias system through “detect_wall_layer_structure()”. Elements (walls, columns, windows, doors, slabs) are extracted with specialized functions, preserving semantic XData (e.g., Revit wall types).

2.2 Detect Rooms

Once the elements are extracted from the parsed DXF, the LLM verifies the outputs and calls wall endpoints, which are connected across small gaps (< 100 mm) at doors/windows, using “_find_and_close_openings()”. Walls are merged and polygonised with Shapely to form a room. Parameters such as wall start and end points, and locations of doors and windows are then returned to the LLM.

2.3 Generate IFC

Standard IFC files are generated through this tool. A standard IFC4 hierarchy (IfcProject → IfcSite → IfcBuilding → IfcBuildingStorey) is created via "create_combined_ifc()". Furthermore, walls are extruded to floor height (default 3000 mm) through IfcWallStandardCase objects. Doors and windows are modelled as IfcOpeningElement voids. All elements are linked to stories to maintain BIM validity.

2.4 Create Multi-storey Building

The generated IFC file is then used to create a multi-storey building as per the user's request. Parameters, such as the number of walls, windows, doors, and the final IFC model, are returned. The ground floor is treated as a reference floor and can be duplicated for the nth stories. The user can also instruct to specifically choose a certain floor to be the reference floor and duplicate it for the nth storey. Each copy is placed at elevation `$Z_i = i \times H\_f$`, with all elements shifted vertically. Specific stories can optionally be replaced with alternate DXF files (e.g., a lobby or penthouse).

2.5 Intent Interpretation Layer

In the intent interpretation layer, the LLM engages in interpreting the user inputs and orchestrates the tools in sequence through the Model Context Protocol (MCP) Standard. The natural-language requests are converted into structured parameters (floor indices, feature flags, heights). LLM callable tools execute functions such as "convert_dxf_to_ifc()" and "create_multi_storey_building()", using the Model Context Protocol (MCP) standard. Inputs are then validated, and structured results with statistics are returned by the LLM to the user.

3 Example demonstration

This section describes the demonstration of the framework proposed to integrate LLM and BIM to generate an IFC file from the 2D floor plan. A DXF file, as shown in Figures 3 and 4 is used as input along with the user request in Figure 5. The DXF file is a layout on an orthogonal alphanumeric grid and uses standard CAD layers for walls, doors, windows, furniture, sanitary fixtures, and stairs. This simple, structured representation is extremely important as it makes it easier for both humans and algorithms to read.

The framework accepts natural language requests alongside 2D DXF floor plans as input. An LLM interprets the user's intent, extracting structured parameters (e.g., number of storeys, floor height, floor swapping specifications) and mapping them to predefined tool functions through MCP configured for Claude code with Sonnet 4.5. From these tools, architectural elements (walls, columns, windows, doors) are extracted through layer-based classification. The final output is an IFC-compliant 3D BIM model, which is compatible with software such as Revit and ArchiCAD, as shown in Figure 5.

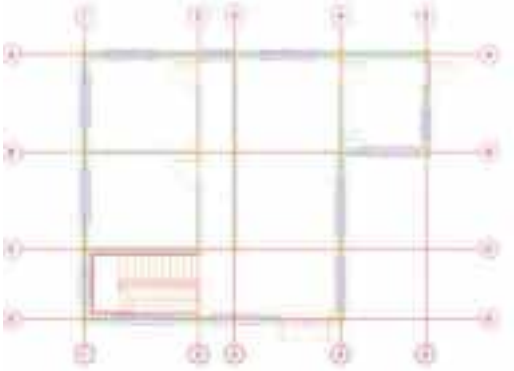

Figure 3. Floor plan 1

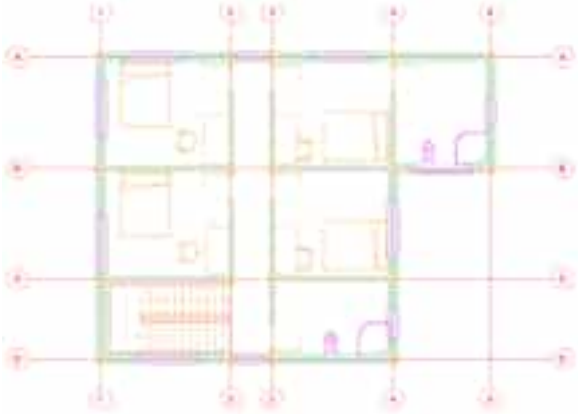

Figure 4. Floor plan 2

Figure 5. User request as input to the LLM to generate the 3D model.

4 Results & Discussions

This section lays out the result of the example demonstrated using the proposed framework to integrate BIM and LLM to generate IFC files from the 2D floor plans. The DXF file (figures 3 and 4), along with the user request, Create a 5-story building with @"../floors/Level 0.dxf" as ground floor and @"../floors/Level 1.dxf" as typical floors. is provided to the LLM to generate an IFC file. The generated IFC file can be viewed through tools such as Revit, ArchiCAD, etc. The IFC file generated in the example demonstration is shown in Figure 6.

Figure 6. IFC 3D Model Viewed In Revit

Figure 7. Three-Stage Generative Modeling Process

The transformation follows a staged pipeline in which geometric primitives are extracted and normalized, processed into element-level representations, and then translated into IFC entities with spatial relationships. This separation enables each element type to be handled using element-specific rules while maintaining IFC schema compliance.

Column entities are extracted during Parse DXF through layer-based classification and converted to IFC columns during IFC generation. The intermediate output (Figure 7(a)) visualizes the extracted vertical elements as isolated volumes at their detected plan locations, providing an immediate check that the layer-based extraction has correctly recovered structural placement before enclosure elements are assembled.

Wall geometry is then reconstructed from the extracted DXF wall elements and is then instantiated in IFC using IfcWallStandardCase objects. In the demonstrated input, the DXF plan is an orthogonal layout using standard CAD naming layers (AIA), which supports reliable extraction and simplifies downstream reconstruction. Table 1 shows how layers are matched to IFC classes. Walls are then extruded to the floor height parameter (default 3000 mm), and all generated elements are linked to their respective storeys to maintain BIM validity. The intermediate wall assembly shown in Figure 7(b) illustrates that the system recovers the external perimeter and internal partitions of the layout with minor inconsistencies with the source drawings.

Openings are handled as semantic voids to preserve IFC validity while delegating solid subtraction to BIM applications. Doors and windows are modelled as IfcOpeningElement voids, and the resulting openings are associated with host walls through standard IFC relationships during IFC generation. The Detect Rooms stage further supports topological consistency by closing wall endpoints across small gaps (< 100 mm) at door and window locations, improving enclosure continuity for downstream interpretation. The final stage shown in Figure 7(c) reflects this semantic modelling choice: openings appear consistently placed within the wall system, and BIM viewers render these voids during visualization.

Table 1. Mapping from AIA CAD naming layer to the Architectural Elements

DXF Layer Name	Architectural Element	IFC Class Generated
A-WALL	Wall	IfcWall
A-COLS	Column	IfcColumn
A-DOOR	Door	IfcDoor
A-WIND	Window	IfcWindow
A-SLAB	Floor slab	IfcSlab
A-STAIR	Stair	Not Generated
A-FURN	Furniture	Not Generated

The integration of natural language input with MCP-based orchestration provides a practical interface for specifying conversion parameters (e.g., storey count and height) without requiring direct interaction with BIM authoring tools. In this example, the produced BIM model preserves the orthogonal layout and storey structure of the source drawings, and the resulting IFC file is usable in standard BIM environments for inspection and further editing.

The proposed proof of concept workflow demonstrates architectural scalability through the automated generation of multi-storey models from 2D floor plan data and text, highlighting that efficiency and accessibility are currently qualitative, based on the reduction of discrete manual modelling steps.

At the same time, the results highlight limitations consistent with the current scope of the pipeline. Performance and accuracy are sensitive to the drawing being structured and layer-disciplined, as assumed by the

layer-based extraction approach used in Parse DXF.

In addition, the current implementation prioritizes orthogonal plan reconstruction (as used in the demonstration), and more complex drafting cases (e.g., diagonal walls, irregular junctions, and inconsistent drafting gaps) require additional geometric reasoning and automated quality checks beyond the current gap-closing strategy. Future work shall focus on expanding geometric coverage (e.g., non-orthogonal walls and junction resolution), increasing semantic enrichment of the exported model while preserving IFC4 compliance, and quantitatively comparing this LLM-assisted approach against traditional BIM authoring workflows for both expert and non-expert users.

5 Conclusion

This research study demonstrates a framework that integrates Large Language Models (LLMs) with Building Information Modeling (BIM) to bridge the gap between 2D architectural floor plans and semantically rich 3D parametric models. By automating the transformation of floor plans into accurate multi-storey representations, the proposed system can significantly reduce time-consuming manual work of building 3D models and reduce reliance on manual labour and specialized expertise traditionally required for BIM authoring. The proposed framework utilizes the capabilities of LLM and orchestrates multiple tools based on the inputs, such as DXF files alongside natural language inputs. The framework automates a staged transformation pipeline—extracting geometric primitives, normalizing element-level representations, and instantiating IFC-compliant entities.

The demonstration results confirm that the system can reliably transform standard 2D layouts into multi-storey IFC models that preserve structural placement, wall perimeters, and semantic relationships such as door and window openings. While the current implementation shows high fidelity for orthogonal, layer-disciplined drawings, it also highlights the necessity for advanced geometric reasoning to handle non-orthogonal layouts and drafting inconsistencies. Furthermore, this study establishes technical feasibility, and quantitative performance metrics shall be employed in future work of this study, with a focus on benchmarking the framework using element detection precision and geometric deviation to provide a statistically significant assessment of its robustness compared to existing non-LLM baselines. Ultimately, this study demonstrates that LLM-assisted BIM workflows can significantly lower the barrier to entry for complex building modeling, providing a scalable and intuitive foundation for future advancements in automated AEC digital transformation.

Abstract –

Precise geolocation of social media is vital for real-time urban flood monitoring. However, researchers are frequently hindered by the scarcity of geotags due to privacy protections and the limitations of coarse localization based on posting frequency, which fails to pinpoint street-level flood sites. We present a robust end-to-end framework that addresses these critical gaps by integrating state-of-the-art Visual Place Recognition (VPR) with a visual evidence verification mechanism. Our pipeline leverages vision foundation models to maintain operational resilience against extreme visual occlusion caused by disasters. To ensure reliability, an inlier-based visual evidence layer is introduced to verify the top-ranked prediction and provide an interpretable confidence cue. This approach establishes a dependable, city-scale monitoring system that bridges the gap between raw social media data and the precise demands of municipal emergency response.

Keywords –

Urban flood; Visual geo-localization; Social media; Situational awareness

1 Introduction

Urban flooding is becoming a persistent stress test for cities as climate change intensifies heavy precipitation events and pushes drainage and transport systems closer to failure [1]. The increasing frequency of intense rainfall heightens the likelihood of cascading disruptions across critical infrastructure and services [2]. Furthermore, current risk management frameworks often struggle when hazards exceed previously experienced magnitudes, leaving emergency operations exposed to unprecedented conditions [3]. From an infrastructure and civil engineering perspective, such events are not only disaster-management issues but also operational challenges for urban resilience. Consequently, rapid, city-wide flood situational awareness is essential to the development of sensing systems and smart, sustainable, resilient cities. While fixed monitoring approaches, such as physical gauges, provide precise measurements, they are spatially sparse and costly to deploy and maintain at scale. Similarly, although satellite remote sensing can expand spatial coverage, optical revisit time constraints often limit the ability to map urban inundation in real time during rapidly evolving events [4,5].

These limitations underscore the need for multi-source data fusion, which supplements traditional monitoring with complementary data streams. Social media serves as a high-velocity stream of Volunteered Geographic Information (VGI), embodying the "citizens as sensors" paradigm, in which individuals act as observers [6]. During disasters, crowdsourced content provides near real-time ground-truth verification, filling critical gaps in sparse official sensor networks [7]. For flood management, visual data complements numerical metrics by capturing the physical reality of hazards, enabling engineers to directly evaluate inundation severity and infrastructure functionality [8, 9]. Therefore, crowdsourced imagery represents a form of opportunistic urban sensing that facilitates infrastructure-aware decision workflows.

However, a critical barrier to integrating this visual data into engineering workflows is the lack of precise geolocation [10]. Due to strict platform policies and growing concerns regarding user privacy, geospatial metadata is often removed from public uploads [11]. Without reliable coordinates, even highly informative photographs cannot be anchored to specific infrastructure assets, isolating visual evidence from location-driven operations such as emergency dispatch and pump deployment [12]. Transforming raw visual information into spatially actionable intelligence is, therefore, a prerequisite for operationalizing social media data within professional infrastructure management systems [13].

Advances in computer vision offer a practical route to operational geolocation via Visual Place Recognition (VPR), which infers coordinates by retrieving the most similar views from a georeferenced street-view database and transferring their associated location priors [14]. The field was notably advanced by NetVLAD, which

introduced trainable aggregation layers for compact global descriptors [15], and more recently by CosPlace, which reframes geo-localization as a classification task to achieve city-wide efficiency without expensive mining [16]. However, these benchmarks predominantly focus on cyclic environmental changes, such as illumination or seasons [17]. In contrast, flooding introduces abrupt visual domain shifts, ranging from submerged roads to complex reflections [18]. Furthermore, raw retrieval accuracy alone cannot support engineering adoption; emergency response requires quantifiable reliability metrics to ensure that location predictions are trustworthy enough to guide operations [19].

This research addresses these gaps by presenting an end-to-end framework for flood image geo-localization from social media imagery, with a specific focus on reliable sensing for resilient urban infrastructure operations. Rather than proposing a new backbone architecture, this study asks a practically important question: which existing VPR paradigms remain reliable under severe flood-induced visual corruption, and how can their predictions be verified before use in human decision workflows? To answer this question, we first benchmark state-of-the-art VPR models against extreme flood scenarios to assess their reliability for street-level localization. To support human-in-the-loop management, a geometric verification layer is added to produce verifiable visual evidence alongside location predictions. This work demonstrates how AI-enabled sensing can be effectively harnessed to support resilient city operations.

2 Methodology

The proposed end-to-end framework for flood situational awareness is illustrated in Figure. 1. This pipeline is designed to transform unstructured social media imagery into actionable engineering intelligence through three interconnected stages. Firstly, the process begins with the data acquisition phase (left panel), where real-time crowdsourced images are captured and referenced against a citywide street-view database. Secondly, the core flood localization module (middle panel) utilizes VPR algorithms to extract query embeddings and perform vector similarity searches, identifying the most probable geographic coordinates from the reference dataset. Lastly, the workflow culminates in the situational awareness stage (right panel), where retrieved locations undergo visual verification to map the flood extent and support municipal decision-making. The specific implementation details of each module are described in the Section 3.1

2.1 Dataset Acquisition and Processing

The city-scale geo-localization framework uses two datasets: a georeferenced database of street-view imagery and a query set of external test images whose locations must be inferred. This study utilizes the San Francisco eXtra Large (SF-XL) dataset as the reference database and evaluates retrieval performance across three separate query datasets whose statistics are summarized in Table 1. Among these query sets, SF-Flood is a newly curated dataset in this study.

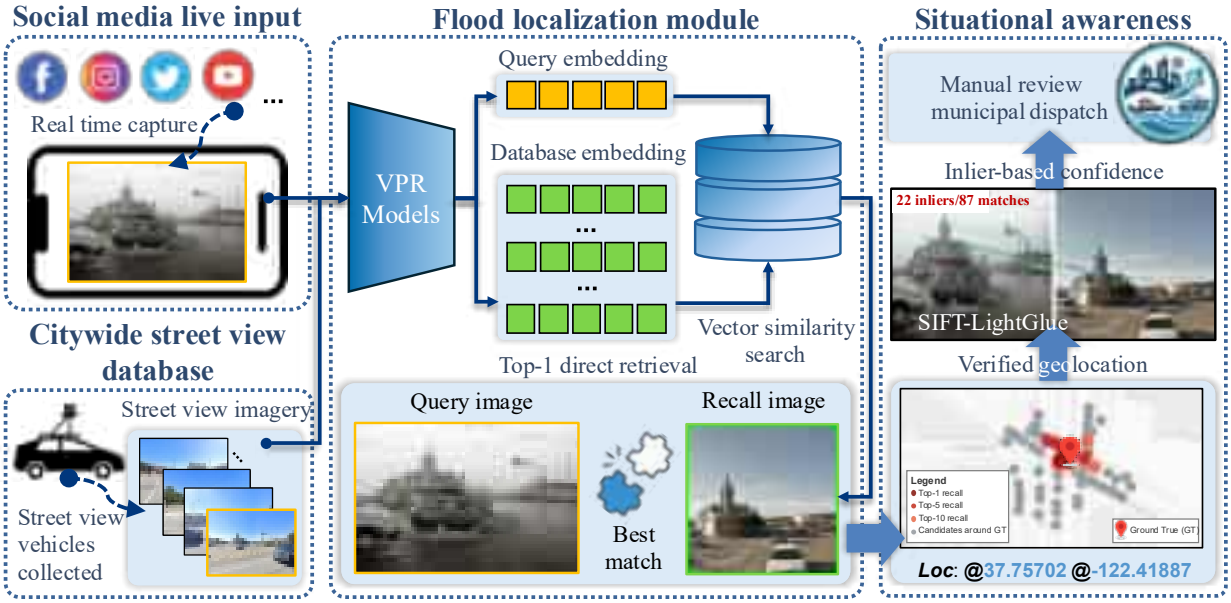

Figure 1. The schematic of the proposed end-to-end framework for urban flood situational awareness. A flood query image is matched against a geo-referenced street-view database using VPR-based descriptor retrieval. The top-1 recalled image provides an initial geolocation estimate, then verified by SIFT-LightGlue matching.

SF-XL, originally introduced by CosPlace [16], is a large-scale open-source street-view benchmark covering San Francisco. The full SF-XL release contains 41.2 million Google Street View panoramas collected across multiple years. In this study, we employ a 2.8 million-image subset as the query set for large-scale retrieval. This choice preserves city-wide spatial coverage and temporal variation, while keeping large-scale vector search computationally viable.

Table 1. Statistics for each subset used in the study.

	SF-XL (Original)	SF-XL test v1 (Test)	SF-XL test v2 (Test)	SF-Flood (Test)
Database	41.2M	2.8M	2.8M	2.8M
Queries		1000	598	400

These sets are designed to benchmark capabilities ranging from general environmental adaptability to extreme disaster resilience:

- **SF-XL Test v1 & v2 :** These serve as baselines for routine localization. v1 contains 1,000 Flickr images representing unconstrained photography [16], while v2 comprises 598 queries from the San Francisco Landmark Dataset [20] with accurate 6-DoF ground truth labels.
- **SF-Flood Dataset:** This specialized query set was curated in this study to evaluate localization under flood-induced domain shifts. Images were crawled from social media and strictly filtered to ensure they contain both visible flood evidence and identifiable geographic anchors (e.g., building façades or road layouts). To ensure the reliability of the 50 m evaluation criterion, each image was manually georeferenced through image-by-image matching in Google Street View. By explicitly incorporating extreme conditions such as water glare, reflections, and nighttime scenes, as illustrated in Figure 2, SF-Flood provides a rigorous stress test for VPR models under severe flood-related appearance changes.

We categorize the query images by their dominant localization challenge into four groups: Rich texture, Low texture, Viewpoint change, and Illumination change. Each image is assigned to the most prominent difficulty source for reporting, as details are shown in Table 2.

Table 2. The index system for crawling and extracting social media images related to flood.

Categories	Number	Definition
Rich texture	146	Repeated or visually similar urban structure; easy to confuse with look-alike locations.
Low texture	108	Low-density or peripheral scene with fewer strong localization anchors.
Viewpoint change	92	Major camera angle or framing change relative to street-view perspective.
Illumination change	54	Appearance dominated by lighting, night scenes, rain haze, or strong reflections.
Total	400	

Figure 2. Examples of images of SF-Flood dataset.

2.2 VPR Mechanism and Evaluated Models

VPR) is formulated as a large-scale image retrieval task. Given a query image I_q and a geo-referenced gallery image I_i, a VPR model $f(\cdot)$ maps each image to a d-dimensional normalized global descriptor:

$$z = f(I), \qquad z \in \mathbb{R}^{\mathbb{d}}, \qquad |z|_2 = 1 \tag{1}$$

Localization is then performed by nearest-neighbor search in the descriptor space using cosine similarity. The best-matched gallery image is obtained by

$$i^* = \arg\max_i \mathrm{z_q^\top z} \tag{2}$$

Where z_q and z_i denote the descriptors of the query image and the i-th gallery image, respectively. The location associated with the best-matched gallery image is taken as the predicted geolocation of the query.

This study evaluates a representative set of global-descriptor VPR methods spanning classic aggregation-based models, scalable classification-based training strategies, modern feature-mixing architectures, and foundation-model backbones. All methods are evaluated using the authors' released architectures and publicly available pretrained weights.

2.3 Reliability Verification and Visualization

While global-descriptor retrieval provides candidate locations, raw similarity alone can be unreliable in flood scenarios because severe appearance changes may lead to visually plausible but spatially incorrect matches.

Therefore, we introduce a post-retrieval verification stage for the top-ranked prediction.

Specifically, local correspondences between the query image and the retrieved image are established through a hybrid matching pipeline. First, Scale-Invariant Feature Transform (SIFT) is used to detect and describe local keypoints [21]. Second, the extracted features are matched using LightGlue [22], a neural feature matcher designed to improve correspondence quality and suppress outliers under challenging visual conditions. This choice is motivated by recent VPR literature, which shows that SIFT-LightGlue is a strong-performing option for post-retrieval verification and that inlier support is an effective indicator of retrieval confidence [23].

In this framework, inlier counts provide an interpretable reliability metric. Verified correspondences are visualized as direct connections, offering a verifiable link that supports manual audits of AI outputs. This stage acts as a confidence-aware module, bridging the gap between automated retrieval and accountable human-in-the-loop decision-making.

3 Experiment and Result

3.1 Experiment setup

To evaluate localization performance, we use Recall@K (R@K) with a success threshold of 50 m. A query is counted as successfully localized at rank K if at least one of the top-K retrieved gallery images lies within 50 m of the ground-truth location. The 50 m threshold is used to represent street-level localization accuracy. In practical terms, this means that the predicted location falls within the correct street or flood vicinity, which is sufficiently precise to help municipal responders perform on-site confirmation. Under this definition, R@1 is the proportion of cases in which the system places the query within 50 m of the true flood location on the first retrieval, while R@10 indicates whether the correct location is included within a short candidate list for follow-up review.

$$R@K = \frac{1}{|Q|}\sum_{q\in Q} 1!\left(\min_{1\le j\le K} d(q, I_j) \le 50\right) \tag{3}$$

Where Q is the query set, I_j is the j-th retrieved gallery image, $d(\cdot)$ is the geodetic distance in meter.

All experiments were conducted in a Linux environment (Ubuntu 22.04, x86-64) using Python 3.12.6, PyTorch 2.5.1, CUDA 12.4, and a single NVIDIA RTX 4090 GPU (24 GB). For global retrieval, images were resized to 224 × 224. For geometric verification, images were resized to 512 × 512 to preserve local structural details for keypoint matching. The number of verified inliers is used as an indicator of prediction reliability. Unless otherwise stated, default hyperparameter settings are used in the geometric verification stage.

Although the present study focuses on retrieval-based evaluation, the ranked candidate list may also support downstream spatial aggregation or map-based clustering analysis for practical deployment. We leave such application-oriented extensions to future work.

3.2 Benchmarking on Flood Scenarios

Table 3 compares VPR performance on two general-purpose query sets (SF-XL test v1/v2) and the flood-specific query set (SF-Flood). On the standard sets, most recent methods achieve high recall, indicating that general urban localization is already relatively mature. For example, Megaloc reaches 95.3% R@1 on SF-XL test v1, while BoQ and DINO-Mix both reach 95.2% R@1 on SF-XL test v2. Even several CNN-based methods remain competitive under these routine conditions.

The picture changes substantially on SF-Flood. Under flood-induced appearance change, conventional global-descriptor methods degrade sharply. NetVLAD drops to 4.2% R@1, while CosPlace and EigenPlaces reach only 16.5% and 20.8%, respectively. MixVPR improves to 35.2%, but still remains far below the best-performing models. These results show that methods that perform well under normal urban conditions may fail when the scene is heavily altered by water coverage, reflections, occlusions, and adverse illumination.

In contrast, methods built on DINOv2 features remain much more robust. On SF-Flood, Megaloc achieves the best performance with 76.8% R@1, 82.8% R@5, 86.5% R@10, and 89.0% R@20, followed by BoQ with 70.5% R@1 and 84.5% R@20. This margin over the strongest CNN-based competitor (53.8% R@1 for ProGEO) suggests that foundation-model descriptors are better able to preserve stable structural cues under severe flood-related appearance change.

From an operational perspective, the result of 76.8% R@1 means that the system can place the query within 50 m of the true flood location in about three out of four cases at the first prediction. In addition, the strong R@10 and R@20 results indicate that the correct location is often contained within a short candidate list, which is useful for human review when the first prediction is uncertain

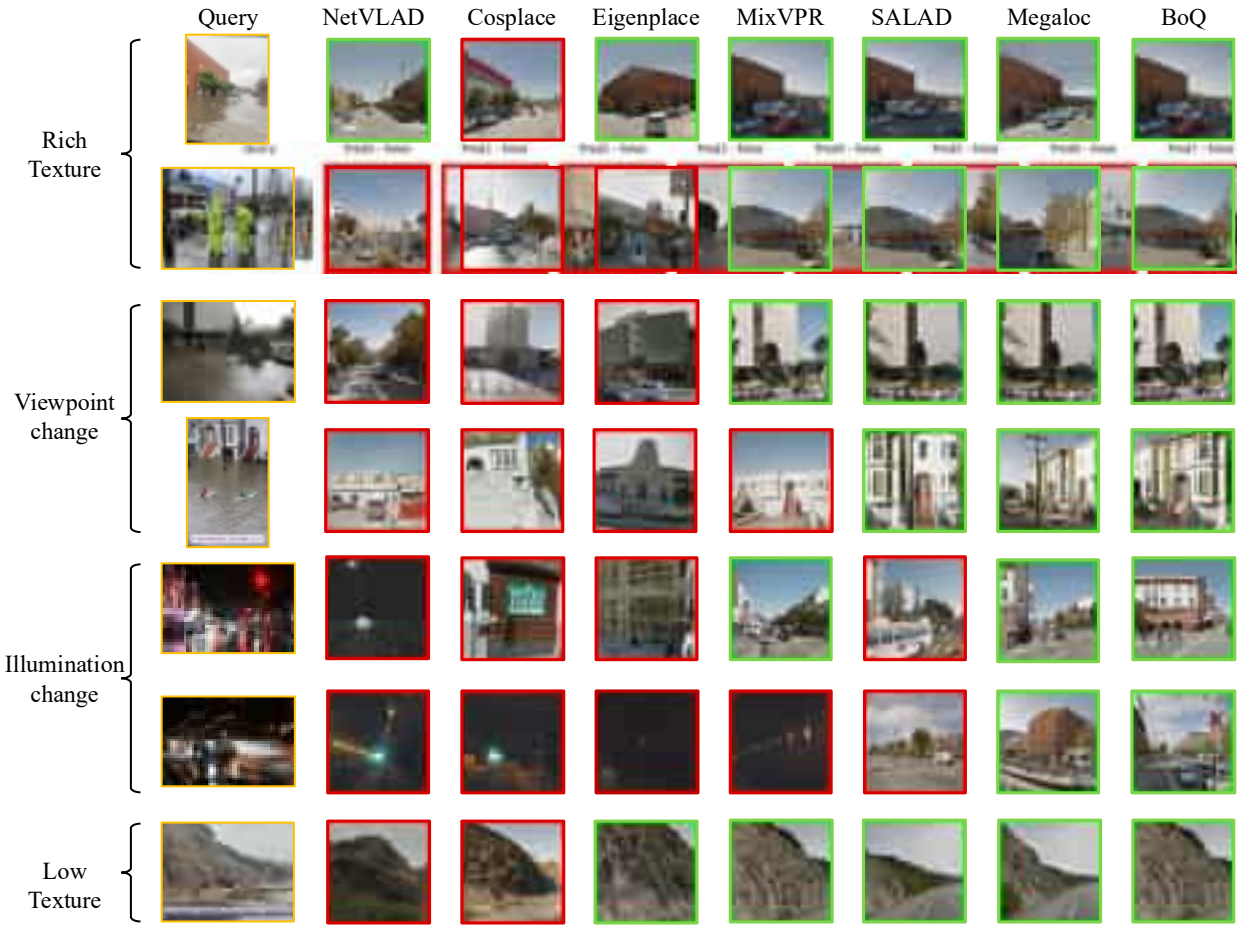

Figure 3. Qualitative retrieval comparison on the SF-Flood dataset under challenging conditions. Green borders indicate correct localizations within 50 meters of the ground truth, while red borders denote failures, illustrating representative mislocalized cases and highlighting failure modes under severe visual ambiguity.

Figure 3 provides qualitative examples under several difficult conditions, including viewpoint changes, nighttime scenes, rich-texture settings, and low-texture settings. In many of these cases, conventional methods retrieve visually similar but incorrect locations, whereas the stronger foundation-model-based methods more often recognize the right place or keep it within the top-ranked list. At the same time, the red-box examples in Figure 3 show that failure cases still remain, especially when visual ambiguity is high. Overall, the results indicate that flood localization is harder than standard urban geo-localization and that foundation-model-based descriptors provide the most reliable retrieval backbone among the methods tested.

3.3 Visual Evidence Validation

Recall metrics summarize retrieval performance at the dataset level, but practical use also requires evidence for whether a prediction is trustworthy. We therefore apply a post-retrieval geometric verification step using SIFT-LightGlue to assess the top-ranked match.

Representative verification examples are shown in Figure 4. Even under floodwater, reflections, nighttime conditions, and partial occlusion, the verified correspondences are concentrated on stable structural elements, such as façades, poles, and traffic infrastructure, rather than transient flood textures. This provides visual evidence for why some heavily degraded queries can still be localized correctly.

Figure 4. Qualitative examples of visual evidence validation.

Figure 5 further quantifies the role of visual evidence extraction. Figure 5(a) shows the localization accuracy within the 50 m threshold across different inlier ranges. All groups maintain relatively high accuracy, indicating that visual evidence is informative for match reliability. Also, the relationship is not monotonic, especially in a sparsely scattered range, which suggests that inlier count should not be interpreted as a universal hard threshold.

Figure 5(b) shows that successful predictions are not only below the 50 meter threshold, but are often concentrated at very small error distances (average 2.4 m), indicating that correct matches are typically spatially close to the ground truth. By contrast, the failed cases form a smaller group (23 cases) above the 50 m threshold and are more common when inlier support is limited. Still, because some correct cases also appear at relatively low inlier counts, the plot does not support a single clean cutoff. Instead, it supports using inlier count as a practical confidence indicator to prioritize stronger matches and flag uncertain ones for review.

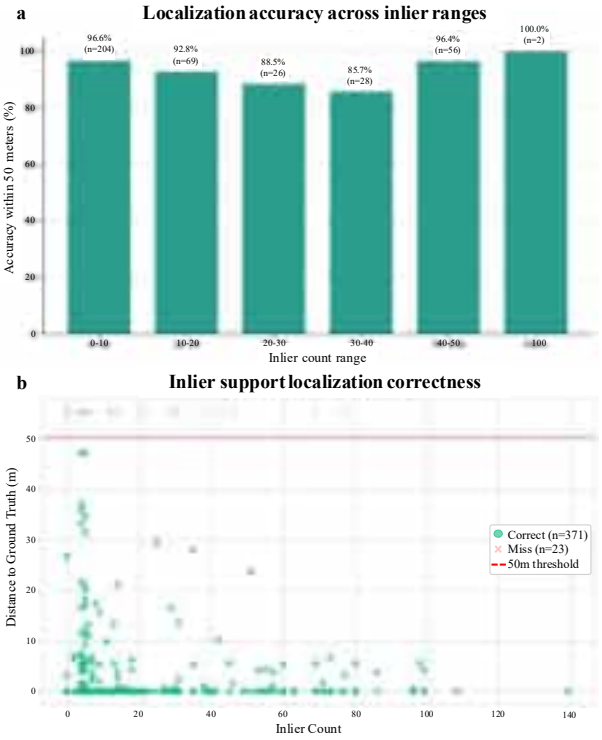

Figure 5. Quantitative analysis of inlier-support visual evidence validation.

This result is consistent with the qualitative examples in Figure 4. Visual evidence verification does not eliminate all failures, but it provides a practical way to distinguish stronger from weaker predictions. In deployment, this makes the retrieved location more interpretable and supports human-in-the-loop review when flood imagery is ambiguous.

4 Discussion and Conclusion

This study presents an end-to-end framework for geo-localizing flood-related social media images, with a focus on reliable sensing for resilient urban infrastructure

operations. Rather than proposing a new VPR backbone, the study addresses a practical question: which existing VPR paradigms remain reliable under severe flood-induced visual disruption, and how can their predictions be verified before entering human decision workflows? The results show that flood scenarios introduce a much harder setting than standard urban benchmarks, and that foundation-model-based descriptors currently provide the most reliable retrieval backbone among the methods tested. More importantly, the added verification stage makes the retrieved result interpretable by attaching explicit visual evidence to the predicted location.

The proposed framework shows how crowdsourced visual data can be transformed into infrastructure-oriented situational awareness, supporting tasks such as rapid identification of affected urban areas and awareness of access routes. In this sense, the study extends social media imagery from online content into an opportunistic sensing layer for urban infrastructure management.

There are several limitations in this study. First, the current evaluation is limited to a single-city case study in San Francisco, and broader validation across cities with different streetscapes, infrastructure conditions, and development contexts remains necessary. Second, the SF-Flood dataset contains 400 query images and, while deliberately designed to include difficult cases such as nighttime scenes, viewpoint changes, and visually degraded flood conditions, it still cannot fully capture the diversity of urban flood imagery. Finally, although the current system is suitable for time-sensitive analysis, lighter verification pipelines and more comprehensive runtime evaluation are still needed for future deployments.

Future work should therefore move in three directions. The first is broader validation, including multi-city testing and more systematic analysis of visually ambiguous urban forms. The second is deployment-oriented refinement, such as lighter matching models and latency tests. The third is multi-modal extension, where visual localization can be combined with textual, temporal, or other contextual signals from social media to improve robustness when image evidence alone is insufficient.

Abstract -

Productivity and disruption monitoring remains a persistent challenge in construction projects. Although digital technologies such as Internet of Things (IoT) sensors, Building Information Modeling (BIM), computer vision, and AI-driven analytics have been introduced, practitioners often lack systematic guidance on aligning these tools with specific monitoring objectives to improve productivity and reduce waste and delays. This study first identifies key productivity measures and disruption indicators. Current digital approaches for capturing these are then clustered into six classes: sensor-based, vision-based, location-based, apps, digitised legacy documents, and audio-based systems. A review of the existing literature is conducted to map the metrics and indicators with suitable digital solutions and assess their maturity. A preliminary case study demonstrates the applicability of the proposed digital solutions in response to monitoring needs. Future work includes developing a decision-support system to select appropriate technologies tailored to monitoring requirements.

Keywords -

Digital solution; Productivity; Disruption; Monitoring

1 Introduction

The construction industry suffers from low productivity growth and persistent schedule and cost overruns that degrade project performance worldwide. Numerous studies have identified that supply chain issues, rework, and disruptions are dominant contributors to poor outcomes [1]. A recent systematic review of construction productivity found that it is shaped by interactions among organisational, technical, and managerial factors, making productivity improvement a persistent industry challenge [2].

Accurate productivity measurement is essential for identifying performance gaps and guiding improvements. Without measurement, inefficiencies remain hidden, causing resource waste, delays, and higher costs [3]. Monitoring productivity enables informed decision-making, helping managers allocate labour and equipment effectively and assess the impact of interventions [2, 4].

Disruption events directly affect construction flow and project performance [5]. Unlike delays, which are typically identified after schedule deviations occur, disruption manifests during execution as interruptions to workflow continuity, resource utilization, and productivity [4]. As such, disruption functions as an early-warning signal; systematic monitoring enables project teams to detect performance degradation before inefficiencies accumulate into delays or cost overruns [6]. However, organisations frequently struggle to establish the structural mechanisms needed to systematically capture, interpret, and act on disruption data, allowing disturbances to propagate into cascading delays [5].

Figure 1. Illustrating the research gap: stakeholders need a tool to support decision-making in selecting appropriate digital solutions for productivity and disruption monitoring across different construction sites.

Monitoring productivity and disruption plays a key role in enabling automation in construction. Real-time measurement provides the basis for identifying opportunities for automation and robotic applications to improve productivity and mitigate disruptions. Building on these data-driven insights, digital solutions can support automated execution and adaptive construction processes. Linking

measurement, decision-making, and automation can significantly enhance project performance.

However, digital monitoring of productivity and disruption faces challenges. Construction firms vary widely in digital maturity, making it difficult to align solutions with capabilities and goals [7]. Unstructured monitoring requirements complicate translation into actionable designs [8]. With the proliferation of ConTech solutions, adoption is often siloed and ad-hoc, lacking systematic evaluation and integration, which limits their ability to generate actionable insights [9]. Therefore, this study addresses the question: How can organisations systematically integrate monitoring requirements with digital solutions to generate data-driven insights for productivity improvement? It proposes a structured approach to help construction companies efficiently select suitable digital solutions, as shown in Fig. 1.

2 Literature Review

2.1 Construction Productivity

Construction productivity refers to the efficiency with which inputs (labour, materials, equipment) are transformed into outputs, commonly expressed as output-to-input ratio and measured as work quantity per unit of labour, time, or cost [10]. Beyond this quantitative ratio, productivity is increasingly understood as dynamic and context-dependent, influenced by work conditions, management practices, and disruptions. Empirical studies have shown that productivity fluctuates in response to changes, interruptions, and cumulative disruption impacts [11]. Contemporary research defines construction productivity as the ability to achieve planned output efficiently whilst minimising productivity losses from disruptions and waste [2, 12]. This definition emphasises real-time measurement of outputs and inputs to accurately reflect execution efficiency under site conditions and inform production planning and control. However, existing research largely focuses on vision-based approaches (i.e., outputs)[13], with limited attention to how other digital technologies can be selected and aligned to simultaneously measure inputs.

2.2 Construction Disruption

Disruption is conceptualised as an unplanned event or condition that adversely affects work execution, resulting in reduced productivity, increased costs, and potential schedule impacts [6]. Disruption is conceptually distinct from delay and waste. Delay refers to time overrun relative to the planned schedule [1]. Whilst disruptions can cause delays, productivity losses may occur without immediately affecting critical path activities. Waste refers to non-value-adding activities consuming resources without contributing to progress [6]. Both delay and waste are often consequences rather than disruptions themselves [2]. As such, a timely detection of disruptions can explain productivity variability and provide site managers with additional insights into performance. Crucially, this is relevant to multi-tiered construction, where agents in the upper tiers (i.e., general contractors) have less visibility into data and outputs from lower tiers (i.e., trade contractors). Disruption is thus a multidimensional performance anomaly manifested through adverse impacts on schedule, productivity, and quality. By identifying and addressing disruptions early, teams can proactively prevent downstream effects. However, disruption monitoring has been less widely addressed than productivity monitoring, partly due to a lack of systematic definitions of disruption causes and associated digital measurement solutions.

2.3 Digital Solutions for Construction Monitoring

Traditional manual monitoring is fragmented and reactive, hindering rapid detection of productivity changes and disruptions. Digital solutions provide real-time, objective, and automated observation via sensors, cameras, and mobile applications. Vision-based approaches using laser scanning and computer vision automate progress monitoring by comparing as-built conditions with planned or BIM-based models [14]. Advances in object recognition and multi-object tracking enable detailed activity-level assessments [13, 15], providing a basis for the project status information digital twin construction [16]. Real-time locating systems (RTLS) using UWB and BLE monitor movement and interaction of workers, equipment, and materials, enabling quantitative analysis of workflow, space utilisation, and non-productive time [17]. Such approaches provide critical inputs for understanding disruption mechanisms related to congestion, waiting, and out-of-sequence work. In addition, mobile devices facilitate on-site data collection and decision support [18]. IoT frameworks enable the integration of heterogeneous data sources for real-time project performance analysis [19]. Audio-based monitoring has emerged as a viable alternative when visual sensing is constrained. Research has investigated the use of ambient sounds and machine learning to identify activities, equipment operation, and safety-critical events [20]. Despite the wide range of options for capturing real-time data, selecting suitable digital solutions tailored to specific requirements remains challenging for stakeholders lacking sufficient technology knowledge.

As the industry moves toward real-time monitoring of productivity and disruptions, the lack of unified disruption indicators creates uncertainty in selecting appropriate digital solutions [8, 13]. In this study, disruption indicators are defined as quantifiable measures captured and analysed

in real-time to support data-driven decision-making, and digital solutions as purpose-built systems integrating one or more technologies for tasks such as data collection, processing, storage, and performance visualisation. Despite extensive research on individual technologies, no framework systematically links productivity measures and disruption indicators to multiple digital solutions; this study addresses that gap.

3 Methodology

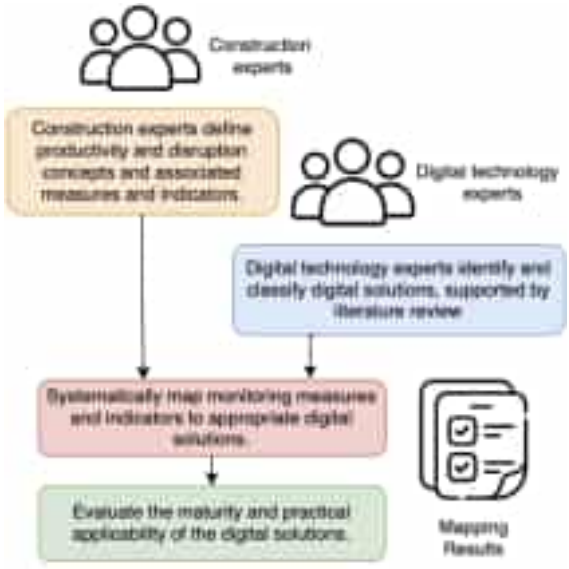

Figure 2. Overview of the proposed methodology.

The overall methodology comprises four key steps, integrating inputs from construction experts and digital technology experts, as illustrated in Fig. 2.

1. *Definition and identification of productivity measures and disruption indicators:* This step involves construction experts defining productivity and disruption concepts, along with associated measures and indicators, supported by evidence from multiple case studies in UK-based projects [4]. To explain variability in production and productivity, it was necessary to standardise data collection on blockers to productivity, which are here defined as disruptions. An initial list of disruptions was derived from Rathnayake and Middleton [2], piloted across three projects, and refined through multiple cycles of industry engagement. Three construction engineering experts were involved in this process.

2. *Identification and classification of digital solutions for data collection:* This step involves digital technology experts identifying and classifying available digital solutions for construction monitoring, supported by a literature review of major construction journals. The literature search was conducted using databases including Scopus, Web of Science, and Google Scholar, with keywords such as "construction monitoring", "productivity monitoring", "disruption", "digital construction", and "computer vision". Approximately 100 key papers were identified through database searches and subsequently selected based on relevance through expert screening (see Section 2.3). These technologies include those capable of capturing visual, spatial, acoustic, and other physical data. Based on the type of data collected and their applicability to monitoring productivity and disruptions, the solutions were grouped into categories to maintain a manageable level of abstraction. This classification enables users to first identify suitable solution types and then refine application details.

3. *Mapping productivity measures and disruption indicators to digital solutions:* This step systematically maps productivity measures and disruption indicators to the most appropriate digital solution types for monitoring. The mapping was conducted through close collaboration between construction professionals and digital technology experts, ensuring alignment between monitoring objectives and technological capabilities. The resulting mapping provides a structured framework for evaluating the suitability of digital solutions for specific monitoring goals.

4. *Evaluation of maturity and practical applicability of digital solutions:* The final step evaluates the maturity and practical applicability of the identified digital solutions. This includes assessing technological readiness, accuracy, scalability, cost, and operational feasibility. Understanding the strengths and limitations of each solution type provides a foundation for selecting appropriate monitoring strategies and supports the effective deployment of digital solutions in practice.

Overall, this study integrates knowledge from construction and digital technology experts to bridge the gap between the requirements for real-time monitoring of productivity and disruptions and the widespread availability of digital solutions that are often underutilised or ineffectively selected in construction projects. It provides a foundation for developing a structured approach that links monitoring requirements to the development and deployment of digital solutions in construction.

Table 1. Types of digital solutions for productivity and disruption monitoring.

Solution Type	Description	Examples
Sensor-based Monitoring Systems	Use of IoT-enabled sensors to collect real-time data related to equipment condition, environmental parameters, and worker activities.	Equipment condition monitoring; process monitoring; energy usage monitoring
Vision-based Monitoring Systems	Use of cameras or laser scanners to observe site activities, detect events, and track construction progress.	Progress monitoring; working conditions monitoring; automated quality inspection
Location-based Tracking Systems	Technologies such as GPS, RFID, or BLE used for real-time tracking of workers, equipment, and materials on construction sites.	Inventory tracking and status updates; tool and equipment tracking and assignment
Web-based / Mobile Applications	Web- or mobile-accessible user interfaces for data entry, storage, analysis, and visualisation.	Visualisation of financial KPIs; sales tracking; progress payment tracking; integrated change management and issue reporting between design and construction
Digitised Legacy Documents	Conversion of legacy documents (e.g., handwritten notes, PDFs, word documents, spreadsheets) into structured digital formats.	Digitalisation of printed labour task allocation sheets into structured digital records
Audio-based Monitoring Systems	Use of microphones and acoustic analysis techniques to capture and interpret sound patterns from machines, environments, or workflows for monitoring and anomaly detection.	Detection of abnormal machine noises; noise-level compliance monitoring; identification of process issues through sound patterns; recording managerial instructions or voice logs

4 Results

4.1 Productivity Measures

Three productivity metrics were defined: production rates (output/duration) and labour productivity (output/worker-hour), and cost-effectiveness (output/cost) for both planned and actual values. The output is measured as progress, which refers to the amount of work completed over time, such as the number of square meters constructed each day [21, 15]. Inputs are measured using labour data, which can be monitored by recording labour hours or workforce utilisation on each activity or work package [22]. Cost can be tracked by estimating expenditures and resource consumption over time [10, 6].

Two additional measures are derived from the programme and BIM models. The programme provides the planned duration for activities and work packages per location, while BIM models provide the planned quantities over time, and serves as a baseline for monitoring progress and productivity [23]. Together, these measures enable real-time monitoring of productivity metrics and allow comparison with planned values.

4.2 Disruption Indicators

Compared to productivity, construction disruption lacks consistent measurement metrics. Unlike traditional disruption measures used in claims analysis or post-event evaluation [24], our indicators are designed to support continuous monitoring through digital solutions, enabling early detection of emerging disruptions.

The resulting indicator set is organized into ten major categories: labour, materials, equipment, planning, logistics, health and safety, design and constructability, quality, weather, and external factors. These indicators span multiple dimensions of project performance. Labour-related indicators capture workforce availability and efficiency losses [22], while material and equipment indicators reflect interruptions in resource flow [10]. Planning and logistics indicators represent workflow reliability and spatial constraints [21], and design and quality indicators capture upstream information gaps and rework-related disturbances [6]. Weather and external indicators account for exogenous shocks affecting site operations [1]. This multidimensional structure supports a system-level understanding of disruption as a dynamic production anomaly rather than a single, isolated event.

We further divided them into 33 monitoring indicators, as shown in Section 4.5. These indicators specify information that enables digital solutions to directly detect and monitor events during execution, as detailed in the subsequent mapping sections.

4.3 Classification of Digital Solutions

In Section 2.3, we reviewed digital solutions for construction monitoring and further classified these techniques into six solution categories, as shown in Table 1. These solution types include sensor-based monitoring systems, vision-based systems, location-based tracking systems, web-based and mobile applications, digitised legacy documents [25], and audio-based monitoring systems. A

Table 2. Mapping of productivity measures to digital solution types (H = High maturity, M = Medium maturity, L = Low maturity).

Productivity Measure	Sensor	Vision	Location	Apps	Digitised Documents	Audio
Progress	M	H		H	M	L
Labour	H	M	M	H	M	L
Cost				H		
Planned duration (from programme)				H		
Planned quantity (from BIM model)				H		

detailed description of each solution type is provided in Table 1. This classification also builds on the work of Yilmaz et al. [26], who identified 58 digital solution areas for construction SMEs through eight interactive workshops with 70 UK SMEs. By organising these solutions into the six categories presented here, we cover most of the 58 solution areas identified by Yilmaz et al. [26], some of which are provided as examples in Table 1.

To further evaluate the applicability of these digital solutions, we define three maturity levels as follows: High maturity technologies are well-established, commercially available, and easily integrated into existing workflows. Medium maturity technologies are technically feasible and validated in pilot studies but require configuration, integration, or specialist expertise and are not yet widely adopted. Low maturity technologies are experimental, primarily at the prototype or conceptual stage, and require further development and validation before reliable application in construction projects.

4.4 Mapping of Digital Solution to Productivity Monitoring

Table 2 presents the mapping of construction productivity measures to different categories of digital solutions, along with their corresponding maturity level. Progress data are most effectively captured using vision-based and application-based solutions (H), whereas audio-based monitoring remains at a low maturity level (L). However, voice logging is an emerging area of development. Labour data can be monitored efficiently with sensor- and application-based systems (H), while location- and vision-based systems provide medium-level support. Cost, programme, and BIM model data are primarily supported by high-maturity, application-based solutions, reflecting the widespread use of integrated project management software in industry practice.

4.5 Mapping of Digital Solution to Disruption Monitoring

Table 3 presents a detailed mapping of 33 disruption indicators to appropriate digital solution types, classified by maturity levels. Compared to productivity measures, disruption indicators capture deviations in workflow execution, requiring targeted monitoring approaches for early detection.

Software applications represent high-maturity solutions widely used in construction, from which most disruption indicators can be derived. However, their reliance on manual input may delay early warnings, and AI-driven analysis is needed to extract critical information from large datasets. Sensor-based systems are mature for monitoring equipment, materials, and weather-related disruptions, while wearable sensors such as IMUs are emerging for labour activity monitoring. Tracking technologies are well established for logistics disruptions and show further potential in material, equipment, and safety tracking (e.g., detecting workers in hazardous zones). Vision-based systems are widely applied to site monitoring but depend heavily on advanced AI and are sensitive to occlusion and lighting conditions; their role in disruption monitoring is expected to grow as reliability improves. Application-based solutions provide broad coverage but are limited by data latency from manual input, while digitisation and AI-based document analysis can unlock valuable information from legacy data. Audio-based monitoring is less common and primarily used for equipment anomaly detection; however, advances in voice logging may allow abnormal work patterns to be recorded efficiently.

5 Preliminary Study

A preliminary study was conducted with a construction company on a recent project. Productivity had previously been recorded manually and calculated monthly or over longer periods using spreadsheets. Although the company sought more real-time monitoring, it lacked awareness of suitable digital solutions, making technology selection difficult. Using the mapping table developed in this study, the company's monitoring needs were systematically linked to relevant digital solution types, enabling a more structured and objective selection process.

After further criteria-based discussions, several solutions were selected and implemented. Two CCTV systems were deployed to capture image data, and progress information was extracted using an advanced segmentation approach (SAM2 [27]). This selection was guided by the mapping framework, which identified vision-based so-

Table 3. Mapping of disruption indicators to digital solution types (H = High maturity, M = Medium maturity, L = Low maturity).

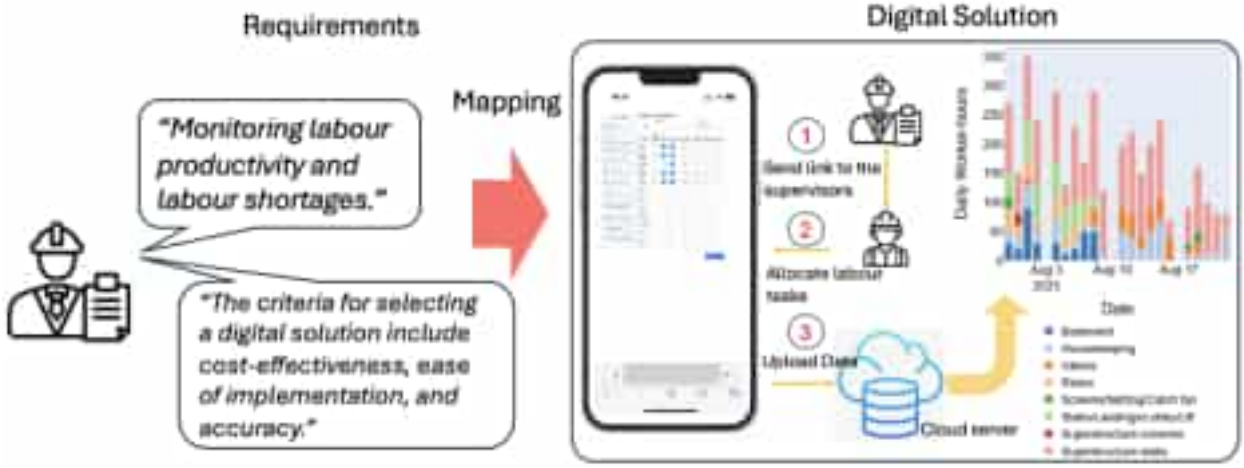

Figure 3. Case study of labour productivity and disruption monitoring.

lutions as suitable for progress monitoring due to their high maturity and ability to capture output-related data. Due to space constraints, detailed methodology and results will be reported in a future publication.

Labour data was initially captured through the turnstile system, which only records site entry and exit and does not capture task-level activity information for labour productivity measurement. A web application was developed and deployed on a cloud server (see Fig. 3). Each working day, site managers assigned activities to construction crews, while supervisors used the system to allocate tasks to workers. The application allowed supervisors to monitor labour input for each activity and to send messages reporting labour shortages for specific activities or task re-allocations to managers. This approach addressed a key disruption indicator, labour shortage, by enabling daily visibility of workforce allocation and deviations from planned activities.

The web application has been in use on-site for over two months. Data collected through the system has been successfully used to monitor daily labour productivity. Alerts can be generated by supervisors to identify potential disruptions caused by labour shortages, enabling site managers to reallocate labour accordingly. During the preliminary study, positive feedback from the company confirmed that the initial requirements of productivity monitoring had been met. Furthermore, the use case demonstrates how the proposed mapping framework supports construction managers in selecting and deploying digital solutions by linking monitoring requirements with appropriate technologies. The daily collected data also enabled timely decision-making, such as reallocating labour tasks.

However, disruption measurement of labour shortage using the web application relies on manual input and does not support fully real-time or automated monitoring. Location-based tracking systems may enable more automated and real-time disruption detection in the future, although their maturity remains limited. The mapping also highlights potential research directions for industry implementation.

6 Discussion and Conclusion

This paper proposes a structured mapping approach of digital solutions for productivity measurement. To achieve this, we first identified the key productivity measures and disruption indicators. The various digital solutions were then clustered into six groups to facilitate straightforward mapping. Based on this framework, two mapping tables were created, and the maturity of the available digital solutions was evaluated. A preliminary study was conducted to gather user requirements, apply the mapping tables, and select and deploy the most suitable solution. This approach provides a practical guideline for construction companies to efficiently deploy digital solutions for monitoring productivity and disruptions.

However, the mapping tables require further refinement through additional pilot studies and by linking to a broader range of off-the-shelf solutions. Further work is also needed to deepen disruption-focused analysis and validate the effectiveness of these solutions through additional case studies. The selection criteria can be enhanced by incorporating additional factors to support improved decision-making.

Finally, the proposed framework can be developed into a decision support tool that leverages the mapping tables and selection criteria to make solution selection more objective and automated. By enabling the systematic selection of sensing and monitoring solutions, the framework supports reliable data collection and digitalisation, providing a foundation for construction automation, including data-driven decision-making and robotic applications.

Acknowledgments

We would like to thank Trimble for funding this research and our industry partners for their continued engagement.

Abstract -

Infrared thermography is a widely adopted non-destructive technique for infrastructure inspection, enabling the detection of defects such as thermal bridges, insulation deficiencies, moisture accumulation, and material degradation. In recent years, the use of this technique alongside Unmanned Aerial Vehicles (UAVs) has attracted growing interest due to their ability to access hard-to-reach areas such as facades and bridges. This work presents an automatised workflow for the efficient acquisition of facade temperature fields using UAVs. RGB imagery is employed to perform Structure-from-Motion and camera pose estimation, which is then used to reconstruct radiance fields of the facade surface. Radiometric calibration is performed using reference temperature probes, allowing the reconstruction of absolute temperature fields from raw infrared imagery. The proposed method enables the direct integration of calibrated thermal fields into Building Information Models (BIM), providing per-component thermal information for detailed inspection and data analysis. A practical case study on a multi-material facade demonstrates the workflow, highlighting its potential to enhance preventive maintenance and support energy-efficiency evaluations.

1 Introduction

Infrared thermography has become a widely used non-destructive technique for the condition assessment of building facades, as it enables the detection of surface-temperature anomalies without physical contact [1, 2]. By measuring the spatial distribution of thermal radiation emitted by facade materials, the method can reveal a wide range of defects that may go unnoticed during visual inspections, including thermal bridges, insulation deficiencies, moisture accumulation, air leakage, and areas of material degradation [3, 4]. These anomalies are closely related to energy efficiency and structural integrity, making thermal imaging an effective tool for the preventive maintenance of built infrastructure [5].

Traditionally, facade inspections have been carried out by trained personnel using cranes, scaffolding, or specialised elevated platforms to access different areas of the structure and collect imagery. However, these methods are not only costly and time-consuming but also expose workers to significant risks associated with working at height [6]. To overcome these limitations, the use of Unmanned Aerial Vehicles (UAVs) has increased significantly in recent years. These platforms can be equipped with infrared cameras and complementary sensors, enabling the rapid, and efficient acquisition of data in hard-to-reach locations [7, 8, 9]. Furthermore, through the use of photogrammetric techniques, UAV imagery can be processed to generate high-resolution orthomosaics and detailed 3D reconstructions, thereby facilitating the integration of thermal and visual data within Building Information Models (BIM).

Although photogrammetry is well established for visual imagery, its direct application to infrared data remains challenging due to the lower spatial resolution of thermal cameras and the difficulty of identifying Ground Control Points (GCPs) in thermal images [10, 11]. To address this issue, several studies employ targets made of materials with contrasting emissivity or reflectivity as GCPs, which are easily detectable in infrared imagery. These targets are typically combined with high-accuracy positioning systems such as RTK-GNSS or terrestrial laser scanning to obtain precise reference coordinates [12]. While effective, this approach can be impractical for facade inspection because placing and surveying the targets at significant heights is often difficult and unsafe.

Conversely, other methods reconstruct the scene by combining RGB and infrared imagery. The RGB images are used to detect reference features such as corners or edges, which are then associated with their corresponding 3D coordinates [13, 14]. A Perspective-n-Point (PnP) approach is employed to estimate the camera poses, and the known relative transformation between the RGB and infrared cameras is used to project thermal textures onto

the 3D model. Commercial software packages such as Agisoft Metashape and Pix4Dmapper currently support this workflow [15, 16]. However, their integration with BIM environments remains limited. Although they produce 3D reconstructions with mapped thermal textures, these results do not allow for the direct analysis of individual facade components. In addition, the thermal textures correspond to raw radiance values measured by the sensor, which require radiometric calibration to recover the actual temperature field. In light of these limitations, this work presents an IR inspection pipeline for reconstructing facade temperature fields using UAVs. The main contributions are as follows:

1. **Radiometric calibration:** Using a temperature probe and a set of radiometric control points, the proposed method reconstructs absolute temperature fields from raw infrared imagery.

2. **Direct integration with BIM:** The workflow enables the direct incorporation of calibrated temperature fields into BIM models, providing per-component thermal information that facilitates detailed inspection and data analysis.

The remainder of this article is structured as follows. Section 2 outlines the methodology used to reconstruct the facade temperature field, Section 3 presents and analyses the results, and Section 4 summarises the main findings.

2 Methodology

Figure 1 presents the workflow diagram of this work. First, experimental data are acquired, including UAV imagery, ground control point (GCP) data, and thermal reference point data of the building facade (Section 2.1). Next, this information is processed to perform structure-from-motion reconstruction and compute all camera poses (Section 2.2). Finally, the thermal field is calculated and integrated into the BIM reference frame (Section 2.3).

Figure 1. Thermal field reconstruction workflow.

2.1 Experimental data acquisition

As a practical case study, the facade shown in Figure 2 is selected for the IR inspection. It is a flat wall with different surface finishes and materials, as well as windows and a roof with varying reflectivity properties, which makes it particularly suitable for IR inspections. The facility is located in Ourense and belongs to Misturas SA, a company with which the University of Vigo collaborates through the RADIANCE project to develop intelligent robotic solutions in construction.

Figure 2. Facade chosen for the study.

To relate the camera poses to the BIM model, the positions of the Ground Control Points (GCPs) were first surveyed using a Leica DISTO X6 laser rangefinder [17] mounted on a Leica DST 360-X station. The DST 360-X includes a calibrated inclinometer and a horizontal encoder, allowing the direct measurement of 3D points with centimetre-level accuracy. Using this setup, the 3D coordinates of all window corners were recorded, providing a total of 20 GCPs distributed across the facade surface.

For the RGB and thermal data acquisition procedure, a UAV-based approach was chosen for practicality given the height of the building, for which a DJI Matrice 300 was employed. This UAV is equipped with a Zenmuse H20T hybrid camera system, which enables the synchronised acquisition of both RGB and infrared (IR) imagery. Table 1 summarises the main specifications of this imaging system. As shown, the visible-light sensor provides substantially higher resolution and a wider field of view, which facilitates the identification of GCPs and improves the accuracy of the camera pose estimation.

Table 1. Zenmuse H20T hybrid camera specifications according to the manufacturer [18].

RGB Wide Camera	
Sensor	1/2.3” CMOS, 12 MP
Resolution	4056×3040
Spectral Band	Visible spectrum
DFOV	82.9°
Focal Length	4.5 mm (24 mm eq.)
Aperture	f/2.8
Thermal IR Camera	
Sensor	Uncooled VOx Microbolometer
Resolution	640×512 (16 bit, R-JPEG)
Spectral Band	8–14 μm
DFOV	40.6°
Focal Length	13.5 mm (58 mm eq.)
Aperture	f/1.0
Temperature Range	-40°C–150°C (HG)

With this set-up, a survey of the facade was conducted. Photogrammetry on vertical structures presents several

challenges for path planning, particularly due to the absence of a reference plane for defining parallel trajectories. For this reason, the survey was performed manually by following a zigzag flight pattern at a stand-off distance of 5 m from the building. A total of 1,300 images were captured at 0.5 m intervals to ensure sufficiently high overlap for computing the Structure from Motion (SfM) of the scene. Image acquisition was synchronised, allowing the IR and RGB images to be correlated, and their timestamps were recorded in a .txt file.

2.2 Camera Pose estimation

For the camera pose estimation, Agisoft Metashape software is used. First, Ground Control Points (GCPs) are manually annotated within the images, and their corresponding 3D coordinates, measured independently, are input into the software. Using this information, the Structure from Motion (SfM) of the images is computed. The software applies feature extraction algorithms to detect distinctive points in the images, which are then matched and correlated across overlapping photos to compute the 3D camera poses (position and orientation).

All data are expressed in the reference frame of the DISTO X6 rangefinder, whose origin and orientation are defined by the base reference station. To integrate this information within the BIM model, the 3D point cloud derived from Metashape is used to compute the coordinate transformation. First, a coarse registration is performed by aligning corresponding point pairs from the BIM geometry and the point cloud. Reference points, such as corners and window locations, are manually selected in both geometries, and a rigid transformation is computed to align the two datasets. To further improve the registration, the Iterative Closest Point (ICP) algorithm is applied to locally refine the alignment and maximise the overlap between the two geometries. Once these transformations are computed, the camera poses in the BIM reference frame are obtained, as illustrated in Figure 3. Note that the displayed geometry corresponds to the BIM 3D model rather than the photogrammetry point cloud; the point clouds are used solely to align the camera poses within the BIM reference frame.

To verify the reconstruction accuracy, the Root Mean Square Error (RMSE) in the fitting of GCPs was measured in Metashape, yielding a value of 2.8 cm. Overall, all camera poses could be computed with high precision, which minimises projection errors in the IR imagery. As both cameras are mounted in a rigid dual-camera setup, the resulting pixel errors in the IR projections are expected to be on the same order of magnitude, which is highly accurate given the resolution of the thermal imagery. This result was achieved thanks to the precise measurement of GCPs with a laser system and the presence of textured, recognisable patterns on the building facade, which facilitated the SfM calculation.

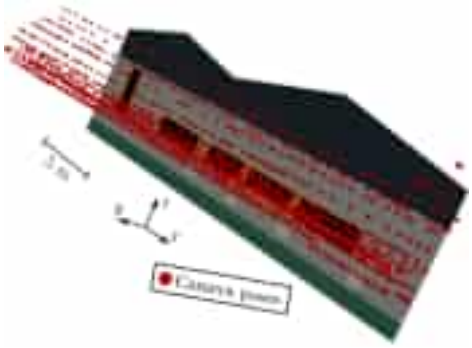

Figure 3. 3D camera-pose estimation using Agisoft Metashape. Red dots indicate the camera poses next to the BIM geometry.

Although this approach requires photogrammetry post-processing, its main advantage is the high accuracy of camera pose estimation, which minimises projection errors in the reconstructed temperature field. Furthermore, because the sensors are synchronised, the pose of the IR camera can be computed automatically from the RGB camera, streamlining the reconstruction workflow.

Alternative approaches, such as LiDAR, do not allow for direct pose calculation because they do not acquire data in a shutter-like manner, which complicates sensor synchronisation. Instead, LiDAR sensors steer infrared beams continuously, recording returns over multiple timestamps during each scan sweep. Another limitation is that the geometric accuracy of LiDAR strongly depends on precise navigation or SLAM systems for point cloud motion correction. To prevent potential drifts that could cause geometric distortions, GNSS RTK systems are typically required. However, these systems are highly susceptible to GNSS signal occlusions and multipath effects, which can be particularly limiting during close-range inspections where accurate positioning is critical. Furthermore, the geometric accuracy of lightweight LiDAR sensors—commonly mounted on UAVs—is generally comparable to, or even lower than, that of photogrammetry, with RMSE values typically on the order of a few centimetres [19].

2.3 Thermal field reconstruction

For the thermal field reconstruction, the surface of the BIM model is rasterised at a 3 cm resolution. For each point, denoted as $\mathbf{X}^i_{\mathrm{BIM}}$, the corresponding radiance values from the IR images are extracted using a pinhole camera model. First, the coordinates of each point are expressed in the camera reference frame using Equation (1):

$$\mathbf{X_c}^{i,j} = \begin{bmatrix} X_c^{i,j} \\ Y_c^{i,j} \\ Z_c^{i,j} \end{bmatrix} = \mathbf{R}^j \, \mathbf{X}^i_{\mathrm{BIM}} + \mathbf{t}^j . + \begin{bmatrix} d \\ 0 \\ 0 \end{bmatrix} \qquad (1)$$

where:

- $\mathbf{X_c}^{i,j}$ are the coordinates of $\mathbf{X}^i_{\text{BIM}}$ in the reference frame of camera pose j.
- $\mathbf{R}^j$ and $\mathbf{t}^j$ are the rotation matrix and translation vector associated with camera pose j.
- d is a translation constant equal to 4.5 cm. Note that the camera poses computed in Section 2.2 correspond to the RGB sensor. In the Zenmuse H20T, the IR sensor is aligned with the RGB camera but is spatially separated, as shown in Figure 4.

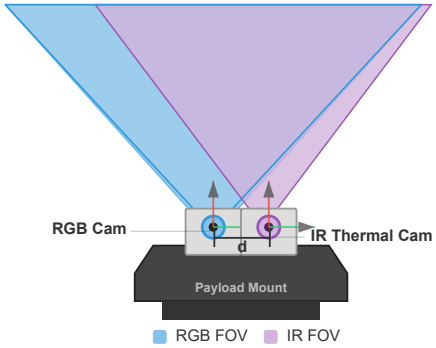

Figure 4. Layout of the Zenmuse H20T. The IR and RGB sensors are aligned along the camera's x-axis but are separated by a distance d.

The corresponding pixel coordinates $u^{i,j}$ and $v^{i,j}$ are then obtained using Equation (2):

$$u^{i,j} = f\frac{X_c^{i,j}}{Z_c^{i,j}} + c_x, \qquad v^{i,j} = f\frac{Y_c^{i,j}}{Z_c^{i,j}} + c_y, \tag{2}$$

where f is the focal length of the camera in pixel units, and c_x and c_y are the coordinates of the principal point (optical centre) on the image plane. All these quantities are derived from the specifications listed in Table 1.

For each pixel coordinate, the following verifications are performed to ensure projection robustness:

1. **Incidence angle filter.** Using the facade STL mesh derived from the Metashape photogrammetry reconstruction, the surface normal vector $\mathbf{n}$ at each facade point $\mathbf{X}_{\text{STL}}$ is obtained. For each camera position $\mathbf{t}^j$, the viewing direction vector is defined as

$$\mathbf{d} = \mathbf{t}^j - \mathbf{X}_{\text{STL}}. \tag{3}$$

The incidence angle θ is computed as

$$\cos\theta = \frac{\mathbf{n}\cdot\mathbf{d}}{\|\mathbf{d}\|}. \tag{4}$$

To ensure robustness with respect to normal orientation, the absolute value is considered. A sample is accepted only if

$$|\cos\theta| \geq \cos(\theta_{\min}) = 0.5, \tag{5}$$

which corresponds to a maximum allowable incidence angle of $\theta_{\max} = 60°$. This condition rejects grazing views, which are more sensitive to emissivity effects, ensuring that camera viewing directions are approximately perpendicular to the facade surface.

2. **Visibility / self-occlusion test.** For each valid projection, defined by the direction vector $\mathbf{d}$ and camera pose $\mathbf{t}^j$, a visibility check is performed using the Möller-Trumbore algorithm. Ray-triangle intersection tests are carried out with the STL mesh obtained from the photogrammetric reconstruction, removing projections that fall on occluded regions.

Only the values of $u^{i,j}$ and $v^{i,j}$ that satisfy these conditions are retained, and the corresponding radiance values are extracted from the infrared images. The average radiance at each facade point is then computed. Note that only camera poses for which the point lies within the camera field of view are considered in this calculation.

To obtain absolute temperature fields, reference temperature values are sampled at the facade points shown in Figure 5 using a contact probe Testo 720. The measurements are performed manually by directly recording the in-situ temperature at each point (Figure 6). Thermal paste is applied to ensure good thermal contact with the surface, thereby improving the accuracy of the probe readings. Measured temperatures are correlated with IR camera radiance values at the same locations, and linear regression is used to obtain the absolute temperature fields of the facade surface.

Figure 5. Probe contact point location across the facade surface

Note that this approach assumes uniform thermal emissivity across the facade surface. While this simplification is convenient, it may introduce temperature measurement errors in cases where the facade exhibits significant variations in emissivity, as is typically the case for glass surfaces such as windows. However, since the majority of the surface consists of concrete—with relatively uniform optical properties—and given that the primary focus of the inspection is on this material (as windows provide limited relevant information), a simple linear calibration was deemed appropriate for this case study. Nevertheless, for buildings with more heterogeneous material compositions, the proposed methodology could be extended by

incorporating material-specific calibration procedures for different facade elements.

Figure 6. Reference temperature sampling using a Testo 720 probe.

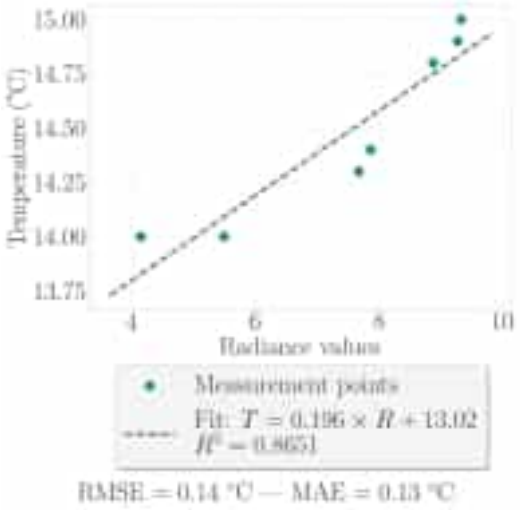

Figure 7. IR camera calibration. A linear regression is employed to correlate radiance values with absolute temperatures measured with the probe.

3 Results

Figure 7 shows the results of the IR-camera calibration (Section 2.3), obtained using the absolute temperature values measured by the contact probe. The probe measurements and the average radiance recorded by the IR camera over the rasterised facade surface deviate to some extent from the fitted line. However, this scatter is expected and consistent with typical error sources in IR imagery [20, 21]. Differences in emissivity among facade materials, sensor noise, and temperature variations during the acquisition can fully explain the observed deviations, which are on the order of several tenths of a degree. Nevertheless, the data still exhibits a reasonable linear correlation, with an R^2 coefficient of 0.8651. The fitted line indicates that temperature changes only slightly with radiance, with a slope of 0.196 and an intercept of 13.02. A Root Mean Square Error (RMSE) of 0.14ºC between the adjusted line is obtained, a fairly accurate value. These differences can be attributed to several factors, including sensor noise, temperature variations between probe sampling and image acquisition, or measurement errors.

Figure 8 shows the reconstructed temperature field of the facade overlaid with the semantic surface segmentation of the BIM model. Overall, the temperature remains nearly constant across the facade wall, with only minor variations of a couple of degrees near the upper left and right corners. These differences are likely due to measurement errors from the IR camera. In these corners, the camera was pointing in the direction of the sun, and this radiation may have affected the readings.

Although the different facade components are made of materials with varying absorption coefficients, the facade remained in the shade during the inspection and in the preceding hours of the morning, which explains the observed uniformity in the temperature field.

For the integration of inspection data within standardised BIM formats such as IFC, the semantically segmented facade components are mapped to BIM-native entities, creating a structured, object-based representation of the building envelope. In this framework, thermographic analysis can be used to detect potential deficiencies, such as localised thermal anomalies, which are then associated with the corresponding BIM elements. When identified, these deficiencies can be incorporated as property sets linked to the affected objects, optionally including their spatial coordinates. This enriched, object-level representation enables the integration of inspection results into a unified BIM model, supporting condition assessment and maintenance workflows while ensuring interoperability.

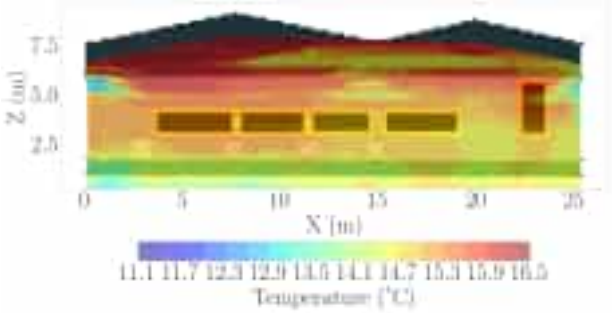

Figure 8. Overlay of the facade temperature field on the components of the BIM model.

Figure 9 displays a histogram of the temperature distribution across the raster points of the facade. As shown, most points remain at a temperature of around 15 °C, with

only a few outliers reaching values as low as 12 °C. However, the frequency of these outliers is minimal and, as discussed previously, they can likely be attributed to IR measurement errors. Overall, the temperature field remains uniform, and no insulation deficiencies or moisture accumulation issues are observed.

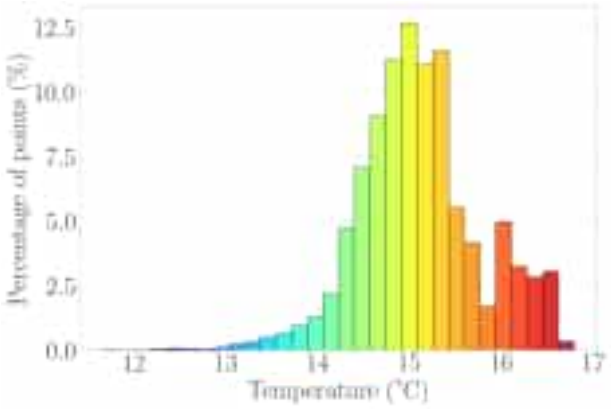

Figure 9. Histogram of the facade temperature distribution.

To verify the consistency of the results, the reconstructed temperature field is compared with the air temperature at the time of the inspection. Table 2 shows the air temperature during the inspection, retrieved from a nearby meteorological station managed by MeteoGalicia in Ourense [22], the region's main meteorological agency. The station is situated within the University of Vigo campus, at a distance of approximately 1 km from the inspected building facade. As shown, the air temperature remained within 15–16 ºC during the inspection, which is consistent with the measured temperature field.

Table 2. Temperature measurements from MeteoGalicia's station on 06/11/2025 [22].

Time	**Temperature (°C)**
12:00:00	14.92
12:10:00	15.00
12:20:00	15.20
12:30:00	16.20
12:40:00	16.66
12:50:00	15.86
13:00:00	15.62

Figure 10 shows the number of viewing cameras at each point of the projected raster model. As observed, the distribution of viewing cameras is not uniform, since the facade inspection was conducted by manually piloting the UAV. To improve inspection uniformity, automatic path planning tools could be employed. In general, however, almost all raster points exhibit a high camera count. During the facade survey, a total of 1,433 images of the wall were captured (Figure 3), resulting in a high level of overlap between photographs.

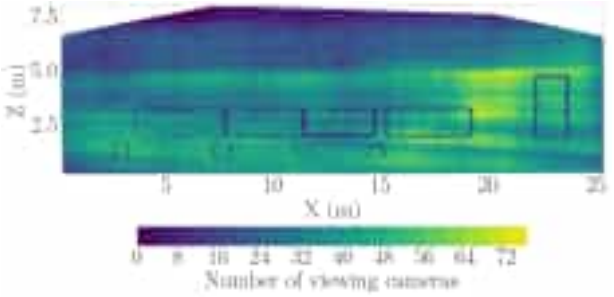

Figure 10. 2D map of the number of cameras viewing the facade surface.

Figure 11 presents a histogram of the distribution of viewing cameras. Most points are observed by 10 or more cameras, with an average of 36.76 viewpoints across the facade surface. Only in isolated cases does the camera count fall below 10, primarily at points near the building roof where fewer images of the facade were acquired. This highlights one of the main advantages of UAV imagery over traditional methods: up to thousands of images of the entire facade can be captured in just a few minutes, significantly reducing both inspection time and the associated operational risk.

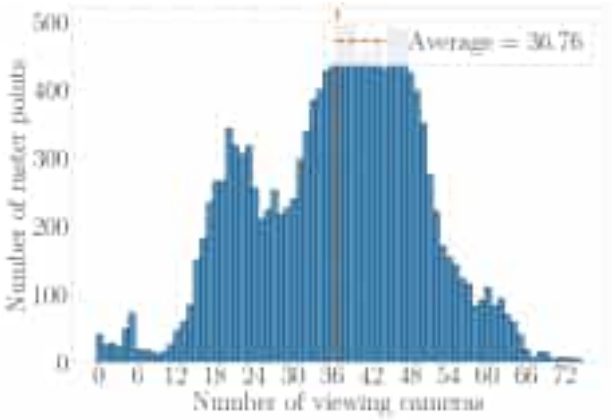

Figure 11. Histogram of the number of cameras viewing the facade.

4 Conclusions

This work presents an automated workflow for the efficient reconstruction of facade temperature fields using UAVs. Visual imagery is used to perform Structure-from-Motion and estimate camera poses, and this information is then employed to project IR radiance fields onto a BIM model of the structure. Absolute temperature values are

obtained through a radiometric calibration using contact probes. To validate the proposed approach, a case study was conducted in Ourense, where a temperature field of the facade was reconstructed and segmented according to the BIM model surfaces. Overall, a uniform temperature field was observed, as the inspected wall was in the shade. The results were also consistent with the air temperature values recorded at a nearby meteorological station, further supporting the validity of the method.

In future work, the methodology will be integrated with path planning and autonomous navigation systems to enable more efficient and fully automated facade inspections. Additionally, artificial intelligence algorithms will be incorporated for automatic defect detection, and the approach will be validated on facades exhibiting moisture, thermal bridges, and insulation deficiencies to quantify the accuracy of the proposed pipeline. Inspections of facades under sunlight exposure will also be conducted to assess the impact of solar radiation on the measured temperature values and the accuracy of insulation defect detection, thereby further validating the methodology under varied environmental conditions.

Abstract –

Modular Construction Manufacturing (MCM) has attracted considerable attention in recent years due to its potential to increase productivity, minimize waste, and improve the predictability of building projects. Despite these benefits, effective coordination and real-time information exchange among multiple stakeholders in the delivery of modular construction remains a significant challenge, particularly in managing production line data for module components. Current data-sharing practices in MCM are often fragmented and rely on manual reporting, leading to inconsistencies, limited traceability, and reduced trust among stakeholders. To address these challenges, this paper introduces a permissioned blockchain method for MCM. The proposed method includes: *(i)* network design, *(ii)* smart contract development, and *(iii)* transaction execution and evaluation. A smart contract (chaincode) is developed to automate the creation, updating, and querying of production data, while enforcing validation rules and access control exclusively among participating stakeholders. The blockchain network is established with two peer organizations representing key stakeholders to facilitate decentralized transaction endorsement. This method ensures consistent ledger synchronization, strengthens data integrity, and provides tamper-resistant and traceable documentation of module component records throughout the production line. The implementation of the proposed method utilizing the wall panel production line data confirms the feasibility of permissioned blockchain-enabled information management in MCM and highlight its potential to support more transparent, reliable, and collaborative production workflows. In addition, it protects data privacy by allowing only authorized project members to participate in and maintain the network.

Keywords – Modular Construction; Blockchain; Hyperledger Fabric; Smart Contracts; Production Data Management

1 Introduction

Modular construction has emerged as a transformative approach within the construction industry, offering significant advantages over conventional construction. By shifting major construction activities to a controlled factory environment, modular construction enhances production efficiency and reduces production line waste (e.g., worker waiting time) [1-2]. In particular, Modular Construction Manufacturing (MCM) enables standardized fabrication of module components (e.g., wall panels) in the production line, supporting higher levels of automation and repeatability [3]. This construction process has become increasingly relevant as governments and industry pursue scalable and sustainable solutions to address housing shortages [4]. Despite its benefits, the MCM process is characterized by fragmented information flows and limited interoperability between stakeholders [5].

Production line managers and on-site supervisors often maintain independent systems to record and exchange information, resulting in inconsistencies and duplicate records. These inefficiencies become more pronounced when stakeholders participate in multiple projects. Considering the dynamic nature of the production line, which requires frequent changes in production line planning (i.e., change orders), and delays/inaccuracies in sharing these module components production information (e.g., estimated process time of module components) propagate downstream, affecting production line planning, on-site assembly sequencing, and project makespan [6]. Moreover, the success of MCM relies heavily on the accuracy, transparency, and coordination of production line information (e.g., start and finish time of module components) shared among multiple stakeholders (e.g., production line manager and on-site supervisor).

The modular construction industry requires a reliable, tamper-proof mechanism to capture and share production data in real time across all participating stakeholders (e.g., production line managers and on-site supervisors). Such an approach must ensure trust, traceability, and data

integrity without relying on a centralized system. In this regard, Blockchain has been proposed as a promising solution due to its decentralized architecture, immutability, and built-in consensus mechanisms [7]. Studies have examined blockchain applications in supply chain management, smart contracts for construction payments, and document management for construction applications [8-10]. However, most prior works focus on conceptual frameworks and overall supply chain-level applications, with limited research demonstrating practical blockchain deployment specifically for production-level applications in modular construction. In addition, there is a notable gap in operational prototypes that integrate blockchain with actual production data, smart contract logic, and multi-stakeholders within an MCM environment. Considering the broader adoption of blockchain in the MCM production line, it is necessary to test its potential benefits with a case study. In particular, a smart contract should be designed and implemented to demonstrate its potential to efficiently manage and share production line data to improve the MCM production line process. To address these gaps, this paper proposed a Hyperledger Fabric-based blockchain method for MCM. The proposed method consists of the following procedures: (i) creating a blockchain architecture tailored for MCM, (ii) developing a smart contract for managing module component data, and (iii) evaluating the proposed blockchain method through transaction execution and ledger validation using a MCM case study. The contributions of this study include: (i) a permissioned blockchain network with peer organizations representing key stakeholders (i.e., production line manager and on-site supervisor) in the MCM; and (ii) a custom smart contract (chaincode) is developed to record, query, and manage module components information, ensuring authorized project members to participate in the network and tamper-resistant information management and exchange. It is worth mentioning that Hyperledger Fabric is chosen due to the following reasons: (i) it protects data privacy by allowing only authorized project members to participate in and maintain the network; and (ii) it is an extensible open-source platform that users can customize according to their needs [8].

2 Literature Review

2.1 Blockchain Technology in Construction

Blockchain has recently emerged as a transformative technology that can enhance transparency, trust, and data integrity in construction projects. As a decentralized and immutable ledger system, blockchain enables distributed parties to record transactions securely without relying on centralized authorities [11]. Early construction-oriented studies highlight blockchain's potential benefits in supply chain, contract administration, and automated payment mechanisms [12]. Moreover, blockchain's ability to ensure tamper-proof and auditable records aligns with the construction industry's need for verifiable information exchanges among fragmented stakeholders [13]. However, most blockchain research in construction focuses on supply chains and payment automation, with limited work at the production-line level in modular construction. Moreover, many studies propose conceptual frameworks rather than operational prototypes, and research on permissioned blockchains, such as Hyperledger Fabric in a modular construction production line environment, is limited.

2.2 Digital Technologies for Modular Construction

Modular construction relies heavily on digital technologies to support precision, standardization, and coordination. Building Information Modeling (BIM) enhances design integration and clash detection, enabling improved off-site fabrication planning [14]. Likewise, cloud-based platforms also facilitate data sharing and decision-making across the modular construction lifecycle [15]. Despite these advances, digital systems in MCM often operate as isolated platforms controlled by single organizations, resulting in fragmented and inconsistent production data. Studies note persistent issues, including a lack of interoperability, limited trust in shared information, and difficulty maintaining accurate records across stakeholders [16]. These challenges highlight the need for decentralized solutions that can complement BIM and cloud systems by ensuring secure, tamper-resistant, multi-party data integration.

2.3 Blockchain Adoption for Manufacturing and Modular Construction

Manufacturing research highlights blockchain's role in enabling transparent production monitoring, machine-to-machine communication, and component traceability [17]. Smart contracts have been used to automate quality checks, material verification, and workflow approvals, demonstrating the potential for blockchain to enhance cyber–physical coordination in factory environments [8-10]. Modular construction shares similar challenges with general manufacturing, such as multi-stakeholder interactions, frequent design changes, and strict quality control requirements. In this regard, Blockchain has been proposed as a suitable enabler for secure data exchanges between manufacturers, suppliers, and contractors [9]. However, most existing studies remain conceptual, and few have developed and tested blockchain solutions integrated with real modular production data. In addition, there is a gap in end-to-end blockchain prototypes demonstrating live transactions for module components (e.g., wall panels) production line data.

3 Proposed Method

This paper adopts a structured method to design, implement, and validate a blockchain-enabled information management method for modular construction manufacturing (MCM). As illustrated in Figure 1, the proposed method consists of three main steps: (i) network design; (ii) smart contract (chaincode) development and deployment; and (iii) transaction execution and evaluation. The proposed method begins by designing a permissioned blockchain network (i.e., Hyperledger Fabric) tailored to the MCM process. Subsequently, smart contracts are developed to automate module components (e.g., wall panel) production data transactions (e.g., estimated process time). Finally, the proposed system is evaluated through transaction execution and ledger evaluation.

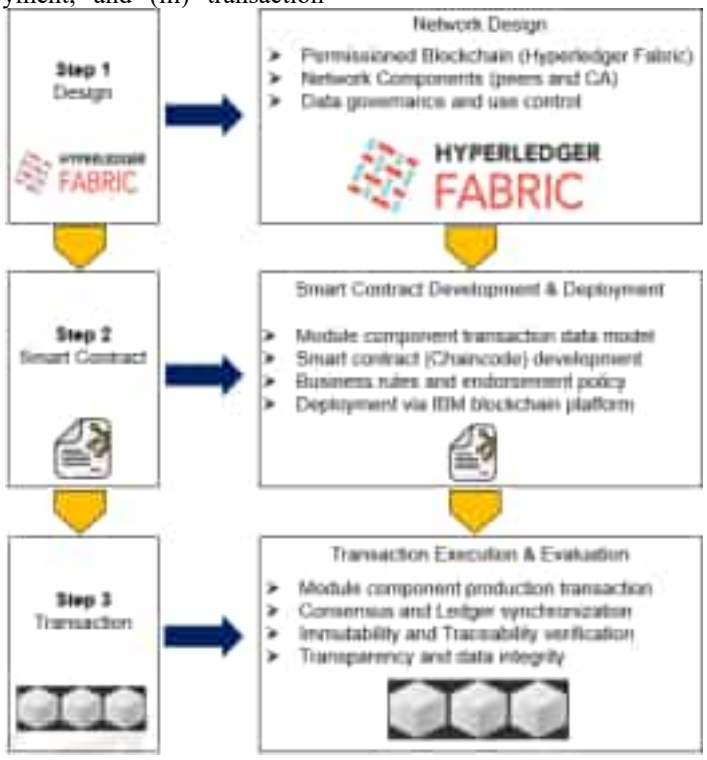

Fig. 1: Overview of the proposed Hyperledger Fabric-based blockchain method for MCM

3.1 Network Design

The first step focuses on designing a blockchain network that supports a secure, transparent, and multi-stakeholder information exchange in MCM. The prefabrication process of module components (e.g., wall panels) was selected as the target use case due to its repetitive nature and reliance on accurate production data. A permissioned blockchain architecture was adopted to ensure controlled access and data privacy among participating stakeholders (e.g., production line manager and on-site supervisor). Core network components, such as peer nodes, channels, ordering services, and certificate authorities (CA), are defined to enable secure identity management, transaction ordering, and ledger synchronization. In addition, data governance rules and access permissions were established to govern the recording, sharing, and querying of production information within the network. This design ensures that production data remain tamper-proof, traceable, and accessible only to authorized participants; thereby addressing common information fragmentation challenges in current MCM.

3.2 Smart Contract Development

The proposed blockchain method incorporates a set of smart contract components to regulate information exchange and data governance in MCM, as illustrated in Figure 2**.** These components are implemented as executable smart contracts (chaincode) on a permissioned blockchain network and designed to manage participant access, record production line transactions, and support secure data querying. Authorized stakeholders, including the production line manager and on-site supervisor, are registered through a certificate authority (CA) and assigned predefined roles to ensure controlled access to production data. Production-related transactions for module components,

such as process time, are validated against predefined endorsement policies and recorded on the distributed ledger following consensus. In addition, query functions are provided to enable authorized participants to retrieve real-time and historical production information without permitting data modification. By formalizing access rules within smart contracts, the proposed components enhance transparency, traceability, and data integrity while eliminating reliance on centralized information management systems.

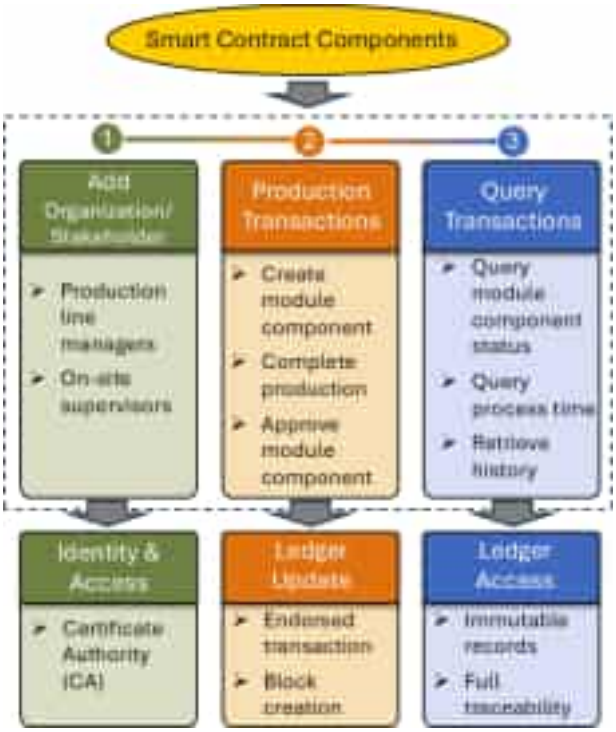

Fig. 2: Proposed smart contract components for MCM

As shown in Figure 3, smart contracts were developed to encode manufacturing business rules governing the creation, update, and querying of module components (e.g., wall panel ID). These contracts ensure that production information is recorded in a consistent and standardized manner while enforcing predefined validation rules. Endorsement policies were specified to require transaction approval from relevant stakeholders (i.e., production line manager and on-site supervisor) before records are committed to the distributed ledger. The blockchain network and smart contract were deployed using the IBM Blockchain platform, which provides a graphical interface for configuring Hyperledger Fabric infrastructure. The deployment process included: (i) installing the smart contract on both organization peers; (ii) approving the chaincode definition to reach endorsement consensus; (iii) committing the chaincode to the channel, making it operational; and (iv) instantiating the ledger to begin recording production transactions. Additionally, the module component data (e.g., number of studs, windows, start and finish times of module components at the workstation) used in the blockchain environment was collected utilizing an RFID system. The process times (i.e., the time required to complete one module component at a given workstation) are extracted using Equation 1:

$$PT\,m,w = IRT\,m,w+1 - IRT\,m,w \qquad (1)$$

Where PT is the process time of module component ID “m” at current workstation “w”, “w+1” is the next workstation, and IRT is the initial read time of the module component at a given workstation of the production line. The process times are initiated as transactions in the smart contract using a deep neural network (DNN) based prediction model [18]. Hyperparameter tuning—the process of identifying optimum parameters (i.e., number of hidden layers, number of neurons, learning rate and momentum) is performed by employing a genetic algorithm (GA). The optimization objective is to minimize the model's prediction error (i.e., MAE), as expressed in Equation 2:

$$MAE = \frac{\Sigma^{n}_{i=1} |A_i - P_i|}{n} \qquad (2)$$

Where Ai is the actual process time of a module component, and Pi is the predicted process time of a module component. A detailed discussion of the developed prediction model is beyond the scope of this paper and is reported in a paper by Bhatia et al. [18].

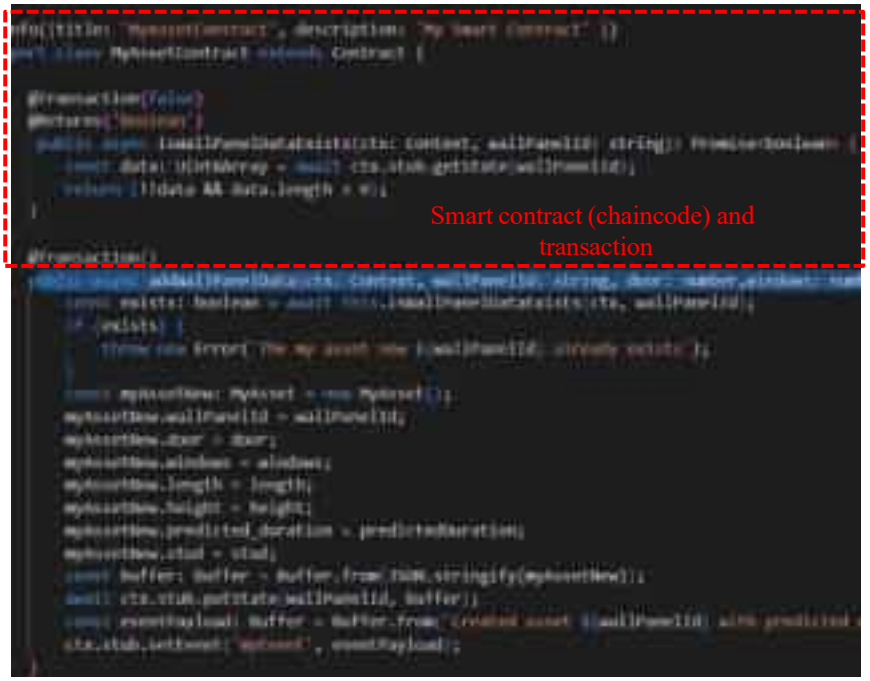

Fig. 3: Snippet of the Smart Contract

3.3 Transaction Execution and Evaluation

The final step evaluates the blockchain network through transaction execution utilizing a case study. Blockchain transactions corresponding to module components information (e.g., number of doors and windows) were executed to simulate real-time manufacturing operations. These transactions were endorsed by peer nodes, ordered into blocks, and committed to the distributed ledger in accordance with the defined consensus mechanism. When transactions were submitted, peers endorsed the transaction according to the network policy, and the ordering service generated a new block. Ledger synchronization across peer nodes was examined to verify the consistency and immutability of recorded production data. The traceability of wall panel records was assessed by querying historical transactions and validating their resistance to unauthorized modification. The evaluation focuses on the system's ability to enhance transparency, ensure data integrity, and support trustworthy information sharing among stakeholders. This demonstrates the feasibility of applying blockchain technology to MCM and highlights its potential to improve information reliability and coordination across production environment.

4 Case Study

The proposed method utilized data from a wood-frame wall panel production line in Edmonton, Canada. The production line consists of framing station, sheathing station, multifunction bridge, window/door installation lines, where windows/doors are installed on the wall panels and transferred to the wall magazine line (i.e., storage area). Process times at workstations were collected by the modular fabricator company using an RFID system. The data for the workstations includes the time between July 2015 and August 2018. As such, it contains 416,950 timestamps (i.e., start and finish times) for wall panels at various workstations and design attributes (e.g., number of studs and number of windows), for a total of 93,660 wall panels. A detailed discussion of the RFID data and the development of predictive model is beyond the scope of this paper and is reported in papers by Altaf et al. [1] and Bhatia et al. [18]. The objective of the case study is to demonstrate the application of the proposed method by deploying smart contracts, transaction execution and validation through data querying to retrieve immutable production line data of a wall panel production line.

Figure 4 illustrates the deployment of the proposed smart contract within a Hyperledger Fabric network using the IBM Blockchain platform. The smart contract definition, including its name and version, was deployed to a dedicated blockchain channel (i.e., Blockchain-4) and approved by two peer nodes (e.g., Org 1 Peer representing production line manager) operated by separate blockchain organizations. Deploying the smart contract across multiple peers ensures that transaction execution and ledger updates are jointly validated in accordance with predefined endorsement policies. This configuration establishes decentralized trust, prevents unilateral data modification, and enables consistent synchronization of wall panel production data across participating stakeholders (i.e., production line manager and on-site supervisor).

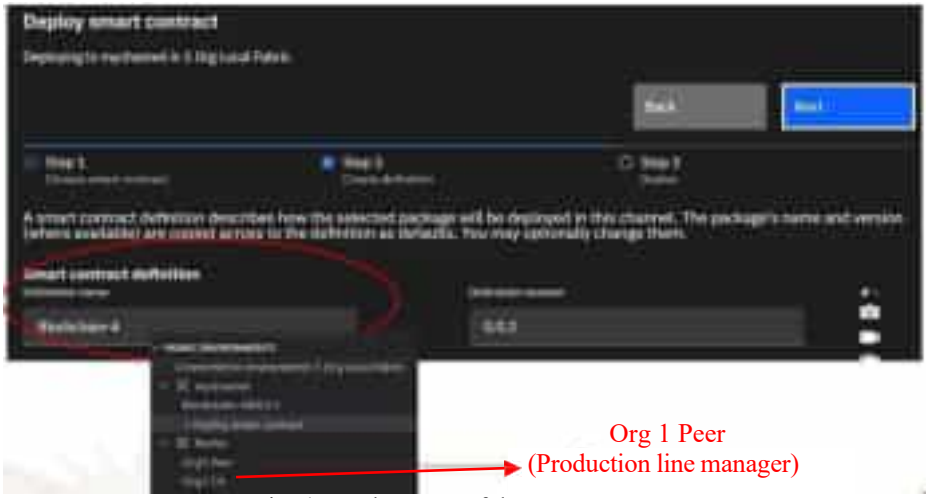

Fig. 4: Deployment of the smart contract

Following smart contract deployment, blockchain transactions were executed in response to wall panel production events. Figure 5 presents the invocation of a smart contract transaction, where a specific 'Wall Panel ID' is submitted as an input parameter. For example, the user submitted 'Wall Panel ID:7' to generate the wall panel information. The submission of this identifier represents the occurrence of a manufacturing event associated with the corresponding wall panel. Upon submission, the transaction is endorsed by peer nodes and committed to the distributed ledger following the defined consensus mechanism. This process demonstrates that physical production events in MCM are translated into blockchain transactions, enabling real-time and tamper-resistant recording of manufacturing activities.

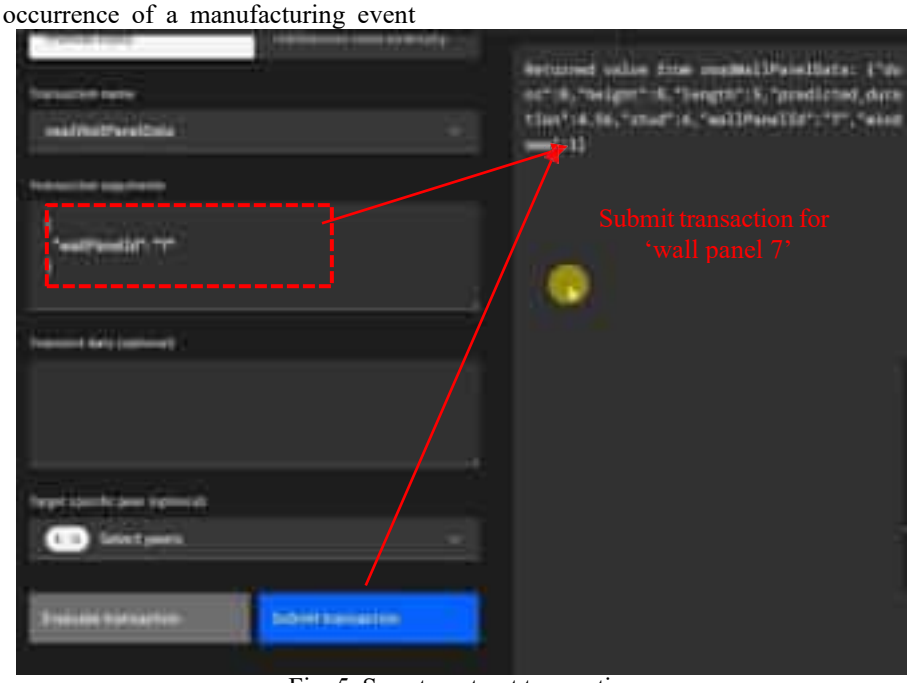

Fig. 5: Smart contract transaction

To ensure data integrity and consistency, manufacturing workflows were formalized within the smart contract logic. Figure 6 shows an excerpt of the implemented smart contract (chaincode) for the case study. The smart contract includes validation mechanisms that verify the existence of wall panel records (e.g., new window value, new height value and new predicted duration) before allowing updates to be committed to the ledger. This logic prevents duplicate entries and enforces predefined business rules governing production data submission. Invalid transactions are automatically rejected, ensuring that only verified manufacturing events are immutably recorded. This implementation confirms that data validation is enforced at the blockchain layer without reliance on centralized control.

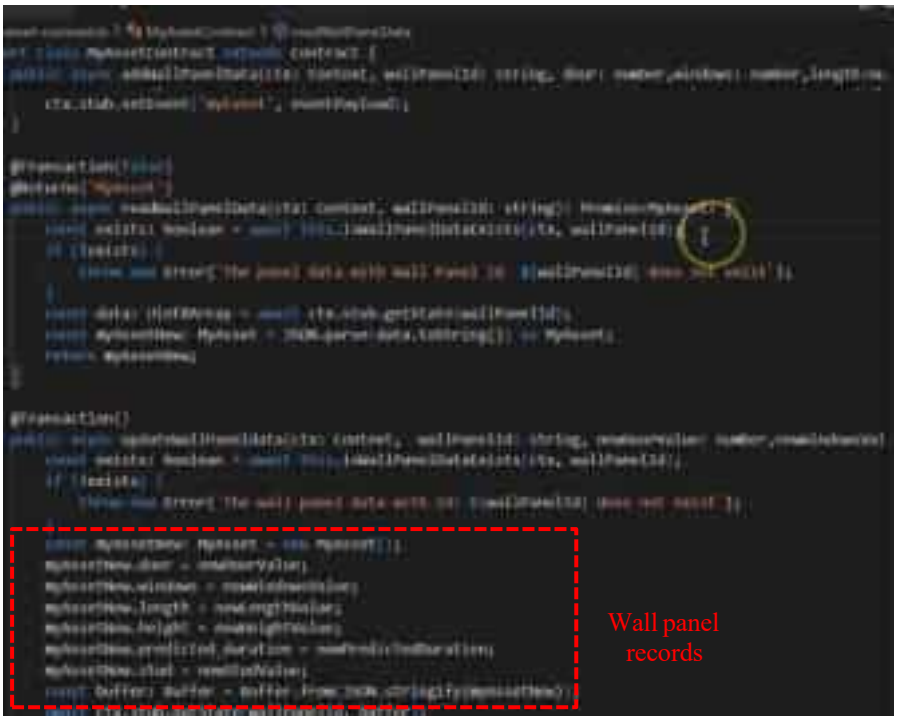

Fig. 6: Implemented smart contract

In addition to transaction execution, this paper evaluated the system's ability to retrieve and verify stored production data. Figure 7 illustrates the execution of a read-only query transaction used to retrieve wall panel production information from the blockchain ledger. For example, the 'wall panel ID 2' has: 3 doors, 11ft height, 12 studs and an estimated process time of 14.12 minutes. The query output confirms that production data recorded during earlier manufacturing events remain persistently stored and accessible in a structured format. Authorized participants can retrieve wall panel status, timestamps, and historical records without modifying ledger contents. This capability demonstrates the traceability, transparency, and immutability of the proposed method, supporting post-event verification and informed decision-making in MCM.

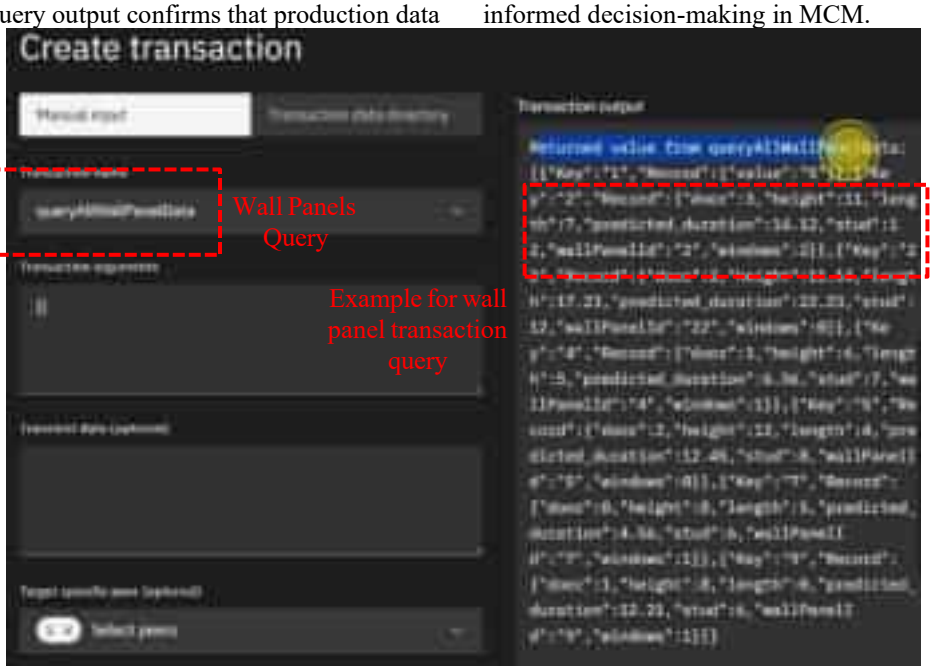

Fig. 7: Execution and query of a transaction

Collectively, this demonstrates the end-to-end application of the proposed method, from smart contract deployment and event-driven transaction execution to validation and data retrieval. The successful implementation enhances data integrity, transparency, and stakeholder trust. In addition, it supports the feasibility of integrating blockchain as a digital infrastructure for managing production information in modular construction.

5 Conclusion and Future Works

This paper presented a newly developed permissioned blockchain-based method using Hyperledger Fabric to enhance data integrity, transparency, and multi-stakeholder coordination (i.e., production line manager and on-site supervisor) in MCM. The method integrates a multi-peer blockchain network, customized smart contracts for managing wall panel production information, and a distributed ledger structure capable of securely recording and synchronizing manufacturing events. Through a case study implementation, the system successfully executed event-driven transactions, enforced smart-contract-based validation rules, and enabled the immutable storage and retrieval of production data. This demonstrates that wall panel information from the production line can be systematically translated into blockchain transactions and subsequently queried for verification and traceability.

However, the implementation involved only two peer organizations (i.e., production line manager and on-site supervisor), which limits the evaluation of scalability and interoperability across a broader modular construction supply chain. Future research should therefore focus on expanding the blockchain network to additional stakeholders and evaluating system performance in full-scale manufacturing environments.

Abstract –

Accurate and real-time recognition of construction workers' behaviors is critical to intelligent safety supervision and productivity assessment. However, existing skeleton-based methods struggle to balance recognition accuracy with inference latency, while lacking robustness against noisy keypoints caused by frequent occlusions. This study proposes RepCA-GCN, a high-efficiency architecture specifically tailored for construction site action recognition. The method integrates Structural Re-parameterization to decouple training capacity from inference latency, Coordinate Attention to capture long-range spatial dependencies, and a Confidence Gating mechanism to suppress noise from unreliable pose estimations extracted via YOLOv11-Pose. Validated on our constructed SiteWorker Action Recognition (SWAR) dataset of 7,424 video clips, we systematically explored skeletal configurations, finding that a streamlined 14-keypoint scheme helps to mitigate facial keypoint noise. Experimental results demonstrate that RepCA-GCN achieves 95.35% accuracy, matching state-of-the-art complex models (e.g., CTR-GCN) while significantly reducing FLOPs to 0.413G and achieving a low latency of 1.36 ms. Furthermore, a deployed monitoring system utilizing a dual sliding-window strategy achieves over 60 FPS in multi-person scenarios on a workstation equipped with an RTX 4090 GPU. This framework offers a superior speed-accuracy trade-off, making it well-suited for edge deployment in dynamic construction environments.

Construction Safety; Action Recognition; Pose Estimation; Structural Re-parameterization; Graph Convolutional Network; Real-time Monitoring

1 Introduction

The construction industry remains a high-risk sector, where unsafe behaviors of workers are a primary cause of accidents [1,2]. While traditional manual inspections suffer from insufficient coverage and high costs [3], the advent of computer vision has enabled automated monitoring using standard RGB cameras, which are cost-effective and non-intrusive compared to wearable sensors [4,5] or depth cameras [6].

In recent years, skeleton-based action recognition has emerged as a promising direction. By extracting human keypoints using pose estimation models (e.g., OpenPose [7], YOLO-Pose [8]) and processing them with deep learning networks, researchers can effectively classify worker actions [9,10]. Compared with Long Short-Term Memory (LSTM) based methods [10], the Spatio-Temporal Graph Convolutional Network (ST-GCN) [11] serves as a more advanced foundational framework with superior performance. However, applying ST-GCN directly to construction sites faces two critical bottlenecks:

Noise Sensitivity: Construction sites are cluttered, leading to frequent occlusions. Standard GCNs treat all keypoints equally, allowing low-confidence (occluded) keypoints to introduce noise and degrade accuracy.

Computational Efficiency vs. Accuracy: Advanced GCN variants (e.g., 2s-AGCN [12], CTR-GCN [13]) improve accuracy but introduce heavy computational burdens (high FLOPs and latency), making them unsuitable for real-time edge deployment on site. Conversely, lightweight models often sacrifice recognition performance.

To bridge this gap, this paper proposes RepCA-GCN, a lightweight yet powerful network tailored for real-time construction monitoring. We leverage Structural Re-parameterization technology [14], which allows the model to utilize a complex multi-branch architecture for feature extraction during training but collapses into a

single, efficient convolution layer during inference. This effectively decouples training capacity from inference speed. Furthermore, we integrate Coordinate Attention (CA) to enhance spatial feature representation and a Confidence Gating mechanism to filter noise based on keypoint reliability.

Our main contributions are:

We propose RepCA-GCN, incorporating Structural Re-parameterization modules, Coordinate Attention, and Confidence Gating. This architecture achieves SOTA accuracy (95.35%) with significantly lower latency (1.36ms) compared to existing methods.

We construct the SiteWorker Action Recognition (SWAR) dataset. To enhance robustness, we employ a rigorous occlusion-aware data augmentation strategy (including scaling, flipping, and random occlusion) on the training set, expanding the data scale to four times its original size to ensure generalization.

We validate the system's effectiveness through comprehensive experiments, demonstrating its capability for both safety monitoring (e.g., fall detection) and efficiency analysis in real-world scenarios.

2 Related Work

2.1 Vision-based Construction Safety Monitoring

Computer vision has been widely adopted for site safety. Early works focused on object detection, such as detecting Personal Protective Equipment (PPE) using YOLO or Faster R-CNN [15–17]. While effective for static compliance checking, these methods fail to capture temporal dynamics required for identifying complex actions (e.g., working vs. idling). Video-based approaches like 3D-CNNs [18] and Two-Stream networks [19] can capture motion but suffer from high computational costs, limiting real-time application [20].

2.2 Skeleton-based Action Recognition

Skeleton-based methods offer a balance between performance and efficiency. Yan et al. [11] proposed ST-GCN to model skeletal data as graphs. In construction, Wu et al. [9] and Zhou et al. [10] applied pose-based methods for behavior analysis. Zhou et al. [10] utilized a lightweight LSTM model; however, RNN-based structures lack the ability to explicitly model spatial structural dependencies compared to GCNs.

Recent advancements in GCNs focus on adaptive graphs (e.g., 2s-AGCN, CTR-GCN) to improve accuracy, but their complex topology computations increase inference latency. To address the efficiency issue, Structural Re-parameterization (e.g., RepVGG [14]) has gained attention in CNNs for speeding up inference without accuracy loss. In this study, we adapt this technique to the temporal modeling of GCNs, combined with YOLOv11-Pose, to achieve a high-performance, real-time solution for construction sites.

3 Methodology

To address the challenges of occlusion and high computational latency in construction site monitoring, we propose a high-efficiency framework for worker action recognition. As illustrated in Figure 1, the system operates in a two-stage pipeline. First, the YOLOv11-Pose model is employed to extract spatiotemporal human skeletal keypoint sequences from raw video streams. These sequences, which contain both coordinate data and confidence scores, serve as the input for the subsequent stage. Second, the proposed RepCA-GCN model processes these skeletal sequences to classify worker behaviors. This decoupled design allows for the independent optimization of pose estimation and action recognition, ensuring both precision and system flexibility.

3.1 RepCA-GCN Model Architecture

The core of our methodology is the RepCA-GCN (Reparameterized Coordinate-Attention Graph Convolutional Network). As shown in Figure 2, the network processes a skeletal sequence with dimensions (B, T, N, C). The backbone comprises four stacked RepBlock stages. To primarily resolve the conflict between model capacity and real-time inference speed, we employ Structural Re-parameterization in the temporal modeling layers. During the training phase, the temporal block adopts a multi-branch topology consisting of parallel 5×1, 3×1, 1×1 convolutions, and an identity mapping. This design enables the model to learn multi-scale temporal features. However, for deployment, these branches are mathematically fused into a single 9×1 convolutional layer via linear transformations of kernels and biases. This decoupling ensures the model retains the representational power of a complex topology while achieving the low memory access cost and latency of a single-path network during inference.

Complementing this efficient architecture, we integrate Coordinate Attention to refine features. Unlike standard channel attention, Coordinate Attention aggregates the $C \times T \times N$ skeletal graph features along distinct temporal (T) and spatial (N) directions, capturing long-range dependencies with minimal overhead. Additionally, a Confidence Gating mechanism is applied. By using the input confidence score c_n to modulate features via $X_{\text{out}} = X_{\text{gcn}} \odot \sigma(W \cdot c_n + b)$, the model effectively suppresses noise from occluded keypoints.

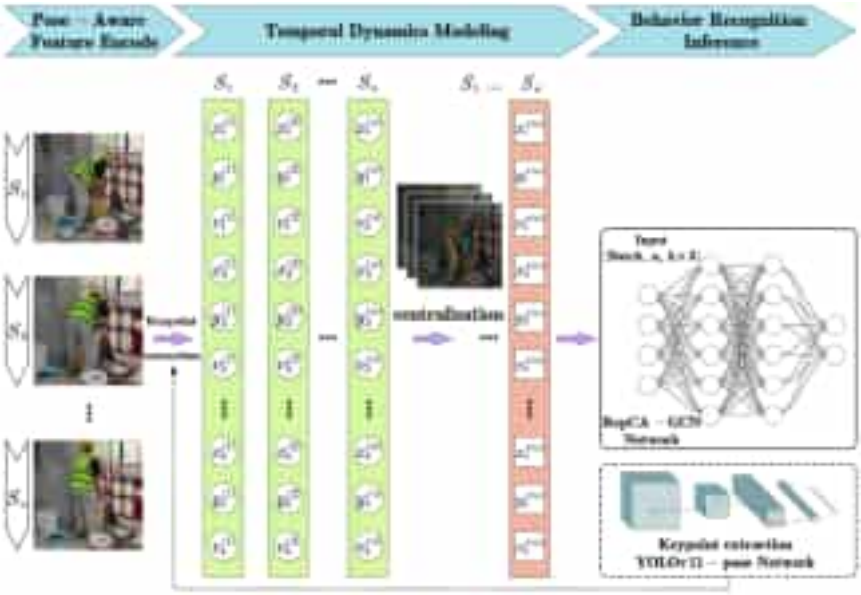

Figure 1. The Proposed Methodological Framework for Skeleton-Based Action Recognition

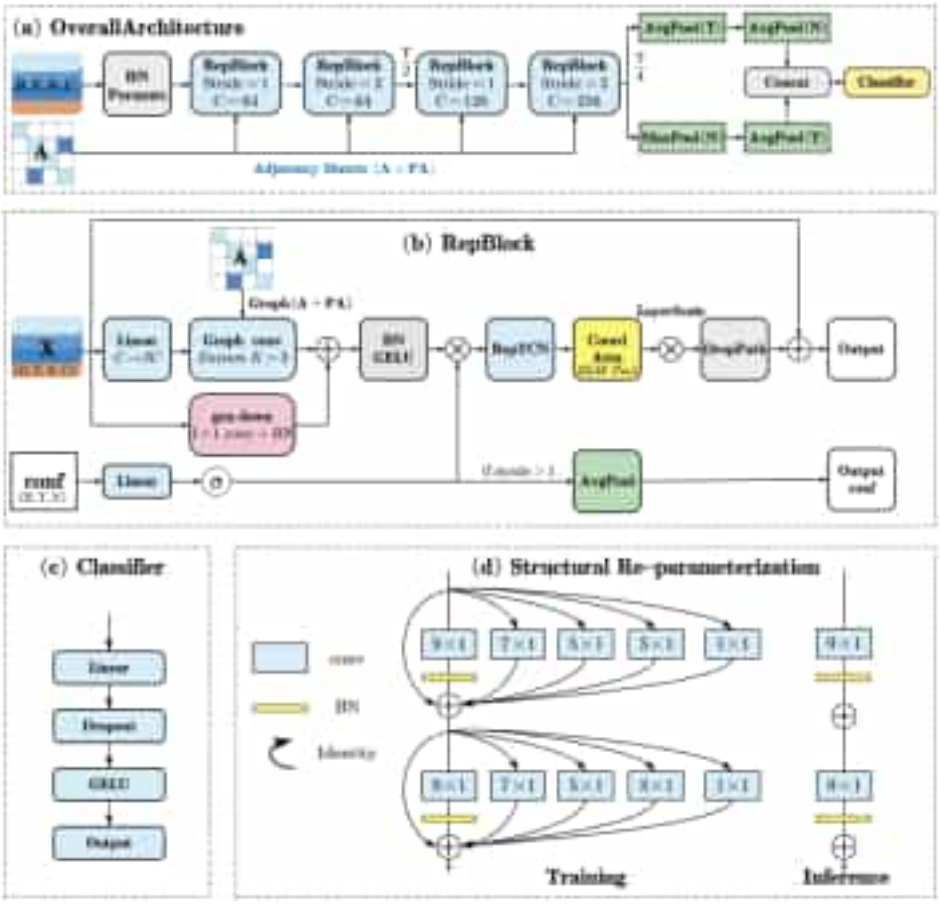

Figure 2. RepCA-GCN Model Architecture

3.2 Data Preparation and Workflow

The comprehensive workflow, ranging from data preparation to model training and practical recognition, is depicted in Figure 3. The process begins with the construction of the SiteWorker Action Recognition (SWAR) dataset. We collected video data from diverse sources, including real-world construction site surveillance, drone footage, and simulated environments, to ensure scenario diversity.

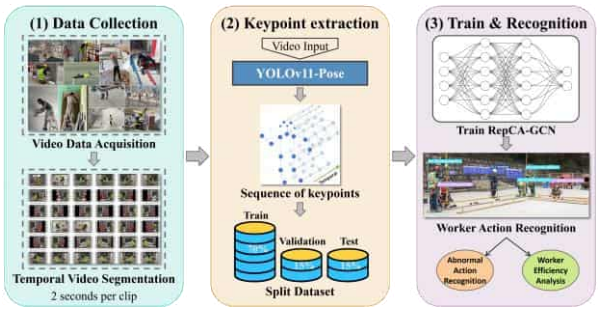

Figure 3. Workflow of data preparation, model training and recognition for the RepCA-GCN

As shown in Figure 4, the dataset is collected from actual construction sites, covering various environmental conditions and camera angles. It includes multiple categories of behaviors recorded under different lighting levels to reflect the complexity of real-world scenes.

Figure 4. SWAR dataset

The composition of the dataset is analyzed in Figure 5. The dataset exhibits a relatively balanced distribution across the six behavioral categories. 'Squatting operation' constitutes the largest portion (24.2%), while 'fall' represents the smallest category (13.1%), thereby mitigating the risk of severe class imbalance. The 'squatting operation' and 'standing operation' categories specifically denote the active construction states of workers in their respective postures. Most videos in the SWAR dataset are in 1080p resolution (1920 × 1080 or 1080 × 1920), with a small portion recorded at 720p. The specific number of video clips for each category is summarized in Table 1.

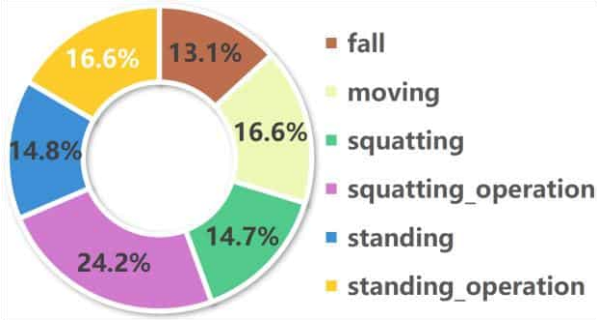

Figure 5. Composition of the SWAR Dataset

Table 1. Number of Video Clips in the SWAR Dataset

Behavior	Count
Fall	976
Moving	1230
Squatting	1091
Squatting operation	1794
Standing	1100
Standing operation	1233
Total	7424

For skeletal representation, we adopt the standard 17-keypoint configuration defined by the COCO format (Figure 6), with all coordinates undergoing normalization and centralization to ensure spatial consistency. Additionally, alternative 13-keypoint and 14-keypoint schemes (Figure 7) were explored and evaluated in the subsequent experiments.

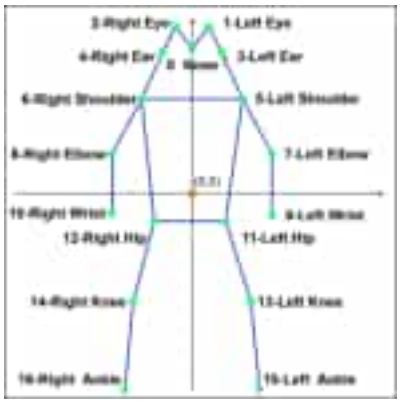

Figure 6. COCO 17 Keypoints Layout

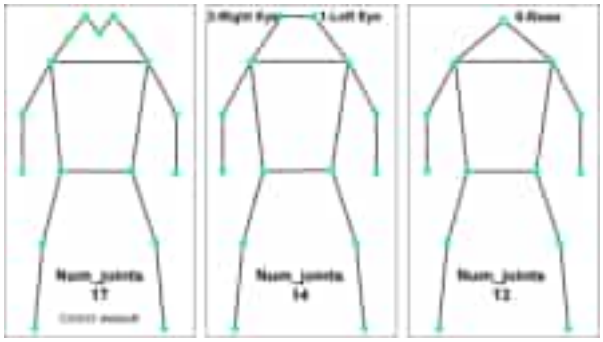

Figure 7. Three Keypoint Selection Schemes

4 Experiments and Results

4.1 Experimental Setup

The dataset partitioning and augmentation strategy are detailed in Table 2. The original SWAR dataset was split into training, validation, and testing sets with a ratio of 70:15:15. To strictly prevent data leakage and ensure realistic evaluation, we implemented a hybrid splitting strategy. Specifically, 30% of the validation and testing samples were randomly selected to ensure global data representation, while the remaining data were allocated sequentially based on video indices. Because raw videos capture continuous actions of identical subjects, this sequential allocation guarantees that frames from the same subject do not overlap across the training and testing sets.

Table 2. Dataset Partition

Subset	Original Samples	Augmented Samples
Train	5195	20780
Validation	1111	-
Test	1118	-
Total	7424	-

To enhance robustness against scale variations and frequent occlusions on construction sites, we exclusively applied three distinct data augmentation pipelines to the training set: (1) adaptive spatial scaling combined with a 50% probability of horizontal flipping; (2) scaling and flipping coupled with random occlusion; and (3) pure random occlusion. The occlusion operation intentionally masks 1 to 2 skeletal joints to simulate the noisy keypoints commonly generated by pose estimators in cluttered environments. This process expanded the training set to four times its original size.

All experiments were conducted on an Ubuntu workstation equipped with an NVIDIA RTX 4090 GPU using PyTorch 2.5.1. The models were trained for 50 epochs with a batch size of 128, optimized via AdamW with a cosine annealing learning rate schedule (decaying from 1e-3 to 1e-5) and gradient clipping for training stabilization.

4.2 Performance Analysis

The training dynamics of the proposed model are illustrated in Figure 8, demonstrating stable convergence without severe overfitting, owing to the rigorous anti-leakage data splitting and occlusion-aware augmentation. As presented in Table 3, the SWAR dataset under the new strict partition proves to be a challenging benchmark. RepCA-GCN achieves a highly competitive accuracy of 92.58%, outperforming the baseline ST-GCN (91.32%) and performing on par with the computationally heavy 2s-AGCN (92.47%).

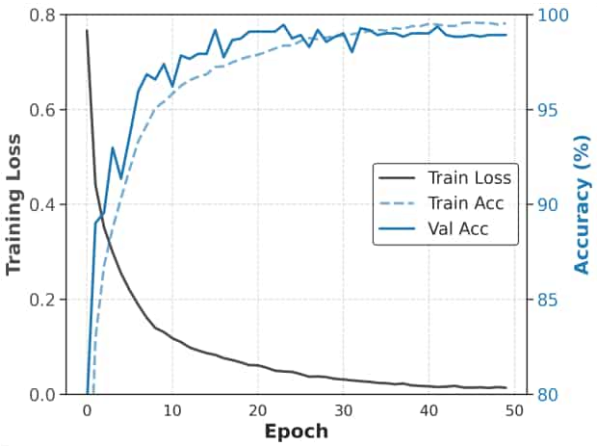

Figure 8. Training and validation results of RepCA-GCN

Table 3. Comparative performance of different models on the SWAR dataset (17 Keypoints)

Model	Acc(%)	Params(M)	FLOPs(G)	latency(ms)
ST-GCN	91.32	2.07	0.795	1.76
2s-AGCN	92.47	3.45	1.305	3.41
CTR-GCN	**93.11**	1.42	0.595	5.53
RepCA-GCN	92.58	**1.19**	**0.413**	**1.36**

Although slightly lower than CTR-GCN (93.11%), RepCA-GCN demonstrates a vastly superior speed-accuracy trade-off. By leveraging structural re-parameterization, it requires only 0.413 GFLOPs and achieves an ultra-low inference latency of 1.36ms, making it a well-suited choice for resource-constrained edge deployment.

Table 4. Accuracy (%) comparison across different models and keypoint configurations

Model	13 Points	14 Points	17 Points
ST-GCN	92.13	90.16	91.32
2s-AGCN	90.52	95.08	92.47
CTR-GCN	**92.31**	94.54	**93.11**
RepCA-GCN	92.22	**95.35**	92.58

Furthermore, we investigated the influence of skeletal representations on model performance (Table 4). Interestingly, RepCA-GCN achieves its peak accuracy of 95.35% when utilizing the 14-keypoint scheme, significantly surpassing the standard 17-keypoint COCO format (92.58%). This confirms that standard pose layouts may not be optimal for construction action recognition. The 17-keypoint format contains dense, highly localized facial keypoints that contribute little to macroscopic body actions but introduce significant noise when partially occluded by hardhats. The streamlined 14-keypoint scheme effectively filters out this redundant facial noise while preserving essential structural integrity, thereby maximizing the efficacy of our Confidence Gating mechanism and yielding the best recognition performance.

4.3 Ablation Study and Efficiency Analysis

As shown in Table 5, activating the structural re-parameterization deployment mode (ON) losslessly reduces parameters and FLOPs by ~40%, lowering latency to 1.36 ms without accuracy degradation.

Table 5. Efficiency comparison of RepCA-GCN before and after structural re-parameterization

Rep deploy	Params(M)	FLOPs(G)	latency(ms)
OFF	2.01	0.697	1.80
ON	**1.19**	**0.413**	**1.36**

This efficiency gain is mathematically guaranteed by the additivity of linear transformations. During training, the multi-branch temporal block outputs $Y = \sum_{i \in S} \mathrm{BN}_i\left(\mathrm{Conv}_i(X)\right)$, where $S = \{9 \times 1, 5 \times 1, 3 \times 1, 1 \times 1, \text{identity}\}$. For inference, each Conv-BN sequence is linearly fused into a single weight W_i' and bias b_i'. By zero-padding smaller kernels and the identity matrix (formulated as a 1×1 Dirac delta) to match the maximal 9×1 kernel (denoted by a padding operator $\mathcal{P}$), all branches equivalently collapse into a single generic convolution:

$$Y = \left(\sum_{i \in S} \mathcal{P}(W_i')\right) X + \sum_{i \in S} b_i' = W_{\text{fused}} X + b_{\text{fused}} \quad (1)$$

This structural decoupling ensures high training capacity while yielding an ultra-fast, single-path network for edge deployment.

5 Application and Evaluation

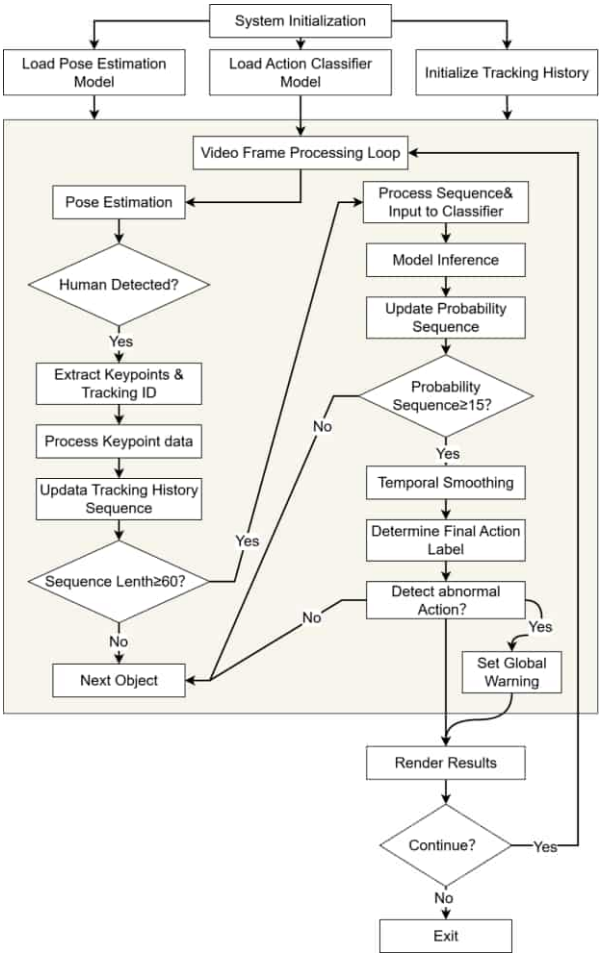

Figure 9. Flowchart of the proposed worker action recognition system for construction sites

To verify its practical utility, we developed a real-time monitoring system (Figure 9) that integrates YOLOv11-Pose for multi-object tracking with RepCA-GCN for action classification. The pipeline assigns unique IDs to detected individuals to extract and preprocess continuous skeletal keypoint streams.

5.1 Real-time Monitoring System Design and Visualization

For robust monitoring, a dual sliding-window mechanism—a 60-frame Temporal Buffer for context and a 15-frame Probabilistic Smoothing Window ($\alpha = 0.96$)—is implemented to filter transient noise and classification jitter. As visualized in Figure 10, the system accurately identifies diverse actions (e.g., "falls") and provides real-time visual feedback for immediate safety alerts.

5.2 System Performance Evaluation

Table 6 details the end-to-end throughput in multi-person scenarios, achieving 60.5 FPS on an RTX 4090 and 22.6 FPS on an RTX 4060. These baseline PyTorch metrics already satisfy real-time constraints, with further acceleration possible via TensorRT, proving RepCA-GCN an efficient and scalable solution for safety supervision.

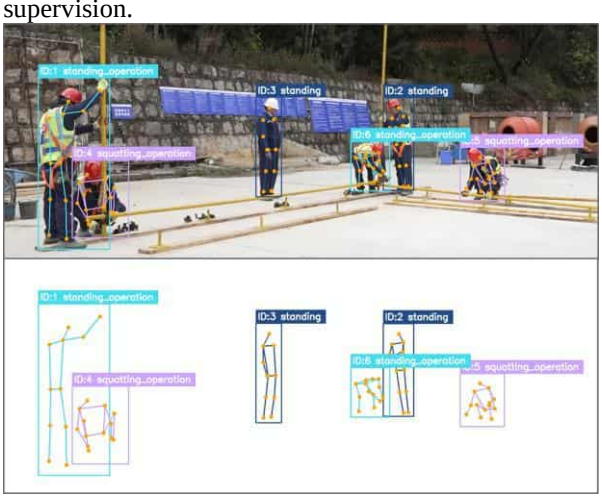

Figure 10. Visualization of Recognition Results

Table 6. End-to-End System Throughput (FPS) on Different Hardware Platforms

Model	Server (RTX 4090)			PC (RTX 4060)		
	Single-person	Multi-person	Avg	Single-person	Multi-person	Avg
ST-GCN	65.1	41.5	53.3	**24.9**	18.9	21.9
2s-AGCN	52.1	27.7	39.9	23.9	15.2	19.6
CTR-GCN	47.6	24.0	35.8	18.9	10.9	14.9
RepCA-GCN	**70.6**	**50.3**	**60.5**	24.1	**21.0**	**22.6**

6 Conclusion and Limitations

This study proposes RepCA-GCN, a lightweight framework for construction worker action recognition. By integrating Structural Re-parameterization and reliability-aware feature modulation, the model addresses computational latency and noisy keypoints caused by occlusions. We constructed the SWAR dataset with extensive augmentation to facilitate robust training. Results show RepCA-GCN achieves state-of-the-art accuracy (95.35%) with reduced computational costs (0.413 GFLOPs) and low latency (1.36 ms). The monitoring system demonstrates robust real-time performance for intelligent safety supervision. However, skeleton-based methods completely discard background information, making them unable to recognize environment-interactive actions.

Abstract

The current prefabricated material tracking method in construction projects usually uses RFID or GPS technology. This technique requires tagging materials, which can be labour-intensive for large volumes of materials on a construction site. Deep learning-based object detection can provide a solution for material tracking in construction projects without the need for material tagging. To obtain this result, a deep learning architecture must be trained to automatically detect construction materials. However, there is a limited dataset of construction material objects in outdoor environments for training. Therefore, this study proposes a framework for material detection at construction sites using a modified dataset and transfer learning from other LiDAR data mainly used for autonomous driving (e.g., cars, pedestrians, and cyclists). The method includes workflows for data acquisition using a Mobile Laser Scanner (MLS) system, data preprocessing, training, and testing. A site-specific case study using concrete pipe material was used to validate the proposed approach. The technical performance of the material object detection model trained with transfer learning increased from 35.40% F1 score to 80.56% F1 score. Furthermore, with an additional modified dataset, the F1 score increased to 87.18%.

1 Introduction

Tag-based material-tracking technologies, such as Radio Frequency Identification (RFID), require significant manual effort and are often prone to errors and inefficiencies. For instance, workers must manually attach tags to materials and traverse construction sites to scan and extract information at close range. On large construction sites, this process becomes time-consuming and error-prone because of the widespread distribution of materials [1]. Furthermore, positioning technologies such as RFID, ultra-wideband (UWB), infrared, and Global Positioning System (GPS) often depend on additional infrastructure such as Wi-Fi, cellular networks, or Bluetooth to function effectively. This dedicated infrastructure requirement increases the complexity and cost of tag-based methods.

Considering the current challenges of using RFID, UWB, and GPS, which require manual tagging and dedicated infrastructure for data transfer, the application of visual perception technology has gained significant interest. Some technologies, such as image-based technology and point cloud processing, do not require dedicated infrastructure [2]. Although image-based methods for object detection are promising, they only capture 2-dimensional (2D) data, making it difficult to obtain information about the material's 3-dimensional (3D) size. To address this, point cloud data is a possible alternative, as it provides detailed 3D information about the material at a construction site. However, processing large point cloud datasets often requires significant computational power, which may delay real-time applications of the technology.

The current point cloud data used in construction projects is mostly generated by Terrestrial Laser Scanners (TLS), which produce highly accurate, dense point clouds. The TLS method is considered more suitable for scanning small and dense areas. However, for an infrastructure project with a large area, such as a toll road or airport, TLS data generation can be too slow. On the other hand, Mobile Laser Scanning (MLS) provides faster data acquisition for large areas [3], but faces challenges with occlusion and sparse point clouds.

To address the challenges of detecting construction materials from mobile laser scanning (MLS) data, this study proposes a transfer-learning-based framework. A real dataset from a large infrastructure project was used

to evaluate the proposed approach's feasibility. The data were collected using an MLS system and pre-processed through subsampling, segmentation, and data labelling.

A Point Voxel Region-based Convolutional Neural Network (PV-RCNN) [4] was used for 3D object detection. Transfer learning was applied by initialising the model with weights pre-trained on an autonomous driving dataset and then fine-tuning it using the construction MLS data. The results were compared with a model trained from scratch using the same dataset to evaluate the benefit of transfer learning.

2 Related Work

This section provides an overview of current material object detection in construction projects. It highlights relevant studies on the processing of 3D point cloud data and on the application of deep learning methods for the detection of construction materials.

2.1 Construction Material Recognition Method

To support material recognition in construction, several technologies, including 3D object detection and vision-based scene understanding, have been applied in construction projects. One study demonstrated a vision-based method for material recognition to automate construction progress monitoring and generate Building Information Models (BIM) from unordered site image collections [5]. This approach utilised 3D point cloud models created from site photo logs using Structure-from-Motion (SfM) techniques. The primary aim was to classify material types based on appearance to facilitate progress tracking. This approach primarily targets materials that have already been installed on site, which limits its applicability for detecting and managing on-site material inventory.

In terms of material quantification, one recent research developed a method for automatic measurement of corrugated pipes and rebars for large precast concrete beams from a TLS [6]. The segmentation framework was based on the application of radius nearest-neighbours, covariance, and a density-based spatial clustering algorithm to detect pipes and rebar and to extract their sizes, including radius and length. Although the algorithm accurately extracted the object size with 98% accuracy, the method still required a manual clutter-removal stage and relied on dense TLS data.

Previous work introduced a vision-based machine learning method for counting steel pipes on construction sites [7]. This method utilised a Convolutional Neural Network (CNN) combined with image processing technologies to enhance counting accuracy and reduce labour intensity. The primary aim was to automate the counting process to improve efficiency and accuracy. Despite its effectiveness, the method may face challenges in highly cluttered environments where steel pipes overlap significantly.

3D point cloud object detection methods in the construction industry, including vision-based recognition, semantic segmentation, and volumetric measurement, have significantly enhanced monitoring and material management. However, challenges such as occlusion, noise, and data completeness, especially for the MLS point cloud, remain unresolved. Therefore, further research and development to improve the robustness of these techniques are needed to ensure their applicability across diverse construction environments.

2.2 3D Point Cloud Processing

In automatic 3D object detection for point cloud processing, three methods are generally used. The methods are simple geometric models, feature descriptors, and deep learning [8]. The first method assumes that objects can be detected by utilising simple geometric models, such as planes and cylinders, from point cloud data. This method usually uses random sample consensus (RANSAC), which computes the least-squares error between the known object and the points in the point cloud, or the Hough transform, which searches for the object using its parametric shapes, such as the radius or slope-intercept.

The second method uses feature descriptors divided into local and global categories. The local descriptor tries to summarise statistics of the object's features, such as curvature, density, and normal, to describe the neighbourhoods around interest points. Meanwhile, the global descriptors define objects using their lengths, areas, and angles in a single feature vector. Examples of research using global descriptors include [9] that uses the Principal Axes Descriptor to automatically detect construction equipment from a TLS point cloud. In the context of material detection, recent studies have explored the use of geometric feature extraction from mobile laser scanning point clouds to enable tracking and volume estimation of precast concrete pipes [10]. While this method achieved 78.5% accuracy, its performance indicates room for improvement in material object detection.

The last method of object detection uses deep learning to find a direct mapping from the 3D point cloud input to its object labels. The deep learning method requires extensive training on a large number of objects before it can correctly predict the type of object to be detected. Compared to traditional geometric feature extraction, deep learning offers advantages in robustness. One key benefit of deep learning is that it minimises the need for manually engineered feature descriptors and employs more flexible yet robust classification rules [8].

However, there are some concerns about the applicability of machine learning data, especially related to the amount of data required to train the model.

In the construction industry, the most publicly available point cloud dataset with its labelling is an indoor dataset, such as the Stanford Large-Scale 3D Indoor Spaces Dataset (S3DIS) [11] and the ScanNet [12] dataset. Meanwhile, another point cloud dataset in outdoor settings is usually used for the autonomous driving process, such as the Karlsruhe Institute of Technology and the Toyota Technological Institute (KITTI) [13]. This dataset class usually contains cars, pedestrians, trees, and cyclists.

Despite growing interest in point cloud technology for construction applications, its use for automated material tracking remains limited. Most existing studies focus on progress monitoring using TLS. While MLS, which is faster and more practical for large infrastructure, generates sparse and occluded point clouds that are more challenging to process. Furthermore, most existing 3D object detection algorithms and publicly available datasets are developed for autonomous driving, covering common classes such as cars and pedestrians, rather than construction-specific materials such as pipes, concrete, and steel. Existing MLS-based approaches for pipe detection have also shown limited accuracy. As a pilot project, this study aims to develop and test a deep learning framework trained on custom MLS data for automated concrete pipe detection under the challenging conditions of single-pass MLS scanning.

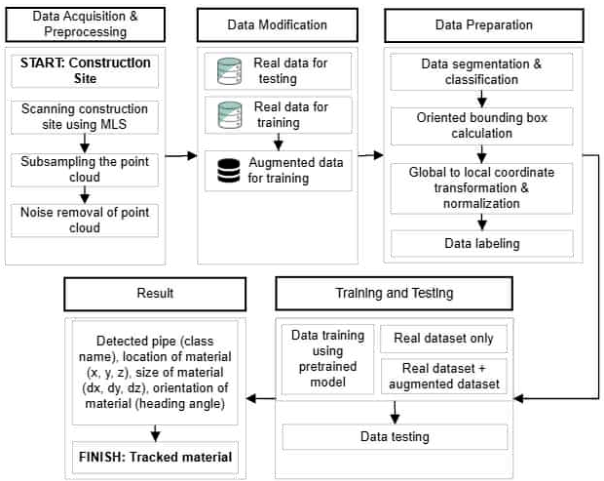

Figure 1. A step-by-step method for 3D point cloud object detection in a construction project.

3 Methods

The proposed methodology aims to detect prefabricated concrete pipes from MLS point cloud data. Figure 1 illustrates the 3D material object detection step-by-step method used in this paper. Point cloud data from a real construction site was used as a case study. From this dataset, only 8 areas can be used. To increase the amount of training data, a preprocessing stage was introduced. Then, a transfer learning approach for 3D object detection was used to detect the pipe.

3.1 Data Acquisition

The 3D point cloud data was obtained using MLS in a single pass with the specifications mentioned in Table 1. MLS was selected in this study due to its fast data acquisition capability, which allows large areas to be scanned in a single continuous pass. Since the MLS system performs only one scan along the road, many of the data is dense on one side and sparse on the other. The resulting data was large, noisy, and mostly occluded, as can be seen in Figure 2. Although multi-pass scanning could improve point density, it was not possible due to this constraint. Furthermore, single-pass data collection reflects how MLS is used in practice, where fast data acquisition is one of its main advantages. Testing our method under these conditions shows that it can work well in real inspection scenarios. To obtain data for labelling and training, the area containing prefabricated concrete pipes was segmented into distinct regions. The initial data for each area includes concrete pipes, ground points, other materials around the pipes, and the scene.

Table 1. Mobile laser scanner specification.

Criteria	Specification
Laser Sensor	XT32
Range Accuracy	±3cm
Vertical Field of View	-16° ~ 15°
Horizontal Field of View	0° – 360°
Maximum Range	120 m

Figure 2. 3D point cloud data.

Point cloud subsampling was performed to reduce the number of points and reduce computational requirements. The subsampling method was obtained using open-source cloud-compare software. To ensure that point features are not removed, the subsampling method used a spatial mode with a minimum distance of 0.02 meters between points. This subsampling method reduced up to 50% of the points for each area.

3.2 Data Preprocessing and Modification

The dataset preparation was obtained to increase the number of areas for data training. From the data-acquisition stage, 8 areas containing prefabricated concrete pipes formed the real dataset for this case study as can be seen in Figure 3. The real dataset was partitioned into training and test sets, with six areas allocated to training and two to testing. To ensure the integrity of the evaluation process, the testing data were entirely excluded from both the training phase and the generation of modified data. This approach prevents the model from acquiring any prior knowledge of the testing dataset's properties.

The additional dataset was obtained by modifying the current dataset. The ground points of each dataset were segmented and deleted to get the modified dataset (Figure 4). Next, only the good pipe from each dataset is segmented without the ground points and scene (Figure 5). Both modifications to the datasets aim to train the model to recognise the correct pipe in a clean environment. From this stage, the training data increased from 6 to 18 areas.

Figure 3. Example of the current dataset.

Figure 4. Current dataset without ground point.

Figure 5. Good pipes only dataset.

3.3 Dataset Preparation

All areas were prepared to match the algorithm. The data was segmented into pipes and scenes. A bounding box was generated for each pipe and the scene. An oriented bounding box (OBB) was used to capture the size and orientation of each pipe. Since the concrete pipes are located on the ground, only the heading angle (also known as the yaw angle) was calculated. The pitch and roll angles were assumed to be zero [13]. The heading angle describes the rotation of the object around the vertical (z) axis and indicates the direction the object faces horizontally. The illustration of the object bounding box, coordinates and heading angle can be seen in Figure 6. Each object was labelled with its centre coordinate (x, y, z), 3D size generated from its bounding box (length: dx, width: dy, height: dz), heading angle, and class name.

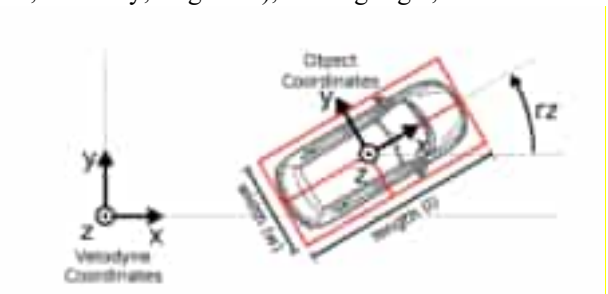

Figure 6. Object coordinates illustration.

Given that the PV-RCNN algorithm utilises both point and voxel features, the intensity data must also be included in the point cloud dataset. Additionally, the data needs to be verified for compliance with the point cloud range and voxel size specified in the OpenPCDET custom dataset information. Each point from the laser scanner data contains information about its global coordinates. Since the area is divided into regions containing pipes, the coordinate information was transformed to local coordinates. To ensure the point cloud range was not too large, each data point was transformed again so that the first point in each point cloud was located around the 0, 0, 0 coordinate (normalisation).

3.4 Dataset Training and Testing

The methodology described was implemented in a Python environment on a Personal Computer with an Intel(R) Core (TM) i7-6700 CPU@ 3.4 GHz processor and installed RAM of 64 GB. The model training time ranged from 20 minutes to 1 hour depending on the dataset size and configuration and to evaluate a single scan took approximately 30 to 40 seconds to process. The primary library used for 3D processing was Open3D. From 8 real datasets, areas 1 and 5 were selected as the test datasets. The baseline for object detection was calculated by training only on a real dataset (6 areas) and testing on 2 areas. The next scenario involved adding a pre-trained model to the dataset and an additional modified dataset for training.

The model's performance was evaluated using precision, recall, and F1 scores as defined in equations 1, 2, and 3. Precision measures the proportion of detected objects that are correct, calculated as the ratio of true positives (TP) to the sum of true positives (TP) and false positives (FP). Recall measures how many of the actual objects are correctly detected, defined as the ratio of true positives to the sum of true positives and false negatives (FN). In this context, TP represents correctly detected objects, FP refers to incorrect detections, and FN indicates objects that were present but missed by the model. The F1 score combines precision and recall into a single metric by computing their harmonic mean.

$$Precision = \frac{TP}{TP + FP} \quad (1)$$

$$Recall = \frac{TP}{TP + FN} \quad (2)$$

$$F1\ Score = 2 \times \frac{Precision \times Recall}{Precision + Recall} \quad (3)$$

4 Results and Discussion

Each dataset configuration was trained separately, and performance was measured at each epoch. This analysis highlights variations in results across different data types and demonstrates the impact of pre-trained models on 3D object detection performance.

4.1 Real Dataset

From 8 real datasets, Areas 1 and 5 were selected as the test datasets. Area 1 represents a region with high-quality pipe data and minimal noise, while Area 5 contains more occlusions and noise. As a baseline, the model was trained on only six real datasets and evaluated on the designated test data. The Ground Truth (GT) bounding box, shown in Figure 7 indicates that Area 1 contains 14 pipes and Figure 8 indicates that Area 5 contains 19 pipes.

Figure 7. Ground truth for Area 1

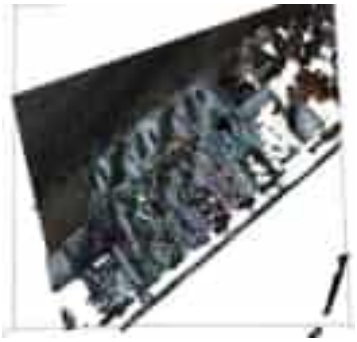

Figure 8. Ground truth for Area 5

In the first experiment, PV-RCNN was trained using six real MLS datasets without pretraining. The baseline detection results, shown in Figure 9 (a) and Figure 9 (b), indicate poor performance due to the limited number of training samples. The model failed to accurately detect pipe objects, with predicted bounding box centres and orientations misaligned from the ground truth. In addition, clutter was frequently misclassified as pipes, and several actual pipes were missed, leading to unreliable detections.

Intersection over Union (IoU) measures the overlap between a predicted bounding box and the ground truth to evaluate object detection accuracy. The IoU 50% means detection is considered correct if at least 50% of the predicted box overlaps with the ground truth. In terms of quantitative performance, object detection using only real data resulted in a precision of 25% and a recall of 60.6% for IoU 50%. Although no pipes were correctly detected according to the visualisation criteria, the precision, recall, and F1 scores at the 50% threshold were non-zero. This is because some predicted bounding boxes partially overlapped with ground-truth pipes and were counted as true positives under the relatively loose 50% IoU criterion, despite their inaccurate geometry.

After incorporating a pre-trained model, detection performance improved substantially. In Area 1, the model correctly detected 13 out of 14 pipes, with bounding box locations, dimensions, and orientations closely aligned with the ground truth, as shown in Figure Figure 9 (c). In the more challenging Area 5, which contains higher noise and clutter, the model detected 17 out of 19 pipes, with two clutter objects misclassified as pipes as can be seen in Figure 9 (d). When the pre-trained model was introduced, precision improved to 72.73%, while recall increased to 90.28%. The recall of 90.28% indicates that the model correctly identified most of the actual pipes, though some remained undetected. These results highlight the effectiveness of integrating a pre-trained model with real data to improve object detection performance compared to the baseline approach.

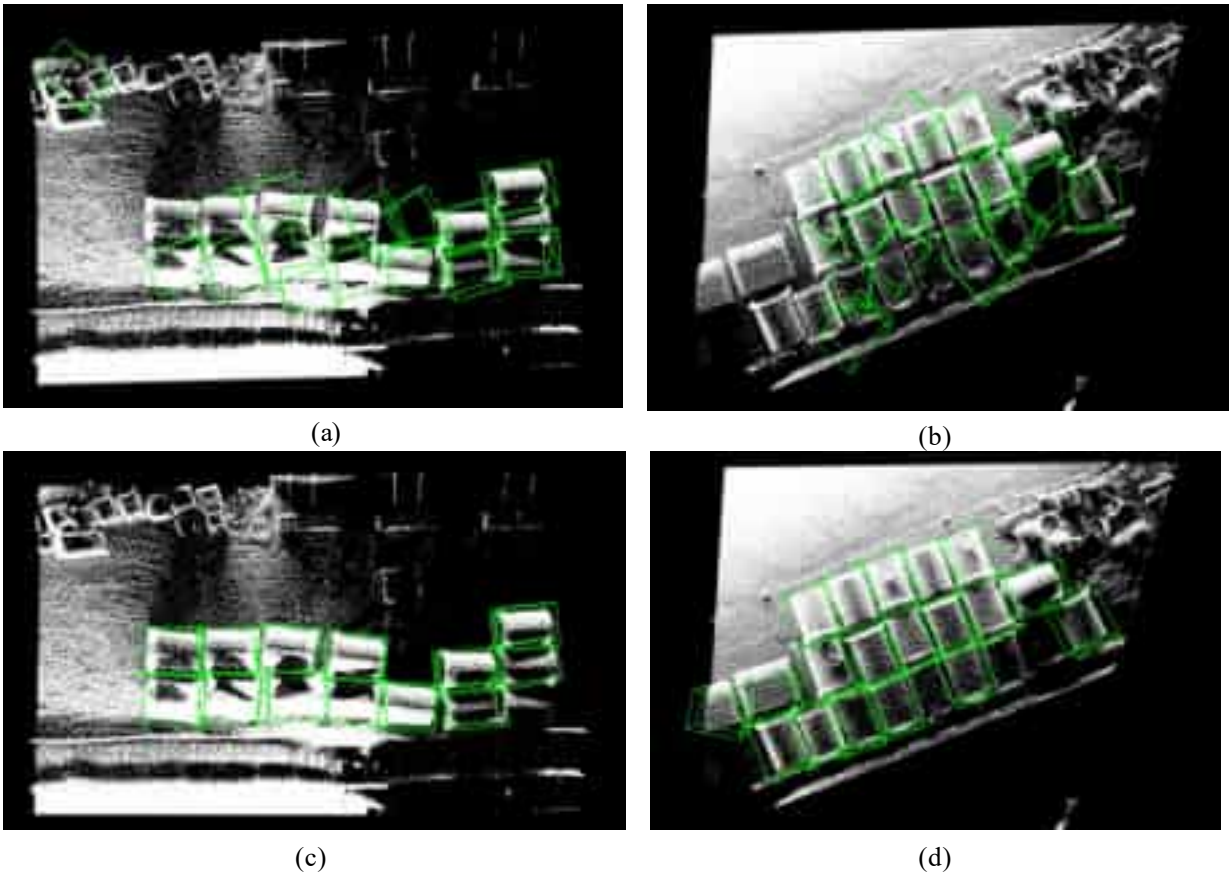

Figure 9. Predicted bounding box from 6 real data: (a) Area 1 without pre-trained model; (b) Area 5 without pre-trained model; (c) Area 1 with pre-trained model; and (d) Area 5 with pre-trained model.

4.2 Real Dataset plus Modified Dataset

The modified datasets were generated to increase the amount of training data. As a result, an additional 12 data points were added to the real data. The remaining areas were then trained using a pre-trained PV-RCNN model for 80 epochs. As shown in Figure 10, the introduction of additional modified datasets significantly improved the results. The algorithm successfully detected 100% of pipes in both Area 1 (14 out of 14 pipes) and Area 5 (19 out of 19 pipes), with no misclassifications. The incorporation of modified datasets into the object detection model increased the F1 score from 80.56% to 87.18%. While the results for Area 1 showed minimal differences between using only real datasets and real plus modified datasets in terms of the number of detected pipes and bounding box size, the improvements are more evident in Area 5. The bounding box locations and orientations in Area 5 became more aligned with the ground truth, and fewer objects were misclassified. The result of object detection performance for all datasets can be seen in Table 23.

The results at IoU 70% are slightly lower than those at IoU 50%, which is expected since a stricter threshold requires more precise bounding box localization. Nevertheless, both thresholds show a consistent improvement in detection performance. At IoU 50%, the F1 score improves from 35.40% in the baseline to 87.18% in the best configuration. Similarly, at IoU 70%, the F1 score increases from 0.00% to 81.97%. This result demonstrates the effectiveness of integrating modified data in refining the model's performance. The poor performance of the baseline model highlights the sensitivity of the proposed methods to the availability of labelled training data. Detection performance also varied across test areas, depending on scene complexity.

Table 2. 3D object detection performance for all datasets.

Real Data	Modified Data	Training type	Precision (50%)	Recall (50%)	F1 (50%)	Precision (50%)	Recall (50%)	F1 (50%)
6 real data	-	-	25.00%	60.60%	35.40%	0.00%	3.03%	0.00%

Real Data	Modified Data	Training type	Precision (50%)	Recall (50%)	F1 (50%)	Precision (50%)	Recall (50%)	F1 (50%)
(baseline)								
6 real data	-	Pretrained model	72.73%	90.28%	80.56%	50.17%	81.81%	62.20%
6 real data	6 modified data	Pretrained model	72.42%	93.93%	81.78%	36.02%	69.69%	47.49%
6 real data	12 modified data	Pretrained model	77.27%	100.00%	87.18%	77.27%	87.27%	81.97%

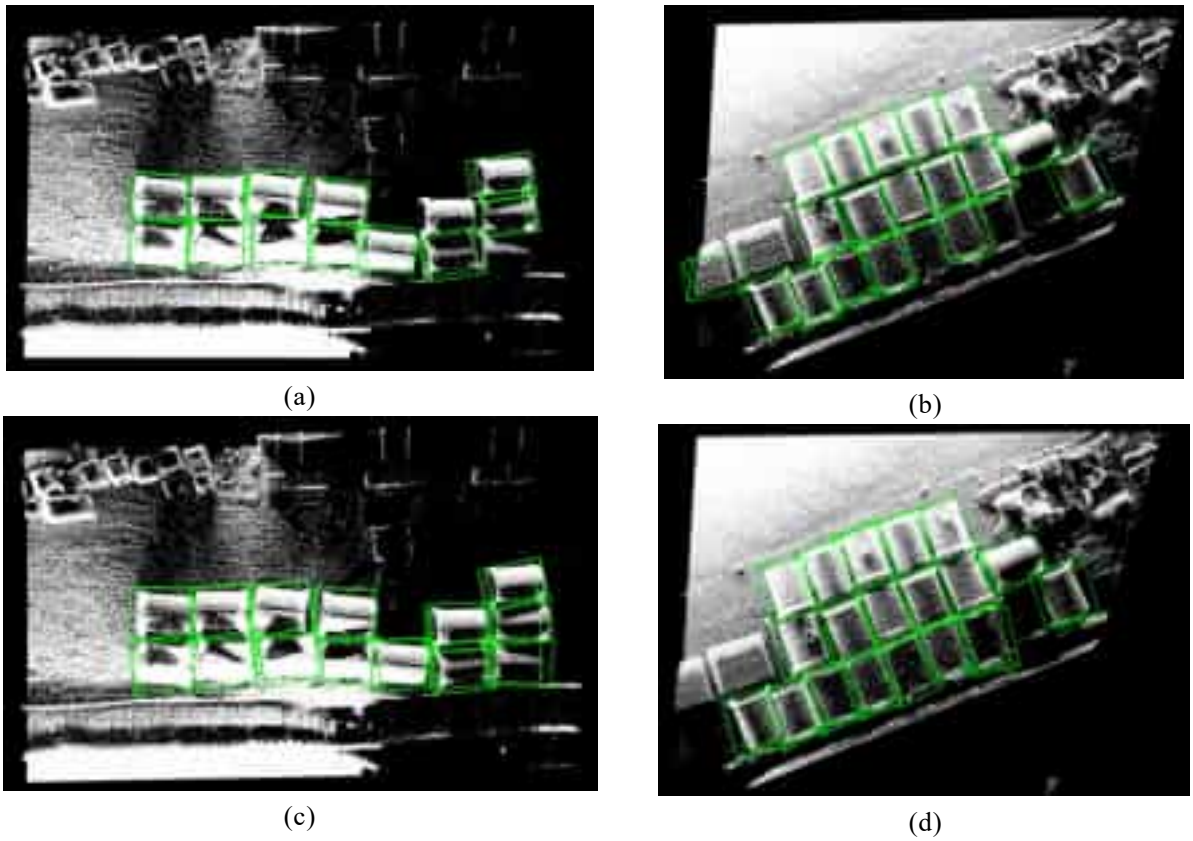

Figure 10. Predicted bounding box from real and modified data with pre-trained model: (a) Area 1 from real and 6 modified data; (b) Area 5 from real and 6 modified data; (c) Area 1 from real and 12 modified data; and (d) Area 5 from real and 12 modified data.

5 Conclusion and Future Work

This research focuses on the application of 3D point clouds for on-site detection of construction materials. The main challenge was the limited actual data and occluded point cloud generated from MLS. This paper addresses the gap by proposing a material-detection method based on transfer learning and modified datasets.

A case study was conducted to verify the proposed method. Two datasets were used: the real dataset and the modified dataset. From the case study results, 3D point cloud object detection improves from 35.40% F1 score on the real dataset without a pre-trained model to 80.56% with a pre-trained model. The results demonstrate that transfer learning combined with dataset preparation can substantially improve pipe detection performance when only a limited amount of real MLS data is available. This improvement is largely due to the use of pre-trained models trained on autonomous driving datasets, which provide strong geometric priors due to their relatively similar scanning conditions. Additionally, the introduction of modified datasets further enhances the F1 score to 87.18%. This result suggests that using additional modified datasets can improve the model's performance.

Although the method shows promising results for material object detection, this study has several limitations. First, the number of testing areas is limited. To comprehensively assess the model's accuracy, additional areas, including those without pipes, should be tested. Second, the detected material is restricted to a single type and size. Future research should explore different material types to evaluate the algorithm's performance across a wider range of conditions. Third, the parameters used in this study, such as subsampling threshold, model hyperparameters, and other preprocessing settings, were not fully optimized. Only a single configuration was tested, and future work should explore the sensitivity of the method to different parameter settings to better understand their impact on detection performance. Additionally, the data used in this study is limited to 3D point clouds from MLS only. Further research could incorporate other data sources, such as images, videos, and 3D point clouds from airborne laser scanners, to assess whether integrating multiple data types improves detection accuracy.

Abstract

The construction industry is characterized by a high degree of structural complexity, making it difficult to achieve a high level of modularization at the current stage. During operations involving robotic arms, human operators are often required to enter the robot's workspace at certain stages to perform fine adjustments, which may expose them to safety risks. Therefore, this study aims to develop a human-robot collaboration safety system framework that utilizes multi-view cameras to monitor, in real time, the positions of both the robotic arm and the operator. Object detection techniques are applied to streaming video for human tracking, while human pose estimation is used to analyze body posture. In addition, multi-view trajectory integration is employed to fuse information from different camera perspectives, enabling the system to determine whether the operator has entered a hazardous operating zone of the robotic arm. Ultimately, the proposed system provides real-time risk alerts while minimizing unnecessary interruptions to normal construction workflows, with emergency stop triggered when safety is compromised. This design reduces the likelihood of accidents caused by unintended entry into dangerous areas and enhances overall safety in human-robot collaborative operations.

Keywords -

Human-robot collaborative; Safety monitoring; Object detection; Human Pose Estimation

1 Introduction

The use of robotic arms has been widely adopted in many highly modular industries, such as automotive manufacturing, electronics assembly, and warehouse logistics. However, the introduction of robotic arms into the construction industry faces far greater challenges. In addition to the inherent complexity of construction projects, even components of the same type may vary in size, specifications, and construction requirements due to differences in design conditions, site constraints, and client demands. Moreover, to accommodate on-site conditions, design modifications are often made during the construction process. These high levels of uncertainty and environmental variability pose significant challenges to the integration of robotic arms into prefabrication and assembly workflows in construction.

In the early stages of design and planning, operators must repeatedly test processing workflows and related parameters to ensure production efficiency and product quality. At the same time, robotic arms used in construction can weigh several tons, and their end-effectors are often equipped with high-risk tools, such as nail guns and cutting machines, for timber cutting and assembly tasks. To prevent irreversible accidents caused by human error, this study proposes a safety framework for construction-site robotic arm operations. By integrating multi-camera human tracking and safety-zone assessment, the proposed framework not only improves the efficiency of human-robot collaboration but also provides enhanced safety supervision in robotic construction environments.

2 Literature Review

Human-robot collaboration (HRC) has gradually become a key trend in the development of smart manufacturing industries [1][2]. However, when operators and robotic arms work within the same workspace, potential safety hazards may arise, including collision, crushing, pinching, and puncture injuries. To prevent such safety incidents, a common protective strategy is to establish a protective field , typically implemented through the Safety-Rated Monitored Stop (SRMS) mode, in which a robot and its human partner

are not allowed to operate simultaneously within the same workspace [3]. Under SRMS, personnel are restricted from entering the operational area while the equipment is active. This can be achieved using physical barriers or sensor-based solutions such as light detection devices. Once human presence is detected within the operational zones during robot operation, the system automatically stops the equipment. However, this approach inevitably reduces the effective shared workspace between the robot and the human operator, potentially constraining task flexibility and productivity. To overcome this limitation, an alternative collaboration strategy is the Speed and Separation Monitoring (SSM) approach, which allows humans and robots to move simultaneously within the shared workspace while maintaining a minimum protective distance at all times [3]. Such safety strategies rely on reliable perception of worker locations in real time. To capture worker locations in complex construction environments, multi-camera system plays an important role in a wide range of domains, including motion capture, surveillance, robotics [4]. Multi-camera people tracking (MCPT) is a challenging task, particularly in complex real-world environments, and is essential for the development of intelligent surveillance and monitoring applications [5]. This task also involves solving multiple computer vision challenges, such as object detection and multiple object tracking (MOT) [6]. However, most existing MCPT research has focused on general surveillance or crowd monitoring scenarios, and is often conducted in controlled or simulated environments. In contrast, HRC settings present additional real-world challenges such as frequent occlusions, limited camera viewpoints, real-time safety requirements, and the need to associate tracking results with robot operating zones. Therefore, a reliable multi-camera tracking framework tailored for HRC scenarios is required to accurately monitor human positions and safety-critical movements in real time. In this study, we develop a multi-camera human tracking and safety monitoring system that integrates object detection, MOT, and human-robot spatial interaction analysis to support SSM-based collaborative operations.

3 Method

This study develops a Multi-camera human tracking and safety-warning system framework designed for construction-site robotic arm operations (Figure 1). The system consists of three main modules: a tracking module, a projection module, and a safety-zone decision module. Two cameras are installed around the robotic arm workspace to capture on-site operation videos from multiple viewpoints. The tracking results are then projected onto a 2D ground-plane representation, enabling analysis of the relative spatial positions between workers and the robotic arm during operation. Based on the proposed three-stage safety-zone design, the system further determines the robot operating speed in a sequential manner, including full speed, reduced speed, and emergency stop.

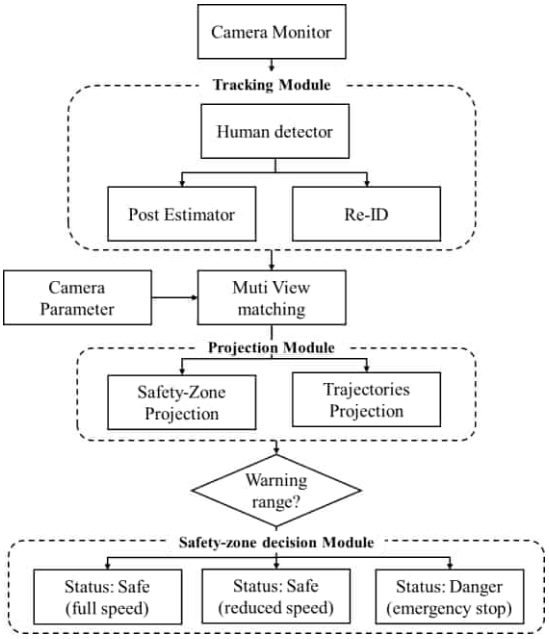

Figure 1. Multi-camera human tracking and safety-warning framework.

3.1 Tracking Module

The tracking module extracts identity-consistent worker trajectories from multi-view videos. First, each camera frame is processed using a YOLO-based detector to localize workers with bounding boxes. The model is fine-tuned using project-specific construction-site videos to improve robustness under real-world conditions. Next, a pose estimation model predicts 2D skeletal keypoints for each detection, providing structural cues that support cross-view association. Finally, person re-identification (ReID) features are extracted to match workers across cameras and time. By integrating appearance similarity, pose consistency, and temporal proximity, fragmented single-view tracks are fused into unified multi-camera trajectories.

3.2 Projection Module

In the projection module, fused multi-camera trajectories are mapped onto a 2D ground-plane representation of the workspace. Camera views are geometrically aligned with the site layout, and predefined safety-zone boundaries are projected onto the same ground-plane coordinate system. The system then computes worker-robot proximity by analyzing distances

between workers and predefined hazardous regions within the robotic arm's working envelope. This projection supports real-time proximity monitoring and safety-aware decision-making under SSM-based human-robot collaboration scenarios.

3.3 Safety-Zone Decision Module

The safety-zone decision module evaluates operator proximity based on the projected 2D worker positions and predefined safety zones associated with the robotic arm's working envelope. Following the Speed and Separation Monitoring (SSM) principle, the workspace is divided into three staged zones reflecting different safety risk levels. The system continuously computes the relative distance between each worker and the hazardous operational region of the robotic arm. According to the zone in which the worker is located, the module determines the robotic arm operating mode sequentially:

1. Full speed operation when no workers are within the warning zones.
2. Speed reduction when a worker enters the intermediate zone.
3. Emergency stop when a worker enters the closest/high-risk zone.

This design provides an explicit safety supervision mechanism for real-time human-robot collaboration and reduces the likelihood of accidents caused by human error.

4 System prototype

To validate the feasibility of the proposed framework, a proof-of-concept prototype was developed with a focus on the tracking module. Since accurate human localization and identity-consistent trajectory generation provide the essential inputs for both ground-plane projection and safety-zone decision-making, tracking performance largely determines the effectiveness of the overall pipeline. To verify whether the estimated movement paths are consistent with real operator trajectories, a Unity-based simulation environment was constructed to replicate the robotic arm workspace (Figure 2)

The prototype implements multi-view tracking using three components: human detection, pose estimation, and person re-identification (ReID). Multi-view MP4 videos are decoded frame by frame, and a YOLO-based detector is applied to obtain worker bounding boxes. A top-down pose estimator predicts 2D keypoints for each detection, while a ResNet-50-based ReID model extracts appearance embeddings to maintain identity consistency across frames and camera views. The system then performs tracking integration by associating detections over time using fused cues from pose similarity, geometric constraints, bounding-box overlap (IoU), and ReID similarity.

Finally, for each confirmed track, the system projects the person's position onto a common 2D ground plane and compares the worker's location with the predefined safety-zone boundaries (Figure 3). When the operator is outside the robot work area, the robotic arm operates normally. Once the operator enters the fenced work zone, the robot is required to slow down. If the operator further enters the red danger zone, the robotic arm must stop immediately. This process is used to verify positional accuracy and assess whether the tracking result is consistent with the expected safety-zone relationship.

To quantitatively evaluate tracking accuracy, we measure the spatial error between predicted trajectories and ground-truth paths under different distance thresholds. The accuracy is defined as the percentage of frames where the localization error is within a given threshold. The results are summarized as follows: 0.1 m threshold: 26.3%, 0.3 m threshold: 80.4%, 0.5 m threshold: 88.9%, 1.0 m threshold: 95.3%. These results indicate that the proposed system achieves high localization reliability under practical safety margins (0.3-1.0 m), which are consistent with safety requirements in human-robot collaboration scenarios.

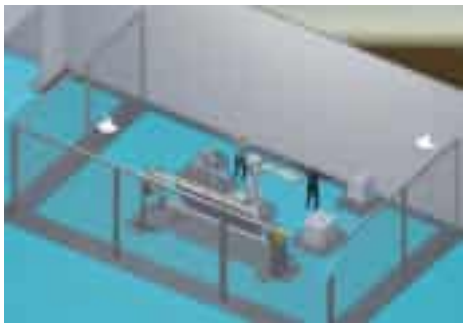

Figure 2. 3D on-site environment simulated in Unity.

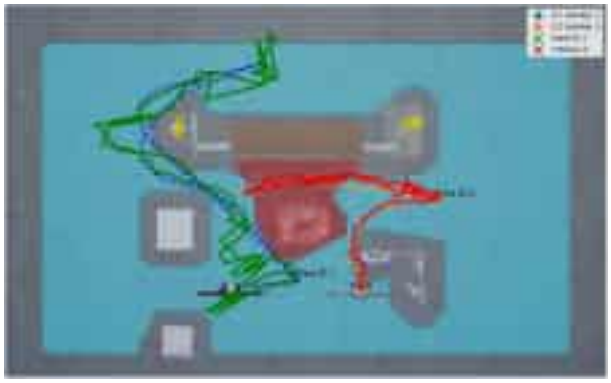

Figure 3. Human movement trajectories.

5 Future works

The proposed framework provides a safety supervision mechanism for human-robot collaboration in complex construction-site robotic arm workspaces. Compared with the traditional Safety-Rated Monitored Stop (SRMS) mode, which often reduces collaboration efficiency, this framework follows the Speed and Separation Monitoring (SSM) principle to gradually adjust the robotic arm operation state according to the actual safety risk. However, the current implementation adopts predefined safety zones for simplicity and real-time feasibility, which may not fully capture task-dependent hazards in dynamic construction environments. In practical scenarios, safety risks are influenced by multiple factors, including the robotic arm's reachability, tool path, and tool geometry. Therefore, future work will focus on integrating robotic arm motion planning and task-level information to dynamically model the working envelope of the robotic system. By incorporating task scripts and kinematic constraints, the system can generate adaptive safety zones that reflect real-time operational conditions. This enhancement will enable more accurate and context-aware safety assessment, improving the applicability of the proposed framework in real-world construction environments.

6 Conclusions

This study develops a Multi-camera human tracking and safety-warning system framework designed for application in robotic-arm operation environments within construction and factory settings. By deploying multiple video cameras around the robotic workspace, the system enables synchronized monitoring of operator activities and tracks human movement trajectories in relation to the robot's operating zone. The proposed framework is composed of three main modules: the tracking module, the projection module, and the safety-zone decision module. Through this pipeline, the system converts multi-camera visual information into a unified 2D spatial representation of worker positions, allowing the analysis of proximity and potential safety-risk interactions between operators and the robotic arm.

The proposed framework demonstrates the feasibility of using multi-camera human tracking as a safety-oriented perception layer for human-robot collaboration in construction-site robotic arm operations. By transforming tracking results into a spatial representation of worker-robot proximity, the system enhances situational awareness and supports collaborative operation strategies such as SSM, thereby contributing to safer interactions between workers and robotic systems. The system is designed to balance operational efficiency and safety by minimizing unnecessary interruptions while ensuring immediate emergency stop when hazardous conditions are detected, aligning with safety requirements in SSM-based human-robot collaboration.

Acknowledgements

The authors would like to thank Prof. Jacob J. Lin and Mr. Cheng-Yun Tsai (Department of Civil Engineering, National Taiwan University) for their support in prototype development, including coding assistance and constructive feedback. The authors also acknowledge RoBIM Technologies Inc. for sharing practical knowledge and providing support for this study.

Abstract -

New Zealand's school building programme is deploying modern methods of construction (MMC) and nationwide IoT sensors faster than almost any other public sector, yet this descriptive multi-case analysis of 17 schools shows that this is disconnected from net-zero goals. Government data indicate that 60% of new classrooms now use MMC, but only 18% of audited schools published any details about their modular systems, and none disclosed embodied-carbon targets or energy-performance benchmarks. Similarly, while every school received IoT sensors for temperature, humidity and CO_2 under the Ministry's Te Haratau rollout, no project documents reveal data-privacy protocols, cybersecurity standards or performance dashboards. The descriptive, multi-case analysis demonstrates that MMC and IoT are being adopted to solve capacity, cost and resilience pressures, not to deliver measurable carbon reductions. Mandatory public reporting of construction typology, lifecycle carbon metrics and sensor governance would align New Zealand's most standardised building portfolio with its climate commitments and create a replicable model for other public infrastructure.

Keywords -

Modern Methods of Construction (MMC); Internet of Things (IoT); School buildings; New Zealand; Net-Zero

1 Introduction

New Zealand (NZ) has committed to net-zero greenhouse-gas emissions by 2050, placing the building and construction sector under increasing pressure to deliver both capacity and carbon reductions simultaneously [1]. School buildings are central to this transition: they represent one of the country's largest, most standardised, publicly funded building portfolios, governed centrally by the Ministry of Education (MoE), and are already the focus of policy initiatives to improve performance and resilience [1, 2].

Recent policy pushes have accelerated two major forms of innovation in the school property programme. First, a 2024 government directive instructed the MoE to prioritise MMC, contributing to a rapid increase in modular and prefabricated classrooms: over 60% of new classroom builds used MMC in Q1 2024, up from under 20% in Q4 2023 [2, 3, 4]. Second, the MoE's Te Haratau programme (TeH) is deploying IoT-based Internal Environment Monitoring (IEM) devices across more than 2,500 state schools to capture indoor air-quality and comfort data at scale [5, 6]. Together, these initiatives create an unprecedented opportunity to link construction innovation and smart monitoring with national climate objectives.

However, existing research and reports on zero-carbon buildings in New Zealand highlights institutional, regulatory and knowledge gaps that hinder the translation of high-level climate targets into project-level decisions [7, 8, 9]. Little empirical evidence currently shows how MMC and IoT are combined in completed school projects, how they are framed in publicly available documentation, or whether they are explicitly aligned with net-zero, embodied-carbon or energy-performance targets.

In this context, MMC is understood to include prefabrication, modularisation, volumetric off-site manufacturing and digitally integrated design-to-production workflows [2], while IoT encompasses sensor networks and building-management systems capable of streaming data on energy use, environmental quality, occupancy and equipment performance [10, 11].

This paper addresses these gaps through a descriptive multiple-case study of 17 New Zealand school projects with identifiable MMC typologies and confirmed IoT sensor deployment. The objective is to map how MMC and IoT are documented and justified in these projects, and to assess the extent to which sustainability and carbon-reduction narratives are integrated into their public reporting.

2 Methods and Materials

2.1 Study Design

The study adopts a descriptive multiple-case research design following Yin's approach to case study research [12], focusing on mapping patterns of adoption and framing rather than testing causal relationships. The unit of

analysis is the individual school campus (primary, intermediate, secondary and kura kaupapa Māori).

Purposive, multi-stage sampling was used to identify and select cases from the national Directory of Educational Institutions and associated MoE property information [13]. Eligible schools were state or state-integrated institutions that:

- completed significant capital works between 2015 and 2024
- demonstrated some use of MMC
- deployed IoT monitoring systems, and
- showed at least some net-zero or sustainability framing at policy or design level.

Initial screening of MoE and public documentation yielded approximately 35–40 schools with recent capital activity and potential MMC involvement. A more detailed documentary review then confirmed the presence of (1) MMC components, (2) IoT systems and (3) sustainability framing. From these, 17 schools were selected to ensure variation in region, school type and project type (new builds, major redevelopments, roll-growth additions and resilience/recovery works). Schools are anonymised as S1–S17.

2.2 Data Sources and Coding Framework

Data were collected from publicly accessible sources including GETS tender documents, MoE property data, council consent records, architect and contractor case studies, Education Review Office (ERO) reports, media coverage and vendor listings. For each school, a within-case summary was compiled, and key information was extracted into structured coding tables.

A multi-dimensional coding framework operationalised three primary domains:

- **MMC typologies** – manufacturing location (off-site/hybrid/traditional), component scale (volumetric/panelised/structural) and deployment intent (permanent/temporary/adaptive), drawing on MMC literature and UK off-site classifications [2, 14].
- **IoT functions** – confirmation of hardware deployment; intended function (environmental monitoring, building management system, occupancy detection); platform governance (stand-alone vs. integrated, cloud management, open vs. proprietary protocols); and occupant-facing transparency (real-time dashboards vs. opaque backend systems) [6, 10, 11, 15].
- **Carbon reduction claims** – presence and strength of sustainability framing, ranging from explicit building-level net-zero targets to broader programme-level or values-only statements, covering both operational and embodied emissions where stated [7].

Modular classroom blocks were coded as OP-V (off-site, prefabricated, volumetric, permanent) and OP-V-R (off-site, prefabricated, volumetric, relocatable) for analysis. The multi-stage case selection and analysis process is shown in Figure 1.

3 Results

3.1 Audit Group Overview

The audit examined 17 NZ school campuses across eight regions (Auckland, Wellington, Waikato, Bay of Plenty, Hawke's Bay, Christchurch, Palmerston North, Lower Hutt). Group composition: primary schools (8), intermediate (4), secondary (4), kura kaupapa Māori (1). Projects ranged from new builds (3), major redevelopments (7), roll-growth additions (4), and resilience/recovery initiatives (3). For each school, approximately 6–28 distinct documents were available, providing sufficient material to reach theoretical saturation for the descriptive aims of the study.

3.2 MMC Adoption

Only 18% of schools (3 of 17) demonstrated MMC. Despite government policy accelerating MMC adoption to 60% of new classrooms in Q1 2024, only a minority had publicly documented evidence of MMC, reflecting a public-sector documentation gap.

3.2.1 Case 1: TKKM Te Ara Wahanui (S8)

Minister Erica Stanford announced OP-V construction for 8 modular classrooms [16], emphasizing operational efficiency: "By using modular construction, we can deliver classrooms more quickly." Classrooms designed for 20-to-50-year lifespan. Public narrative focused on safety and warmth; no explicit sustainability or carbon-reduction language despite government climate commitments.

3.2.2 Case 2: Addington Primary (S9)

CEBUS relocatable block (OP-V-R, 192 m^2, $235,594) deployed May 2024. Previously relocated; designed for future relocation. Part of post-earthquake rebuild (2015–2020), exceeding Building Code standards. Framed as "stronger, safer" rebuild without net-zero claims.

3.2.3 Case 3: Ōtūmoetai College (S14)

$47M redevelopment addressing weathertightness and capacity [17]. Multiple prefab classrooms on field to be removed [18]. Existing OP-V-R stock; unclear if new modular units will replace structures. Carbon narrative driven by "leaky buildings" rather than sustainability.

Figure 1. Multi-stage case selection and analytic workflow of MMC and IoT-enabled school buildings.

3.3 IoT and Smart Building Systems

All 17 schools had confirmed IoT infrastructure via MoE TeH programme documentation and IoT provider lists. Zero schools publicly documented BMS, data governance, or performance expectations, creating a transparency gap. Without school-level documentation, system functionality cannot be classified.

The MoE TeH programme plans national rollout to all 2,500 state schools by 2030. Investment: $12.5–25M ($5,000–10,000 per installation). All 17 schools are part of a managed, standardised IoT rollout. Heterogeneity in outcomes (energy performance, occupant comfort) is unlikely to reflect system design but rather building typology, envelope performance, and occupancy patterns.

3.4 Carbon Reduction Claims and Sustainability Narratives

Overall, the carbon claim distribution for the 17 schools showed that none used explicit terms like "Net-Zero," "Zero Carbon," or "Carbon Neutral." Only 12% of 17 schools demonstrated any form of implicit sustainability framing through formal environmental certifications or embedded programmes.

Sustainability framing dissociated from procurement. Capacity, cost, and schedule are primary drivers, environmental performance secondary or absent.

3.4.1 Case 4: Waterloo School (S16)

S16 demonstrates institutional commitment to sustainability as a whole-school ethos through Enviroschools Bronze certification active since 2014, with evidence from ERO reports stating that ecological sustainability is highly evident in the school's philosophy and values, although there are no explicit net-zero claims or building-specific carbon targets in its substantial property redevelopments [19].

3.4.2 Case 5: Te Kauwhata Primary School (S17)

Strongest implicit sustainability commitment: Enviroschools Green-Gold certification (2024, highest level). Formal programmes include Community Compost Hub and solar-heated pool for GHG reduction. However, capital activity tenders lack construction method or embodied carbon documentation. Focus on operational metrics (waste, solar) without building-level net-zero strategies.

3.5 Co-Adoption Patterns: MMC, IoT, and Sustainability Alignment

Fusing the three domains reveals three main co-adoption patterns:

- **Full convergence (MMC + IoT + explicit net-zero claim)** – No school in the sample combined documented MMC use, IoT monitoring and explicit building-level carbon-reduction targets.

- **Hardware-only adoption (all 17 schools)** – Every school had IoT infrastructure through TeH, but almost none linked this hardware to measurable energy or carbon-performance expectations, and only a small minority documented MMC. In these cases, MMC and IoT appear as independent responses to capacity and operational pressures rather than components of an integrated net-zero strategy.
- **Split adoption (~82%)** – Most schools combined IoT deployment with traditionally documented or unspecified construction typologies. In other words, smart-monitoring infrastructure is being rolled out regardless of whether buildings use MMC or conventional construction, with little evidence that the two are co-designed for carbon outcomes.

These patterns point to a structural gap: technology adoption is not currently being harnessed to deliver or verify progress towards net-zero commitments at the level of individual school projects.

As shown in Table 1, only 3 schools (18%) had documented MMC components, despite national policy pushing for 60% adoption. All 17 received IoT sensors, yet none reported data usage or governance publicly. Similarly, no schools set explicit carbon targets.

4 Discussion

4.1 The Documentation Paradox: MMC Adoption versus Visibility

The gap between 60% national MMC adoption (Q1 2024, up from 20% in Q4 2023) and only 18% documented MMC use in this cohort signals systematic transparency deficits in public-sector reporting [4]. This discrepancy does not indicate low adoption; rather, it reveals that construction innovation proceeds without public accountability mechanisms.

Documented cases (S8, S9, S14) consistently emphasized operational efficiency, speed, cost, resilience, over embodied carbon reduction, despite NZ's legally binding net-zero by 2050 target. S8's ministerial announcement framed modular construction as delivering "classrooms more quickly" without referencing lifecycle performance. S14's decommissioning of existing prefab classrooms in favour of permanent structures suggests institutional preferences for traditional construction despite MMC availability. This pattern reflects immediate capacity pressures overriding environmental considerations in procurement decisions.

Addressing this gap requires standardized reporting protocols that mandate disclosure of MMC typology, embodied carbon estimates, and operational performance expectations in all publicly funded school projects. Without such mechanisms, policy acceleration proceeds independently of climate accountability.

4.2 Universal IoT Deployment, Opaque Governance: The Te Haratau Programme

The TeH programme's three pillars: condition assessment, fitness for purpose and operational efficiency (energy monitoring), establish a data infrastructure unprecedented in the sector.

Table 1 also shows that 17 schools (100%) confirmed IoT deployment measuring CO_2, temperature, and humidity, yet zero schools publicly documented BMS configurations, data governance protocols, or environmental performance dashboards. This opacity raises critical questions about transparency and occupant agency, particularly in educational settings where children constitute the monitored population. While the MoE centrally manages TeH data via cloud platform, lack of school-level documentation on algorithms or system interoperability prevents independent evaluation of effectiveness.

Aligning TeH with net-zero ambitions would therefore require not only technical rollout but also governance frameworks that specify responsibilities, transparency requirements and mechanisms for linking IoT-derived insights to measurable energy and carbon-performance indicators at school level. The national IoT infrastructure therefore represents a latent platform for net-zero implementation, but only if governance, transparency and integration with BMS are strengthened.

4.3 Decoupled Narratives: Construction Innovation without Sustainability Targets

The most consequential finding is systematic decoupling of MMC and IoT adoption from explicit sustainability performance targets. No schools articulated net-zero, zero-carbon, or carbon-neutral claims. As summarised in Table 1, only 12% (n=2) demonstrated implicit sustainability commitment through formal Enviroschools certification, while 41% (n=7) framed capital projects through resilience and post-disaster recovery rather than climate mitigation.

This decoupling from the Carbon Neutral Government Programme [8] and 2022 Emissions Reduction Plan [9] suggests procurement narratives prioritize operational drivers capacity, cost, speed, resilience over environmental performance. The gap reflects immediate capacity pressures, absence of mandatory embodied carbon caps in Building Code, and persistent institutional knowledge gaps identified in zero-carbon building research [7]. Without enforceable mechanisms linking MMC and IoT adoption to carbon performance targets, technological innovation proceeds independently of climate commitments, under-

Table 1. MMC, IoT, and Carbon Framing Across 17 NZ Schools.

Dimension	Category	Count (n=17)	%	Notes
MMC Documentation	Documented MMC Use	3	18%	All were off-site volumetric; 2 temporary, 1 permanent
	Unknown / No Documentation	14	82%	Indicates a significant public documentation gap
IoT Deployment	Sensors Installed	17	100%	Standard MoE rollout (Temp, CO_2, Humidity)
	Public Data / Dashboards	0	0%	No BMS, transparency, or governance disclosed
Carbon Framing	Explicit Net-Zero Targets	0	0%	No formal carbon or energy benchmarks published
	Implicit Framing (e.g. Enviroschools)	2	12%	Green-Gold and Bronze certifications
	Resilience-Focused Framing	7	41%	Projects linked to earthquakes / recovery
	No Sustainability Framing	8	47%	No carbon / environmental goals evident

mining policy coherence between infrastructure delivery and emissions reduction objectives.

Given their scale, standardisation and central governance, New Zealand schools represent an ideal scene for developing structured net-zero procurement and reporting practices that could subsequently be extended to broader public infrastructure.

5 Conclusion

This case study reveals a paradox in New Zealand's school-building programme: despite accelerated MMC deployment (60% of new classrooms, 2024) and universal IoT rollout, these innovations remain disconnected from net-zero-by-2050 commitments. Across 17 schools, only 18% published construction documentation; none disclosed carbon targets or data-governance protocols. The gap is institutional: procurement rewards speed and cost while Building Code imposes no embodied carbon limits. As New Zealand's most standardized public infrastructure, schools offer strategic opportunity to develop reporting protocols linking construction innovation to measurable emissions reduction, providing a replicable framework for broader public infrastructure decarbonization.

Identifying and Classifying Residents' demand for Smart Community Development: An Empirical Analysis from China

Yujia Shan[1] and Tiantian Gu[1]

[1] School of Mechanics and Civil Engineering, China University of Mining and Technology, Xuzhou, China

ts24030295a31tm@cumt.edu.cn, 6072@cumt.edu.cn

Abstract

Smart community development is pivotal for modernizing grassroots governance. However, few studies have established a systematic classification model for residents' multi-dimensional needs. To fill this research gap, this paper constructs a comprehensive demand analysis framework covering three core dimensions: community safety, livability services and community governance. Based on the survey data of 191 valid samples from 5 typical smart communities in Huizhou, this study uses hierarchical clustering and K-means clustering to identify and classify residents' demand types. The results divide residents into four clusters: weak service-oriented demand group, safety and governance priority demand group, strong service demand group and comprehensive demand group. This taxonomy framework offers a replicable methodology for smart community planning with diverse resident demand priorities. Additionally, grounded in empirical analysis of Huizhou, China, it provides smart community development strategies for the Chinese context to enhance smart community development efficacy.

Keywords –

Smart community; Residents' demand; Community governance; Cluster analysis

1 Introduction

Smart community development plays a pivotal role in driving sustainable urbanization, serving as the operational backbone of broader smart city frameworks [1]. Generally, such initiatives adopt digital technologies to enhance urban quality of life, operational efficiency, and governance structures [2]. During public health emergencies, smart communities also showed obvious advantages in rapid early warning, closed management and resource allocation [3]. Yet the effectiveness of these efforts hinges on a systematic grasp of what residents actually need [4]. Given that residents hold diverse and often competing priorities, failing to quantitatively capture this demand landscape risks misallocated investments, poor uptake, and ultimately project failure [5]. Therefore, a deep understanding of residents' needs is essential to shift the focus of smart community development from a technology-first approach to one that puts people at the center [6].

In existing literature, the governance functions of smart communities have been extensively analyzed, but discussions on the actual demands of residents remain fragmented. For instance, the roles of various stakeholders have been clarified, and the development orientations of community property service enterprises, government agencies, and other participants have been further analyzed in the process [7]. From the property management side, researchers have examined how firms adapt their operations and business models under digital transformation [4], while public administration scholars have focused on policy execution and governance outcomes [8, 9]. However, in existing research, residents typically occupy a passive position. Consequently, another strand of literature has concentrated on residents' needs and experiences to evaluate specific smart community functions and adjust development strategies. Scholars have investigated satisfaction and supply-demand matching in specific functional domains, including older adult care services [10], residential energy scheduling [11], and water demand management [12]. Additionally, few studies have explored residents' demands for smart community development [13]. Taken together, this work points to two related shortcomings. On the one hand, most studies examine isolated service functions rather than constructing a comprehensive demand indicator framework. On the other hand, rigorous quantitative tools for mapping multi-dimensional demand profiles across resident groups remain absent.

To address these gaps, this study developed a resident demand indicator system covering three dimensions of smart community development, then built a classification model by combining hierarchical

clustering with K-means analysis. Drawing on 191 valid survey responses, the approach identifies empirically grounded demand clusters among residents. Theoretically, this research filled the theoretical gap of lacking a systematic indicator system that integrates multi-dimensional residents' demands. It also introduces a data-driven taxonomy that moves the field beyond isolated functional analyses toward an integrated view of demand patterns. Practically, suggestions were designed for the case communities directly and offered a transferable reference for smart community projects with comparable demand profiles, supporting more effective project implementation in similar contexts.

2 Methodology

2.1 Establishment of the residents' demand indicator system

The selection of resident demand indicators drew on two complementary theoretical foundations: Maslow's Hierarchy of Needs and the Kano Model [14]. These frameworks were chosen because their respective strengths align well with the dual task of ordering and categorizing demands in a smart community context [15]. Maslow's hierarchy traces how human needs progress from basic survival concerns to higher-order aspirations [16], while the Kano Model offers a mechanism for classifying demands based on their impact on satisfaction [17]. Used in combination, the two models support a structured analysis of resident demands that spans from foundational safety concerns to active participation in community governance.

The resulting integrated indicator system (see Figure 1) organizes resident demands into three core dimensions. The first, Community Safety, corresponds to Maslow's safety needs level and captures residents' baseline expectations for protecting life and property [18-22]. Under the Kano Model, these function as Must-be Quality attributes: their absence triggers strong dissatisfaction, yet their presence alone does not generate positive responses. The second dimension, Community Services, maps onto the love and belongingness and esteem needs in Maslow's framework, covering services that raise living standards and reinforce social identity [23-27]. The Kano Model treats these largely as One-dimensional Quality demands, where satisfaction climbs in step with service performance. The third dimension, Community Governance, reflects Maslow's self-actualization level and concerns residents' involvement in community decision-making processes [8, 28-30]. In Kano terms, these are Attractive Quality attributes. Their presence can substantially lift satisfaction, but their absence does not provoke dissatisfaction.

Figure 1. The residents' demand indicator system

Demand indicator selection relied on an expert scoring exercise drawing on 38 valid responses from a panel of 50 invited participants, spanning both academic researchers and seasoned practitioners. The expert panel composition is shown in Table 1. This process resulted in the final demand indicator system, consisting of 3 primary and 25 secondary indicators, as summarized in Figure 1.

Table 1. Information of the 38 experts surveyed

Variable	Items	Percentage (%)
Gender	Male	47.37

2.2 Development of the residents' demand classification model

Building on this indicator system, a demand classification model was constructed by combining hierarchical cluster analysis (HCA) with k-means clustering to categorize resident demand profiles in a systematic way. The two methods were paired for their complementary roles. HCA was used first to determine the appropriate number of clusters by interrogating the underlying data structure, after which k-means clustering was applied to partition samples into stable, well-

separated groups [31]. Cluster analysis is a multivariate statistical technique that groups samples according to similarity, making it well suited to uncovering typologies within complex resident demand data [32].

(a). Calculation of initial distances

$$d_{ij} = \sum_{k=1}^{m} (x_{it} - x_{jt})^2 \quad (1)$$

$$S = \sum_{i=1}^{n} (x_{i1} - \frac{\sum_{i=1}^{n} x_{i1}}{n})^2 + \ldots + \sum_{i=1}^{n} (x_{im} - \frac{\sum_{i=1}^{n} x_{im}}{n})^2 \quad (2)$$

where x_{it} and x_{jt} represent the data of the t-th indicator in the i-th sample and j-th sample, respectively. d_{ij} denotes the distance between the i-th sample and the j-th sample in terms of three dimensions. S denotes the sum of squared deviations.

(b). Cluster merging based on minimum distance

If clusters p and q are merged into a new cluster l, the sum of squared deviations of cluster l was:

$$S_l = S_p + S_q + \frac{n_p n_q}{n_p + n_q} (\overline{x_p} - \overline{x_q})^2 \quad (3)$$

$$d_{pq} = \triangle S_{pq} = \frac{n_p n_q}{n_p + n_q} (\overline{x_p} - \overline{x_q})^2 \quad (4)$$

The distance between the new cluster l and any arbitrary cluster r was calculated using the following formula:

$$d_{lr} = \frac{n_p + n_r}{n_l + n_r} d_{pr} + \frac{n_q + n_r}{n_l + n_r} d_{qr} - \frac{n_r}{n_l + n_r} d_{pq} \quad (5)$$

where p and q contain n_p and n_q samples and their corresponding sums of squared deviations are denoted as S_p and S_q.

(c). Determination of the optimal number of clusters (k).

Step (b) is repeated iteratively, merging the two nearest clusters at each pass until all samples converge into a single cluster. This process generates agglomeration coefficients for successive cluster solutions, and the relationship between these coefficients and the number of clusters is then examined to identify the optimal cluster count (k).

(d). Calculation of the new distance matrix

K-means clustering was applied with the optimal cluster number (k=4) determined from the hierarchical clustering analysis. The algorithm employed k-means++ initialization, which selects initial cluster centers based on distance. With k centers established ($c_{j\prime}$, where j'=1, 2, …, k), the Euclidean distance $D(x_i, c_{j\prime})$ between each sample and every center was computed, and the resulting distance matrix was constructed as follows:

$$D = (d_{ij}) = \begin{bmatrix} d_{11\prime} & d_{12\prime} & \ldots & d_{1k} \\ d_{21\prime} & d_{22\prime} & \ldots & d_{2k} \\ \ldots & \ldots & \ldots & \ldots \\ d_{n1\prime} & d_{n2\prime} & \ldots & d_{nk} \end{bmatrix} \quad (6)$$

Each sample is then assigned to the cluster j' with the min $D(x_i, c_{j\prime})$, which satisfied: $D(x_i, c_{j'}) = \min\{D(x_i, c_{j'})\}$ (i=1, 2, …, n; j'= 1, 2, …, k), the sample belongs to the j'-th cluster.

(f). Calculation of the k new cluster centers:

$$C_{j\prime}(I+1) = \frac{1}{n_{j\prime}} \sum_{x' \in C_{j\prime}} x' \quad (7)$$

Where $n_{j\prime}$ denotes the number of samples in cluster $C_{j\prime}$; x' denotes the samples classified into cluster $C_{j\prime}$.

This process continued until cluster assignments no longer changed and the sum of squared errors reached convergence. The procedure yielded k distinct clusters, each carrying a characteristic demand profile across the three core dimensions. Together, these clusters constitute an empirically grounded typology of smart community development patterns, organized around the underlying structure of resident demand.

3 Study area and data collection

3.1 Study area

Huizhou, located in Guangdong Province, China, was among the first batch of 20 pilot smart cities approved by the Chinese government in 2013. In the field of smart community, the Huizhou Municipal Government has been committed to advancing community digital governance, promoting age-friendly and barrier-free renovations, constructing community digital facilities, and establishing information management platforms. These persistent efforts have yielded remarkable achievements in optimizing community services and enhancing governance efficiency. Given that Huizhou is a representative city with a long-standing development history, rich practical experience, and outstanding accomplishments in China's smart community development, it serves as a typical study area for analyzing the residents' demand for smart community development.

To ensure the validity and representativeness of the sample, five communities with smart community outcomes were selected as the study cases, including

Banzhangling, Qingxi, Siqian, Tangjing and Tongxin. These communities all have smart upgrades in community safety and governance dimensions, and are equipped with functions such as resident demand management, grid-based governance, management of the floating population and intelligent patrol systems. Additionally, the five communities have integrated community service functions, such as home-based eldercare, smart healthcare services, intelligent charging facilities and community service centers. This selection ensures that the sample represents actual smart community development while capturing variation in residents' demand.

Figure 2. Study area

3.2 Data collection

Survey data were collected through 'Wenjuanxing', a professional online platform for questionnaire distribution and data collection. A total of 230 questionnaires were sent to residents across the 5 selected smart communities (see Figure 2), and after standard validation procedures, 191 responses were retained as complete and usable, corresponding to a response rate of 83.04%.

4 Results

4.1 Quantification of residents' demands for smart community development

Based on the 191 valid resident questionnaires, the demand of residents for smart community development was assessed. The results revealed significant disparities in demand level across the three dimensions of community safety, community services, and community governance. Overall, residents demonstrated their highest prioritization for community safety (avg. 3.85), followed by community services (avg. 3.77) and community governance (avg. 3.66), revealing that current security concerns take precedence over broader issues of service quality and governance participation. A detailed examination of secondary indicators provides further insights. The average demand scores for these indicators are summarized in Figure 3. Within community safety, residents exhibited particularly strong demand for D1-1 (Digital emergency plan) and D1-3 (Propaganda and education of emergency safety), while showing relatively lower demand for D1-8 (Public facilities monitoring). In community services, D2-6 (Community medical services) received the highest average score, while D2-3 (Smart childcare) scored the lowest. The seven indicators of community governance dimension all showed relatively low demand scores, with D3-1 (Integrated government service system) and D3-7 (Multi-sectoral linkage) recording the lowest scores. These patterns indicated that most residents place greater emphasis on safety outcomes in smart community development, particularly in emergency preparedness and safety education, while expressing lower demand for infrastructure monitoring, smart childcare, and community governance functions.

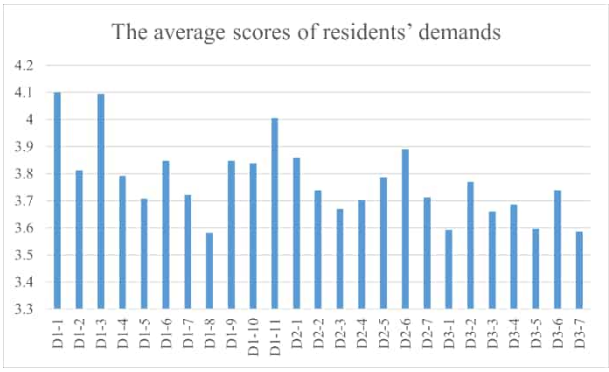

Figure 3. The average demand scores for all indicators

4.2 Clusters of residents' demands for smart community development

To further identify the diverse patterns of residents' demands, a classification model was employed on the demand scores of the 191 respondents. The dataset demonstrated high reliability and validity, with a Cronbach's Alpha of 0.833 and a KMO measure of 0.83 (Bartlett's test $p<0.001$).

The optimal cluster number was subsequently determined using hierarchical clustering with Ward's method. Based on the agglomeration schedule, the optimal cluster number was identified at $k = 4$. Specifically, the growth rate of the agglomeration coefficient exhibited a marked deceleration after the cluster number reached 4, decreasing from 21.07% ($k = 3$ to $k = 4$) to 7.65% ($k = 4$ to $k = 5$). This indicates that

more clusters would gradually diminish the differentiation between resident demand clusters, thus validating k = 4 as the optimal number. Following this, resident demands were partitioned into four clusters using k-means clustering. The clustering process regarded as convergent when the relative change in cluster centers fell below the tolerance threshold of 10^{-4}, indicating that the resulting cluster assignments had stabilized.

The final cluster centers resulting from this analysis are illustrated in Figure 4. The result showed a Silhouette Score of 0.283 and a Calinski-Harabasz index of 106.1, supporting the validity of the cluster structure. Cluster 1 comprised 14 respondents, Cluster 2 comprised 55, Cluster 3 comprised 56, and Cluster 4 comprised 66.

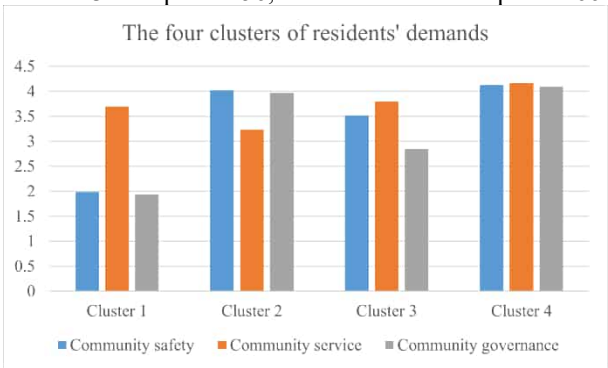

Figure 4. The four clusters of residents' demands

The four clusters showed markedly different demand profiles. Cluster 1 recorded uniformly low scores across all three dimensions (community safety, community services, and community governance). Cluster 2 stand out for its low community services demand, alongside high scores in safety and governance. Cluster 3 posted a high average in community services while falling below average in both safety and governance. Cluster 4 exceeded the overall average across all three dimensions, reflecting a broadly elevated demand profile.

Drawing on these profiles, the four clusters were defined as follows. Cluster 1 (weak service-focused demand) recorded low scores across all three dimensions with a marginal tilt toward basic livability, accounting for the smallest subset of only 14 respondents. Cluster 2 (prioritized safety and governance demand) concentrated demand on safety and governance while showing limited interest in community services, a pattern consistent with the sample-level finding that community safety achieved the highest overall average score. Cluster 3 (strong community services demand) was marked by elevated demand for community services, particularly medical services, alongside lower scores in safety and governance. Cluster 4 (comprehensive demand across all dimensions) maintained high scores across all three domains and represents the largest group at 66 respondents. This empirically grounded grouping captures the demand heterogeneity among residents and offers a practical foundation for formulating differentiated smart community development strategies.

4.3 Strategies to Satisfy residents' Demands for the Smart Community Development

Drawing from quantified demand profiles that identify four distinct resident clusters, effective smart community development requires moving beyond one-size-fits-all solutions toward tailored strategies that address specific resident needs.

For the communities where the residents' demand fell under cluster 1, priority could be given to establish fundamental smart community capabilities that improve daily living. The initial stage focuses on developing digital infrastructure for daily services to bring convenience to residents' everyday lives, including basic medical care, elderly care, community service centers, and other essential services [33]. This objective can be accomplished through the deployment of professional operators, who can enter into performance-based contracts with explicit service-level agreements. These contracts ensure that residents receive reliable and high-quality smart services [34].

For Cluster 2 communities, where residents demonstrate strong demand for safety and governance, targeted public investment is required to address functional deficiencies that affect resident security and civic participation. Emphasis could be placed on establishing centralised community data platforms to improve the efficiency of community safety response and enable active resident participation in governance [35]. Financial sustainability could be supported through instruments such as municipal bonds earmarked for smart city projects [36]. In addition, parallel administrative reforms clarifying jurisdictional boundaries and streamlining service workflows are essential to build digital governance platforms [37], and the clear and streamlined service workflows can enhance public willingness to participate in community governance and improve service experiences.

For communities characterized by Cluster 3, where service demand is high but safety and governance expectations are comparatively low, policy efforts should target market-driven innovation in sectors that directly shape residents' daily lives. A regulatory environment that incentivises private investment in domains residents prioritise, such as community healthcare and smart recycling, can help to achieve this [38]. At the same time, minimum service standards for smart community security [39] and operational oversight arrangements [40] should be put in place to guard against the under-provision of safety and governance functions.

Finally, for communities exhibiting the demand profile of Cluster 4, residents present strong and comprehensive demands across all dimensions. In addition to the three strategies mentioned above, such communities need to address stable funding chains and sustainable business environments. Consequently, the strategic focus should shift toward establishing structured public-private partnerships that draw on combined strengths to directly serve resident needs directly [41]. Delivered services include intelligent safety systems with real-time alerts, digital medical services with seamless access, and governance platforms that support direct resident participation [42]. To achieve stable cooperation, the governments are suggested to develop standardized contractual frameworks that clarify responsibilities, risk sharing and service delivery standards, which ensure that residents receive consistent and high-quality integrated services in safety, healthcare, and governance [43]. This clarity is critical for attracting investment and technical expertise that can be translated into tangible benefits for residents, and practical service outcomes can guarantee residents' willingness to use community services.

5 Conclusion

This study proposed and applied a multi-dimensional classification model to map the demand landscape of residents in smart community development. Drawing on a hybrid clustering approach applied to 191 survey respondents from China, four resident demand clusters were identified: Cluster 1 (weak, service-focused demand), Cluster 2 (prioritized safety and governance demand), Cluster 3 (strong community services demand), and Cluster 4 (comprehensive demand).

This study presented valuable insights in theoretical, and practically terms. On the theoretical side, it offers a data-driven taxonomy that quantitatively organizes resident demands across multiple dimensions, moving the field away from isolated and function-specific analyses toward a more integrated interpretive framework. On the practical side, the findings give policymakers and planners a concrete classification tool. Matching a community to its demand profile allows for the design of targeted interventions, ranging from building foundational digital capabilities in Cluster 1 communities to instituting collaborative governance structures in Cluster 4, thereby improving resource allocation and strengthening the strategic impact of smart city programs.

Despite these contributions, two limitations should be acknowledged. On the one hand, the model's application has been within the specific socio-political context of Chinese cities, which may affect the generalizability of the demand cluster definitions. Future research could validate and refine this taxonomy in diverse international settings. On the other hand, it is necessary to conduct a further analysis of the evolutionary pathway among the clusters of residents' demands, thereby generating more precise strategy framework for smart community development.

Abstract

Worksite trailers are widely used as rapidly deployable prefabricated units, yet their design process must balance standardization for efficiency with customization for diverse functional needs. This study proposes a proof-of-concept early-stage design workflow that integrates a Large Language Model (LLM) with Building Information Modeling (BIM) to support requirement interpretation, historical case reuse, and preliminary layout generation for worksite trailers. The system accepts natural-language descriptions and dimensional constraints, converts them into structured JSON-based parameters, and connects them to BIM generation in Autodesk Revit.

To reduce repetitive modeling effort and improve design reuse, the workflow includes three modules: Historical Case Retrieval, Unit-Based Spatial Assembly, and Conversational Parametric BIM Modeling. Historical cases are matched through a weighted multi-criteria process based on function, spatial composition, occupancy, dimensions, and special-space requirements. Retrieved cases may be reused directly or decomposed into reusable spatial units for recombination. When no suitable precedent is available, or when further refinement is needed, users can generate or modify layouts through natural-language commands that are translated into executable BIM operations.

Prototype demonstrations show that the workflow can generate editable preliminary configurations, support iterative refinement, and improve early-stage design reuse. However, the system remains a proof-of-concept prototype, and formal time-efficiency testing, user studies, and large-scale retrieval benchmarks have not yet been conducted.

off-site manufacturing, Large Language Model (LLM), human–machine interface (HMI)

1 Introduction

Worksite trailers are a prevalent form of prefabricated modular construction, widely deployed as temporary accommodation units, offices, and command centers in construction sites and remote working environments due to their rapid deployment and transportability [1]. In principle, modularity should benefit from standardization to enable efficient delivery and time savings [2]. In practice, however, diverse usage scenarios create a persistent tension between "standardization for efficiency" and "customization for flexibility," where customer-specific requirements often challenge standardized production logic [3]. Even seemingly minor changes in spatial proportions, functional zoning, or dimensional adjustments can still require substantial modeling effort, partly because current BIM tools often provide limited user-centered support for rapid early-stage adaptation [4]. Meanwhile, high investment costs in digital hardware technologies may further discourage stakeholders from adopting advanced digital workflows at scale [5].

Current workflows typically address this tension through manual model modification or template-based extension, yet a lack of project-to-project knowledge transfer remains a persistent barrier [6]. Past cases are commonly scattered across drawings, model files, and individual experience, and a large portion of construction data remains unstructured and difficult to retrieve and reuse [7]. Consequently, case reuse still depends heavily on manual interpretation and rework, limiting the potential for digital data to optimize assembly processes and reduce waste in offsite contexts [8]. In early-stage design, stakeholders often need not a fully detailed model, but a usable preliminary model that can be generated quickly and refined iteratively; language-guided early layout generation has therefore become an emerging direction [9]. Prior work also indicates that integrating BIM with DfMA-oriented parametric and algorithmic collaboration can strengthen client engagement during

offsite configuration, but practical workflows for fast customization are still developing [10].

Building on these challenges, this study integrates Large Language Models (LLMs) with BIM-based modeling to support requirement understanding and early-stage spatial configuration generation for worksite trailers. The system accepts natural-language descriptions and dimensional constraints, translates them into structured and executable parameters, and uses these parameters to drive BIM modeling operations, enabling iterative refinement toward a usable configuration [11]. To address fragmented knowledge organization and limited reuse, the framework further incorporates a structured representation and matching mechanism for historical cases to support retrieval and reuse. Unlike one-shot generative layout methods, the proposed approach emphasizes stepwise refinement, reusable case knowledge, and direct editability in the BIM environment. Accordingly, the objectives of this study are to: (1) develop an LLM-centric requirement interpretation workflow that converts natural-language inputs into executable design parameters; (2) establish a reusable design knowledge workflow by structuring historical configuration cases for retrieval and adjustment; and (3) implement a BIM-based prototype to demonstrate an end-to-end pipeline—from requirement input to the generation of a usable early-stage configuration—thereby validating the feasibility of language-driven BIM for worksite trailer design.

2 Methodology

2.1 System Overview

This study proposes an early-stage worksite trailer design workflow that integrates Large Language Models (LLMs) with Building Information Modeling (BIM). The primary goal is to rapidly generate a usable initial configuration during the early design phase while supporting iterative adjustment and convergence. As shown in Figure 1, the proposed workflow comprises four stages: requirement input and interpretation, historical case retrieval and matching, parameterized model generation and update, and data saving and output. Through this structure, case reuse and parameterized BIM modeling are unified into a single coherent process, enabling consistent model creation whether users start from a retrieved seed layout or directly specified parameters.

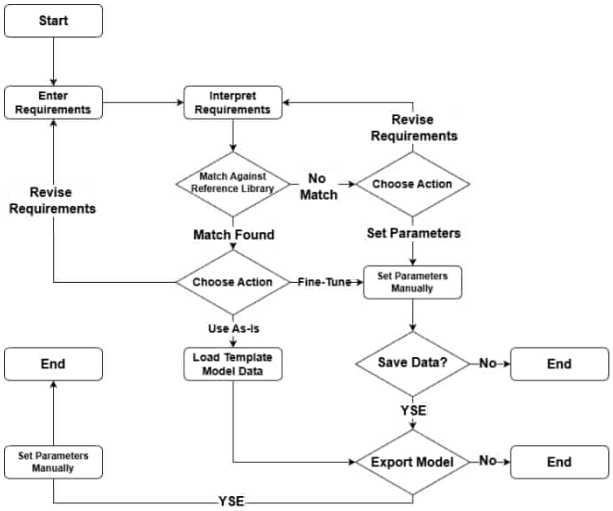

Figure 1. Framework of the proposed approach.

2.2 System Architecture

Figure 2 illustrates the system architecture of the proposed workflow. The framework is composed of three core modules: Historical Case Retrieval, Unit-Based Spatial Assembly, and Conversational Parametric Modeling. These modules do not function independently; instead, they are coordinated through a shared data mechanism based on JSON representations and a centralized ProjectStore for global state management.

Within this architecture, the Historical Case Retrieval module provides reusable reference cases based on user-specified requirements. The Unit-Based Spatial Assembly module enables the decomposition and recombination of reusable spatial units from retrieved or predefined cases. The Conversational Parametric Modeling module interprets user instructions and translates them into executable BIM parameters for model generation and update in Autodesk Revit.

A key feature of the proposed system is its common data mechanism. Rather than maintaining isolated intermediate results in each module, the system uses structured JSON data and ProjectStore to record global design states, shared schema definitions, reusable unit information, and BIM-related parameter mappings. This design supports multi-turn interaction, traceable parameter updates, and consistent synchronization between semantic interpretation and geometric model execution. The resulting BIM parameters are then exported to the Revit environment for model creation and modification.

Figure 2. System architecture of the proposed workflow

2.3 Historical Case Retrieval and Reuse

To improve retrieval consistency, each historical case is stored in a structured JSON-based representation containing key attributes such as function type, spatial composition, occupancy, approximate dimensions, and special-space requirements. Candidate cases are then scored through a weighted multi-criteria matching process based on these attributes. To reduce semantic inconsistency, room names are normalized into canonical categories, and partial similarity is allowed for related room types. The final ranking is generated from the aggregated similarity score, and the top-ranked cases are presented as candidate seed layouts for further reuse and refinement.

When a similar case is identified, the retrieved configuration is treated as a seed layout. The selected case is loaded as an editable set of design parameters, allowing users to adopt it as a starting point and refine it according to project-specific needs. This mechanism reduces modeling ambiguity, shortens the exploration cycle, and enables structured reuse across recurring worksite trailer scenarios.

If the retrieved seed layout still deviates from the user's requirements, the system supports iterative customization through parameter editing. Such parameterization not only supports geometric adjustment but also ensures that subsequent BIM updates remain consistent with the retrieved case context. The system does not require users to provide a complete specification at the beginning; requirements may be supplied progressively. In general, richer and more explicit inputs yield more complete retrieval conditions, which improves similarity ranking and increases the stability of case matching.

In the current prototype, retrieval effectiveness is examined mainly through qualitative inspection of returned cases rather than a formal large-scale benchmark, because the present case library is relatively small and manually curated.

2.4 Unit-Based Spatial Assembly

In addition to whole-case retrieval, the proposed workflow supports unit-based spatial assembly. This module allows users to decompose historical cases into reusable spatial units, such as bedrooms, washrooms, kitchens, office areas, or other functional spaces, and recombine them into a new configuration. As a result, the system supports not only case retrieval, but also case decomposition and case recombination.

The extracted spatial units preserve not only geometric properties but also basic semantic information, including space type, unit dimensions, functional role, and relative layout relationships with adjacent spaces. This enables the system to perform semantically informed spatial recomposition rather than simple geometric block placement.

The system also supports case decomposition preview. After a case is retrieved, users may inspect its internal composition and review which spatial units it contains before deciding which parts should be preserved or discarded. This function helps users better understand the internal structure of a precedent case and provides a basis for subsequent recombination.

A further advantage of this module is that spatial units may be selected across different cases. For example, users may choose a bedroom from one case, a washroom from another, and a kitchen from a third, and then reorganize these units into a new solution. This extends design knowledge reuse beyond rigid template-based reuse and allows a finer-grained design recombination process.

After the desired units are selected, the assembled result is converted into a new design basis for downstream modeling. The recombined configuration can then be connected to subsequent processes such as outer frame generation, room allocation, interior wall generation, opening placement, and space labeling. In this sense, Unit-Based Spatial Assembly serves as an intermediate design-restructuring mechanism between historical case knowledge and parameterized BIM generation.

2.5 Parameterized Layout Generation

When case matching is insufficient or no suitable case exists, users may directly specify model parameters, and the system generates an initial configuration through the same parameterized workflow. This design ensures that a usable early-stage model can still be produced even when the case library provides limited coverage.

In the parameterized modeling stage, the system drives BIM generation and updates using an editable set of model data. The process sequentially performs: (1) overall envelope dimension setting, (2) room space partitioning, (3) interior wall layout, (4) door/window

and other opening placement, and (5) room labeling. User instructions are interpreted through task-specific prompts and converted into structured JSON outputs, which are then mapped to internal data objects and BIM parameters.

After each parameter change, the system updates the BIM model and provides visual feedback, enabling low-cost iterative refinement and rapid convergence of the initial configuration. This approach allows the generated model to remain editable and traceable throughout the design process.

Finally, the workflow includes two post-processing options. First, users may store the generated result as a new case to enrich the case library. Second, they may export the BIM model as a baseline for subsequent detailing and engineering coordination.

3 Implementation

The proposed workflow has been implemented as a functional proof-of-concept prototype within a Building Information Modeling (BIM) environment. Autodesk Revit is adopted as the modeling platform, and the system operates as a Revit add-in that uses the Revit API (Application Programming Interface) to transform structured design data into corresponding BIM elements. The current prototype uses an API-based Large Language Model, GPT-4o mini, for requirement parsing and command interpretation. During development, another lightweight model was also tested; however, GPT-4o mini was selected because it provided sufficiently stable parameter extraction performance at a lower cost. This implementation enables an end-to-end pipeline from natural-language requirement input to BIM model generation.

To connect semantic interpretation and BIM execution, the prototype employs a unified structured data format as an intermediate layer. Rather than relying on a single universal prompt, the system adopts a task-specific prompt design strategy. Different prompts are used for subtasks such as requirement extraction, room partitioning, wall operations, opening placement, dimension modification, and intent routing. Each prompt explicitly requires a single valid JSON (JavaScript Object Notation) object without additional explanatory text, and the returned content is parsed into predefined internal data structures for storage and subsequent BIM execution.

In the implemented system, Historical Case Retrieval serves as an important starting point for early-stage design. When a user enters a request such as “I need a dorm unit for 3 people, including a kitchen, bedroom, and bathroom,” the system first analyzes the request and extracts key conditions, such as function, capacity, required spaces, and required dimensions. Figure 3 presents the case retrieval and selection interface, where the system displays candidate historical cases, matching levels, and selected projects based on the parsed conditions for further comparison and confirmation. This mechanism allows users to quickly identify potentially relevant configurations from previous cases, reducing the burden of manually searching and reviewing existing designs, while enabling early-stage design to begin from precedent knowledge.

Figure 3. Case retrieval and selection interface

In addition to presenting candidate cases, the system also provides more detailed matching information to help users understand why each project is recommended. Figure 4 shows the matched project results together with their associated attributes, including project function, spatial composition, capacity, dimensional conditions, and their degree of correspondence with the user’s requirements. Through this information, users can not only review the recommended cases, but also understand how each candidate aligns with the intended design conditions, thereby improving the transparency and interpretability of case comparison and selection.

Figure 4. Matched project results and associated attribute information

After candidate cases are obtained, the system further supports Unit-Based Spatial Assembly. Instead of only allowing whole-case reuse, the system can decompose

selected cases into smaller reusable spatial units, such as bedrooms, washrooms, kitchens, and service spaces. Figure 5 illustrates the preview of decomposed units from historical cases. This allows users to inspect the internal composition of each case, determine which spatial units should be retained, and identify which parts may be replaced. In this way, historical cases are no longer treated merely as complete templates, but are transformed into finer-grained design resources.

Figure 5. Preview of decomposed reusable spatial units from selected historical cases

Furthermore, the system supports selecting and recombining spatial units across different historical cases. Users may choose rooms or functional units from multiple projects and reorganize them into a new customized configuration. Figure 6 shows a recombined layout assembled from reusable spatial units originating from different precedent cases. This demonstrates that the system supports not only case reuse, but also flexible spatial recombination for early-stage customization.

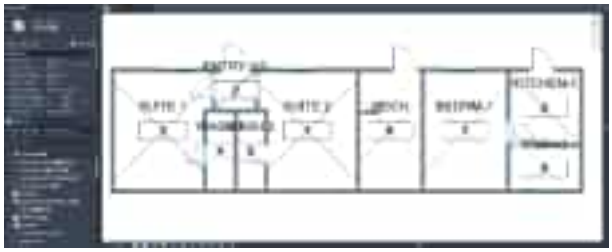

Figure 6. Recombined layout assembled from reusable spatial units

When Historical Case Retrieval and Unit-Based Spatial Assembly cannot provide a satisfactory solution, or when users need to further refine the configurations produced by the previous modules, the system can activate the third module, namely Conversational Parametric BIM Modeling. This module allows users not only to move beyond existing precedent cases, but also to directly describe spatial requirements in natural language or issue localized modification commands for an existing configuration. The system then progressively translates these inputs into executable modeling parameters and corresponding BIM operations, thereby supporting model creation, modification, and iterative refinement.

To achieve this, the system does not rely on a single universal prompt. Instead, it adopts a task-specific prompt design strategy. Dedicated prompts are defined for different subtasks, including outer-frame extraction, room-segmentation extraction, interior-wall command interpretation, wall trimming, opening placement, opening resizing, wall-thickness modification, and intent routing. These prompts explicitly require the model to output only a valid JSON object without any additional explanatory text. The returned content is then immediately parsed into predefined internal data structures for storage and subsequent BIM execution. If the returned output is empty, malformed, or violates predefined geometric or modeling constraints, the system does not execute the corresponding modeling action and instead requests a revised instruction. After user input is processed, the extracted information is written into the shared data structure, and corresponding modeling actions are triggered based on the interpreted parameters. At present, the prototype supports parameterized operations covering overall building dimensions, room count and target sizes, internal spatial subdivision through wall placement, opening placement (e.g., doors and windows), and room label generation for identification and model management. Figure 7 presents the input interface of the third module, where users issue natural-language instructions for direct generation or further refinement, while Figure 6 shows the recombined layout that may serve as the basis for subsequent conversational refinement.

Figure 7. Input interface of the conversational parametric BIM modeling module

Representative examples further illustrate how natural-language commands are translated into executable modeling actions. For overall dimensions, an input such as “Create a building with a total length of 526.875 inches and a width of 159.5 inches” is parsed and stored as envelope parameters in the structured data,

forming the basis for subsequent modeling. For room specification, an instruction such as “Divide it into three rooms with lengths of 211.625, 103.75, and 211.5 inches” updates the room count and assigns target dimensions to each room for later spatial partitioning.

For interior subdivision, the system supports wall placement commands to control room separation. For example, a vertical wall instruction such as “In Room 1, add a vertical wall 98.5 inches from the right side” is interpreted as a vertical partition wall with a specified offset relative to the room boundary, whereas a horizontal wall instruction such as “In Room 3, place a horizontal wall 60.5 inches above the bottom edge” is converted into a corresponding horizontal wall parameter. These wall definitions are recorded in the structured data together with orientation and relative offset information, enabling subsequent BIM generation.

For opening placement, the system allows users to specify doors, windows, or other openings through natural-language descriptions. For instance, a command such as “On the top wall of Room 1, put a door in the center of the right half” is parsed to determine the target room, host wall, relative placement region, and opening type. The system then generates an opening record containing wall references, positional information, and size parameters for BIM execution.

The system also supports label and identification updates. For example, an instruction such as “Rename the label of Room 1 to BEDRM-1” updates the corresponding room identification fields in order to maintain naming consistency within the BIM model. Such label adjustments not only improve model management, but also help align the generated result with subsequent design communication and engineering coordination.

All parsed design information is persistently stored and reused during subsequent modeling steps. The BIM modeling module sequentially reads these structured data and uses the Revit API to generate or update the building envelope, space partitions, walls, openings, and labels. Through this step-by-step update process, the model provides immediate visual feedback after each parameter change, thereby enabling low-cost iterative refinement and rapid convergence. Overall, the third module is capable not only of generating a new model directly from textual requirements when no suitable precedent exists, but also of serving as an effective mechanism for detailed refinement after the first two modules have produced an initial configuration. This prototype implementation demonstrates the feasibility and repeatability of natural-language-driven BIM configuration generation in an operational modeling environment.

4 Discussion and Future Work

This study investigates the integration of Large Language Models (LLMs) with Building Information Modeling (BIM) to support early-stage layout design for worksite trailers. The proposed workflow demonstrates that natural-language interaction can be effectively linked to structured parameter generation and BIM-based modeling, enabling preliminary configurations to be developed more directly than in conventional manual workflows. For worksite trailer projects, where repeated customization is often required under dimensional and transport constraints, this approach offers a practical means of reducing the need to begin each design task from scratch.

A key strength of the proposed workflow lies in its integration of Historical Case Retrieval, Unit-Based Spatial Assembly, and Conversational Parametric BIM Modeling within a unified data mechanism. Through this structure, prior design cases are not treated merely as static references, but can instead be retrieved, examined, reorganized, and further refined according to project-specific needs. This makes the workflow particularly valuable in situations where both design reuse and flexibility are required, especially when user requirements do not fully correspond to any single precedent case.

At the same time, several limitations remain in the current study. The existing case library is still limited in scale and diversity, which affects the breadth of retrieval and the stability of case-based reuse. In addition, the present validation is based mainly on prototype implementation and representative demonstrations. Formal time-efficiency testing, user studies, and quantitative comparisons with conventional workflows have not yet been conducted. Although task-specific prompts and validation rules are applied to improve execution reliability, ambiguous or incomplete user input may still lead to inconsistent interpretation results. Furthermore, the current prototype focuses primarily on orthogonal layouts for container-type modular units and does not yet incorporate code compliance checking or deeper integration with downstream construction processes.

These observations suggest that the system should currently be understood as a proof-of-concept prototype rather than a fully deployable practical platform. Its main contribution lies in demonstrating that LLM-based requirement interpretation, reusable design knowledge, and BIM-based model generation can be organized into a coherent early-stage design workflow. This provides a meaningful foundation for subsequent development toward more robust, scalable, and practically applicable modular design support systems.

Future work should therefore focus on strengthening both the technical robustness and practical applicability

of the workflow. One important direction is the expansion and systematic organization of the historical case library. A broader and more diverse collection of cases would improve retrieval quality, enhance recommendation stability, and support more reliable reuse of spatial units across different design scenarios. Another important direction is the adoption of more rigorous evaluation methods, including time-efficiency analysis, controlled user experiments, and comparisons with conventional design workflows, in order to better assess the actual benefits of the system in practice. Such studies would also help clarify its effectiveness for users with different levels of design expertise. In addition, the interpretation of natural-language input can be further improved through stronger rule-based validation, better handling of vague or approximate expressions, and more advanced semantic reasoning mechanisms. In the longer term, the workflow may be extended beyond single-unit layouts to support larger-scale planning scenarios, such as multi-unit trailer arrangements and mixed-function camp configurations, together with building regulation checking, structural considerations, and mechanical-electrical-plumbing (MEP) integration.

5 Conclusion

This study proposed an LLM-integrated BIM workflow for rapid early-stage layout generation of worksite trailers. By connecting natural-language requirement interpretation with structured parameter processing and BIM-based modeling, the workflow supports the creation of editable preliminary configurations while also enabling the reuse and adjustment of prior design knowledge.

The prototype implementation confirms the feasibility of this approach and suggests that language-driven BIM workflows can provide a useful foundation for improving accessibility, efficiency, and design reuse in modular construction. Overall, this research offers an initial step toward more responsive and knowledge-supported design methods for worksite trailer planning.

Abstract –

Automated productivity monitoring and robotic learning in prefabrication are hindered by the scarcity of structured demonstration data. To address this, this study investigates a Vision-Language Model (VLM) workflow for extracting engineering logs from wall panel assembly videos. We conducted a comparative empirical evaluation using a 2 × 3 factorial design to evaluate the interaction between video processing strategies (Continuous vs. Segmented) and prompt complexity. Results indicate that relying on internal attention mechanisms for long videos leads to significant temporal hallucinations. In contrast, the proposed "Segment-and-Caption" framework, combining physical temporal segmentation (visual constraint) with domain-specific prompting (semantic constraint), achieved the highest reliability, yielding a Duration-weighted Accuracy of 65.44% and a Macro-F1 score of 0.547 to account for class imbalance. Crucially, we identify a fundamental trade-off: while this "stateless" segmentation eliminates attention drift, it introduces an "Identity Gap" that precludes consistent worker tracking. This work establishes that decoupling visual context from temporal search is a critical strategy for reliable VLM-based monitoring, providing a validated baseline for converting unstructured footage into machine-readable data for downstream robotic planning.

Prefabrication; Prompt Engineering; Vision-Language Models; Action Recognition

1 Introduction

1.1 Industrial Background and Practical Motivation

Prefabrication relies heavily on synchronized assembly-line workflows to enhance efficiency [1, 2]. Despite this industrial shift, core tasks like wall panel assembly remain labor-intensive, with essential actions (e.g., fastening, alignment) performed manually due to automation limitations [3, 4]. Consequently, accurate monitoring is essential. However, current practices relying on manual supervision or passive CCTV are labor-intensive and fail to generate the structured, machine-readable data required for productivity profiling and human-robot collaboration [5].

1.2 Limitations of Existing Automation and Vision-Based Approaches

While sensor-based technologies like RFID track location effectively [6], they require intrusive instrumentation and lack the semantic context of specific assembly actions. Computer vision offers a non-intrusive alternative, yet conventional task-specific models require extensive training data and struggle to generalize across diverse site conditions [7]. Even emerging open-vocabulary models often underperform specialized detectors in identifying domain-specific elements [8]. Moreover, scaling these tools to real-world scenarios remains challenging due to robustness issues [9] and the difficulty of transforming raw visuals into digital twin-ready data [10].

1.3 Vision-Language Models for Construction Video Understanding: Opportunities and Challenges

Vision-Language Models (VLMs) offer a promising alternative by jointly reasoning over visual and natural language inputs. Unlike task-specific models, VLMs facilitate flexible, zero-shot activity understanding through text descriptions, eliminating the need for massive annotated datasets [11, 12]. Recent studies demonstrate that ontology-based prompting can guide VLMs to interpret construction images [13]. Theoretically, this allows for generating detailed activity logs directly from visual data, offering a pathway to automated productivity analysis.

1.4 Research Gap and Study Objectives

Despite their potential, applying VLMs to long, untrimmed prefabrication videos presents challenges. Models relying on internal attention often suffer from temporal hallucinations, inaccurately timestamping actions [14]. Furthermore, VLM performance is highly sensitive to prompt engineering [13]. While Video-LLMs are evolving, the specific interaction between prompt formulation and video segmentation strategies remains underexplored. To bridge this gap, this study provides initial empirical evidence by employing a 2 × 3 factorial design to evaluate how physical segmentation and domain-informed prompting jointly impact VLM performance and mitigate temporal hallucinations.

2 Methodology

2.1 Proposed Approach

We propose the "Segment-and-Caption" framework to strictly constrain VLM inference (**Figure 1**). As illustrated, the **baseline (top path)** applies temporal prompting directly to the raw, continuous video, relying on internal attention mechanisms, a process often leading to contextual hallucinations due to attention drift. In contrast, our **proposed method (bottom path)** introduces a modular decomposition to isolate temporal constraints. Specifically, the workflow enforces two primary mechanisms:

Physical Temporal Segmentation slices the footage into discrete clips based on ground truth timestamps. This "hard constraint" effectively renders the input stateless, limiting the model's focus to visual evidence within a specific time window. Complementing this visual isolation, Domain-Informed Prompting acts as a "semantic constraint." By injecting a construction knowledge into the prompt logic, we prevent generic descriptions and ensure outputs remain structurally consistent with engineering standards.

2.2 Experimental Design

To evaluate reliability, we adopted a 2 × 3 factorial design intersecting Input Strategy and Prompt Complexity. The Input Strategy compares the full-length Continuous baseline against the Segmented Input strategy, where action events are physically isolated to remove the burden of temporal search. Superimposed on these are three prompt levels: (1) P-Natural (naive instructions), (2) P-Syntactic (employing structural delimiters like XML to optimize parsing and enforce CSV outputs), and (3) P-Domain (integrating the construction knowledge). This progression allows us to determine whether improvements stem from formatting rules or domain-specific knowledge.

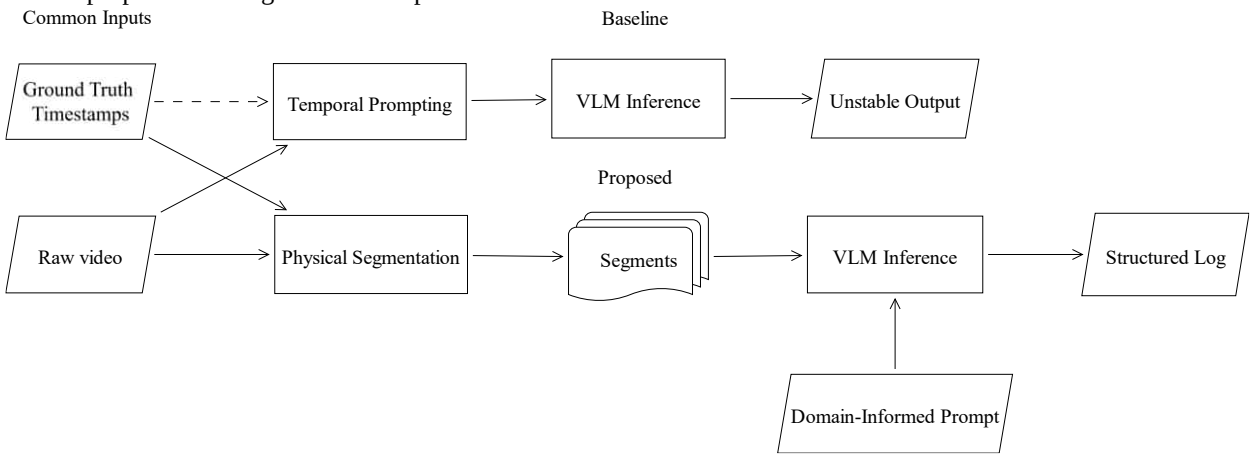

Figure 1. Workflow comparison between the Continuous Baseline and the Proposed Framework

3 Experimental Results and Analysis

3.1 Experimental Setup

The experiment utilized a high-density collaboration sequence (Duration: 6:57, 720p, 60fps) captured from a Canadian prefabrication factory, characterized by frequent occlusion and complex multi-worker interactions. The selection of this specific duration was governed by the native technical constraints of the Gemini 3 Pro web-based interface, which imposes a 2GB file upload limit. At approximately 1.87GB, this sequence represents the maximum continuous temporal context currently supportable by the platform's native multimodal pipeline, providing rigorous evaluation context for temporal stability without exceeding ingestion boundaries.

To simulate an open-world industrial monitoring scenario and ensure dataset transparency, the VLM was prompted with a construction knowledge comprising 8 task categories: *prepping*, *waiting*, *handling*, *fastening*, *process*, *measuring*, *fixing*, and *unsure*. While the ground-truth (GT) sequence contained 27 instances distributed across 4 active classes (*fastening*, *measuring*, *prepping*, *waiting*), the remaining 4 categories were treated as distractor classes to evaluate the model's robustness against over-classification.

All evaluations were performed using the Gemini 3 Pro (Web Version) with system-level decoding parameters (e.g., Temperature, Top-K, and Top-P) maintained at their default platform settings to ensure a standardized baseline and eliminate manual tuning bias. For the Continuous Input baseline, we fed the maximum possible context length directly into the Gemini 3 Pro web-based interface. Unlike API-based approaches that allow for programmatic chunking, this setup meant we were bounded by the platform's native file upload limits. Conversely, the Segmented Input strategy involved slicing this sequence into 27 discrete clips based on ground truth timestamps, isolating individual action events to test the efficacy of our "hard constraint" approach.

3.2 Quantitative Results

To provide a comprehensive evaluation and clarify the performance metrics against inherent class imbalance, we report three indicators in Table 1: Duration-weighted Accuracy, which reflects the proportion of total video time correctly classified; Clip-level Accuracy (Top-1), representing the standard discrete instance-based classification rate; and the Macro-F1 score, calculated exclusively over the active ground-truth categories to account for the recall of minority tasks.

As detailed in Table 1, the experimental data confirms that the proposed Segmented P-Domain strategy yielded the most reliable performance across all metrics, achieving a Duration-weighted Accuracy of 65.44%, a Clip-level Accuracy of 55.56%, and a Macro-F1 score of 0.547. This result validates the hypothesis that layering physical segmentation as a visual constraint serves as an effective method for stabilizing VLM outputs.

It is worth noting, however, that these metrics require careful interpretation, particularly regarding the Segmented P-Syntactic model. While this configuration achieved a seemingly competitive accuracy of 58.17%, a deeper inspection and the resulting lower Macro-F1 score (0.419) reveals this score was inflated by frequency bias (class imbalance). Given that the dataset is naturally dominated by repetitive "Fastening" tasks, the P-Syntactic model adopted a heuristic strategy of predicting the majority class for nearly every segment. Consequently, it failed to register minority but critical tasks such as "Checking" or "Alignment". In contrast, the P-Domain strategy demonstrated a genuine sensitivity to action variance as evidenced by its superior Macro-F1 performance, making it far more practically viable for industrial monitoring despite the modest numerical gap in raw accuracy.

Table 1. Comparative Performance of VLM Workflows

Input Strategy	Prompt Level	Duration-weighted Acc	Clip-level Acc (Top-1)	Macro-F1
Segmented	P-Domain (Proposed)	65.44%	55.56%	0.547
Segmented	P-Syntactic	58.17%	48.15%	0.419
Continuous	P-Syntactic	47.54%	37.04%	0.383
Continuous	P-Domain	47.09%	33.33%	0.257
Continuous	P-Natural	42.62%	37.04%	0.246
Segmented	P-Natural	42.06%	33.33%	0.167

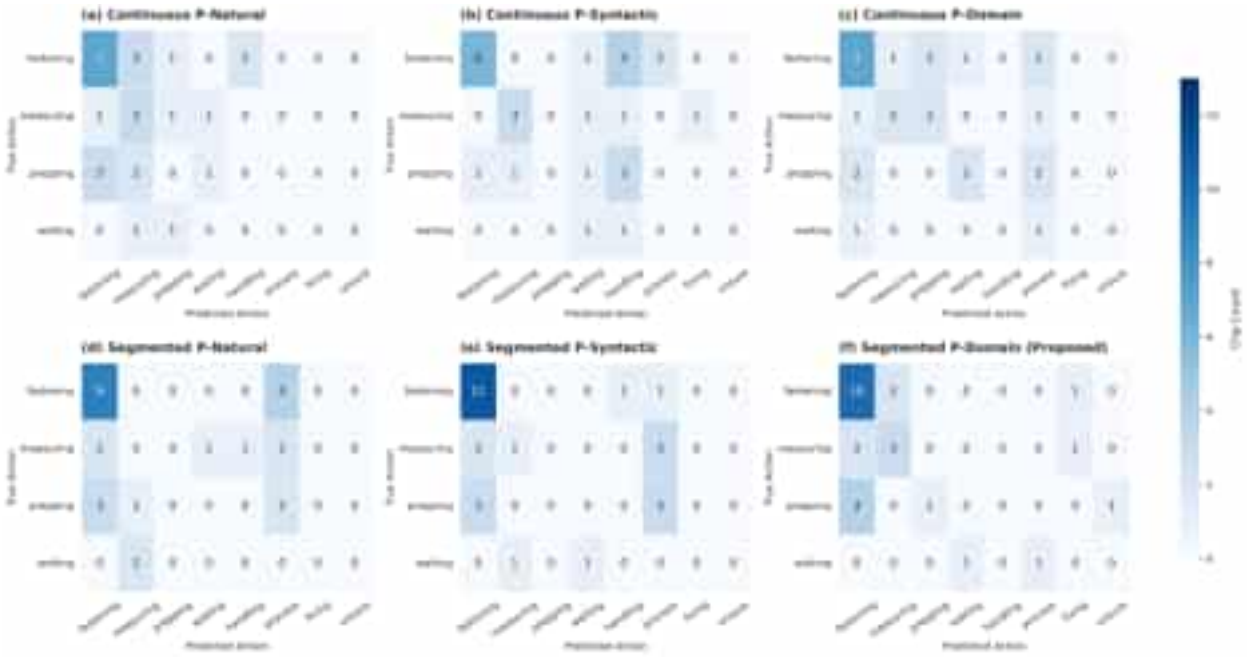

Figure 2. Comparison of action recognition performance across six experimental configurations.

3.3 Qualitative Analysis

While the quantitative metrics demonstrate the stability of the proposed method, a granular analysis utilizing the comprehensive 6-panel Confusion Matrix (Figure 2) reveals distinct operational characteristics and vulnerabilities of VLMs. As illustrated in Figure 2, the Proposed Method (f) achieves the highest concentration of correct predictions along the diagonal. This visually demonstrates the superior reliability of combining physical temporal segmentation with domain-informed prompting, effectively mitigating the attention drift and temporal inconsistency observed in continuous baselines.

The most prominent limitation is Small Object Blindness. Across all testing configurations, the models consistently struggled to resolve small tools, such as chalk lines or spray cans. The continuous baseline often compensated for this visual deficit by leveraging the full temporal sequence to infer actions (e.g., deducing "Chalking" from walking motions). However, the segmented approach, lacking this sequential context, frequently misclassified these same motions as generic "Measuring."

This visual limitation was mirrored by a semantic rigidity in the domain-informed models. By enforcing a strict construction knowledge, the VLM exhibited a tendency toward Taxonomy Over-fitting. As illustrated in Figure 2, by evaluating the model against 8 predefined options, we observed that it frequently misclassified ambiguous manual segments into distractor categories like *'fixing'* or *'process'* that were absent in the physical sequence. In its attempt to satisfy the "cognitive constraint," the model often forced nuanced or ambiguous behaviors into the nearest predefined category. This semantic hallucination explains the performance gap between raw accuracy and Macro-F1, as misclassifications into zero-support distractor classes directly penalized the recall of actual minority tasks like *prepping*. This indicates that while domain constraints successfully standardize output formatting, providing an overly broad knowledge without dynamic context-awareness can inadvertently degrade precision.

4 Discussion and Conclusion

4.1 Limitation and Future Work

Our results confirm that physical segmentation effectively eliminates the temporal hallucinations observed in continuous baselines; however, the relatively small sample size derived from this initial high-complexity sequence precludes a rigorous inferential statistical analysis at this stage. Consequently, these findings provide initial empirical evidence supporting the efficacy of the 'Segment-and-Caption' framework. While the current sample size precludes broad statistical claims of universal superiority, the mechanistic advantages of decoupling visual context from temporal search are clearly demonstrated.

Furthermore, this architectural choice creates a fundamental trade-off: by gaining temporal stability, we sacrifice narrative continuity. This results in an "Identity

Gap," where the "stateless" processing prevents the system from maintaining consistent worker identities across discrete clips (e.g., labeling the same individual as "Worker A" then "Worker B"). Consequently, while action recognition is accurate, individual productivity profiling remains challenging. Additionally, the current workflow relies on ground-truth timestamps. Future iterations will address these dual constraints by: (1) developing an Automated Event Detection module to dynamically slice video streams, removing manual dependency; and (2) fusing the VLM workflow with traditional computer vision-based tracking (Re-ID) to link worker identities across disjointed segments, thereby restoring continuity without sacrificing the stability gains of segmentation.

4.2 Conclusion

This study addresses the critical bottleneck of converting unstructured construction videos into machine-readable engineering logs. By validating the "Segment-and-Caption" framework, we demonstrated that decoupling visual context from temporal search is a necessary evolution for industrial monitoring. Our results confirm that applying physical segmentation as a hard constraint significantly outperforms continuous baseline methods in metric stability, achieving an Action Type Accuracy of 65.44%. While trade-offs in semantic depth and identity continuity remain, this framework establishes a viable technical pathway for automating granular productivity tracking in the next generation of prefabrication factories.

Abstract – Mechanical, Electrical, and Plumbing (MEP) engineering drawings serve as the contractual foundation for construction projects, yet verifying their consistency remains manual and error-prone. While Vision-Language Models show promise, they exhibit symbol fragility, spatial reasoning failures, and limited cross-document reasoning on technical drawings. We propose SAGE, a multi-agent framework employing: (1) YOLO11 for region segmentation (0.912 mAP50); (2) Cache-Augmented Generation for project-specific knowledge grounding; (3) a dual-mode adaptive extraction engine with coordinate grid overlay; and (4) hierarchical assembly combining extractions across project drawings. Evaluation across three construction projects (23 drawings, 1043 components) demonstrated 91.9% precision, 98.6% recall, and 97.4% spatial accuracy—substantially outperforming zero-shot VLM baselines (GPT 5.2, Claude Opus 4.6, Gemini 3 Pro) which achieved comparable precision but recall degrading sharply with drawing complexity (20–29% across projects vs. SAGE's consistent 98–100%). Ablation studies confirm the critical role of each architectural component.

Keywords –
MEP Drawings; Vision-Language Models; Multi-Agent Systems; Construction Automation; Drawing Interpretation

1 Introduction

The construction industry struggles to maintain consistency between CAD drawings and specifications, especially in retrofit projects where existing conditions overlap with new designs. Most design errors arise during handovers between architects, engineers, and contractors, causing costly rework, delays, and material conflicts. MEP systems account for over 50% of project investment [1], while rework consumes 4–10% of costs—52% linked to poor data and miscommunication [2] leading to $88.7 billion in global losses and $15.8 billion in annual interoperability costs [3]. Recent Vision-Language Models (VLMs) show promise for document understanding [4] but still face spatial reasoning and symbol interpretation challenges [5]. Fine-tuning improves accuracy—up to 52% F1 gain on GD&T extraction [6]—yet scales poorly with new component types.

In MEP projects, information flows sequentially from architects to MEP engineers to contractors, with each handover introducing potential for specification drift and interpretation errors. Design-intent drawings may reference equipment schedules, legend sheets, and specification documents that reside in separate files, creating cross-document dependencies that manual review struggles to verify consistently. Discrepancies such as mismatched equipment ratings between schedules and plan drawings, or spatial conflicts between HVAC ductwork and electrical conduit routing, often remain undetected until construction, when correction costs escalate significantly.

This paper presents SAGE, a multi-agent framework addressing these limitations through: (1) YOLO11 [7]-based region segmentation isolating drawing blocks, legends, notes, and title blocks; (2) Cache-Augmented Generation for knowledge grounding, enabling project-specific symbol interpretation; (3) a dual-mode adaptive extraction engine with coordinate grid overlay for spatial referencing; (4) hierarchical assembly combining extractions across all project drawings; and (5) industry validation on real construction projects. Unlike prior automated drawing interpretation pipelines that rely on static processing, SAGE introduces four novel mechanisms: (a) an adaptive grid density function that dynamically adjusts tiling granularity based on measured drawing complexity; (b) a Surgical Merge Agent implementing zone-based deduplication for overlapping tile regions; (c) the first application of Cache-Augmented Generation for domain-specific symbol grounding in

technical drawings; and (d) a multi-agent orchestration pattern with hierarchical semantic assembly, representing a principled four-stage decomposition specifically designed for the MEP drawing domain, where each agent targets an identified VLM failure mode through focused task specialisation. Importantly, as the underlying VLM capabilities continue to advance, the agentic architecture is designed to inherit these improvements—stronger base models directly translate into improved extraction quality within the orchestrated pipeline, without requiring architectural changes.

2 Related Work

Engineering drawing digitization has evolved from rule-based systems to deep learning approaches [8]. For P&ID diagrams, deep learning pipelines have achieved 94.5% symbol recognition accuracy [9], while transformer-based approaches demonstrate 83.6% AP for simultaneous node and relationship detection [10]. Hybrid frameworks combining rotation-aware object detection with transformer-based vision-language parsers have demonstrated promising results for mechanical drawings [11].

VLMs face significant challenges with technical drawings, exhibiting 10-30% hallucination rates on complex scenes [12] and 50-60% spatial reasoning accuracy. Recent work demonstrates that fine-tuned open-source VLMs (e.g., Florence-2 with 0.23B parameters) can achieve 52% F1 improvement over zero-shot GPT-4o and Claude-3.5-Sonnet [6]. However, fine-tuning suffers scaling limitations, motivating our agentic approach leveraging zero-shot VLMs with structured knowledge grounding. Set-of-Mark (SoM) prompting enhances VLM visual grounding by overlaying markers on image regions [13], providing foundation for SAGE's grid overlay. Multi-agent architectures like AutoGen enable task decomposition with iterative refinement [14].

Despite these advances, no existing framework addresses the complete MEP drawing interpretation pipeline—from region isolation through cross-document knowledge grounding to spatially-aware component extraction. Rule-based systems lack the semantic flexibility to handle diverse drafting conventions across projects, while fine-tuned VLMs require costly per-project retraining. SAGE bridges this gap through a multi-agent architecture that preserves zero-shot VLM generality while grounding interpretation in project-specific context via CAG, eliminating the need for per-project fine-tuning. Notably, because SAGE treats the VLM as a replaceable inference engine within a structured agentic workflow, improvements in base model capabilities—such as enhanced spatial reasoning or reduced hallucination in future VLM generations—are expected to propagate directly into improved pipeline performance without architectural modification.

3 VLM Limitations on MEP Drawings

Systematic evaluation of zero-shot VLMs (GPT-4V, Claude 3.5, Gemini Pro Vision) on real-world MEP drawings identified four critical failure modes: Symbol Fragility—custom drafting symbols cause systematic misclassification without legend context; Spatial Reasoning Failure—models fail to establish spatial relationships, achieving only 50-60% accuracy [12]; OCR Degradation—performance on rotated, scaled, or densely packed annotations degrades significantly [15]; Limited Cross-Document Reasoning: VLMs struggle to incorporate information from referenced schedules and legend sheets. These findings motivated SAGE's multi-agent architecture, where specialized agents address each limitation through focused task decomposition. Section 5 presents a systematic quantitative baseline study using current-generation models (GPT-5.2, Claude Opus 4.6, Gemini 3 Pro) to validate that these limitations persist and intensify with drawing complexity despite substantial advances in base model capabilities.

4 Methodology

4.1 Framework Overview

SAGE decomposes MEP drawing interpretation into four sequential stages following multi-agent design principles [14]: S1 (Region Isolation) for semantic segmentation into functional regions; S2 (Knowledge Grounding) for pre-loading project-specific context; S3 (Adaptive Extraction) for dual-mode component extraction with coordinate grid overlay; and S4 (Assembly) for synthesis into structured semantic representation as shown in the Figure 1. We utilised Gemini 3 Pro (Vision API) for developing extractor, merging and assembly agents due to its superior visual reasoning capabilities. Each stage introduces a targeted mechanism addressing a specific VLM failure mode identified in Section 3: region isolation reduces visual search space, CAG eliminates symbol ambiguity, the adaptive grid forces exhaustive spatial traversal, and hierarchical assembly enables cross-document reasoning.

4.2 Stage 1: Region Isolation

YOLO11, fine-tuned on 200 annotated MEP drawings, partitions each sheet into four semantic region classes: Drawing Blocks (primary schematic content), Legend Blocks (symbol definitions), Note Blocks (specifications), and Title Blocks (drawing metadata).

The model achieved 0.912 mAP50 and 0.696 mAP50-95 on held-out test data.

4.3 Stage 2: Knowledge Grounding

SAGE constructs project-specific context by aggregating legend symbol-to-specification mappings, note block content, and project documentation. This context is pre-loaded using Cache-Augmented Generation (CAG) [16], enabling interpretation of project-specific symbol conventions.

4.4 Stage 3: Adaptive Extraction Engine

The extraction implements dual-mode processing with adaptive visual grid overlay inspired by Set-of-Mark prompting. Grid density G (Complexity Decision) = f(ρs, ρt, R) is computed from symbol density (ρs), text density (ρt), and resolution (R), estimated via a preliminary VLM assessment call on each Drawing Block. Standard-density drawings are processed by a single VLM instance (Baseline Mode); high-density schematics are partitioned into overlapping sub-regions processed in parallel (Dynamic Tiling Mode). Both modes extract: (1) component identification, (2) metadata (specifications, model numbers, sizing), and (3) grid cell location.

In Dynamic Tiling mode, 10% tile overlap ensures boundary components are fully visible but introduces redundant detections. A "Surgical" Merge Agent accepts components outside the seam zone as "Safe Entities" while forwarding "Conflict Candidates" within overlap boundaries for IoU-based deduplication and attribute union—keeping processing linear to overlap count.

4.5 Stage 4: Semantic Model Assembly

The Aggregation Module combines results from all project drawings into unified JSON representation. Stage 4 performs hierarchical merger across drawing blocks via Global Coordinate Registration: local coordinates transform to global system using block origins from YOLO segmentation. Output encodes component instances, spatial relationships from grid proximity, and system membership classification.

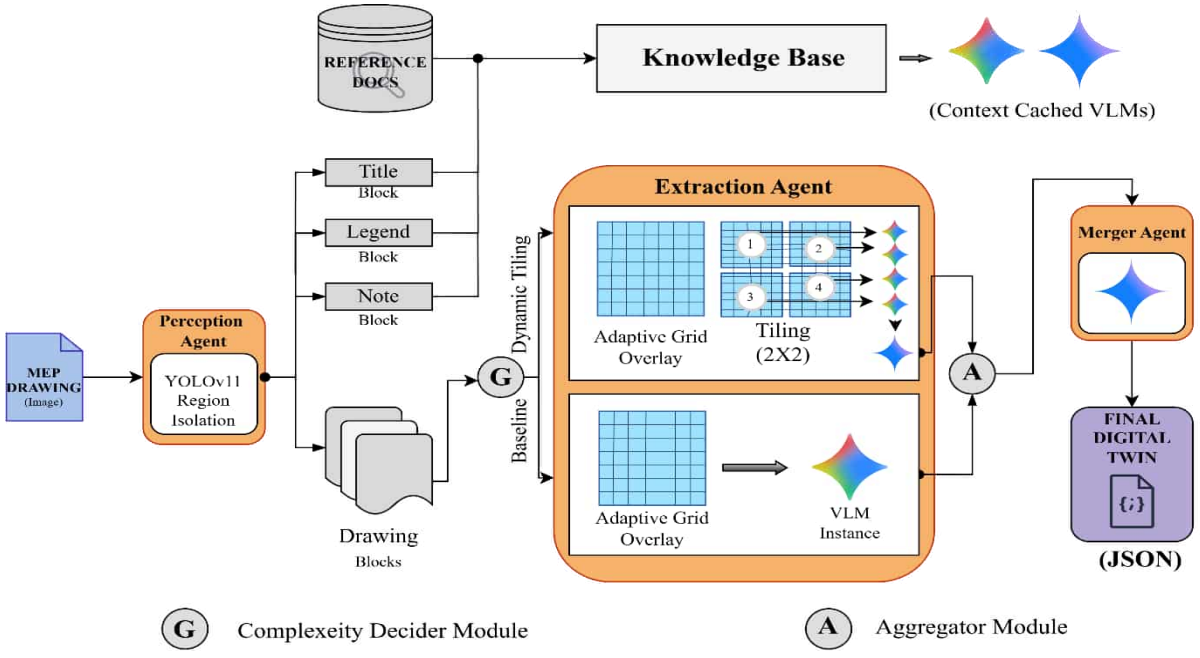

Figure 1. Multi-Agent Architecture (SAGE) for MEP drawing interpretation and Semantic Model Generation

5 Industry Case Study

5.1 Experimental Setup

We evaluated SAGE across three active construction projects provided by FHP Group (UK-based MEP consultancy). The dataset comprised 23 drawing sheets with 1,043 total extracted components spanning diverse MEP systems as detailed in Table 1. All drawings were exported as PDF from the original CAD/DWG files, representing the typical document format used in contractor handover and tendering workflows.

Table 1. Dataset Characteristics

Project	# of Drawings	Components	MEP System
1	5	66	Controls/BMS, Electrical, HVAC
2	6	339	HVAC, Electrical
3	12	638	Electrical, Public Health

5.2 Results

Results were obtained in JSON format as shown in Figure 2 and were accordingly compared with the ground truth validated by the expert design team at FHP Group.

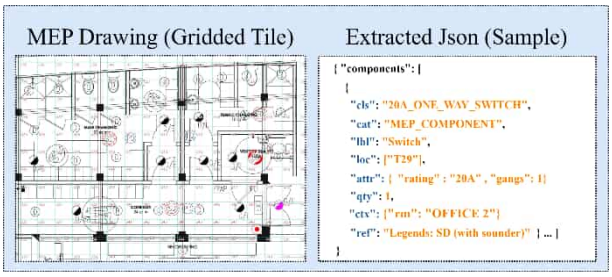

Figure 2. Sample extraction result showing a localized MEP drawing tile and its corresponding semantic JSON representation.

Precision measures the proportion of SAGE's extracted MEP components that match ground truth annotations, while recall captures the proportion of actual drawing components successfully detected. Spatial accuracy evaluates whether components are correctly localized to their grid cell positions.

Table 2. Evaluation Metrics

Project	Precision (%)	Recall (%)	F1-Score (%)	Spatial Accuracy (%)
1	100.0	98.48	99.24	100.0
2	90.16	99.71	94.69	97.05
3	92.05	97.96	94.91	97.44

To systematically quantify the failure modes identified qualitatively on earlier models, we conducted a baseline evaluation using current-generation VLMs. Notably, SAGE itself employs Gemini 3 Pro as its underlying VLM, making the Gemini 3 Pro baseline a direct controlled comparison—isolating the contribution of the agentic pipeline (region isolation, knowledge grounding, adaptive tiling, hierarchical assembly) from the base model's zero-shot capabilities. Spatial accuracy (Table 2) is excluded from the baseline comparison because it is architecturally inseparable from SAGE's coordinate grid overlay: without the grid, zero-shot VLMs produce only coarse qualitative localisations (e.g., "upper-left area") that are not commensurable with the grid-cell-level metric. The baseline comparison therefore focuses on detection quality (Precision, Recall, F1), where the models can be compared on equal terms. The results confirm that the same failure patterns persist even with substantially more capable models—and intensify with drawing complexity. Zero-shot VLMs achieve precision comparable to SAGE (88–91%) but weighted average recall of only 20–29%, with performance degrading sharply on complex drawings: on Project 1 (66 components), recall ranged from 51–92%, while on Project 3 (638 components, dense multi-system layouts), it collapsed to 8–23% across all three baselines. SAGE maintains near-complete recall (98–100%) regardless of drawing complexity. This demonstrates that raw VLM visual reasoning is adequate for sparse, well-separated layouts but fundamentally insufficient for the dense, information-rich drawings typical of real-world MEP projects; a limitation that persists across model generations. It is worth noting that as VLM architectures continue to mature with improved spatial reasoning, reduced hallucination, and stronger OCR on rotated annotations—these baseline capabilities are expected to improve. Because SAGE employs VLMs as inference components within a structured multi-agent workflow rather than as monolithic end-to-end systems, such advances in base model performance will propagate directly into improved pipeline-level metrics without requiring architectural changes to the framework.

Table 3. Zero-Shot VLM Baseline Comparison (Average across 3 Projects)

Model	Precision (%)	Recall (%)	F1-Score (%)
GPT 5.2	88.2	19.5	31.0
Claude Opus 4.6	89.3	29.3	43.3
Gemini 3 Pro	90.8	23.0	32.3
SAGE	91.9	98.6	95.1

As with the baseline comparison, the ablation evaluates detection quality rather than spatial accuracy, which is architecturally inseparable from the grid overlay.

Table 4. Ablation Study (Weighted Average across projects)

Configuration	Precision (%)	Recall (%)	F1-Score (%)
SAGE w/o CAG	50.5	49.7	48.0
SAGE w/o Region Isolation	91.5	79.5	86.2
SAGE w/o Grid Overlay	90.3	75.6	82.3
SAGE w/o Dynamic Tiling	89.9	45.2	59.3
SAGE	91.9	98.6	95.1

Project 1 (66 components, low-density) showed negligible ablation effects, as simpler layouts fall within zero-shot VLM capability; the impact is concentrated on Projects 2 and 3. Removing CAG caused the most severe degradation (F1: 95.1%→48.0%), as the VLM hallucinates without legend-to-specification grounding for visually homogeneous MEP symbols. Removing dynamic tiling caused the largest recall drop (recall: 98.6%→45.2%, F1→59.3%), as single-pass extraction misses dense component clusters. Removing the grid overlay maintained precision (90.3%) but penalised recall (75.6%), confirming its role as a deterministic spatial traversal mechanism. Removing YOLO produced moderate degradation (F1: 86.2%) from increased background noise exposure. The full pipeline achieves the optimal balance: CAG grounds semantics, the grid ensures spatial completeness, YOLO isolates signal from noise, and tiling ensures exhaustive extraction.

6 Discussions

SAGE demonstrates that knowledge-grounded multi-agent architectures effectively overcome zero-shot VLM limitations in technical drawings. The coordinate grid overlay achieved 97.4% spatial accuracy, while the Surgical Merge Agent eliminated duplicate detections in low-to-medium density cases. High-density seam regions remain challenging. The baseline comparison (Table 3) confirms that zero-shot VLMs maintain high precision (88–91%) but only 20–29% weighted recall. This high-precision/low-recall pattern reflects three limitations: VLMs lack mechanisms for exhaustive spatial scanning of dense technical layouts; project-specific drafting symbols fall outside pre-training distributions, causing systematic omission; and attention mechanisms struggle with counting repetitive elements in dense arrays. SAGE targets each limitation through CAG (symbol grounding), the adaptive grid (exhaustive traversal), and YOLO (signal-to-noise isolation). The framework accurately extracted and validated drawing details against specifications, identifying discrepancies in parameters such as pressure and power ratings—highlighting its value for automated compliance verification.

Current limitations include incomplete topological inference, reduced counting accuracy in dense regions, and a 3× computational overhead from dynamic tiling. Average processing time per drawing block is ~20 seconds when tiling is not included and ~120 seconds in Dynamic Tiling Mode. The grid density function $G = f(\rho s, \rho t, R)$ determines mode selection based on symbol density, text density, and resolution; across our dataset, approximately 40% of drawing blocks exceeded the complexity threshold triggering Dynamic Tiling, yielding an effective ~3× computational overhead at the project level. This cost is concentrated on high-density drawings where the accuracy-cost trade-off is most favourable. Early experiments using recursive legend-symbol prompting and integrating non-VLM methods (e.g., YOLO, R-CNN) show promise for improving counting.

Future work will extend region detection to new drawing types, explore graph-based spatial reasoning, adapt tile sizes dynamically, and develop hybrid pipelines combining VLM semantics with deterministic detection for greater robustness.

7 Conclusions

This paper presented SAGE, a multi-agent framework enabling automated semantic model generation from MEP drawings, providing AI-powered quality assurance before contractor handover. Evaluation across three real-world construction projects demonstrated 91.9% precision and 98.6% recall (F1: 95.1%), with 97.4% spatial accuracy. Zero-shot VLM baselines (GPT-5.2, Claude Opus 4.6, Gemini 3 Pro) achieved comparable precision (88–91%) but only 20–29% weighted average recall, confirming that knowledge grounding and structured spatial traversal, not raw visual reasoning alone, are necessary for reliable MEP drawing interpretation. Ablation studies confirmed the complementary roles of CAG (semantic grounding), adaptive grid overlay (spatial completeness), YOLO-based region isolation (signal-to-noise filtering), and dynamic tiling (exhaustive extraction in dense regions). As VLM capabilities continue to advance, SAGE's architecture is designed to inherit these improvements: stronger base models translate directly into enhanced pipeline performance without structural modification, positioning the framework for sustained relevance in construction automation workflows.

Abstract –

Construction project operations remain difficult to automate due to dynamic site conditions, limited workflow standardization, and the absence of adaptable robotic platforms. General-purpose service robots (GPSRs), while mature in navigation, sensing, and data acquisition, lack a structured methodology for deployment in construction environments. This paper proposes a domain-specific systems engineering framework to systematically transform existing GPSRs into operationally viable tools for construction project operations such as monitoring and inspection. Using a Modified V-Model with iterative prototyping loops, the framework integrates requirements engineering, modular system architecture design, and field-based validation. A case study based on a GPSR identifies functional gaps related to environmental variability, collaboration safety, and data interoperability. Implementation workflows demonstrate how GPSRs can be systematically integrated into construction projects. The results establish a reproducible engineering process that reduces development time and enables scalable, practical use of GPSRs on construction sites.

Construction Robotics; Digitalization; Mobile Robots; Monitoring; Requirements Engineering; Service Robots

1 Introduction

Experts believe that robotics has the potential to improve productivity in the construction industry [1]. However, its fragmented, project-based nature, dynamic environments, and reliance on conventional practices have slowed the adoption of robotics [1]. While other industries, such as manufacturing and agriculture, have successfully integrated robots, construction remains largely underserved. Existing solutions struggle with environmental variability, task versatility, safe human-robot collaboration, high cost of operation and maintenance, and integration with project workflows [1], [2]. General-purpose service robots (GPSRs) are general robotic platforms designed for monitoring and operational support in various environments such as factories and industrial facilities [3]. However, these robots are often not originally intended for the construction industry. Their adaptability, modularity, and robust sensing make them a promising foundation for new applications. This paper explores how GPSRs can be transformed to meet the unique demands of construction sites, overcoming current limitations while enhancing functionality, safety, and workflow integration. By leveraging existing capabilities in a new context, this paper aims to demonstrate a systematic pathway for robots to contribute to construction automation for the purpose of operation, monitoring, and maintenance.

1.1 Current Robotics Landscape in the Construction Industry

Most existing solutions are highly specialized for single tasks such as layout marking, welding, or inspection and are called Single Task Construction Robots (STCRs) [4]. While these systems demonstrate technical feasibility, they face persistent challenges:

- **Specialization and limited reuse:** Robots are often built for one task and certain site conditions, making it difficult to reuse them across different projects, phases, or dynamic environments [5]. This lack of generalization restricts long-term value and increases deployment costs.
- **High setup effort:** Many construction robots require extensive calibration, site preparation, or custom workflows, reducing the productivity gains that were intended [4].
- **Fragility in dynamic environments:** Frequent layout changes, unpredictable obstacles, dust, and weather can quickly degrade performance, cause

failures or require frequent human intervention [5].

- **High implementation cost:** High implementation and maintenance costs are often cited as one of the common challenges for construction practitioners to deploy robots [1], [6].
- **Cultural and legal constraints:** Despite technical viability and capability, implementation can also be hindered by site culture, workforce acceptance, and local regulations [1], [2].

In contrast, GPSRs have matured significantly in indoor industrial and commercial environments. The cost and price of general-purpose robots (e.g., service robots, industrial manipulators, humanoids) have continued to decline over the past years [7], largely due to growing scale and intense competition. They provide robust capabilities in:

- **Navigation and mapping:** Autonomous point-to-point and waypoint navigation with obstacle avoidance.
- **Perception and sensing:** Computer vision analysis, high-resolution photo/video capture, thermal imaging, and Bluetooth-enabled sensor data collection.
- **Data and communication:** Live streaming, long-term recording, and two-way communication via network connectivity for remote operations.

This contrast between the narrow, task-specific nature of current construction robots and the reusable capabilities of general-purpose robots creates an opportunity to explore how adaptable service robots can support construction project operations more effectively.

1.2 Problem Statement

To date, construction project operations remain heavily manual and inconsistent across sites. These operational tasks are critical for safety, progress tracking, and decision-making, yet they suffer from limited automation due to constantly changing environments and the lack of adaptable robotic platforms. At the same time, GPSRs have matured in navigation, sensing, and data collection, but are designed for controlled indoor settings such as offices, factories, and hospitals rather than construction sites. Despite advances in general-purpose robotics, there is no established methodology for adapting these systems to construction project operations. Construction sites are highly dynamic, unstructured, and often harsh, presenting challenges in:

- **Environmental variability:** Robots designed for controlled settings struggle with uneven terrain, dust, and constantly changing layouts.
- **Safety and human–robot collaboration**: Effective operation alongside personnel and machinery.
- **Task versatility**: Many operational tasks demand adaptability to irregular objects and variable conditions, yet existing robots are typically single-purpose.

These factors highlight the need for a reproducible engineering framework that systematically translates general-purpose robotic capabilities into safe, reliable, and operationally relevant tools for construction project environments

1.3 Objective

The objective of this study is to develop and (partially) validate a domain-specific systems engineering framework for rapidly transforming GPSRs to support construction project operations with clear requirements from the user. Specifically, the framework addresses inspection, monitoring, and workflow execution without requiring a full redesign.

2 Methods

To accelerate development and introduce more robotics companies to the construction industry, a domain-specific systems engineering framework was created to guide the transformation of GPSRs for on-site applications. Based on a case study, the methodology adapts established systems engineering principles, using a Modified V-Model for lifecycle structure and a structured requirements engineering process for concept development [8], [9].

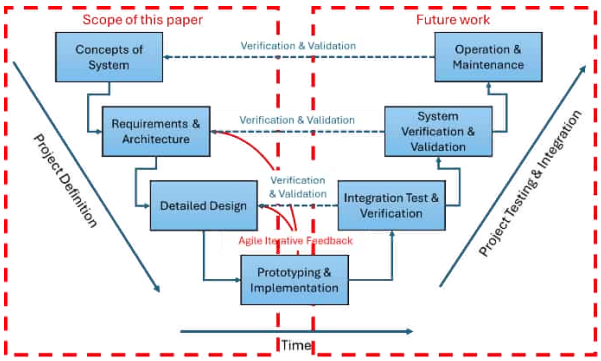

Figure 1. Modified agile V-Model in this research

2.1 Methodological Framework: The Modified V-Model

The V-Model was selected for its structured approach that links development phases with corresponding testing and validation activities. Since the original V-Model was developed for software development, our framework modifies this model by incorporating agile principles

(Figure 1) [8]. While the V-Model provides the overarching structure, small, informal iterative loops are introduced during prototyping to rapidly develop and test Minimum Viable Products (MVPs) [10]. This hybrid approach supports experimental validation of qualitative system features. This paper focuses on V-Model phases from "Concepts of System" through "Prototyping and Implementation," with later phases left for future work.

2.2 Requirements Engineering Process

A structured requirements engineering process is critical for translating multidisciplinary inputs into formal requirements and a coherent System Architecture. The systems engineering process (Figure 2), adapted from [8] and [9], begins with gathering Raw Requirements from domain-specific sources:

- **Key stakeholder interviews:** Structured interviews with key personnel such as site supervisors, engineers, robot operators, and environment safety contractors from the case study site in the target market are essential to understand their needs and pain points in daily construction project operations.
- **On-site observation via Gemba Walks:** Gemba (Japanese term for "real place") Walk is a lean management term referring to physically going to the real site where leaders can identify areas for improvement and cultivate a culture of continuous learning [11]. Direct observation of the construction environment through Gemba Walks at the case study construction site in the target market is essential to understand the dynamic conditions and conventional practices [12].
- **Market and state-of-the-art analysis:** Review of existing robotics solutions is helpful to identify common pitfalls and functional gaps.
- **Initial case study trial:** Baseline field test of GPSRs in the relevant environment is necessary to identify functional deficiencies and collect performance data.

Raw requirements are then converted into Formalized Requirements through (1) categorization, (2) reformulation using standardized syntax, and (3) assignment of reference codes. Requirements were grouped into Functional, Non-functional (i.e., performance), Domain (i.e., the construction sector), and Regulatory (i.e., especially relevant to the target market) categories [8].

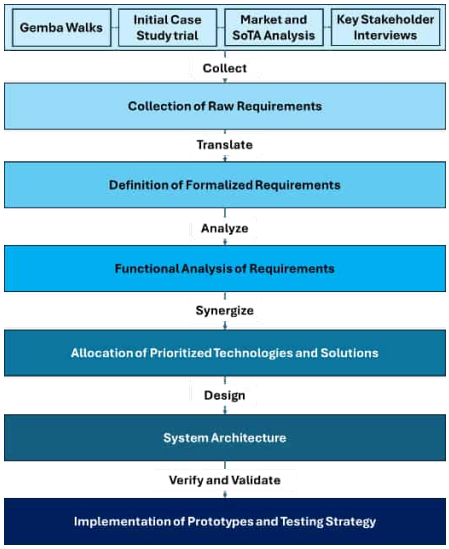

Figure 2. Requirements engineering methodological framework for rapidly transforming GPSRs to construction projects

2.3 System Architecture

Formalized requirements are organized to develop the system architecture, translating the "what" into the "how" [8]. The goal is to define a modular architecture that answers the research question: What system architecture enables modular transformation without full redesign? [9] Requirements are mapped to prioritized solutions—existing and new—to create a development roadmap. The resulting architecture blueprint forms the basis of the "Detailed Design" phase.

2.4 Detailed Design

The "Detailed Design" phase specifies the technical implementations derived from the system architecture. This includes selecting technologies and solutions and prioritizing them according to the requirements engineering outcomes [8]. The phase produces concrete hardware modifications and software integrations required to adapt a GPSR for construction tasks.

2.5 Prototyping and Testing Strategy

The framework then progresses to "Prototyping and Implementation". As outlined in Section 3.1, this phase uses an Agile methodology within the V-Model structure. Iterative prototyping is essential for construction environments where requirements evolve; prototypes validate individual functions quickly, enabling refinement until a stable system is achieved [5].

2.6 Integration Test and Verification

The next phase to be addressed in future work is the

"Integration Test, and Verification" phase. Once an MVP is produced, it undergoes live-environment integration testing. This stage employs the "Early Testing" loops [5] to confirm that the adapted system satisfies the functional requirements from Section 3.2 before progressing to full-scale deployment.

3 Results

As a highly developed tropical city state, Singapore has a robust economy and plays a pivotal role as a regional financial and innovation center in Southeast Asia, linking Eastern and Western markets. Its construction sector is one of the country's most important sectors, employing over 450,000 workers [13]. Like many countries, Singapore's construction sector faces persistent challenges such as stagnant productivity, construction waste, safety risks, labor shortages, and dependence on foreign workers [14]. Against this backdrop, government agencies have introduced a range of incentives to encourage both local and international firms to adopt innovative solutions in the built environment [12]. These conditions make Singapore an especially relevant and suitable setting for a case study, with the potential to scale the outcomes to other markets thereafter. This study introduces a commercialized GPSR platform from Japan to Singapore to explore how such platforms can be adapted to the construction industry in a completely different context (Figure 3).

Figure 3. GPSRs in the case study (credit: ugo, Inc.)

A preliminary field trial was conducted over a 6-month period at an active large-scale manufacturing facility construction site to assess technical and environmental constraints and determine necessary operational requirements. The field trial included participants from the robot manufacturer, construction company, and various project contractors. The robot supported project operations by executing scheduled patrols, monitoring environmental parameters, and providing real-time surveillance. Quantitative and qualitative data were gathered regarding operational metrics, points of failure, and site characteristics. After the conclusion of the field trial, interviews with multiple project managers were conducted, which included feedback from staff members that interacted with the robots directly. The empirical data obtained from this case study, in conjunction with the requirements engineering framework detailed in Section 2.2, were utilized to form both raw and formalized requirements for the construction robot.

3.1 Requirements Engineering Output

Based on the requirements analysis of the key stakeholders, the raw and formalized requirements in Table 1 are split into four categories – Functional Requirements (FR), Non-Functional Requirements (NFR), Domain Requirements (DR), and Regulatory Requirements (RR), representing four key areas that the stakeholders wish to focus on the most.

Table 1. Outputs of requirements engineering process

Requirements No.	Requirements
FR01	**Raw:** Unsafe environment/hazard detection
	Formalized: Capability to detect unsafe environment conditions on construction sites such as holes, steps, and barricades
FR02	**Raw:** Movable live streaming camera
	Formalized: Capability to turn or move livestreaming camera up and down, left and right to monitor more angles (e.g., ceiling, floor)
FR03	**Raw:** Automatic route generation by easy parameter input
	Formalized: Enable user parameter input function to auto-generate robot patrolling route and automatically link routes in different rooms/areas
NFR01	**Raw:** Quick setup and maintenance
	Formalized: Improve and enable rapid system setup (i.e., plug-and-play setup), integration with site management software and smooth maintenance workflows
NFR02	**Raw:** Network connectivity and stability improvements
	Formalized: Improve weak/unstable Wi-Fi/5G signal connectivity issue at remote or underground location
DR01	**Raw:** Sensor protection
	Formalized: Improve design of GPSRs to keep sensors inside free from dust and water from construction sites
DR02	**Raw:** Large language model **(**LLM) functions customized for construction industry
	Formalized: Enable LLM voice

	function for construction specific context
RR01	**Raw:** Comply with Singapore regulations
	Formalized: Adhere to regulatory requirements in the following aspects – Built Environment and Productivity, Workplace and Risk Management, Environmental Health and Pollution, and Cybersecurity and Communication Compliance

3.2 System Architecture and Functional Design

State-of-the-art solutions were surveyed for each requirement to determine the essential technological components. These components were then stratified into their respective requirement categories for the construction sector (e.g., FR, NFR, DR, RR), yielding the system architecture depicted in Figure 4.

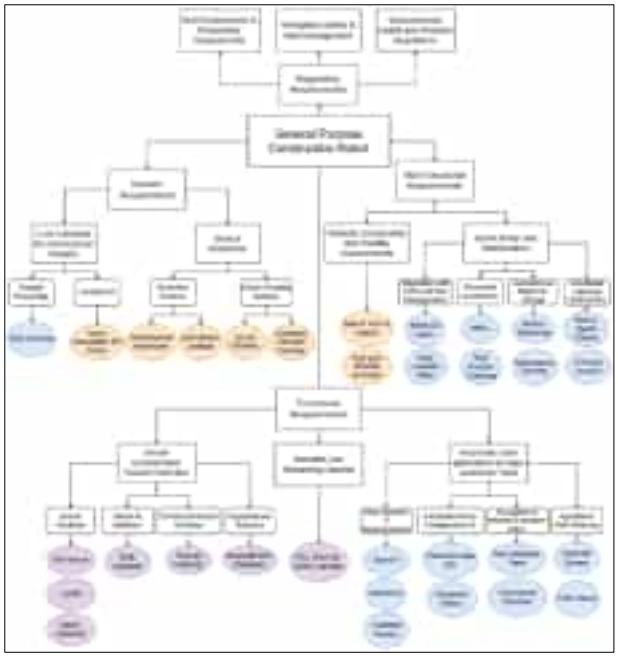

Figure 4. System Architecture of the adapted GPSR derived from requirements engineering

Functionally, it will support multi-modal hazard detection, movable live video streaming, and parameter-driven autonomous navigation. From a performance perspective, it enhances network connectivity and reliability while incorporating weatherproof protection for the sensors. Specifically for the construction sector, it integrates construction-focused LLM capabilities for domain knowledge and on-site interaction and enables quick setup and maintenance. Furthermore, it also complies with regulatory requirements in Singapore related to construction productivity, workplace safety, and environmental protection.

3.3 Development Planning

Based on the system architecture, a development plan was formulated following an evaluation of current systems and an analysis of requisite upgrades across the domains. Subsequent developments were defined based on solution feasibility and priorities, determined in collaboration with construction industry experts.

4 Implementation and Operational Workflow

Following the systems engineering and requirements definition process, the implementation phase aims to operationalize the proposed framework on real construction sites. Rather than focusing solely on technical upgrades, this stage emphasizes how a GPSR can be embedded into real-world construction workflows from preparation and deployment to charging, task execution, and data utilization.

This stage therefore functions as the robot's formal onboarding process. The implementation workflow bridges the gap between technical readiness and operational readiness, ensuring that the robot can function safely, autonomously, and efficiently within real project operations.

4.1 Site Preparation and Integration

Successful deployment begins with a structured preparation and integration process that ensures the robot's capabilities are safely and reliably embedded into site operations. Formalizing these steps makes deployment predictable, scalable, and repeatable across construction projects.

- **Site assessment:** A detailed survey identifies operational zones, access routes, hazard areas, and suitable dock locations. Terrain irregularities, material-strewn paths, temporary installations, and other construction hazards are mapped. Network coverage (Wi-Fi, 5G) is validated to ensure high-bandwidth connectivity across mission zones.
- **Infrastructure setup:** Setup includes installing charging docks, network repeaters, and safety markers along robot pathways. This step ensures stable power and safe dock placement. Physical boundaries are defined to prevent unintended entry into high-risk areas.
- **Software configuration:** Site layouts are imported into the mapping interface, followed by a calibration run to align digital maps with real

conditions. Digital no-go zones, speed-limited corridors, and temporary hazard boundaries are configured.

- **Connectivity integration:** Secure, stable data exchange is established between the robot's management portal and site systems, enabling real-time monitoring of position, mission status, battery level, and system's health.

4.2 Operational Workflow

Daily operation follows modular, repeatable workflows designed for efficiency, safety, and site awareness, balancing autonomy with human oversight.

- **Mission planning:** Operators define patrol, inspection, or monitoring tasks through a graphical user interface (GUI). Routes are generated based on the provided site maps. Typical tasks include safety compliance checks, environmental monitoring, hazard detection, meter readings, and routine visual inspections.
- **Autonomous execution:** The robot executes missions autonomously, navigating slightly uneven flooring, debris, temporary cables, and moving personnel. Onboard perception and hazard-detection algorithms support safe operation.
- **Data capture and reporting:** Images, sensor readings, and hazard detections are continuously recorded and uploaded to the management platform, where they are formatted into actionable reports based on site needs.
- **Human-robot coordination:** Personnel are briefed on robot operations, with clear escalation procedures for unexpected behavior. Supervisors can assign ad hoc tasks or trigger emergency stops without disrupting schedules.

4.3 Charging and Maintenance Procedures

Energy management and maintenance ensure reliable, safe autonomous performance and define the robot's Operational Design Domain (ODD) [15].

- **Autonomous return-to-charge:** After missions or at low battery, the robot automatically docks and begins charging, with status updates displayed in the operator's dashboard.
- **Maintenance scheduling:** Construction environments are particle-rich and harsh, which require proactive maintenance through scheduled tasks including: 1) Sensor integrity checks: Cleaning the LiDAR, cameras, and ultrasonics; running diagnostics, 2) Thermal management: Monitoring temperatures and clearing dust from cooling components, 3) Physical inspection: Checking wheels, actuators, seals, and enclosures for debris or damage, 4) Joint maintenance plan: Jointly defining a coordinated maintenance plan between the robot manufacturer and construction company and executing it by the construction company.

4.4 Workflow Adaptation for Construction Site

As construction environments evolve daily, robotic workflows must remain adaptive to maintain utility and relevance.

- **Periodic map uploads:** Operators upload site maps acquired from the site team, reflecting obstructions, and restricted zones, paralleling the site integration process.
- **Dynamic route regeneration:** The system recalculates routes when encountering new barriers, temporary structures, or shifting pathways, enabling safe navigation without manual reprogramming.
- **Collaborative operation:** Robotic tasks are synchronized with site operations - for example, performing patrols during off-hours, with supervisors reviewing inspection data at shift handover.
- **Data feedback loop:** Collected insights such as hazard detections, environmental metrics, and safety observations are fed back to the site team to facilitate regulatory reporting and proactive risk management.

4.5 Summary of Implementation Steps

The implementation plan follows a structured five-phase approach consistent with systems engineering, incorporating safety, maintenance, and integration practices required for construction sites (Table 2). Overall, implementation focuses on creating a structured yet adaptable operational environment where GPSRs can perform useful functions without a full redesign.

Table 2. Implementation plan derived from the requirements engineering process

Phase	Key Activities	Outputs
i. Preparation	Select pilot site; conduct survey; identify hazards; install dock, connectivity, and safety markers	Deployment-ready infrastructure and safety boundaries
ii. Integration	Import maps; configure no-go zones and tasks; perform calibration runs	Safe, validated operational test environment
iii. Field	Conduct autonomous	Operational

Operation	patrols; verify hazard detection; monitor logs, thermal health, and sensor integrity	data and performance logs
iv. Evaluation	Assess navigation reliability, data sync, detection accuracy, and worker–robot interaction	Pilot performance and safety compliance report
v. Optimization	Refine mission plans, update maps, adjust parameters, improve site workflows	A fully integrated, scalable operational framework

5 Discussion

The following sections highlight the methodology's novelty and effectiveness, the value of the engineering results, and the roadmap for future validation. In addition, the research limitations are outlined.

5.1 Novelty and Implications

The Modified V-Model successfully bridged the historical disconnect between robotic capabilities and construction realities in a rapid manner. By integrating "Gemba Walks", the framework captured dynamic site constraints, such as temporary cabling and dust accumulation, often absent from standard specifications. This observational data was directly formalized into the System Architecture and operational workflows, ensuring that the system was designed around real site operations (e.g., site induction & data handovers) rather than technical autonomy alone. Furthermore, the domain-specific requirements engineering process established a rigorous, traceable blueprint [8]. By linking every System Architecture component to specific "raw" requirements, the framework created a logical audit trail that prevented scope creep and ensured a demand-driven design. This rigor extended to defining a strict ODD [15], which explicitly mapped environmental boundaries such as surface flatness and lighting minimums to clarify the robot's role as a specialized tool for specific zones rather than a universal solution. Moreover, the systems engineering approach rapidly identified and specified all necessary components of the adapted GPSR, enabling early-stage cost-benefit analysis (CBA). By leveraging the established CBA framework for construction robots [16], key financial indicators of the adapted GPSR can be readily estimated prior to on-site deployment, which not only further validates the feasibility of the adapted robot but also strengthens client confidence.

5.2 Limitations

While the framework establishes a robust structural foundation, several requirement categories were excluded from this initial iteration. These limitations fall into three distinct aspects. First, addressable scope limitations such as advanced AI integration (e.g., LLMs) and local 5G infrastructure analysis were deferred to prioritize immediate feasibility but remain part of the future development roadmap. Second, inherent hardware constraints impose fixed operational limits. Specifically, the GPSR's wheel configuration restricts movement on rough terrain, a physical limitation that cannot be resolved through framework adaptation. Furthermore, as the study focuses on framework development, long-term feedback and quantitative metrics have not yet been gathered for verification and validation.

6 Conclusion

This paper presents a domain-specific systems engineering framework for rapidly transforming GPSRs into operational tools for construction project environments. By integrating a Modified V-Model with structured requirements engineering, the proposed framework offers a reproducible methodology that bridges the gap between controlled-indoor robotic platforms and the complex, dynamic conditions of construction sites, laying out the foundation for the next-phase development. The case study demonstrates that, while current GPSRs possess strong baseline capabilities in navigation, sensing, and data acquisition, they require systematic adaptation to address construction-specific challenges such as environmental variability, human–robot collaboration, and workflow integration. With the completion of the remaining work, the study is expected to fully validate the effectiveness and practicality of the proposed methodological framework.

The study mainly benefits construction project teams and robotics providers who want to deploy GPSRs for real site operations without the need for a full robot redesign, further lowering development cost, and accelerating development speed. More broadly, it provides a valuable reference for those who wish to rapidly adapt general-purpose technologies to new application scenarios and industries.

As indicated in Figure 1, future work will advance the project from the "Detailed Design" phase into the "Prototyping and Implementation" phase of the V-Model, eventually verifying and validating the system design, requirements, and project concept. The specific roadmap includes:

- **Prototyping and implementation:** Executing iterative prototyping loops to integrate sensing payloads and software modules.

- **Site testing:** Conducting field trials to validate performance under real conditions and collect quantitative data on localization and docking reliability.
- **Regulatory compliance and expansion:** Addressing deferred scope items, achieving compliance with Singapore's (and potentially other target markets') safety regulations, and integrating capabilities such as LLMs and 5G connectivity.
- **Iterative refinement:** Using site-testing results to drive feedback loops that may return the process to requirements engineering, system architecture, or detailed design for further optimization.

Abstract –

The construction industry is undergoing rapid transformation driven by digitalization, automation, and changing workforce structures. Despite these shifts, career guidance practices within the sector remain largely manual, fragmented, and poorly aligned with dynamic labor market conditions, limiting their effectiveness for workforce planning and innovation adoption. This study addresses this gap through the design and development of an artificial intelligence (AI)-driven career guidance system tailored to the Australian construction industry. The proposed system architecture comprises four integrated layers: knowledge base, reasoning algorithm, user interface, and cloud-based deployment environment. The knowledge base consolidates theoretical insights from a systematic literature review and occupational data from government and industry sources. A hybrid reasoning approach combining rule-based logic and large language model (LLM) capabilities enables automated, scalable, and personalized career recommendations. The user interface was delivered through a web-based platform to support intuitive design and ease of use. Deployment was implemented through Amazon Web Services (AWS) Elastic Compute Cloud (EC2) to support scalable and reliable system hosting. After the prototype was developed, 32 construction students were invited to pilot the system and complete a questionnaire on perceived usefulness, usability, and impact, while also providing recommendations for improvements. This study contributes to construction technology management and service innovation by demonstrating how AI enabled automation tools can support workforce development, enhance career decision making, and inform strategic talent pipelines for education providers and industry stakeholders.

Artificial Intelligence (AI); Australia; career pathways; construction industry; Large Language Model (LLM)

1 Introduction

Technological advancement and the growing emphasis on digitalization and sustainability have substantially increased the complexity of construction work. Modern construction roles now demand not only technical and project management competencies but also digital literacy, data analysis, and sustainability-related skills [1]. For example, the rise of Building Information Modelling (BIM), digital twin technologies, and green building practices has transformed traditional site-based positions into multidisciplinary roles requiring hybrid technical and analytical capabilities [2]. As a result, the career landscape in construction is rapidly evolving, creating new opportunities while intensifying the ongoing skills shortages that threaten the industry's long-term sustainability and productivity.

Career counselling and guidance have long been recognized in literature as key measures for supporting informed and sustainable career decisions [3]. However, despite its importance, traditional career guidance remains limited in both scale and effectiveness. The advice provided rely heavily on the expertise and personal judgement of individual career advisers, and often lack up-to-date, industry-specific insights [4]. For example, career advisers who are unfamiliar with modern construction technologies or professional roles may unintentionally reinforce outdated stereotypes or overlook emerging career pathways such as digital engineering, sustainability consulting, or project data analysis. These limitations highlight the need for more systematic, scalable, and data-driven approaches to career guidance that can deliver accurate, personalized, and up-to-date information aligned with the realities of the modern construction industry.

The rapid advancement of artificial intelligence (AI)

and Large Language Model (LLM) in recent years has introduced new opportunities to address many of the limitations of traditional career counselling. Previous studies have attempted to use AI as a career advisory tool, demonstrating the potential of AI systems to simulate the functions of a human career coach. For example, Kulugh, et al. [5] developed an AI-based career recommendation chatbot that analyzed students' educational profiles to suggest potential occupational paths, while Cheng and Liang [6] combined natural language processing (NLP) with machine learning classifiers to align user goals with their backgrounds. These developments have marked a shift from static career databases to dynamic, conversational systems capable of analyzing user profiles and generating adaptive career suggestions. However, most existing AI career coaching tools are designed for general audiences and rely on global or non-specialized datasets, lacking the domain-specific depth required to address the distinct structure and workforce characteristics of the Australian construction industry. As noted by Miller, et al. [7], integrating structured industry knowledge into AI systems significantly enhances their precision, contextual relevance, and trustworthiness.

To fill this gap, this study aims to design and develop an AI-powered career guidance system for the Australian construction industry, supporting students, graduates, and career changers in making informed career decisions.

2 System Architecture Design

2.1 Knowledge Base Layer

A knowledge base layer serves as the foundation of the system by providing structured and domain specific information to suit reasoning algorithm. It ensures that the AI operates with targeted knowledge rather than relying solely on general purpose information, thereby reducing the risk of irrelevant outputs and hallucinations [8]. In this study, the knowledge base layer incorporates a career information repository that was developed to provide data-driven and evidence-based insights tailored to the Australian construction industry.

To establish the foundation for developing a comprehensive career information repository, this study first identified key factors influencing career decisions in the construction industry through a systematic literature review. As a widely used research method, a systematic literature review facilitates the identification, evaluation, and synthesis of existing studies on a specific topic [9]. The thematic synthesis approach was applied, following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) approach to ensure transparency, reproducibility, and methodological rigor.

Scopus was selected for its comprehensive coverage of peer-reviewed journals in construction management, engineering, and career development. An initial title search using "construction" and "career" returned 493 papers. A three-stage screening process was applied. First, filters limited results to English-language journal or journal/review articles published after 2015 from comparable labor markets (Australia, US, UK, New Zealand, Canada), reducing the set to 110 papers. Second, titles and abstracts were manually screened to confirm relevance to construction careers and full-text availability, yielding 40 papers. Finally, only studies examining or proposing factors influencing career choice or development in construction were retained, resulting in 14 papers. This number aligns with other systematic reviews in the construction field [10].

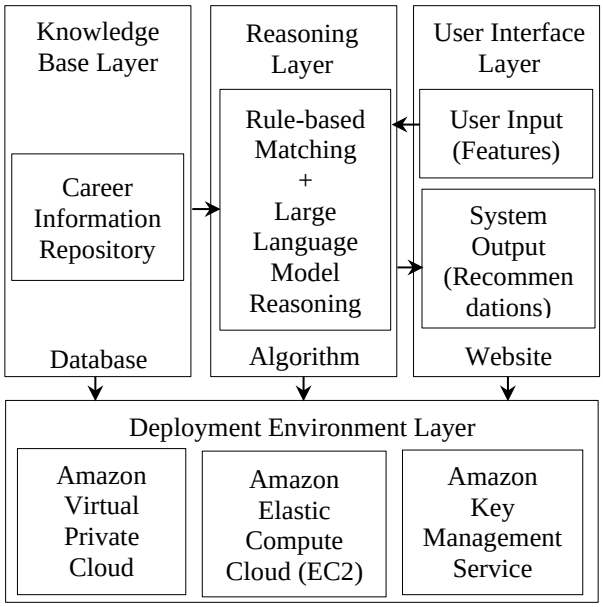

Figure 1. System architecture

The selected papers were analyzed using thematic analysis conducted in Lumivero NVivo 14, which facilitates efficient data management, coding, and theme development [11]. Each paper was reviewed manually, and descriptive codes were assigned to text segments that represented influential factors shaping careers in the construction industry. Codes with overlapping meanings were merged to reduce redundancy. Based on the thematic synthesis, the factors influencing career decisions were grouped into two major categories. Extrinsic factors refer to external conditions and contextual incentives that shape an individual's career choices, including opportunities for future growth, salary expectations, work environment, flexibility, and workplace diversity. Intrinsic factors relate to internal motivations and personal features that influence career preferences, educational background, technical competencies, soft skills, work style, and prior exposure to the industry. Table 1 summarizes the mapping of factors identified across the 14 reviewed studies.

Based on those key factors identified through the systematic literature review, the career information

repository was designed to incorporate 16 features, encompassing general role information, extrinsic factors, and intrinsic factors, as summarized in Table 2.

Table 1. Factors mapping overview

	Factors	Literatures
Extrinsic	Future growth	1, 2, 4, 11, 13,14
	Salary	1, 2, 11
	Work environment	1
	Flexibility	2, 3, 7, 12, 13
	Diversity	1, 4, 7, 8, 9, 13
	Physical demand	1
Intrinsic	Education	5, 9
	Technical skills	1
	Soft skills	8, 9, 10, 13
	Work style	2, 6, 7
	Prior exposure	3, 5, 8, 9, 10

Note: 1 = [12]; 2 = [13]; 3 = [14]; 4 = [15]; 5 = [16]; 6 = [17]; 7 = [18]; 8 = [19]; 9 = [20]; 10 = [21]; 11 = [22]; 12 = [23]; 13 = [24]; 14 = [25].

Table 2. Features included in the knowledge base

	Features	Description
Role	*discipline*	Construction disciplines
	role_description	General scope of daily work
	typical_titles	Variations in job titles
Extrinsic	*future_growth*	Growth outlook for the role
	career_pathway	Example progression
	salary_range	Annual salary range
	work_envir	The primary work location
	outside_hours	Work outside standard hours
	location_flex	Flexibility in work location
	hour_flex	Flexibility in work hours
	gender_ratio	Percentage of women
	physical_dem	Level of physical effort
Intrinsic	*minimum_edu*	Entry qualification required
	technical_skills	Technical competencies
	soft_skills	Interpersonal skills
	work_style	Characteristics of the role

The knowledge base of the prototype was scoped to focus on entry-level roles in the Australian construction industry, reflecting the initial development stage and time and budget constraints, with additional roles to be incorporated in future system iterations. A search was conducted on three commonly used job seeking websites, SEEK, CareerOne, and Workforce Australia, using the keyword “entry level” and the industry classification “construction”. Additional roles were identified through open discussions with industry professionals and members of the research team with backgrounds in the Australian construction industry, informing the selection of roles to be included. As a result, the knowledge base captured 70 commonly found roles across 10 disciplines in the Australian construction industry, as outlined below.

1. Construction Management and Project Management
2. Quantity Surveying and Cost Management
3. Civil Engineering and Structural Engineering
4. Architecture, Design, and Urban Planning
5. Building and Construction Trades
6. Health, Safety, Environment, and Quality
7. Building Surveying and Certification
8. Property, Real Estate, and Facilities Management
9. Mechanical, Electrical, and Services Engineering
10. Surveying, Geospatial, and Geographic Information System (GIS)

A web scraping process was conducted to collect career-related data from a range of credible public sources (n= 83), including government websites, industry associations, educational institutions, and major job-seeking platforms. The scraping was implemented in Python using the BeautifulSoup and Requests libraries to extract structured information. To ensure accuracy and data integrity, the final knowledge base was manually reviewed and validated by the research team, with inconsistencies cross-checked against official government and industry sources.

2.2 Reasoning Layer

The reasoning layer refers to the component responsible for processing user input, matching with the knowledge layer, and generating role recommendations. The core of this layer is the algorithms, which is designed to combine rule-based matching with LLM reasoning, as suggested by recent studies in information systems and artificial intelligence [26]. This hybrid approach allowed the system to balance accuracy with flexibility in handling complex and variable inputs. Among the 16 features, nine were utilized within the reasoning layer, while the remaining features were presented as system outputs.

Categorical features, including *work_envir*, *physical_dem*, *outside_hours*, *location_flex*, *hour_flex*, and *work_style* were designed to be matched using rule-based methods to ensure accuracy and consistency, as these data points in the knowledge base were predefined and discrete. Each feature was assigned a discrete score based on the degree of correspondence between user preferences and role characteristics.

Textual features, namely *minimum_education*, *technical_skills*, and *soft_skills*, were scored using LLM reasoning, as these inputs contain diverse linguistic expressions, synonyms, and contextual nuances that cannot be effectively captured through rule-based matching alone. To guide the LLM’s reasoning process and ensure consistent evaluation across users, prompt engineering techniques were applied to reduce hallucinations. It refers to the process of designing

structured instructions that guide the LLM to generate accurate, consistent, and contextually appropriate responses. The template is presented below.

- System Role: You are a professional career advisor with expertise in the Australian construction industry.
- Task: Analyze the user's background and match it with suitable roles using the knowledge base.
- Scoring Rules: Assign numerical scores for each feature based on the level of alignment between the user's profile and role requirements. Use continuous scoring rather than fixed anchor points to allow finer differentiation. Clearly identify matched and unmatched features, highlighting areas of strength and potential improvement.
- Response Structure: Strengths: Your background aligns well with this role because [analysis]. Areas for Development: Areas that may need further development include [analysis]. Interpersonal Skills: Employers often look for [skills]. Other Recommendations: To expand your career options, [personalized advice, industry associations, mentorship].
- Output Requirements: Return all responses in valid JSON format. Do not include any text outside the JSON structure. Maintain a warm, professional, and easy to understand tone using Australian English. Do not recommend qualifications lower than the user's current education level.

The total score for a given role r, expressed on a 100-point scale, is calculated as:

$$S_{rule}(r) = 5 \times \sum_{i=1}^{6} m_i \quad (1)$$

$$S_{LLM}(r) = (0.4 \times S_{edu} + 0.15 \times S_{tech} + 0.15 \times S_{soft}) \quad (2)$$

$$S_{final}(r) = S_{rule}(r) + S_{LLM}(r) \quad (3)$$

where m_i denotes the discrete score based on the degree of correspondence (0 for mismatch, 0.5 for partial match, and 1 for exact match). The terms S_{edu}, S_{tech}, and S_{soft} represent the feature scores (each on a 100-point scale) assigned by LLM. The weightings used in the formula were determined through research team discussions and remain adjustable through future performance testing. Future versions will also allow users to adjust the weighting scheme according to their preferences. In addition, a comparison was conducted to assess the performance of the system across five LLM backends: GPT-4.1, Claude-sonnet-4, Gemini-2.5-flash, Qwen-plus, and Deepseek-chat. Using ten participant resumes, each model generated career recommendations. The outputs were evaluated by three industry experts within the research team, each with over five years of experience in the Australian construction sector. Scores were assigned on a 1–5 scale, where 1 indicates the lowest level of satisfaction and 5 indicates strong satisfaction. Processing time and estimated computational cost were also recorded. Table 3 summarizes the results.

Table 3. LLMs Comparison Results

Model	Score ($\mu \pm \sigma$)	Time (s) ($\mu \pm \sigma$)	Cost (USD)
GPT-4.1	**4.45 ± 0.37**	10.92 ± 0.94	1.08
claude-sonnet-4	3.84 ± 0.34	11.60 ± 0.25	1.1
gemini-2.5-flash	3.78 ± 0.34	30.63 ± 2.50	0.96
qwen-plus	3.78 ± 0.34	**8.26 ± 0.34**	0.12
deepseek-chat	4.00 ± 0.34	15.65 ± 0.69	**0.05**

Note: μ = the mean value; σ = the standard deviation.

The results revealed performance of trade-offs among the models. GPT-4.1 achieved the highest expert-rated quality, indicating its suitability for high-stakes or decision-critical applications. Deepseek-chat demonstrated the most favorable cost efficiency while maintaining competitive performance, supporting scalable deployment scenarios. Qwen-plus consistently delivered the fastest response times, making it well-suited for interactive applications with modest quality trade-offs. Claude-sonnet-4 showed moderate performance across all metrics without a clear advantage, whereas Gemini-2.5-flash exhibited relatively higher latency without commensurate gains in quality or cost. Future work plans to allow users to select and compare different models within the system.

2.3 User Interface Layer

The user interface layer refers to the component through which users interact with the system. It connects with the reasoning layer to present outputs in clear and readable text. It collects user input, transmits the data to the reasoning layer for analysis, and presents the resulting recommendations in an accessible and user-friendly format. A web-based platform was chosen as the delivery format, as it offers broad accessibility, ease of deployment, and the ability to integrate seamlessly with backend services. The user interface and user experience design followed principles of clarity, simplicity, and accessibility, ensuring that the system is easy to read, navigate, and interact with. This layer was developed using python, Hypertext Markup Language (HTML), and JavaScript connecting to the reasoning layer.

To improve user convenience and minimize manual data entry, a resume importing function was embedded in the interface using spaCy and PyPDF2 for named-entity extraction. This feature allows users to upload their resume in Word or PDF format after consenting to the Privacy Protection Statement. Uploaded resumes are converted into plain text, segmented into key sections

(education, skills, certifications), and analyzed using pattern matching and entity recognition to identify relevant features. The extracted data are automatically mapped to the corresponding input fields in the interface, allowing users to review and edit the pre-filled information before submission. All files are processed temporarily and deleted after use to ensure privacy protection.

Users are required to complete three sections. The first section focuses on educational background, where users list their academic qualifications, certifications, and professional licenses. An example entry is provided to guide users in completing this section. The second section, skills and experience, collects information on users' technical skills, software proficiency, and interpersonal or soft skills. To assist users in formulating their responses, example suggestions are displayed beneath each input field, referencing common competencies in the construction industry. The final section, interest assessment, consists of six multiple choice questions corresponding to the features in the knowledge base, including work environment, physical demands, outside hours, location flexibility, hour flexibility, and work style. Each question is phrased in plain English to ensure comprehension and ease of response. Figure 2 presents the developed prototype.

Upon completion of the three sections, the results page generates a list of five career roles that best align with the user profile based on the provided inputs. Each role includes a brief overview, key characteristics, and AI-generated insights including strengths, areas for improvement, and recommendations for career development. Figure 3 presents an example of a recommended role output screen.

2.4 Deployment Environment Layer

The deployment environment provides the infrastructure necessary for hosting and operating the AI-powered career guidance tool online. It ensures system availability, data security, and scalability for handling multiple user requests simultaneously. Common deployment approaches include cloud-based, on-premises, and hybrid environments. In this study, cloud-based deployment was selected using Amazon Web Services (AWS) due to its scalability, reliability, and cost efficiency [27]. The system was deployed on Amazon Elastic Compute Cloud (EC2), which hosts the application backend, executes rule-based and LLM-driven computations, and manages communication with the knowledge base and user interface. EC2 offers elastic computing resources that can automatically scale to accommodate variable user demand, ensuring consistent system performance. The deployment operates within an Amazon Virtual Private Cloud (VPC), which isolates the system components and controls inbound and outbound network traffic, providing an additional layer of network security. The AWS Key Management Service (KMS) was used to encrypt data stored and processed on the EC2 instance, protecting sensitive information such as user inputs and uploaded resumes. This encryption framework ensures that data confidentiality is maintained in accordance with privacy and security standards. Data exchange between the user interface, backend, and external APIs is managed through AWS Data Transfer, which ensures stable and secure data transmission with low latency.

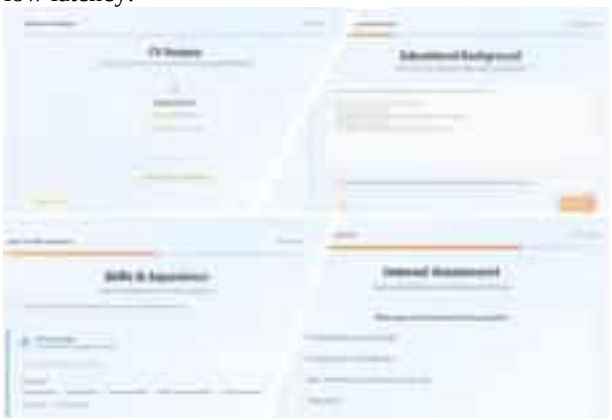

Figure 2. Developed web pages

Figure 3. Results page

The process begins with launching an EC2 instance, followed by configuring the security group to define access permissions. The website code is then deployed to the instance, after which the domain name is configured to enable public access. System monitoring is subsequently set up to track performance and availability. A decision point is used to verify whether the website is running as expected. If issues are identified, troubleshooting is performed before rechecking system status. Once the website is confirmed to be running successfully, the deployment process concludes.

3 Pilot User Experience

After the prototype was developed, users were invited to experience the system and provide feedback to inform

future improvements. A total of 42 students participated in the workshops. The questionnaire responses were screened for completeness and validity prior to analysis. Incomplete submissions (n=2), responses with missing demographic information (n=5), or careless responses (n=3; those in which participants selected the same answer for all questions) were excluded. The final dataset consisted of 32 valid responses. Descriptive analysis was performed using Microsoft Excel to summarize quantitative data, while qualitative feedback was analyzed through manual coding to identify recurring themes and improvement suggestions. The majority were aged between 18-25 years, with 59.3% identifying as female. Most participants (62.5% of total) reported having no prior work experience in the Australian construction industry, reflecting the target user group of the tool.

The quantitative section of the survey consisted of 10 Likert-scale items rated from 1 ("strongly disagree") to 5 ("strongly agree"), measuring three key constructs: usefulness, ease of use, and impact.

Usefulness refers to the extent to which users believed that the tool provided relevant and insightful career guidance. Three items were adapted from Venkatesh and Davis [28] with a Cronbach's alpha of 0.72. *Ease of use* refers to the extent to which users find the system intuitive and user-friendly. Four items were adapted from Venkatesh and Davis [28] with a Cronbach's alpha of 0.88. *Impact* refers to the extent to which users found the tool had an impact on their career and introducing new potential roles within the construction industry. Four items were adapted from Gedrimiene, et al. [29] with a Cronbach's alpha of 0.76. Table 3 presents quantitative results, indicating generally favorable perceptions across all statements.

Two open ended questions were used to capture qualitative insights from participants, focusing on which functions could be improved or made easier to use, and which additional functions users would like to see incorporated into the tool. The findings informed the future development roadmap, which is discussed in the following section.

4 Future Development Roadmap

Regarding existing functions, the most frequently mentioned area for improvement was system response time, noted by more than 40% of users. The commonly requested improvement, supported by over 35% of participants, was the ability to download and share results directly. At present, users can only export their results as a PDF using the browser's print function and share them manually. During the user evaluation workshops, several participants were observed taking photos of their results to keep personal records. Integrating a built-in saving and sharing feature, such as generating downloadable PDF summaries or enabling direct sharing through emails, would further improve the system's usability and accessibility.

Table 4. Descriptive Analysis Results

	Statements	Mean
Usefulness	1. The tool's recommendations were relevant to my skills and experience.	4.09
	2. The tool provided career options that matched my interests.	4.03
	3. The tool offered new career options I had not previously considered.	3.94
Ease of Use	4. The tool was easy to use.	4.44
	5. I felt confident in using the tool.	4.22
	6. The design and layout were clear and intuitive.	4.25
	7. The tool delivered what I expected it to.	3.94
Impact	8. The tool increased my confidence in making career decisions.	3.84
	9. The tool encouraged me to research new career pathways.	4.03
	10. I want to recommend this tool to others.	4.00

When participants suggested additional functions for future development, the most frequently recommended enhancement was career pathway visualization. Currently, the prototype presents future pathways in text only, without visual or interactive elements. Participants suggested that an interactive flow diagram or progression map could help users better understand advancement routes in construction, including transitions from entry-level to middle and senior roles. Such visualization could also enhance user engagement and learning effectiveness, as graphical tools have been shown to enhance users' comprehension of complex information and improve engagement [30].

Another widely supported suggestion was the introduction of an AI-powered mock interview practice module, recommended by approximately half of the participants. This aligns with Shi and Wang [31] emphasizing the value of simulated interview experiences in building communication confidence and employability skills. Such function could offer users a low-pressure environment to practice common industry questions, receive feedback, and prepare for recruitment. Additionally, over 35% of participants proposed the inclusion of an AI-powered chatbot to make the system "more interactive". This chatbot could serve dual purposes, including facilitating mock interview interactions and providing real-time responses to user queries about job recommendations, role descriptions, and next steps. Embedding conversational AI in this way would enhance engagement and deliver a more dynamic, personalized user experience.

In addition, over 40% of users suggested adding a peer stories or role model showcase section. This suggestion aligns with Perrenoud, et al. [32], highlighting the lack of visible role models as a barrier to participation, particularly among women and underrepresented groups in construction. Integrating authentic career stories could humanize the data-driven recommendations, demonstrate diverse pathways to success, and inspire users through relatable real-world examples. Developing this feature would, however, require collaboration with industry partners and professional associations to source and verify participant narratives.

Last but not the least, several participants recommended linking the system directly to current job postings to improve the immediacy and practicality of its recommendations. This could potentially be achieved by connecting the platform with established job-seeking websites such as SEEK or CareerOne. However, implementing such integrations may present challenges related to privacy, data sharing, and potential conflicts of interest. Future research could explore partnership models or API-based data-sharing frameworks that ensure compliance while providing users with up-to-date labor market insights.

5 Conclusion

This study presented the design and development of an AI-powered career guidance system tailored to the Australian construction industry as a technology enabled service innovation. The positive pilot user experience highlights the potential of automation tools and AI to support technology management, workforce planning, and innovative career guidance practices within the construction sector.

This study has several limitations that also present opportunities for future development. First, as the initial stage, the current prototype focuses solely on entry-level positions in the construction industry. Expanding the system to include mid- and senior-level roles would allow users to explore long-term career trajectories and progression pathways within the sector. Second, the features used in the prototype were not exhaustive. Future stages could incorporate additional matching features, such as language proficiency, cultural background, and personal values, to provide a more holistic representation of career decision factors. As with most LLM-based systems, the model remains sensitive to prompt formulation and exhibits potential brittleness, which may affect consistency in outputs. Future work could refine prompt-engineering strategies or adopt hybrid architectures that combine deterministic logic with adaptive AI reasoning to improve reliability. Additionally, future work should include comparison with human advisors to benchmark the system's performance, enabling a systematic evaluation of the relative advantages and limitations of AI- and human-based career guidance. Technical constraints also exist in relation to AWS deployment, including dependence on stable internet connectivity, ongoing server maintenance costs, and token usage fees associated with LLM processing. To enhance scalability and sustainability, future implementations could explore serverless architectures to enable wider accessibility and continuous operation. Last but not least, As the system provides career recommendations, potential bias and fairness issues must be carefully considered. Measures such as bias auditing can help identify whether recommendations systematically differ across demographic groups, such as gender. Providing transparent explanations for recommendations may also help users understand how suggestions are generated. Future work should incorporate bias monitoring and responsible AI practices to support inclusive and equitable career guidance.

Tackling Site-Based Challenges: The Mitigating Role of Construction 4.0 in Advancing Women's Participation

Aba Essanowa Afful[1], Cynthia Changxin Wang[2], Riza Yosia Sunindijo[3]

[1,2,3,]School of Built Environment, University of New South Wales, Australia

Abstract

This paper examines how Construction 4.0 technologies tackle the challenges of site-based women in construction. The study also examines the role of Construction 4.0 in offering a competitive advantage to women in these site-based roles. The study adopts a qualitative method using semi-structured interviews with 9 women in site-based roles, purposefully selected from a broader study of 29 women across on-site, off-site, and fluid roles. This is followed by a mixed-gender focus group discussion to validate the findings of the interviews. The findings reveal construction technologies used by site-based women include hardware devices, enterprise systems, and design/CAD enabled design tools. Further, key challenges faced by women in these roles include gendered culture that undermines their credibility and voice, capability challenges and progression and career mobility. To address these challenges, study participants indicated that technologies enhance women's performance and credibility in meetings, reduce physical and safety burdens, and enable flexibility, thereby creating role-specific advantages around efficiency, safety, and confidence. However, both interviewees and focus group participants caution that Construction 4.0 offers a critical, but not self-sufficient, platform for change. Technologies can help dismantle some of the gendered challenges, yet their potential depends on being embedded within intentional strategies to challenge masculine industry norms and redesign job roles. This study forms part of a broader research seeking to empower women across on-site, off-site, and fluid roles through Construction 4.0 technologies.

Keywords –

Construction 4.0; women in construction; on-site roles; digital technologies, female participation.

1 Introduction

The construction industry remains one of the most gender-segregated sectors globally, with women significantly underrepresented in site-based and trade-oriented roles despite incremental gains in overall participation. Recent studies report that women are concentrated in office, administrative, and professional roles, while representation in on-site and physically intensive positions often remains below 5–10%, reinforcing a perception of site work as a male domain [1]. This imbalance persists even as labour shortages and ageing workforces intensify pressures on the industry to diversify its talent base and align with global agendas such as the Sustainable Development Goals (SDGs), particularly SDG 5 on gender equality and the empowerment of all women and girls [2].

A growing body of construction and built environment literature highlights that women in site-based roles face persistent challenges, including exclusionary masculine cultures, harassment, limited access to mentoring, inflexible working patterns, and inadequate amenities, which collectively undermine attraction, retention, and progression [3]. Empirical work on early-career women and tradeswomen shows that women on site must continually prove their legitimacy, navigate hostile or dismissive behaviours, and often experience constrained career pathways compared with their male counterparts, even where formal equality policies exist [2,3]. Despite policy interventions, many initiatives have focused on broad demographic targets rather than the role-specific constraints of women in site-based positions, limiting their effectiveness and sustainability.

In parallel, rapid digitalisation and the emergence of Construction 4.0 offer new possibilities to reshape site-based work and reduce reliance on traditional, physically intensive practices. Technologies such as building information modelling (BIM), virtual design and construction (VDC), digital collaboration platforms, automation and robotics, wearable safety devices, and remote monitoring tools are increasingly linked to improvements in productivity, safety, flexibility, and decision-making across project lifecycles [4]. Recent systematic reviews emphasise that these technologies are

also associated with the emergence of new job roles notably "fluid" roles that integrate on-site and off-site responsibilities, potentially re-orienting focus from physical strength and continuous physical presence [2].

However, there is a lack of empirical evidence on whether and how digital tools mitigate challenges such as safety concerns, physical demands, and work–life conflict, for women on site, or whether these tools may inadvertently reproduce existing power imbalances in the industry [2].

Existing studies tend to either map women's roles and challenges in general, or examine Construction 4.0 adoption without a gender lens, resulting in limited understanding of how technologies are experienced by women on site [2, 3]. Again, there is the need to further the argument that construction 4.0 technologies generate competitive advantages for women in construction, e.g., in safety, productivity, visibility, and mobility across job roles. Moreover, relatively few studies have explored women's perspectives using in-depth qualitative methods that capture the socio-material and institutional lens of technology use.

Against this backdrop, this paper focuses specifically on women in site-based roles in the construction industry and examines how construction 4.0 technologies can mitigate challenges and create competitive advantages for these women. Some studies define competitive advantage as the presence of superior characteristics or capabilities that enable sustained outperformance, often operationalised through innovation, differentiation, and operational efficiency [5,6]. This study extends this concept to job roles of WIC, defining competitive advantage as role-specific capabilities and conditions that allow women in on-site construction roles to perform their work more efficiently, safely, and visibly. This is achieved by strategically leveraging Construction 4.0 technologies within male-dominated construction site environments. Aligning with this definition, reductions in physical and safety burdens, enhancements in performance and credibility, and increased flexibility and access are treated as key domains through which Construction 4.0 can generate competitive advantages for women on site.

The study aims to address the research question: *What competitive advantage can construction 4.0 offer to women in on-site job roles, and how might these capabilities address identified challenges?* To answer this question, the study adopts a qualitative research method comprising of 29 semi-structured interviews with women in site-based roles, followed by 3 focus group discussions to validate the emergent themes.

2 Method

Prior to the conduct of the study, ethical clearance was provided from the University of New South Wales Human Research Ethics Committee (approval no. iRECS6102). All participants provided informed consent, were assured of confidentiality and anonymity, and were advised of their right to withdraw at any time.

This study adopted a qualitative, two-stage design using semi-structured interviews and focus group discussions. Participants were recruited via purposive and snowball sampling methods. This approach was employed to identify female participants capable of providing in-depth insights into on-site roles and Construction 4.0 technologies. The inclusion criteria stipulated that participants must be female, aged 18 years or older, currently employed within Australia, possess a minimum of four years of experience in the construction sector, and be actively utilising one or more construction technologies in their present capacity. Recruitment commenced with the researcher's professional network on LinkedIn and engagement with women-centric industry organisations, such as the National Association of Women in Construction (NAWIC), the Architecture, Construction, Engineering, Development (ACED) Women Network, and Women in Building Information Modelling (BIM). Subsequently, recruitment was extended through participant referrals to ensure the inclusion of a diverse array of organisations and projects.

In Stage 1, individual semi-structured interviews were conducted with female construction professionals occupying a range of job roles. It is important to note that for this paper, we rely on a subset of data from the broader qualitative study. In the larger study, 29 female construction personnel were interviewed across on-site, off-site, and fluid roles. Specifically for site based roles, the sample (Table 1) included nine women and it is their interview data that form the basis of the analysis presented here. Example questions included: *What is your current job role and how long have you been in this position? What construction technologies are you currently using or have used in your job roles? How have these technologies impacted your work and responsibilities? In what ways do you believe women can gain a competitive advantage in the construction industry using technology?*

Table 1 Interview Participants information

Code	Profession	Years in Construction	Organisation Type
P1	Site Engineer	6 years	Builder
P5	Plumber	10 years	Sub-contractor
P6	Site Engineer	4 years	Builder
P8	WHSE Coordinator	4 years	Builder
P9	Carpenter	4 years	Builder
P11	WHSE Advisor	4 years	Builder

P12	Site Engineer	5 years	Builder
P24	Site Officer	7 years	Off-site Modular company
P27	Carpenter	8 years	Trade Sub-contractor

In Stage 2, an online focus group was conducted via Microsoft Teams for one hour, to validate the interview findings. The broader project conducted 3 focus groups with 18 participants. However, for this paper, only the 6 participants in on-site roles are included as their findings directly answer the research question raised. To minimise bias, participants were recruited from across different organisations and did not know each other prior to the session. The moderator presented a concise summary of the key interview findings on challenges, technologies, and perceived competitive advantages for women, then used open-ended questions to elicit agreement, disagreement, and additional examples. Structured turn-taking encouraged independent responses and ensured that all participants contributed equally. As seen in Table 2, the group comprised three male and three female participants with closely aligned site-related roles to allow for comparison. The focus group was run for a period of one hour and data was recorded and transcribed automatically on Microsoft Teams.

Table 2 Focus Group Participants

	Code	**Profession**	**Years in Construction**	**Organisation Type**
Males	MSR1	Electrician	4 years	Trade Sub-contractor
	MSR2	Senior site planner	12 years	Builder
	MSR3	Site Engineer	8 years	Builder
Females	FSR1	Site Engineer	6 years	Builder
	FSR2	Principal site engineer	7 years	Builder
	FSR3	Carpenter	5 years	Trade Sub-contractor

Both the interview and focus group transcripts were analysed using Atlas.ti version 2025, following an inductive thematic analysis approach. This software aided in coding, theme generation and analysis of data as well as the production of Sankey visualisation of the data. Analysis began with open coding of the interview transcripts, where segments of data were assigned descriptive codes reflecting participants' accounts of technology use, challenges, and perceived competitive advantages. Atlas.ti assisted the analytical process by searching the transcripts and suggesting inductive codes, as well as visualising how codes interrelated with each other across the dataset. Building on these code suggestions, the research team reviewed, refined, and grouped related codes into broader categories, which were further developed into overarching themes through iterative discussion. For the focus group data, the same coding framework was applied to assess the degree to which focus group participants confirmed, extended, or challenged the themes emerging from the individual interviews. Where focus group responses reinforced interview themes, these were retained as validated findings. Where new perspectives or contradictions arose, the themes were refined accordingly. This two-stage analytical process ensured that the final themes were grounded in both individual and group-level data. Thematic comparison between the interviews and focus group confirmed the main themes from the interview findings and led to minor refinements which are incorporated into the analysis presented in this paper.

3 Findings & Discussion

3.1 On Site Technologies

Figure 1 illustrates the range of Construction 4.0 technologies identified by the 9 site-based participants.

Figure 1- On site technologies identified

Interviewees highlighted hardware devices (e.g., laptops, iPads, smartphones, site cameras) as the most prominent technologies (7 mentions) followed closely by site tools such as hand tools, pliers, saws, hammers, etc. which are used on the sites (6 mentions). The technologies with the next highest mention were included enterprise systems such as (Microsoft suite, Aconex, etc.) which aid in collaboration and documentation and computer-aided design (CAD) tools (5 mentions).

Tradies emphasised that traditional hand tools and site tools remain fundamental, and that for some tasks there is still an expectation of physically handling materials. The carpenter (P27) described construction as "*very hands on*," saying "*you can feel the materials while you use it*…". For her, basic hand and power tools, lifting gear, and other site equipment are still core technologies, even as more advanced digital tools appear around them.

As seen from Figure 1, on-site professionals also relied heavily on enterprise systems to connect office and field work. A WHSE advisor (P11) described her role as "*software heavy*," explaining that while on site, she can "*bring my office with me to site on the iPad*," accessing project documentation while physically walking the project. Another engineer (P1) noted that several colleagues use OneNote or digital to-do lists, showing that email, corporate platforms, and digital note-taking tools are becoming routine parts of site-based work.

Finally, design and modelling software were consistently described as critical construction technologies for site-based roles. P1 stated that "*the modelling software is very useful*," and went on to say that having drawings and models "*consolidated in one*" environment "*definitely helps with the time factor*" when working under programme pressure. In another example she described a meeting where, instead of trying to explain a complex issue verbally, she "*brought up a model*" on the screen so that everyone could see the problem in 3D, which "*takes away a lot of tension and pressure*" and helps the group "*get straight to the solution.*" These technologies were corroborated by the focus group as well. This finding is consistent with research by Hasan et al., [7] who posits that mobile devices such as tablets and smartphones are now embedded in everyday site practice, which improves coordination, shortens information loops, and supports faster decision-making during site inspections and coordination meetings. Similarly, the continued importance of traditional hand tools and site equipment alongside these digital systems is also recognised in the literature. Construction studies note that, even under Construction 4.0, many trade tasks remain highly manual and rely on conventional tools, with digital technologies often augmenting rather than replacing hands-on work [8].

3.2 Challenges Site-Based Women Face

The interview findings revealed *gendered culture* was the most frequently mentioned theme and comprised *sub-codes such as gender bias, negative industry culture and relationships, and negative mindsets and attitudes*. Participants described having to continually prove their competence or manage sexist comments. As a site engineer stated: *"…when I was giving instructions on site about additional reinforcement or what I wanted to change it was questioned a little bit because I was younger and probably because I was a girl talking to 50-year-old men… sometimes [they] don't take you very seriously (P1)."* Capability challenges were the second major theme, with the skills and experience gap emerging as the largest sub-code. The third largest theme, progression and career mobility, centred on organisational culture as the largest sub-theme, with participants highlighting opaque promotion processes, a preference for "traditional" male career paths, and a lack of visible female role models in site leadership roles.

These findings are consistent with literature on women in construction, which identifies gendered industry culture as a primary challenge to women's participation and advancement in site-based roles. Galea et al. [8] demonstrate how informal "rules-in-use" and everyday practices normalise sexism and exclusion, reinforcing gendered bias and hostile or dismissive attitudes. Furthermore, recent work on gender diversity in construction notes that women are often denied substantive on-site tasks and mentoring, leading to fewer opportunities to build technical competence and site experience, which then reinforces perceptions that they "lack" capability [9].

3.3 Technology Impact on Site-based Roles

The highest impact of technology was seen in the efficiency and productivity of on-site tasks. Interviewees emphasised that digital tools and modelling software streamline core site tasks and decision-making. A site engineer noted that consolidating drawings and models "*definitely helps with the time factor*," allowing information to be "*all on the one thing*" instead of cross-referencing separate 2D drawings. Another interviewee reported that software tools "*helped me with my role and helped me be efficient… planning and doing sketches and getting things done," (P1)* and that learning advanced features *"really helps with our job and getting information that we need and processing information (P9)."* As echoed by P12, "*[Without the software] I'd be very slow... it would be a lot of paperwork".* Tools such as Bluebeam and similar platforms were described as *"really important… to be able to measure things at a glance"* and *"streamline things more efficiently (P11)"* when reviewing and checking information before issuing it to clients. A site-based carpenter (P27) explained that supervisors and engineers "*have iPads and they just show me what the building is going to look like,"* adding that seeing the model on the tablet "*puts all the pieces together*" and helps her plan ahead because she can visualise "*what's coming*" rather than relying only on what is half-built on site. The same participant referred to "*cameras*" and other site tools when discussing safety, indicating that digital hardware for monitoring and visual access is now embedded in everyday site practice, alongside tablets and phones as standard devices for drawings and coordination.

Interviewees also highlighted risks associated with over-reliance on construction technologies. One participant cautioned that *"a small thing that's done wrong or entered incorrectly… makes a big difference,"* noting *"a lot of room for human error… the more you digitalise things (P8)".* Others observed that younger

staff can *"rely too much on the technology,"*. P1 vividly captured the dependence on digital tools by stating that *"if I left my laptop/iPad at home, I would die,"* illustrating that over-reliance on these devices can create vulnerabilities when systems fail or are unavailable.

Results from the focus group discussion indicated a general agreement that digital tools, especially 3D modelling and design technologies, support increased participation by opening more non-manual roles where traditional physical challenges are less salient. A male participant (MSR3) noted "*a higher proportion of women on the design side*" and suggested that 3D modelling *"is definitely increasing the female participation"* because those jobs are not *"a manual sort of job."*

Several participants also stressed equal opportunity, arguing that technology "*enhances everyone*" and creates *"a pretty even playing field,"* rather than uniquely privileging women. Relatedly, some were wary that framing technology as something *"to make it easier for women*" could backfire and *"actually do the opposite,"* risking perceptions of special treatment and gender imbalance (MSR2, MSR3). Focus group members also highlighted loss of foundational skills as a risk, echoing interview concerns about overreliance on tools: AI and digital aids were seen as helpful but also could make workers *"a little bit lazy because we're not learning the… foundations of how to actually do something," (FSR3)* especially in trades.

They reinforced that technology cannot by itself fix gendered culture, with MSR2 stating they *"just don't see how"* technology can reduce that challenge, while another argued technology is more likely to shift work structure, well-being, and capability (via online upskilling tools) than culture directly.

3.4 Technologies Addressing the Identified Challenges

Across the interviews and focus group validation, participants identified several advantages that construction technologies offer. The following subsections present the findings organised around three competitive advantage themes emerging from the data: (1) overcoming physical challenges, (2) performance and credibility, and (3) flexibility and access. As summarised in Table 3, each theme directly maps to a key challenge identified by the site-based women in this study, and demonstrate how specific Construction 4.0 technologies create competitive advantages for women in site-based roles.

Table 3 Analytical links between site-based challenges, construction 4.0 technologies, and competitive advantages for women

Challenge	Construction 4.0 technologies	Competitive Advantage (Theme)
Physical demands & high-risk tasks on site	Robotics, drones, assisted lifting aids, prefabrication	**Physical burden reduction;** participation without conforming to hyper-masculine physical norms
Being talked over, competence questioned, credibility undermined	BIM/3D modelling, design software, digital collaboration tools	**Performance & Credibility;** visible, undeniable technical authority in meetings and on site
Always-on site presence, rigid work structures	Mobile devices, iPads, cloud platforms, enterprise systems (MS Teams, Aconex)	**Flexibility & Access;** marginal softening of always-on-site expectations, enabling hybrid work

3.4.1 Overcoming physical challenges

Interviewees and focus group participants highlighted how technologies such as robotics, drones and assisted lifting aids can reduce the need for physically demanding or high-risk tasks on site. For example, P24 described how using robots or drones for external quality checks on high-rise façades means women do not need to *"physically go up and down …*" which was seen as especially helpful for those "*scared of heights*." Focus group comments on assisted aids for handling ceiling sheets similarly emphasised that such equipment allows tasks previously requiring two strong workers to be done more safely thereby reducing the physical strength requirement.

P27 emphasised that construction remains *"very hands on,"* involving heavy lifting, yet acknowledged the value of technologies such as plant and lifting equipment that because they ease some of the physical load. Within the focus group, participants pointed to prefabrication, remote inspection tools, and smart machinery as measures that reduce climbing, manual handling, and exposure to high-risk environments, allowing women to perform core site tasks without conforming to an idea of hyper-masculinity. This is consistent with Construction 4.0 literature which argues that automation, robotics, and digital tools progressively separate productivity from brute strength and shift value toward supervision, and coordination [4,10]. Evidence from other sectors indicates that such shifts can open up new technical roles and reduce gender gaps where physical demands had

previously been used explicitly or implicitly to exclude women [4,10].

3.4.2 Performance and credibility

On-site engineers described digital tools as amplifying their technical performance and making their expertise more visible in high-pressure site environments.

P12 noted that Revit "*helps with understanding consultants' drawings and how they will work together in the physical space, as you can overlay the different layers and easily see where clashes occur",* enabling her to coordinate complex design information under programme pressure. Similarly, P6 explained that having a visual tool, such as a "*Bluebeam markup*", helped her "*communicate more clearly with subcontractors*." She noted that "*you are not only relying on your memory… you have an image… to assist you in communicating what you want"* (P6). This reduced the risk of being misunderstood or dismissed in a male-dominated site environment. Technologies that make expertise visible directly counter these assumptions. These accounts mitigate common challenges such as being talked over, having competence questioned, and struggling to have concerns taken seriously. These challenges are well documented in the women-in-construction literature [10]. Studies of BIM-enabled coordination similarly show that 3D and 4D models support shared understanding, reduce disputes, and shift authority toward those who can control and interpret digital information, thereby strengthening positions of women in project decision-making [11,12].

3.4.3 Flexibility and Access

Site-based women also framed technologies as offering an advantage in navigating rigid, site-centred work. A WHSE advisor (P11) described her role as "quite flexible", explaining that although she "*primarily need[s] to stay on site*," she can "*bring my office with me to site on the iPad*" by using the internal safety system in the field and occasionally working from home "*maybe one day a week*" when necessary (P11). An engineer noted that digital tools "*allow that flexibility… to still be engaged with your team through technology, but work from home,*" even though most responsibilities remain site-based (P6). These examples show how mobile devices, cloud-based documentation, and enterprise platforms marginally soften "*always on site*" expectations. This is corroborated by a plethora of literature that posits digitalisation can support hybrid work arrangements and more sustainable careers for women in construction. However, focus group participants were clear that "*technology alone does not change the nature of the work or the industry" (MSR3)* they emphasise that flexibility is highly dependent on the organisation's willingness to accommodate flexible work patterns.

Other advantages identified by interviewees include skill development, and communication and collaboration which were not validated by the focus group.

3.5 Gender Neutrality of Technologies in Construction

Both interviews and focus groups, however, revealed discomfort with presenting technology as something women uniquely "*need*." FSR1 from the focus group argued that while tools like BIM and project software are crucial, "*it's just a tool*" they "*don't help women any more than… a male"*. She also argues that competitive advantage comes from combining underlying skill with digital knowledge. A focus group participant (MSR1) similarly cautioned that suggesting technology is introduced "*to make it easier for women to do a job in construction"* could be "*misconstrued*" and "*actually do the opposite*" by implying women are less capable. These concerns align with Galea's critique that "*fixing women*" via special initiatives can inadvertently reinforce male advantage and leave underlying structures unchallenged [8].

The findings suggest that construction technologies are formally gender-neutral, but they operate within gendered institutions where men already benefit from norms around physicality, long hours, informal networks, and unexamined authority. In that context, women's strategic use of technologies creates specific, competitive advantages that help them navigate and partially resist those norms.

4 CONCLUSION

This study has revealed that Construction 4.0 technologies offer women in on-site roles concrete, advantages in navigating a workplace historically structured around male norms of physical strength, constant site presence, and informal authority. Across interviews and focus groups, women and men in the industry described how digital tools improved their performance, reduced physical limitations and opened up limited flexibility, in male-dominated site environments. These benefits did not arise from technology alone, but from how women strategically mobilised technologies to overcome challenges such as being talked over in meetings, having their competence questioned, and being constrained by constant site presence.

Literature has argued that digitalisation is reshaping job roles by shifting value toward information handling, coordination, and problem-solving, thereby creating conditions under which women can participate and progress on more equal terms. Wider evidence from research in Australia similarly suggests that digital tools,

automation, and remote-capable platforms can reduce physical demands, enable new hybrid site–office roles, and support more flexible work models that are critical for women's retention [2,10]. At the same time, both this study and the literature caution against assuming that "gender-neutral" technologies will, by themselves, close gender gaps. Without deliberate attention to the deeply embedded rules-in-use that normalise male advantage, there is a risk that digital competencies and high-status technical roles will simply be captured by those already privileged in the system [8].

As part of broader research seeking to empower women across on-site, off-site, and fluid roles through Construction 4.0 technologies, this paper contributes role-specific, empirical insight into how women on-site women actually use technologies to carve out micro-advantages in performance, safety, flexibility, and credibility.

The findings of this study suggests that Construction 4.0 offers a critical, but not self-sufficient, platform for change. Technologies can help dismantle some of the gendered challenges, yet their potential depends on being embedded within intentional strategies to challenge masculine industry norms and redesign job roles. The findings point to a future where construction technologies are not merely tools for efficiency, but central components of an integrated framework to make on-site construction work a viable, attractive, and sustainable career path for women.

Future research should examine the barriers to Construction 4.0 adoption at the organisational and industry level, including cost, digital literacy, and resistance to change. Addressing these barriers is critical to ensuring that the competitive advantages identified in this study are accessible to all women in site-based roles, not only those in well-resourced organisations.

4.1 Practical Implications

Construction 4.0 has often been discussed in terms of broad industry change, but the women in this study mainly experienced it through everyday tools such as laptops, tablets, enterprise systems, and CAD/BIM software. These tools helped them do their work more efficiently, reduce some physical and safety risks, giving them clear advantages in on-site roles. However, the study also shows that technology on its own is not enough to improve gender equality. Simply put, the same tools are introduced into workplaces where long hours, strong site presence, and male-dominated decision-making are still the norm.

This has several practical implications. First, companies should not only provide access to digital tools but also offer targeted training so that women in site roles can move into higher-responsibilities or roles. Second, when organisations roll out new digital systems, they should consider how these changes affect women's workloads, flexibility, and progression, rather than assuming that "technology helps everyone in the same way." Third, clients and policymakers can link digitalisation and gender goals by encouraging or requiring projects to create visible Construction 4.0 pathways for women in on-site roles, for example through social procurement or gender targets.

As part of a broader study on empowering women in on-site, off-site, and fluid roles, these findings suggest that Construction 4.0 is a useful platform for change, but only when combined with deliberate efforts to redesign roles, support skills development, and challenge existing site cultures.

Abstract

Building Information Modelling (BIM) has emerged as a transformative digital technology that can improve productivity, reduce errors, and enhance collaboration across construction projects worldwide. Despite its well-recognised benefits, the Architecture, Engineering, and Construction (AEC) industry in Iran continues to encounter substantial challenges in BIM adoption. Research exploring effective solutions tailored to the Iranian context remains limited, creating a gap that this study aims to address. The purpose of this research is to develop appropriate strategies to overcome barriers to BIM implementation within Iran's AEC sector. A comprehensive literature review was conducted to examine barriers and existing strategies at global, regional, and local levels. In addition, semi-structured interviews with Iranian industry experts were carried out to capture practical insights specific to Iran's construction industry. The results indicate that although BIM awareness is gradually increasing, its implementation is hindered by inadequate government support, limited professional knowledge and training, and a significant disconnect between academia and industry practice. Based on these findings, this research emphasizes the need for government-led initiatives, including creating a robust legal and technical framework to mandate BIM, implementing incentive-based measures, and integrating BIM-focused curricula into universities. This study contributes original insights and practical recommendations to accelerate BIM adoption in Iran, supporting broader digital transformation in the construction sector.

Keywords

Building Information Modelling (BIM); AEC industry; Iran; BIM Barriers; Adoption Strategies

1 Introduction

The construction industry has historically struggled with low productivity, inefficient planning, and limited collaboration, with traditional methods in the Architecture, Engineering, and Construction (AEC) sector identified as primary contributors to these challenges [1]. Building Information Modelling (BIM) has emerged over the past decade as a transformative digital technology designed to enhance productivity and improve construction performance [2].

BIM represents a fundamental shift from traditional 2D drawings to comprehensive digital representations of buildings' physical and functional characteristics [3]. As a digital model that organizes and visualizes building information throughout a project's lifecycle [4], BIM encompasses data about building components, structures, materials, and lifecycle processes. This technology enables digital management of design information, facilitating more integrated and data-driven project implementation approaches. Research demonstrates that BIM adoption enhances construction productivity, reduces errors and rework, and improves overall project delivery through better coordination, information sharing, and collaborative decision-making [5]. BIM's digital information management capabilities have significantly transformed traditional construction practices [6].

Globally, many countries have embraced BIM and developed adoption strategies for the AEC sector [7]. The United Kingdom experienced dramatic growth in BIM adoption, rising from 13% in 2011 to 74% in 2018, with similar trends observed across developed regions, including the United States, Europe, and Australia [8]. However, BIM adoption remains low in developing countries, including North Africa and the Middle East, where, despite high awareness in Gulf Cooperation Council (GCC) countries, adoption rates remain insufficient [9].

Several barriers hinder widespread BIM acceptance [10], including a lack of motivation, resistance to change, insufficient knowledge, inadequate technology tools, interoperability issues, and undefined processes and standards [11]. In Iran specifically, the AEC industry faces significant adoption challenges, with only 29.5% of construction companies utilizing BIM tools, while 56.8%

have never encountered BIM and 36.4% lack adoption plans [12]. This research aims to explore obstacles hindering BIM usage in Iran's AEC sector and develop strategies based on expert opinions and literature review to address these barriers.

2 Literature Review

2.1 Barriers to BIM Implementation Worldwide

The global adoption of Building Information Modelling (BIM) remains constrained by a complex set of interrelated barriers despite its well-established potential to enhance project integration, productivity, and decision-making [10]. Existing literature emphasizes that BIM implementation is not merely a technological shift but a systemic transformation requiring alignment across organizational structures, workflows, and stakeholder practices [13]. The literature identifies three dominant categories of challenges. First, technical barriers such as system complexity, interoperability issues, and inadequate data standards [17]. Second, organisational and cultural barriers including resistance to change, and shortages of skilled professionals significantly reduce industry readiness [18]. Third, Legal and institutional barriers further complicate BIM adoption. The absence of regulatory frameworks, and unresolved contractual issues related to liability and intellectual property create uncertainty [19]. However, the relative importance of these barriers varies across regions, particularly between developed and developing contexts [20].

2.2 Barriers to BIM Implementation in the Middle East

In the Middle East, BIM implementation remains at an early stage, where adoption is still limited despite increasing awareness [18]. Unlike developed countries, where technical and legal issues such as data security and interoperability are more prominent, the barriers in the Middle East are primarily driven by organizational and human factors, particularly limited awareness, lack of expertise, and insufficient training [20].

In addition, from a technical perspective, challenges such as interoperability issues, inadequate IT infrastructure, and limited access to advanced BIM tools hinder effective implementation [21]. Financial constraints also play a major role, as high initial investment costs and the absence of clear economic incentives discourage organizations from adopting BIM [18]. Furthermore, weak regulatory frameworks, lack of BIM standards, and limited government support create uncertainty and slow down implementation [22]. Overall, BIM barriers in the Middle East are strongly context-dependent, reflecting broader challenges related to human capital, institutional capacity, and economic conditions, which differ significantly from those observed in developed countries [18]. This highlights the importance of examining BIM adoption barriers within specific national contexts such as Iran.

2.3 Barriers to BIM Implementation in Iran

BIM adoption in Iran remains limited despite its potential to enhance productivity and performance in the construction sector, which plays a significant role in the national economy [12], [9]. Existing studies indicate that BIM implementation is still at an early stage, with low awareness and limited practical experience among industry stakeholders [23]. The literature identifies several key barriers, primarily lack of government support, insufficient regulatory frameworks, and weak organizational readiness. In addition, limited BIM knowledge, shortage of skilled professionals, and resistance to change significantly hinder adoption [24]. Financial constraints and unclear return on investment further reduce motivation for implementation [25]. Overall, BIM barriers in Iran reflect a combination of institutional, organizational, and knowledge-related challenges that require targeted, context-specific strategies.

2.4 Overview of Existing Strategies

The implementation of Building Information Modelling (BIM) requires a structured, strategic approach [27]. Research has identified that effective BIM implementation strategies must include changing organizational approaches, providing appropriate incentives, establishing industry partnerships, integrating BIM into existing processes, and promoting collaboration across the AEC sector [28]. Specific strategies that support successful BIM implementation include investing in BIM-related training programs, supporting adoption through adequate financial and technical resources, ensuring appropriate project budgets for BIM integration, developing technical capabilities required for BIM tools and workflows, cultivating organizational commitment to BIM, promoting collaborative work environments, and establishing robust BIM infrastructure and standards [29].

Governments have been identified as the main beneficiaries and key players in BIM implementation, becoming increasingly active in promoting adoption through various policies and initiatives that can be broadly classified into three approaches: government-driven, industry-driven, and mixed approaches combining both governmental and industry initiatives [30]. Government-led strategies have proven particularly effective in accelerating BIM adoption across multiple

countries, with successful implementation measures including establishment of national BIM programs, mandatory BIM requirements, development of BIM standards and protocols, integration of BIM in procurement and tendering processes, awareness and adoption initiatives, development of BIM infrastructure, and the creation of industry-wide BIM classification standards [10].

Research suggests that developing countries need comprehensive BIM implementation models based on theoretical frameworks derived from implementation process theory, incorporating four key strategic elements: top management commitment strategies emphasizing organizational restructuring and cultural change; motivational strategies including regulatory mandates and BIM guidelines development; capacity development strategies focusing on building skills, knowledge, and competencies through education and training programs; and collaborative network relationships creating essential environments for change [18]. BIM implementation in Iran requires a comprehensive approach due to multiple barriers across resource, financial, organisational, regulatory, and market-related dimensions [9]. Efforts toward digitalisation have been initiated by government-related institutions through training programmes, conferences, and the establishment of BIM-focused organisations [26]. These actions reflect increasing recognition of BIM importance within the industry. However, the lack of locally adapted regulations and reliance on international frameworks limit effective implementation [31]. Overall, the need for context-specific strategies tailored to Iran's conditions is highlighted, as limited research has addressed practical solutions to overcome BIM adoption barriers in the Iranian construction sector.

3 Research Methodology

This study adopts a qualitative research design using a two-phase approach to investigate BIM adoption barriers and develop context-specific strategies for the Iranian AEC industry. In the first phase, a structured literature review was conducted to identify key barriers and strategies across global, regional, and Iranian contexts. Relevant studies were collected from academic databases such as Scopus, Web of Science, and Google Scholar using keywords including "BIM adoption barriers" and "BIM implementation strategies." The selected studies were analyzed and grouped into key themes such as technical, organizational, financial, and regulatory factors. The findings from this phase were used to inform the design of the interview questions. Phase Two employed semi-structured interviews with Iranian AEC experts from design firms, contracting organizations, and government bodies, selected purposively for their direct BIM experience (Table 1). This format was chosen for its flexibility to probe unanticipated issues and its capacity to elicit in-depth contextual insights unavailable in the existing literature [32]. While the study is based on three expert interviews, a limitation that restricts generalizability, the focus was on conceptual depth rather than statistical representativeness, with thematic convergence across participants used to assess data sufficiency. Larger-scale validation studies are recommended for future research.

The interview guide, developed from previous studies Marzouk et al. [30], Alreshidi et al. [33], focused on six main themes: existing BIM regulations, government goals and measures, key implementation barriers, facilitators or champions of BIM adoption, recommended strategies, and potential incentives. Initially, eight member companies of the Iranian BIM Association were contacted via email; after no response, participants were approached through WhatsApp and iMessage. Three experts, two managers, and one consultant agreed to participate, representing an acceptable qualitative sample size [34]. Each interview, lasting approximately 40 minutes, was conducted via Google Meet and recorded for analysis.

Table 1. List of interviewees

No	Stakeholder ID	Position	Work Experience	Organisation Type	Area of Expertise
1	Respondent 1	BIM consultant	10 years	Semi-public (Iran BIM Association)	BIM policy development
2	Respondent 2	Director	20 years	Private	Construction management
3	Respondent 3	Manager	12 years	Semi-public (Iran BIM Association)	Training programmes and BIM standard development

3.1 Data Analysis

Interview data were analyses using NVivo software through systematic content analysis. Each participant's responses were coded into themes and subthemes aligned with the study objectives. Following Gray's [30] interpretive approach, the analysis focused on understanding underlying meanings in relation to existing theories rather than simple description. The coding framework identified two main areas: barriers to BIM implementation and recommended strategies for promoting BIM adoption in Iran. Key coded evidence (Table 2) highlighted critical issues such as a lack of government support, the gap between university and industry, and practical strategies, including government incentive schemes and infrastructure development.

Table 2. Summary of Coding in NVivo

Theme	Key Subtheme / Node	Respondent ID	Example of Coded Extract
BIM Implementation Barriers	Lack of government support	Respondent 2	"The main obstacle is the lack of support from government organizations for the implementation of BIM."
BIM Implementation Barriers	The gap between university and industry	Respondent 1	"The lack of university-led applied research to address effective BIM implementation."
Recommended Strategies	Government incentive strategies	Respondent 1	"Reduction of municipal fees in issuing construction approval and permitting."
Recommended Strategies	Infrastructure development	Respondent 1	"Designing and creating urban planning electronic systems with the ability to utilize BIM software infrastructure."

Note: Extracts derived from NVivo qualitative content analysis of expert interviews

4 Results and Discussion

Through NVivo analysis, ten distinct barriers to BIM adoption were identified: (1) lack of government support, (2) lack of awareness among consultants and contractors, (3) limited software infrastructure, (4) the gap between universities and industry, (5) lack of standard frameworks, (6) high implementation costs, (7) resistance from government design and contracting organizations, (8) limited training opportunities, (9) lack of coordination among government bodies, and (10) insufficient communication between academia and industry. Among these, the most critical were the lack of government support, the lack of stakeholder knowledge, and the persistent university–industry gap as shown in Figure 1.

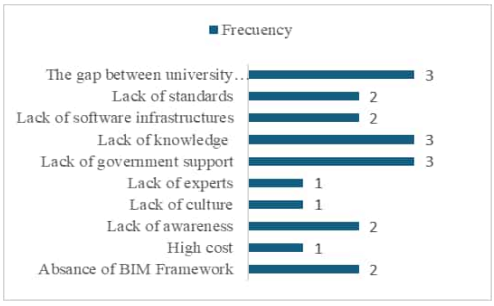

Figure 1. Barriers to BIM adoption

The findings from the semi-structured interviews strongly align with this regional pattern. First, inadequate government support and weak regulatory frameworks emerged as the most critical constraints in the interviews, aligning with previous studies that emphasize the absence of clear BIM standards, mandates, and contractual arrangements in Iran [12], [23]. Second, limited stakeholder knowledge and capacity were widely reported by interviewees, which mirrors global evidence that lack of skills, insufficient training, and resistance to change undermine BIM readiness [11], [14], [17], [27]. Third, the persistent gap between academia and industry, highlighted by respondents and coded as a major barrier in Table 2, echoes findings from both Iranian and international research [9], [18], [12], [23]. Universities in Iran were perceived as insufficiently engaged in applied BIM research and in preparing graduates with practical, implementation-ready skills.

Alongside these core issues, interviewees mentioned high initial costs, fragmented responsibilities among government bodies, limited software infrastructure, and weak inter-organizational coordination. These factors also appear in international and regional studies [10], [14], [18], suggesting that Iran faces many of the same technical and financial challenges documented elsewhere, but under conditions of greater institutional fragility. While the interviews broadly corroborate the literature, they also extend it by providing context-specific nuances

for Iran. International and regional studies frequently stress the role of government as a facilitator of BIM through standards, guidelines, and public-sector procurement [30],[35]. However, the Iranian experts went further, identifying the central government, notably the Office of the Vice President for Technology, as the essential initiator of BIM, with a unique capacity to issue binding executive orders. This emphasis on highly centralized, top-down authority reflects the governance structure of Iran and suggests that models of industry-led diffusion, more common in some Western contexts, are less applicable.

The interviews also revealed a mismatch between policy signals and practical enforcement. For instance, participants referred to Tehran Municipality's 10% discount on construction permits for BIM-based projects and to resolutions that reference BIM in national technical systems. These measures indicate emerging recognition of BIM's importance, yet respondents agreed that they have not translated into systematic adoption, partly due to the absence of a comprehensive national BIM roadmap and partly due to uneven technological maturity across regulatory bodies. This provides an important nuance to the literature on public-sector roles [35]: partial or isolated initiatives, without a robust implementation framework, may have limited impact. Furthermore, whereas global studies often emphasize interoperability issues, and advanced standards [19], [21], the interviews suggest that, in Iran, more basic prerequisites, reliable software access, shared modelling protocols, and digital permitting systems, are still not fully in place. The recommendation to develop "urban planning electronic systems with the ability to utilize BIM software infrastructure" (Table 2) highlights that foundational e-government infrastructure is itself a precondition for BIM, a point less prominent in studies of more digitally mature environments.

Several strategic frameworks for BIM implementation can be found in literature, particularly in developing countries. Olugboyega [27] and Ma et al. [10] emphasize four interrelated elements: (1) top management commitment and organisational change; (2) motivational and regulatory strategies, including mandates and guidelines; (3) capacity development through education and training; and (4) collaborative networks and industry partnerships. The interview findings align closely with this structure and provide concrete, context-specific operationalization terms of top-down leadership and regulation. NVivo node summary for recommended strategies can be found in Figure 2.

All interviewees stressed the need for high-level government directives mandating BIM for selected project types and progressively expanding its scope. This mirrors successful international experiences where mandatory BIM requirements, national BIM programs, and integration into public procurement have accelerated adoption [30], [35], [36]. In the Iranian context, such mandates were seen as necessary to move from pilot initiatives to mainstream practice, while also forcing government agencies themselves to upgrade their digital capabilities.

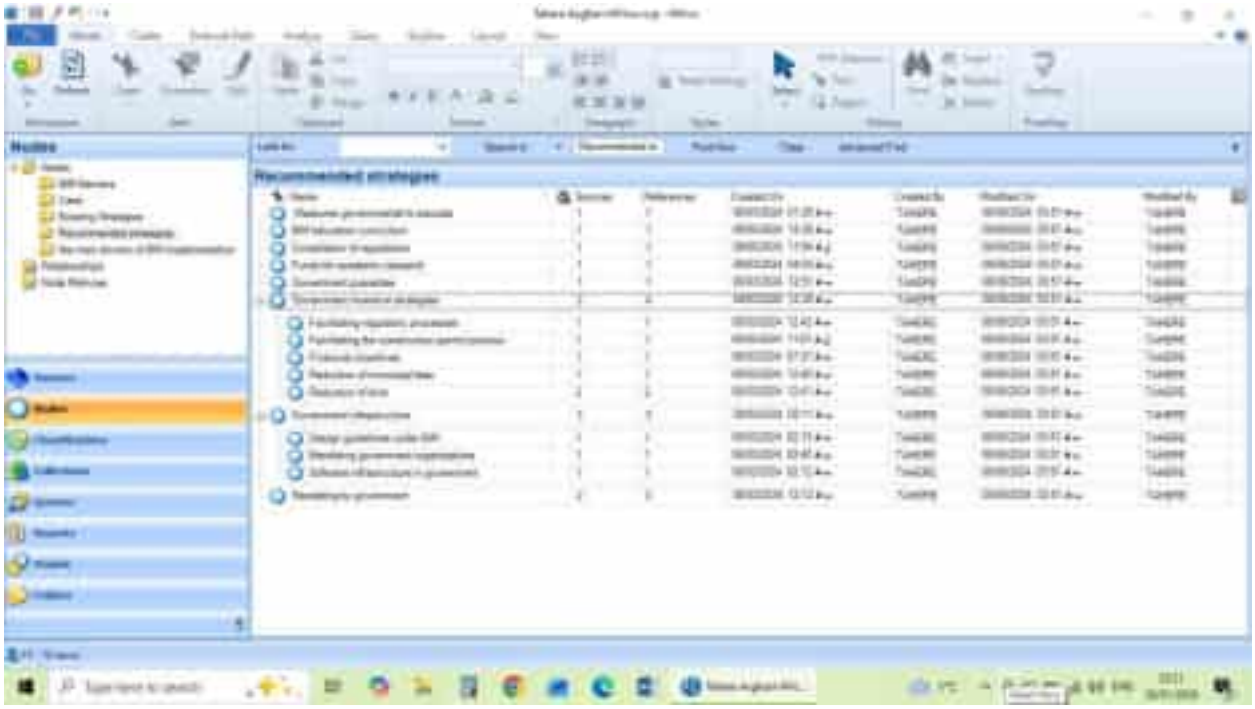

Figure 2. NVivo node summary for recommended strategies

Motivational and incentive-based strategies were the second major cluster of recommendations. Participants proposed streamlined approval processes, reductions in municipal fees, and financial incentives such as discounts on construction and parking permits. These suggestions are consistent with literature that recognizes incentives as effective complements to mandates in mixed policy approaches [35], [36], [38]. The interviews therefore support the view that a combination of regulatory compulsion and economic benefits is likely to be more effective than either approach alone, particularly for resource-constrained firms. Capacity development and education formed the third strategic pillar. Experts called for integrating BIM into university curricula, funding applied research, and expanding professional training opportunities. This directly addresses the university–industry gap identified in both phases of the study and resonates with international evidence that education and continuous professional development are critical success factors for BIM [9], [28], [39]. By explicitly linking curriculum reform and research funding to national BIM objectives, the interviewees extend existing recommendations and emphasize the need for coordinated, state-supported capacity-building.

Taken together, the literature review and interview results indicate that accelerating BIM adoption in Iran requires a dual strategy: strong, centralized government leadership to create a coherent regulatory and technical framework, and sustained investment in human and organizational capacity across the AEC sector. The interviews confirm many barriers previously identified in the literature but also reveal that, in Iran, the absence of an enforceable national BIM framework magnifies other challenges, such as cost, skills, and resistance to change. The proposed strategy therefore comprises three interdependent components: (1) government-led actions, including national BIM standards, clear mandates, and digital infrastructure for BIM-based permitting and procurement; (2) incentive-based policies that reduce financial and administrative burdens on early adopters; and (3) educational and collaborative initiatives to bridge the university–industry gap and develop a skilled BIM workforce.

In addition, continuous professional development and training initiatives for current industry professionals are essential to ensure effective BIM implementation [40]. This emphasis on education and training aligns with global best practices and reinforces the importance of sustained government support for successful BIM adoption. Figure 3 illustrates a visual summary of the recommended strategies for BIM adoption in Iran.

5 Summary and Conclusions

This study examined the barriers to implementing Building Information Modelling (BIM) in Iran's Architecture, Engineering, and Construction (AEC) industry using a comprehensive literature review and semi-structured interviews with experts. Three main barriers were identified: inadequate government support, limited stakeholder knowledge, and a persistent gap between academia and industry. The findings highlight the need for a dual approach combining strong government leadership with targeted capacity-building efforts. To promote BIM adoption, the study proposes three strategic areas: (1) Government-led actions, including legal frameworks and national BIM standards; (2) Incentive-based policies, such as financial benefits and simplified approval processes; and (3) Educational initiatives, emphasizing BIM-focused curricula and collaboration between universities and industry.

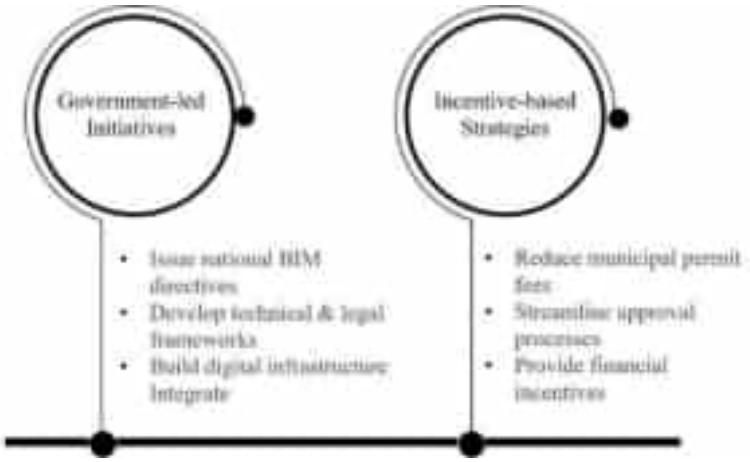

Figure 3. Summary of recommended strategies

Although the study's scope was limited to Iran and based on a small sample, it provides valuable insights into local challenges and offers a foundation for broader, future research incorporating larger datasets and quantitative analysis. However, one of the limitations of this study is its focus on the Iranian context, which may not fully represent BIM implementation challenges in other regions. The small sample size also limits the generalizability of findings, as the study mainly captured perspectives of industry experts without including clients, policymakers, or academics. Additionally, the research relied primarily on qualitative data, suggesting the need for future studies to incorporate quantitative methods. Expanding the scope to include a larger and more diverse group of stakeholders across different regions of Iran would provide a broader and more comprehensive understanding of BIM adoption and its practical implications.

Abstract –

Steel construction currently lacks systematic and validated frameworks that can be used to evaluate innovative systems against established alternatives before field deployment. This contributes to delayed adoption even where there are demonstrated performance advantages. This study presents the development of a conceptual decision-support framework for assessing steel connection systems. It compares an innovative intermeshed steel connection (ISC) with the existing bolted steel connection. The proposed framework integrates building information modeling (BIM) for constructability analysis, computer-vision-based ergonomic assessment for pose estimation, simulation-based performance evaluation, and multi-criteria decision analysis using Technique for Order of Preference by Similarity to Ideal Solution (TOPSIS). Using a simulated assembly scenario, the framework systematically evaluates connection systems across the parameters of worker safety (ergonomic risk), assembly efficiency, and construction cost. The framework development process demonstrates how simulated data informs framework parameters using criterion weights from surveys, performance metrics measured from simulation protocols, and decision thresholds. The simulated results indicate that the ISC system reduces ergonomic risks by up to 40% as measured by the Rapid Entire Body Assessment (REBA) mean scores of 4.57 for bolted connection and 2.57 for ISC. The assembly duration of ISC also decreased by approximately 29% and achieved cost savings of up to 10% across geographic locations. This study provides a replicable conceptual methodology for developing decision-support systems for a systematic evaluation of innovative systems. By applying simulated findings to validated decision-support systems, it illustrates how digital technologies such as BIM and computer vision can improve objective technology assessment in construction. The proposed framework offers a basis for future empirical data-based validation studies to guide decision making in steel connection systems adoption.

BIM, Computer vision, Construction, Decision support framework, Simulation, Steel connection, TOPSIS

1 Introduction

The construction industry faces persistent reluctance in adopting innovative technologies even where there is potential to improve safety, efficiency, and cost effectiveness [1]. Construction practitioners often require systematic frameworks to evaluate emerging construction methods and materials against established practices [2]. This oftentimes leads to conservative decision-making and slow technology diffusion [3]. For structural steel construction, where connection technologies have been evolving over time from riveting to welding and high-strength bolting, each transition still required decades of industry acceptance despite empirical performance advantages available at the time [4, 5]. The unavailability of structured decision-support systems integrating multiple performance dimensions, safety, efficiency, and economics, creates a major challenge for innovation adoption in a risk-prone

industry such as the steel construction industry.

Decision-making in construction technology adoption is more complex, sometimes requiring a concession among the competing performance objectives. These objectives may include cost, quality, productivity, worker safety, and sustainability [6]. Traditionally, evaluation methods would focus on a single criterion, mostly cost, and avoid a comprehensive performance assessment. This overlooks the interconnectedness of construction performance metrics, where a change in one dimension can result in cascading benefits in the others [7]. A connection system that can reduce ergonomic strain on workers may also reduce assembly time, reduce injury-related costs on projects, and improve work quality and worker efficiency due to reduced fatigue. Yet these quantitative synergies are vastly unquantified in the traditional decision processes [8,9]. Multi-criteria-decision-making (MCDM) methods such as Analytical Hierarchy Process (AHP) and Technique for Order Preference by Similarity to Ideal Solution (TOPSIS) have been used as tools to address this complexity. Although interest in MCDM frameworks for innovative construction technology assessments is growing, gaps exist in the literature on conceptual frameworks that systematically integrate digital construction technologies with multi-criteria decision analysis [10]. Most existing studies focus on theoretical MCDM applications while evading data collection limitations in evaluating new innovative technologies [11]. Some studies present case-specific analyses that lack generalizability across various construction contexts, such as steel construction [12, 13]. Conceptual frameworks offer the distinctive advantage of enabling systematic identification of relevant evaluation criteria, establishing relationships between performances, providing a foundation for future empirical validation, and steering the development of measurement protocols ahead of committing major resources to the experimental validation [10].

Integrating digital construction technologies introduces unprecedented opportunities for conceptual framework development. This can be improved by objective, automated performance assessment capabilities. Building information modeling (BIM) is now more than design coordination; it details project constructability analysis, clash detection, 4D scheduling, and assembly sequence optimization [14, 15]. Computer-vision technologies for pose estimation provide a system for objectively assessing worker safety and ergonomics through biomechanical posture analysis. [16, 17]. BIM-based construction sequencing allows for a time-motion analysis used for estimating task duration and productivity rates for comparative assessment [18]. The integration of these tools, alongside expert validation, creates an opportunity to develop a decision framework that bridges theoretical MCDM principles with the practicality of the construction industry.

Steel connection technology is critical to structural integrity, schedule performance, and worker hazard exposure, making it an ideal domain for developing a conceptual decision-support framework. Up to 40% of steel erection labor hours are spent on connection works, ranking the task as high-risk, exposing workers to hazardous risks such as fall from heights and struck-by hazards [6]. An intermeshed steel connection (ISC) is an innovative alternative to bolted steel connections and provides a perfect example for the performance criteria evaluation challenges facing the steel construction industry [19]. ISC uses the interlocking theory to secure steel elements using simple fastening mechanisms that significantly minimize the need for bolts. It potentially reduces assembly duration, minimizing ergonomic hazard exposure, repetitive overhead, and bolt installation work, and decreases material and labor costs [19]. An absence of a standardized evaluation framework, limited performance data, and a level of unfamiliarity among construction professionals pose a challenge, limiting contractors, structural engineers, and project owners in assessing whether the ISC technology is safe for adoption on their specific projects. This uncertainty is aggravated by the interconnectedness of the connection system performance criteria [20].

This study addresses this gap by presenting a comprehensive conceptual decision-support framework for evaluating steel connection systems using ISC and traditional bolted connections on a comparative basis. The conceptual framework will integrate (1) BIM-based constructability analysis, (2) computer-vision-based ergonomic assessment, (3) simulation-based performance evaluation for performance criteria, and (4) TOPSIS-based multi-criteria decision analysis. This study develops a repeatable conceptual methodology for structured decision-support frameworks for both simulation-based estimates and future empirical data. It illustrates the theoretical integration of computer-vision-based ergonomic assessment and BIM constructability, thereby advancing digital tools application beyond design coordination to advance construction method selection. The study also presents an expert validation approach centered on practical applicability, criterion relevance, and implementation of feasibility through professional feedback.

2 Literature Review

2.1 Construction technology adoption and innovation diffusion

The construction sector has a conservative approach to technology adoption. This stems from the industry being driven by project-based production systems,

fragmented supply chains, low profit margins that discourage innovative experimentation, regulatory constraints, and liability from unproven methods [21, 22]. Client demand for innovation, a short-term returns focus, and insufficient collaboration between research institutions and construction practitioners further widen the innovation gap [23, 24]. The study of [25] posited diffusion of innovation theory as a foundational framework for technology adoption patterns. Mitropoulos [26] noted that new technologies must prove compatibility with existing work processes, need minimal learning curves, and provide evidence of advantages with pilot implementations. Where proof of field-tested employment cannot be avoided, it becomes inherently difficult to demonstrate the potential benefits that will justify adoption [27].

Steel connection technology evolution is an example of long adoption curves from riveting to welding and high-strength bolted steel connections. This was despite the clear advantages in connection strength and speed presented at each of these stages [19]. This confirms that the industry requires technical validation and a comprehensive decision-support tool that enables professionals and practitioners to evaluate innovations within their specific context [25, 21]. Intermeshed steel connections are currently facing these same adoption challenges, as they lack an extensive field of performance data and structured evaluation frameworks to provide informed decision-making.

2.2 Multi-criteria decision making in construction management

MCDM enables systematic multi-dimensional evaluation that accommodates diverse stakeholder preferences [10]. It applies across diverse situations, including contractor selection [20], construction method selection [27], sustainable building design [28], safety management strategy evaluation [1], and equipment selection decisions [12]. TOPSIS, an MCDM technique, is particularly suitable for construction applications due to its computational simplicity, large criterion handling, and intuitive logic [29]. The study of [30] successfully applied TOPSIS for green building project delivery methods, [31] utilized TOPSIS for subcontractor selection model, [32] applied TOPSIS for construction optimization decision scheme of urban subway tunnels. However, MCDM applications majorly rely on historical project data, and where innovative technology lacks such data, researchers must rely on expert judgement or develop alternative data generation approaches [1, 24]. These data limitations become even more acute where innovations are evaluated against established alternatives [13]. Recent research in MCDM has proposed framework validation as a means of establishing confidence in decision-support outputs [33].

2.3 Digital technologies in construction assessment

BIM-based constructability analysis evaluates assembly feasibility, detects spatial conflicts, and stimulates installation sequences, providing a significant influence on safety and productivity planning for steel connections [14, 15]. Computer vision pose estimation eliminates subjectivity in ergonomic data collection and enables continuous dynamic monitoring [10]. Its application has been extended to productivity measurement through activity recognition [18] and to simulated ergonomic assessment via virtual reality environments [34]. Despite these advances, systematic integration of computer vision ergonomic assessment into multi-criteria decision-support frameworks for technology evaluation remains unexplored.

Simulation-based research enables controlled investigations of construction processes without full-scale resource requirements, safety, economic concerns, and hidden variables in field experimentation [10, 35]. The extent to which simulation output correctly represents real-world scenarios requires careful consideration of model assumptions, input parameter estimates, and the need for validation against empirical data as soon as it is available [36]. For steel connections, construction process simulation for connection systems remains underdeveloped, with limited research examining the assembly sequences, worker movements, or comparative productivity analysis. Integrating a BIM-based spatial simulation with computer-vision-based ergonomic assessment for connection technology evaluation represents a novel approach to be documented.

Conceptual framework validation organizes challenging dynamics, identifying relationships between variables, and provides step-by-step guides for future empirical designs. The approach varies based on the intent and development stage. Expert panels assess the framework for comprehensiveness, clarity, intended use, and application feasibility [27]. Limited literature guides the development of conceptual decision-making frameworks, especially for incorporating simulation outputs and conducting expert validation in early research stages. This study adopts a simulation-based framework to illustrate how performance data would inform decision processes while awaiting actual empirical data confirmation to address this gap.

3 Framework Development Methodology

This section presents an overview of the process for developing the conceptual decision-support framework. The process follows 4 sequential phases, with each one building on the output of the prior phase. Phase one builds the evaluation criteria by identifying factors that

matter when choosing between steel connection technologies. The factors were identified through a qualitative literature review from academic database searches (Web of Science, Engineering Village, Scopus). Three major performance dimensions of worker safety, assembly efficiency, and construction cost were identified, with a further split into 12 sub-criteria for expert review and feedback. These criteria were confirmed through prior ISC studies [19, 37], which established that up to 40% of steel erection labor hours are devoted to connection work, making ergonomic risks, assembly duration, and cost the most consequential performance dimensions for comparative technology evaluation.

Phase 2 designed the simulation process protocol. The model components (beams, columns, and connection details) were defined (14 ft × 14 ft × 20 ft steel frame comprising four W14×90 columns, four W18×50 beams, and eight connections, modeled in Autodesk Revit and exported to Navisworks for 4D simulation), tools, and equipment set-up positioning. Simulation assembly steps were defined from a work breakdown structure (WBS), and durations for task performance were recorded for analysis. A visualization software, Navisworks, analyzed the 4D timeline, clash detection, worker viewpoints, and time tracking. Next, a computer-vision-based algorithm measured how physically demanding each connection type is for workers. This was achieved through a REBA scoring system that identified worker postures during various stages of steel connections (Openpose algorithm helped to analyze and extract body key points and joint angles), risk levels, and guided required resolution actions. Cost analysis informed by historical cost data of RS Means identified each steel member by line-item description and broke down the assembly costs into material, labor, equipment, and life-cycle costs. A sensitivity analysis across various geographical locations also measured the cost impact expectations.

Phase 3 executed the simulation and data collection process in 3 scenarios: typical assembly process, constrained site conditions, and a detailed production phase. The typical assembly process relied on the ISC dataset from the study of [19] compared against the bolted connection dataset from site recordings. Results were aggregated into a performance data matrix. Weights for each performance criterion and sub-categories were also calculated for a final TOPSIS analysis. A point allocation expert survey was distributed to 8 steel construction professionals, spanning safety managers, general contractors, structural engineers, steel erectors, and project owners. Performance dimensions to be weighed were worker safety, assembly efficiency, and construction costs. Sub-criterion weights within worker safety placed the highest importance on ergonomic risk and fall protection requirements. For assembly efficiency, installation time, and labor requirements were noted as most important, while for construction costs, labor and material costs were both weighted as the highest consideration factors.

Phase 4 is the TOPSIS analysis stage; the two connection technologies are compared mathematically (vector normalization), and the best choice is closest to the ideal solution as much as possible and farthest from the worst solution. This is summarized as presented in Figure 1 above. The TOPSIS model measures the weightings from expert feedback on performance dimensions and sub-criterion factors, and plots against standard ideal ranges of performance. The technology with consistent weighting, closest to the ideal, is selected as a preferred technology.

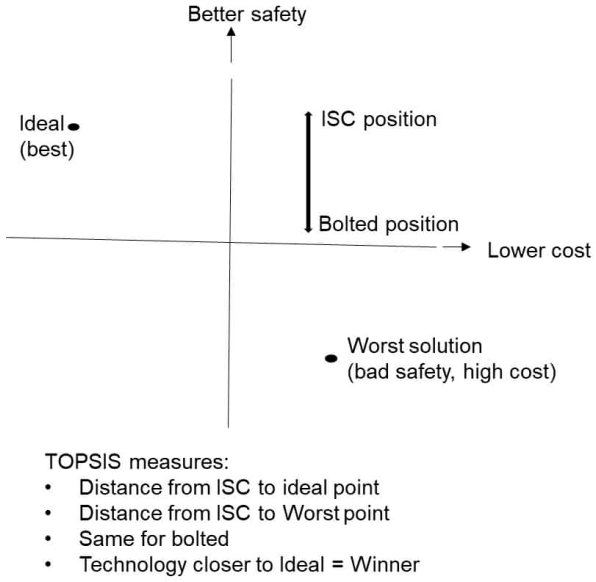

Figure 1. TOPSIS decision support analysis chart

The typical framework outputs and applications can be seen as presented in Table 1 below. The outputs translate analytical evaluation into practical decision support for multiple stakeholders. Overall closeness coefficients provide a single performance score that helps project managers and contractors decide whether the ISC system should be adopted. Criterion-level scores break this result down by technical, cost, or safety dimensions, allowing engineers and safety managers to identify specific strengths and weaknesses. Weight sensitivity results show how stable the recommendation is when priorities change, supporting confidence among risk-averse decision-makers. Cost breakdowns offer location-specific financial insight for owners and estimators, while safety metrics quantify hazard exposure to help safety directors and regulators assess whether the ISC system provides a safer alternative.

Table 1. Proposed Framework Output and Application Process

Output	What it shows	Who uses it	Decisions supported
Closeness coefficients	Overall technology performance score	Project managers, contractors	Should the ISC system be adopted?
Criterion-Level scores	Performance weight on specific dimensions or criteria	Engineers, Safety managers	Where does ISC perform better or worse?
Weight Sensitivity	How robust is the recommendation?	Risk-averse stakeholders	Can this decision be trusted?
Cost Breakdowns	Detailed cost comparison by location	Estimators, Owners	Market cost impact
Safety Metrics	Hazard exposure quantification	Safety directors, OSHA	Is the ISC system safer?

4 Results

The proposed conceptual decision-support framework incorporates three primary performance dimensions: worker safety, assembly efficiency, and construction cost. Each dimension was further split into 12 secondary evaluation criteria (four per dimension), and specific performance indicators were weighed from expert reviews. The framework integrates outputs from BIM-based constructability simulation, computer-vision-based ergonomic assessment, cost database analysis across geographical locations, and TOPSIS multi-criteria decision analysis for systematic technology comparison.

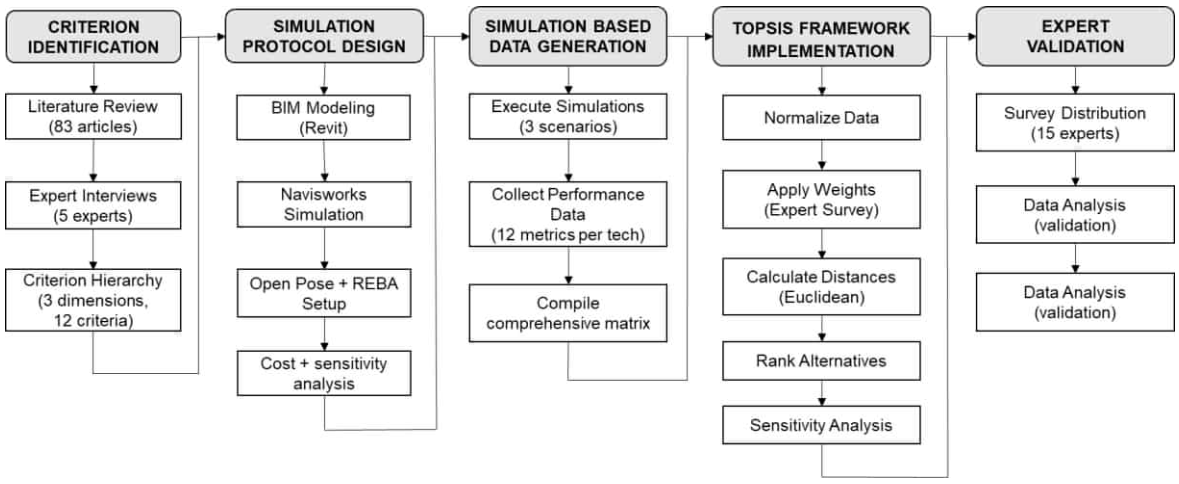

Figure 2. Conceptual Decision-Support Framework for Evaluating Steel Connection Systems

The proposed framework in Figure 2 addresses a critical gap in construction management by providing a structured, repeatable process for evaluating innovative steel connection systems, such as the intermeshed steel connection, against established traditional connection systems. The 3 dimensions of performance review offer practitioners a comprehensive overview of the technology when field performance data remains limited. The framework contributes to a systematic framework for integrating digital construction technologies with a thorough MCDM methodology, providing objective evaluation approaches. The proposed expert feedback weights from the survey and sensitivity analysis protocols enable the framework to accommodate several stakeholder priorities while maintaining robust decision recommendations. While this conceptual framework architecture establishes protocols and analytical procedures, further empirical data-based validation will be essential to confirm the framework's effectiveness and refine measurement approaches. Robust empirical data would also aid in verifying the criterion of relevance through expert review surveys and illustrating practical application through a pilot study.

Applying the survey-derived weights to the normalized performance matrix, the TOPSIS analysis yielded closeness coefficients of 0.664 for ISC and 0.344 for the bolted connection, ranking ISC as the preferred

technology across all 12 evaluation criteria. ISC outperformed the bolted connection on 11 of the 12 criteria, with the bolted system retaining an advantage only on the learning curve due to established industry familiarity. Sensitivity analysis under three alternative weight scenarios (equal weights, safety-focused, and cost-focused) confirmed ISC as the ranked-first technology in every scenario, demonstrating ranking robustness regardless of stakeholder priority orientation. Panelists evaluated the framework on comprehensiveness, criterion relevance, measurement feasibility, TOPSIS appropriateness, and practical applicability using a 5-point Likert scale, with an acceptance threshold of ≥ 4.0 on each dimension and ≥ 60% likelihood of adoption.

5 Conclusion

The study presents a conceptual decision-support framework for evaluating steel connection systems. This framework was tested through simulated performance data drawn from prior ISC research. Although the framework is conceptual in design, its development was informed by empirical and simulation-based evidence. A computer vision REBA assessment using OpenPose on steelworker image datasets quantified a 40% ergonomic risk deduction for ISC over bolted connections. 4D assembly simulations also documented a 29% reduction in installation time with a reduction in fall hazard exposure. RS means cost data analysis across five geographic locations confirmed a consistent 10% life-cycle cost advantage for ISC. These data-informed inputs strengthen the credibility of the TOPSIS ranking outputs and demonstrate how digital construction technologies can objectively support technology adoption decisions before full-scale empirical validation is available. The framework offers construction researchers and practitioners a replicable, evidence-based methodology for evaluating innovative steel connection systems. Future research should operationalize the framework through controlled laboratory or field-based pilot tests using live assembly data to validate the simulated performance metrics. A formal expert validation survey spanning professionals, academia, and industry practitioners will provide additional criterion-weighting feedback. The framework is also extensible to connection technologies beyond ISC and bolted systems, and automation through user-friendly TOPSIS-based decision tools would further support industry adoption.

Abstract –

This paper presents a systematic review of intelligent construction robots and their readiness for real-world deployment. Intelligent construction robots are defined as software-based or physically embodied agents that operate in a Perception–Reasoning–Action loop—sensing the environment, reasoning over observations and/or human commands, and executing actions through control or actuation. Using a structured search of Web of Science, the ASCE Library, and Scopus, 134 peer-reviewed journal and conference papers were identified and analyzed. A construction-oriented Technology Readiness Level (TRL) assessment framework was developed by adapting the classic TRL model and prior civil engineering TRL studies to evaluate technical maturity and deployability. Results reveal a step-up maturation trajectory: after an extended plateau near mid-level readiness, the literature shows accelerated growth in 2017–2025 with increasing dispersion in study quality. Only two studies achieved TRL 9 field validation, while most 2025 studies clustered at TRL 8. Findings highlight a persistent "valley of death" barrier between validation and deployment and motivate multi-condition field testing, safety assurance, and workflow integration to advance site-ready robotics.

Construction Robotics; Technical Readiness Level; Artificial Intelligence; Deep Learning; Reinforcement Learning

1 Introduction

The adoption of construction robots is increasingly necessary given the industry's severe labor shortage. Since 2023, the construction labor gap has reached 546,000 workers [1]. This sustained scarcity of skilled labor slows project delivery and substantially increases costs. A recent poll found that more than 90% of contractors report difficulty hiring qualified workers, which in turn raises operating expenses [2].

One prominent response is increased automation and robotics. Automated construction methods can reduce repetitive manual work by 25–90% and cut workers' exposure to hazardous activities by 72%, while improving accuracy and reducing rework [3]. Accordingly, construction robotics has been widely recognized as both necessary and productive [4,5]. Early diffusion, however, was constrained by high capital costs, the inherently unstructured nature of jobsites, and limited sensing and cognition in robotic platforms [6]. Today, simultaneous advances in artificial intelligence (AI), sensing, and building information modeling (BIM) are enabling a resurgence—from single-purpose tools toward more capable autonomous systems that can execute complex tasks. These developments are ushering in a new era of intelligent construction robots that can perceive, reason, and act autonomously to perform high-quality craft operations.

With rapid technological progress, construction robots increasingly leverage advanced perception and decision-making methods, including deep learning and reinforcement learning. Many successful prototypes have been demonstrated across a wide range of tasks, such as ceiling installation [7,8], window installation [9], drywall installation [10], inspection [11], welding [12], and human–robot interactive operations [13,14]. However, although these systems often show strong performance in high-fidelity simulation or controlled laboratory environments, the field still lacks a systematic evaluation framework that enables industry managers and decision-makers to assess the technical readiness of these technologies for deployment on real construction sites.

To address this gap, this paper adapts the widely used NASA Technology Readiness Level (TRL) framework [15] for construction robotics products and applies it to systematically evaluate the technical readiness of current intelligent construction robotics research. We analyze 134 papers published from 2017 to 2025 on intelligent construction robots and use the adapted framework to quantify their readiness levels. We further examine overall trends in readiness and product evolution to

characterize research progress, identify roadmaps, and highlight key challenges that must be addressed to accelerate real-world deployment.

2 Technical Readiness Level Framework

As mentioned in the Introduction section, this paper is theoretically supported by the classic TRL framework proposed by Nasa (15 Mankins 1995), which is shown in Table 1.

Table 1 Original TRL framework [15]

TRL Level	Definition (Operational Environment)
TRL 1	Basic principles observed and reported
TRL 2	Technology concept and/or application formulated
TRL 3	Analytical and experimental critical function and/or characteristic proof-of-concept
TRL 4	Component and/or breadboard validation in laboratory environment
TRL 5	Component and/or breadboard validation in relevant environment
TRL 6	System/subsystem model or prototype demonstration in a relevant environment (ground or space)
TRL 7	System prototype demonstration in a space environment
TRL 8	Actual system completed and "flight qualified" through test and demonstration (ground or space)
TRL 9	Actual system "flight proven" through successful mission operations

In this framework, the general hierarchy is from proposing the concept - component validation - system validation in controlled environments - system validation in true environment (space). It also fits the development of construction automation products. For construction robotics, it will also generally go through the similar phases: conceptualization (TRL)- prototyping in the lab- test in the field.

To understand how the traditional TRL scheme can be fit for construction technology development, the authors referred to two sources:

1) The core of development in NASA TRL: The authors conceptualized and abstracted the essence of TRL to three phase: conceptualization - prototyping in lab -test in the field. For construction robotics, it will also generally go through the similar phases: conceptualization (TRL)- prototyping in the lab- test in the field.

2) The previous work adapting TRL to civil engineering or construction related technologies. The following two representative TRL schemes were discovered, as shown in Table 2 and 3:

Table 2 TRL for construction and civil engineering [16]

TRL Level	Definition (Operational Environment)
TRL 1	Basic principles and research: Scientific principles observed
TRL 2	Applied Research: Application formulated and potential identified
TRL 3	Proof of Concept: Critical function validated in separate elements
TRL 4	Lab Validation (Low Fidelity): Component validation in a laboratory environment
TRL 5	Lab Validation (High Fidelity): Integrated components demonstrated in a laboratory environment
TRL 6	Prototype (Relevant Environment): Prototype demonstrated in a relevant environment
TRL 7	Prototype (Operational Environment): Prototype demonstrated in an operational environment
TRL 8	System Proven: Technology proven in an operational environment
TRL 9	Implementation: Technology refined and adopted

For a more abstract type, the following example on construction material development was also used in Table 3 [17].

Table 3 An abstract version of TRL for Civil Engineering [17]

TRL Phase	Construction-Specific

	Definition
TRL 1–3 (Concept)	Chemical formulation of the biocomposite (liquid wood) and basic mechanical testing (tension/compression) on small samples.
TRL 4–5 (Validation)	"Component Testing: Producing standard construction shapes (profiles, boards) and testing them for fire resistance, water absorption, and UV stability in a lab."
TRL 6–7 (Demonstration)	"Pilot Projects: Installing the material in a non-critical real-world structure (e.g., a park bench, facade cladding, or small shelter) to monitor weathering over 1–2 years."
TRL 8–9 (Deployment)	"Standardization: The material is included in national building codes (e.g., Eurocodes) and is available in commercial catalogs for structural use."

As summarized in Table 4, we aggregate the nine original TRL levels into four tiers to better reflect the typical development trajectory of construction robotics. Tier 1 (TRL 1–3) emphasizes conceptualization, including knowledge integration across disciplines (e.g., construction engineering, robotics, sensing, and AI) to clarify potential technological solutions to a construction-domain problem. Tier 2 (TRL 4–5) corresponds to component-level validation, where key subsystems are tested to verify that individual components can perform their intended functions within the proposed system architecture. Tier 3 (TRL 6–7) focuses on system-level prototyping and validation, in which integrated robotic systems are demonstrated and evaluated as complete solutions. Finally, Tier 4 (TRL 8–9) addresses deployment in relevant environments, where systems with established performance through prior validation are implemented and assessed under jobsite-representative conditions.

Building on these tier definitions, this paper proposes a TRL assessment framework specifically tailored to intelligent construction robotics (Table 4). This framework utilizes two primary criteria: Test Environment and Model Performance. The Test Environment (rated 1–6) evaluates the physical context of deployment, ranging from low-fidelity simulations to real-world construction sites. Simultaneously, Model Performance (rated 1–3) assesses the accuracy of perception and reasoning. To ensure reliability, if a robot's performance falls below 60% for any given rating, the overall TRL is downgraded by one level.

The specific criteria for each factor are as follows:

- Test Environment: 6 (field deployment on real-world construction sites); 5 (construction-similar lab environments); 4 (simplified lab environments); 3 (high-fidelity simulations); 2 (low-fidelity simulations); and 1 (non-construction environments with no direct task applicability).
- Model Performance: 3 (near-perfect; such as >95% object identification accuracy); 2 (moderate; such as 80% accuracy in human state inference); and 1 (low; such as ~60% accuracy in object identification).

Table 4 TRL for intelligent construction robots

TRL Level	Definition (Operational Environment)
TRL 1	Basic principles and research: Scientific principles observed
TRL 2	Applied Research: Application formulated and potential identified
TRL 3	Proof of Concept: Critical function validated in separate elements
TRL 4	Lab Validation (Low Fidelity): Component validation in a laboratory environment, such as perception results in general datasets or trajectory planning in simplified simulation environment
TRL 5	Lab Validation (High Fidelity): Integrated components demonstrated in a laboratory environment, such as perception results in task-relevant dataset or motion planning in high-fidelity simulation or simulations with task-relevant elements
TRL 6	Prototype (Relevant Environment): Prototype demonstrated in a relevant environment, such as integrated intelligent system in high-fidelity and task-relevant simulations
TRL 7	Prototype (Operational Environment): Prototype demonstrated in an operational environment, such as embodying all elements in a robot to perform construction tasks in simplified

	environment
TRL 8	System Proven: Technology proven in an operational environment, such as embodying all elements in a robot to perform construction tasks in lab environment that has all construction task elements but less cluttered
TRL 9	Implementation: Technology refined and adopted

However, it should be noted that the authors also considered the performance of the demonstrations. For example, if a lab prototyping of intelligent robot was demonstrated (TRL7) but the performance does not show its capabilities to perform high-quality construction tasks, the authors will rate this as TRL 6.

3 Data from Literature Review

This paper reviews intelligent construction robots that integrate deep learning (DL), reinforcement learning (RL), and other AI methods to perceive site conditions, interpret human intent or task specifications, and execute goal-directed actions. In this review, "intelligent robots" refers to agents: software-based or physically embodied, that operate in a Perception–Reasoning–Action loop: they sense the environment, reason over observations and/or commands, and generate actions through control or actuation [18].

Using this inclusive definition, the review covers two categories that are essential for understanding methodological progress in the field. First, it includes robots without physical embodiment (e.g., simulation-based or purely computational agents). Because construction robotics hardware deployments were relatively sparse prior to 2020, a substantial portion of foundational research validated learning-based perception and control using simulated platforms; these studies are therefore included for their algorithmic contributions and their role in establishing DL-based robotic control pipelines. Second, the review includes automated construction equipment under a broad robotics lens—ground robots, robotic manipulators, unmanned aerial vehicles, and sensorized construction machinery such as excavators or other articulated equipment. When such systems are equipped with environmental sensing, DL-driven reasoning modules, and actuation/control capabilities, they satisfy the criteria of intelligent construction robots.

The literature search was conducted across three major scholarly repositories: Web of Science (WoS), the American Society of Civil Engineers (ASCE) Library, and Scopus. The search was executed on August 10, 2025 and limited to publications from 2017 through 2025 to emphasize the most recent wave of advances in DL-enabled construction robotics. Although neural-network-based work in construction robotics predates this window (e.g., studies appearing as early as 2017), the selected timeframe reflects the rapid acceleration in DL architectures, data-driven control, and foundation-model capabilities that have materially changed the state of practice. The review scope was restricted to peer-reviewed journal articles and conference proceedings written in English. Searches were performed over titles, abstracts, and author keywords using three keyword groups combined with Boolean "AND": (i) robot-related terms ("robot" OR "robotic"), (ii) the domain term ("construction"), and (iii) learning-related terms, with "deep learning" as the primary keyword supplemented by "neural networks," "reinforcement learning" (given its growing role in robot control and long-horizon decision-making), and "large language model" (included because it is DL-based and increasingly leveraged for robotic reasoning and human–robot interaction).

Studies were excluded if the search terms appeared incidentally but the content was not substantively related to construction robotics or DL/RL methods, and review papers were also removed to avoid duplicating secondary syntheses. After screening and applying these criteria, 134 publications were retained for analysis (Appendix I). The year-by-year distribution shows a sustained rise in output over 2017–2025 (Figure 1), indicating expanding research attention at the intersection of robotics, construction, and learning-based methods. In terms of publication venues, Automation in Construction emerged as the dominant journal outlet, followed by leading conference proceedings including *the Construction Research Congress (CRC) and the International Conference on Computing in Civil Engineering (IC3E). Additional high-frequency sources included the Journal of Computing in Civil Engineering and the Journal of Field Robotics*, underscoring both the construction-engineering and robotics communities' increasing engagement with DL-enabled construction automation.

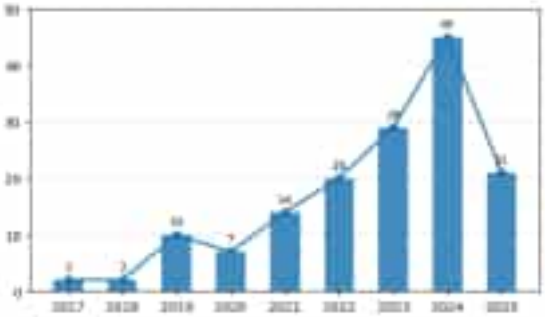

Figure 1. Publication trends and major publication venues.

4 Results

The TRL has largely improved from 2017 (averagely TRL3) to 2025 (averagely TRL 6.7). There are two studies testing the robotic products on construction sites and reached TRL 9. However, the majority does not show readiness to be directly deployed on construction sites. \

The authors also observed the large variation of the TRL in the prototypes or systems, all mean, median, and mode were used to show the patterns. The results are shown in Table 5.

To provide easier understanding of the trend, the visualization of the table is performed. The result is shown in Figure 2.

Table 5 Average TRL for intelligent construction robot studies 2017-2025

	Mean	Median	Mode
2017	3	3	3
2018	5	5	5
2019	5.625	5	5
2020	5.571	5	4.5
2021	6.25	5.5	5
2022	6	5	5
2023	6.444	6	6
2024	5.641	6	5
2025	6.667	7	8

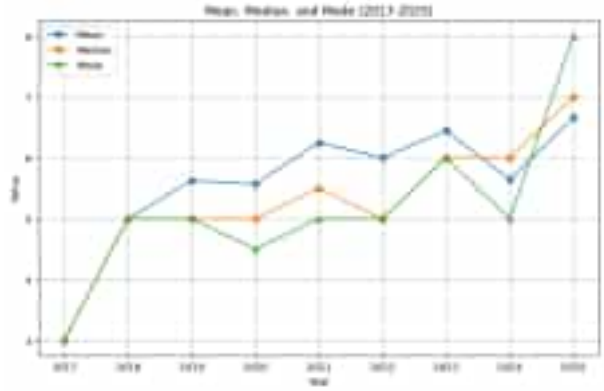

Figure 2. Average TRL for intelligent construction robot studies 2017-2025.

As can be seen in Figure 2, the TRL for intelligent construction robots illustrates a classic "step-up" maturation trajectory, characterized by a distinct phase of stabilization followed by a recent period of volatile growth. The jump from 2017 to 2018 established a solid baseline around a value of 5.0, where the technology or metric sat for several years with minimal deviation, suggesting a period of consistency or stagnation. However, beginning in 2021 and accelerating into 2023–2025, the data shows a breakout from this plateau. The divergence between the Mean, Median, and Mode in these later years indicates varying performance; specifically, the high Mode (8.0) in 2025 suggests that while the most common outcome is now high-performing, the lower Mean (6.667) indicates that significant low-performing outliers are still dragging the average down. This indicated the variation in the quality of research.

In addition, from the innovation perspective, the average TRL from 2020-2025 stabilized around 6. Innovation management to describe this as the difficulty of moving from TRL 4–6 (Research/Validation) to TRL 7–9 (Commercialization/Deployment) [19][20]. The "stagnation" seen in your data (flatline at 5.0 for years) is the textbook statistical signature of a project stuck in this valley. However, the majority of studies in 2025 has reached TRL 8, suggesting the completion of a full-scale robot embodiment in a construction-relevant lab environment.

In addition, the authors performed stratified analysis to further explore the reasons behind the TRL trend. The intelligent robots are categorized to: manipulators (robot arm and hand), soft robots, self-made robots (assembled from scratch), industrial equipment (modified excavator and cranes), combined robots (off-the-shelf solution modified), mobile robots, UAV, and 3D printing machines. The max and mode TRL were both used for each category, as shown in Figure 3.

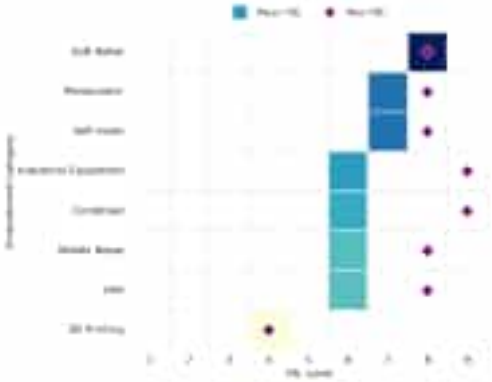

Figure 3. Stratified TRL analysis with eight robot types.

As illustrated in Figure 3, most construction robot categories now possess near-field-ready configurations. 3D printing remains the primary outlier with limited site deployability for intelligent systems. This is largely because 3D printing trajectories are typically pre-programmed to prevent structural defects and ensure material integrity, with relatively few studies successfully integrating adaptive, ML-based control. Conversely, both industrial equipment and combined robotic systems demonstrate viable prototypes for direct on-site deployment. It is important to note that while these specific categories reach high maturity, the high

volume of simulation-based research across the broader field pulls the aggregate mean TRL toward lower validation levels, highlighting how sample composition can mask the operational progress of specific sub-sectors.

5 Conclusions

This paper systematically reviewed 134 publications on intelligent construction robots and assessed their technical readiness for on-site deployment. Intelligent construction robots were defined broadly as software-based or physically embodied agents that implement a Perception–Reasoning–Action loop—sensing the environment, reasoning over observations and/or human commands, and executing actions through control or actuation [18]. Building on the classic Technology Readiness Level (TRL) framework [15], and informed by prior TRL adaptations in civil engineering research [16][17], this study developed a domain-appropriate, methodologically rigorous readiness assessment tailored to the realities of construction environments.

The readiness trends reveal a "step-up" maturation pattern rather than smooth linear progress. The TRL metrics show an extended period of stabilization around mid-level readiness (approximately TRL 5) through the late 2010s, followed by a clear breakout beginning around 2021 and accelerating through 2023–2025 (Figure 2). In the most recent years, the widening spread among central tendency measures (mean, median, and mode) indicates uneven progress across the literature: although the most common outcome has shifted to high maturity (mode near TRL 8 in 2025), the average remains noticeably lower, implying that a subset of studies still lag behind and pulls down overall performance. This dispersion suggests increasing variation in methodological rigor, validation quality, or the extent of real-world testing as the field scales.

Consistent with innovation management theory, the evidence also suggests that the field has faced a persistent transition barrier between research validation and deployment. Across 2020–2025, the average TRL hovering around ~6 aligns with the well-documented difficulty of moving from TRL 4–6 (research/validation) into TRL 7–9 (commercialization/deployment), often described as the "valley of death" in technology maturation [19][20]. In this context, the earlier multi-year plateau near TRL 5 can be interpreted as a statistical signature of technologies that demonstrate feasibility but struggle to secure the field access, integration pathways, safety assurance, and robustness needed for sustained deployment.

The readiness evaluation indicates that full site-ready maturity remains uncommon. Only two studies achieved TRL 9, meaning robotic systems were validated in real construction settings under varied conditions sufficient to represent real-world variability. Most of the remaining work clustered below that threshold, reflecting persistent barriers such as unstructured environments, safety constraints, limited access to field trials, and challenges in generalization across tasks, sites, and work practices. At the same time, the evidence points to rapid progress: by 2025, the dominant maturity level shifted to TRL 8, indicating that many systems are approaching deployability through late-stage validation and near-field testing, even if they have not yet demonstrated sustained performance across diverse live jobsite conditions.

Overall, the findings suggest the field has moved from early-stage feasibility demonstrations around 2017 (typically TRL ~3) to near-deployment prototypes within less than a decade, underscoring the accelerating impact of deep learning, reinforcement learning, and AI-enabled perception and planning. The primary gap is no longer proof-of-concept capability, but robust translation to the field—especially generalization, safety assurance, and integration into work-zone operations and workflows. Future research should therefore prioritize multi-site, multi-condition field evaluations, standardized benchmarking protocols, and human-centered deployment procedures that ensure reliability and safety while delivering measurable gains in productivity, constructability, and reduced disruption to construction operations.

Overall, to address the lack of a standardized technical maturity baseline in current literature, this study employs the TRL framework as a vital "first-pass" screening tool. By establishing this technical baseline, we provide a curated starting point for the research community and industrial decision-makers to identify viable candidates for adoption. However, we acknowledge that TRL is a high-level metric with inherent limitations; it does not, on its own, guarantee safety, generalization, or robustness across diverse construction environments, which are all important operational factors to consider for a technology adoption decision. In this paper, the authors position TRL as a preliminary filter that allows stakeholders to judiciously apply resource-intensive evaluations: such as safety audits and cross-environment generalization tests, to a more targeted subset of technologies. This tiered framework bridges the gap between laboratory-based technical maturity and field-proven technical maturity.

Abstract -

The AECO sector increasingly calls for digital transformation to support sustainable development and a more human-centred built environment. In this context, the Society 5.0 dimensions, which emphasise *human-centred values*, *cyber-physical intelligence*, *socio-technical embeddedness*, *societal challenge orientation* and *system-level impact potential*, provide a lens for examining how digital technologies are conceived and deployed in the sector. Despite rapid technological advancement, challenges remain in operationalising these principles within complex socio-technical systems. Gamification has been explored as a potential response, yet its contribution to Society 5.0-oriented transformation remains fragmented. This study conducts a systematic literature review of 98 publications from the past five years (2021-2025), each presenting a game or gamified application in the sector. The review analyses their correspondence to the Society 5.0 dimensions. The results indicate that many existing games are not primarily designed for engagement or enjoyment. Research-oriented games are predominantly targeted at students rather than industry practitioners or the general public. Most applications operate at the building scale and focus on the operation phase of the lifecycle. Furthermore, a heatmap analysis reveals systematic patterns: Amongst the minority that are engagement-oriented games, these tend to strengthen *human-centred values* and *socio-technical embeddedness*; decision-making games are more closely associated with *system-level impact*. Notably, no reviewed games address the end-of-life stage of buildings, while scenario-based interactive games often align with individual-level human values. The study concludes by identifying key gaps and outlining future gamification requirements to better align digital innovation in the AECO sector with the human-centred and system-oriented aspirations of Society 5.0.

Keywords -

Digital Games; Gamification; Society 5.0; Technology; Sustainability; Literature Review

1 Introduction

1.1 Society 5.0

Industry 5.0 has been emerging globally to rethink the role of humans and place humans at the centre of industrial development through sustainability, resilience and human-centredness. This aligns with a new overarching vision for society - Society 5.0 - that envisions a human-centred physical and cyber space with advanced technologies including artificial intelligence (AI), information and communication technologies (ICT) that enable sustainable development in environment, economy and society. Ageing societies, inclusiveness and equality are considered through technological development. In Europe, policy-makers and scholars are exploring a neighbouring concept to envision decentralised autonomous cities and human digital twins [1]. In Japan, the government has been pushing a human-centred system in Society 5.0 that includes the transdisciplinary concepts of digitalisation, integration and sustainability [2]

Nevertheless, there are clear challenges in Society 5.0 regarding humans, technologies and values in a sustainable society in the physical space. These multi-dimensional challenges include how to achieve *human-centred values*, such as health and wellbeing, safety and inclusiveness in society, as well as unknowns in *societal challenge orientations* to different extents. The interactions between humans, humans and technologies, physical and cyber space and amongst each other as complex systems within systems entail *socio-technical embeddedness* Also, the complexity within physical and cyber spaces with AI and intelligence-based technologies entails new forms of *cyber-physical intelligence*. In general, a system-level rethinking of the potential impacts in the physical world is necessary to adapt and optimise these challenges to foster sustainable development in Society 5.0 through digital transformation, which refers to an inter-connected set of discoveries and inventions [3].

1.2 Construction 5.0

The World Economic Forum reveals that the architecture, engineering, construction, and operations (AECO) sector is responsible for 13% of the global gross domestic product (GDP), employs more than 100 million people, and accounts for 79% of total greenhouse gas emissions and 88% of climate adaptation costs. However, the sector suffers from low digitalisation and innovation. It is one of the least digitised in the world and requires a systematic approach to digital transformation to foster a sustainable development. The industry embraces a new movement of Construction 5.0, in reference to Industry 5.0 and Society 5.0 in AECO, to drive digital transformation through digitalisation, integration and sustainability to different extents [4, 5].

In correspondence to the five dimensions of Society 5.0, the AECO sector has been trying to achieve *human-centred values* to improve human wellbeing such as worker health and safety, as well as continuous improvement in knowledge and skills [6, 7]. The industry has adopted automa-

tion and robotics in construction to address broader social challenges such as ageing society and labour shortages [8, 9]. In addition, recent research reveals the complex ontology networks and interactions between the different human roles, resources, conditions, artifacts, processes, attributes, values and risks in adopting automation technologies to achieve sustainability in AECO. This shows that *socio-technical embeddedness* is significant and requires more integrated management for Construction 5.0 [10]. Recent studies have also examined real-time digital twins for automation and robotics in construction management [11] *Cyber-physical intelligence* enables human-centred controls in, for example, human-robot collaborations [12].

1.3 Gamification

Given the complexity of the AECO sector, gamification has been one approach to encourage and assist the industry to comprehend and stimulate strategies through experiential learning to different extents. Suits [13] defines a game as 'the voluntary attempt to overcome unnecessary obstacles'. He suggested that a game possesses three components of prelusory goal, constitutive rules and lusory attitude. The term gamification was coined by Pelling in 2002 and hit the mainstream around 2010 [14]. The elements of a gamified system can be categorised into three groups [15]: (1) *dynamics* defines the big-picture aspect of the game and includes elements such as constraints, narratives, progression and relationships; (2) *mechanics* defines the processes that drive actions forward and includes elements such as challenges, chance, competition, cooperation, feedback, resource acquisition, rewards, transactions, turns and win states; and (3) *components* specify the corresponding instantiations of *dynamics* and *mechanics* such as quests and points [16]. Garneau [17] identifies fourteen forms of fun in games, ranging from beauty and immersion to competition, discovery and social interaction, while Heeter et al. [18] shows these more prevalent in commercial than educational games.

1.4 Gamification in AECO Research

Recently, researchers have been exploring gamification approaches for research and education on technology and sustainability to different extents. Yanai and Ishikawa [19] developed an immersive environment in VR to investigate the learning experience at Osaka Castle. Ng and Chen [7] developed a teaching game using the online platform *Slido* to investigate students and practitioners' perceptions of lean terminology. Tan et al. [12] reviewed the literature on augmented reality (AR) for human-robot interactions to investigate innovations in pedagogy. Ng and Hall [20] developed an online game to allow players to experience a round of traditional design-bid-build design process and a second round of lean-based Target Value Design for digital fabrication. Kastner et al. [21] designed an online game in 3D BIM to let players learn about lifecycle thinking for renovating a historic building in Switzerland. Harichandran et al. [22] presents a virtual reality (VR) game with digital twins to train workers about construction safety.

Some scholars had reviewed existing academic games or gamification in AECO. For example, Ilbeigi et al. [16] conducted a scoping review on Scopus of 103 game-based educational solutions for construction engineering in the past two decades. They differentiated the basic information of the article, such as titles, and analysed several factors, such as whether each study developed a novel gamified solution based on a learning theory and specific its specific area of domain. Bhatnagar et al. [23] reviewed 96 lean simulation games from a selection of 52 articles. Articles were analysed for basic information, such as authorship, using social-networks analysis. They found that the International Group for Lean Construction (IGLC) developed a large number of lean games in AECO. They show that a few authors collaborate extensively, while others in the periphery are beginning to publish and collaborate. Oke et al. [24] identified five challenges to the adoption of gamification for sustainable construction, including hesitation in adopting and lack of budgeting for innovation, with a questionnaire survey.

Nevertheless, no recent articles have reviewed academic games, in particular, about technology and sustainability in AECO.

1.5 Research Objectives

To help researchers and industry think about technology and sustainability in Society 5.0 and Construction 5.0, this work presents a systematic review of the literature of publications from the past five years to investigate the recent trends of digital games in AECO and their relevance to the promotion of technology and sustainability. This research possesses two overarching research questions of **(RQ1)** what are the recent trends in game development in AECO? and **(RQ2)** what can be the foci when researchers develop games for AECO in Society 5.0? In this regard, this work correlates gamification to the five dimensions in Society 5.0 of *human-centred value*, *socio-technical embeddedness*, *cyber-physical intelligence*, *societal challenge orientation* and *system-level impact potential*. The research objectives of this work include **(OB1)** identifying recent trends and features of recent game development in AECO through a systematic review of the literature; **(OB2)** to analyse the correlations between the indicated features and the five dimensions in Society 5.0; **(OB3)** to elaborate on potential topics in game development to foster Society 5.0 in AECO. This article summarises the preliminary of this systematic literature review and a further in-depth analysis will be presented in future publications.

The structure of this article is organised as follows: Section 2 describes the systematic literature review methodology; Section 3 presents the results of recent trends and features; Section 4 discusses the co-occurrence pattern analysis with Society 5.0 dimensions; and Section 5 concludes with limitations and future research directions.

2 Research Methodology

To conduct a systematic literature review, the first author of this work ran a first-round Scopus search with the keywords of keyword group 1, which comprises "gamification" or "digital games", and keyword group 2, which comprises "construction" or "building" or "architecture". The search includes journal articles and conference proceedings published in the past five years (2021-2025) in the fields of AECO only. This resulted in 1279 articles. The first author then screened the abstract of every article to eliminate those that do not include an original development of gamified solutions, those about research of game theory or game modelling, those that gamify a survey or other types of research but not a game development, those

Table 1. The basic information of the selected 98 articles in this work. "J" refers to a journal article; "C" refers to a conference proceeding.

that do not involve any digital tools, as well as those that review existing commercial games or those review literature about games. In case of those presenting the same game in multiple articles, only the most relevant article was selected. This resulted in 98 relevant articles as shown in Table 1.

To answer RQ1 and achieve the objective OB1, all authors reviewed each article in detail to identify the features of each of the 98 games from the selected literature. The features are identified under six categories of *target player*, *scale*, a *building lifecycle stage*, the *research goal*, any focused *digital features* significantly involved, as well as any *Society 5.0 concepts* involved [2, 4]. Moreover, this work includes an evaluation of the five dimensions presented in Section 1. The results of this analysis are explained in Section 3. Furthermore, this work analyses the correlations amongst the features through heatmap visualisation. The results answer RQ2 and achieve the objectives OB2 and OB3 are discussed in Section 4.

Each article was independently coded by at least two authors across six feature categories (target player, scale, lifecycle stage, research goal, digital features, Society 5.0 concepts) using binary present/absent labels. Multi-label coding was permitted, and disagreements were resolved through discussion or third-author adjudication. The heatmap in Figure 3 shows conditional co-occurrence percentages: each cell = (articles tagged with both the row and column features) /(articles with the row feature) × 100, rounded to the nearest integer. For example, 16 of the 23 'Cultural Preservation' games involve the 'Building' scale, yielding approximately 70%. These values represent co-occurrence patterns, not statistical correlations; normalisation is row-based, and multi-label articles contribute to all applicable categories.

3 Recent Trends and Features

This section presents the results of the identified features in the seven categories for the analysis.

Target Player: Based on systematic review of the literature, recent trends in digital games show that 45% are designed to target AECO students at universities, while 40% target professionals in the sector. For example, Arbesser-Rastburg et al. [47] developed an escape room game in VR to teach AECO students about building energy. In addition, 28% are targeted at visitors or end-users of the facilities involved in those games. For example, Yanai and Ishikawa [19]'s VR experiment aims to improve visitors' experience when visiting Osaka Castle in Japan. 6% target on general households. For example, Hao et al. [28] uses a game approach to help the decision-making of general households and governors, respectively, about the management of solid waste. 5% target kids and/or teenagers. For example, Emiroglu et al. [27] used minecraft to teach primary and secondary K-12 students about flood mitigation. 4% target on governors or policymakers; while only 1% target on elderly. For example, Hung et al. [31] gamified a cycling exercise for residents in long-term care homes.

Scale: The recent trends show eleven scales in game development. 41% of the games developed in the past five years are games with buildings. For example, Kastner et al. [21] developed an online 3D building game of the existing Hotel Schatzalp in Davos, Switzerland, for a case study of lifecycle thinking for architecture renovation. 28% present games with a project scenario. For example, Ng and Hall [20] developed a game to make a salad plate that mimics van Gogh's The Starry Night painting as a design project for students and professionals to learn about the lean-based Target Value Design approach for digital fabrication. 20% of the games developed comprise a campus, a site or a landscape in the gaming environment. For example, Turk and Bozkurt [40] presents an AI-based board game to teach AECO students about landscape architecture. 18% are about an individual person or a role. For example, Ng and Chen [7] developed a game for everyone to learn their own perception of lean terminology from Japan. 18% gamified user experience and 16% gamified urban and cityscape; while 14% games are about infrastructure assets such as bridges. 5% are community-based games. For example, Wang et al. [43] presents a community game in a smart green village in China. 2% of the gamifications are specifically about climate such as wind and furniture, respectively, such as the gamified bike in [31]. Only 1% gamified softscape such as audio.

Lifecycle Stage: This work also presents which of the commonly known six lifecycle stages are more frequently presented in a game. 38% and 27% of the games reviewed are developed for the operational stage and the construction stage, respectively. For example, Boyacioglu et al. [25] presents a game to address the delays of construction projects. 19% developed games for the design stage, while 12% developed games for the pre-design planning and initial design stage. 9% games are designed for urban

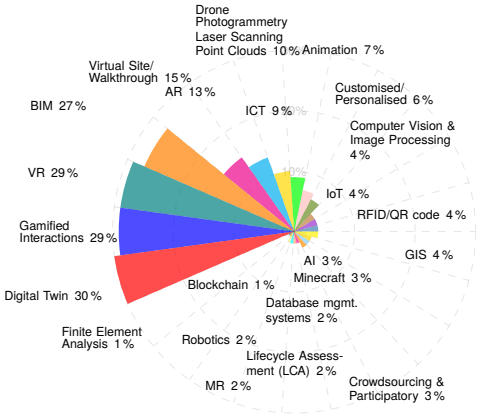

Figure 1. Recent 23 trends of digital features in digital games in AECO.

planning. Nevertheless, no game has been developed in the last five years for the end-of-life stage (afterlife) of a building or infrastructure.

Research Goal: To assist researchers and game developers understand how games could be developed in the future, this work also reveals that there are 18 research goals that have been addressed in the past five years. 62% of the games were developed for educational and communication purposes. Surprisingly, only 37% of the 'games' were gamified for people to play. Many of the developments in the reviewed literature do not aim for fun. In this regard, a further discussion is provided in Section 4. 26% and 20% of the games aim to assist decision-making and improve efficiency, respectively, such as reducing project delays in Boyacioglu et al. [25]. 19% aim for co-creation and collaboration amongst players. For example, de Sena et al. [38] developed a participatory planning system to collect spatial data from minecraft and improve collective governance in urban planning for co-creation. 18% of the games were developed to explore cyber-physical interaction and resource management, respectively. 17% were developed to provide information to players for knowledge sharing. 10% aim to improve site management and safety training, such as Harichandran et al. [22], respectively. 9% gamified, for example, on the urban scale, to mitigate safety and resilience. 7% aim for collective governance; while 7% promote modular construction and 6% explore new processes or innovation in the built environment. For example, Jang et al. [33] presents a gamification of crane lifting tasks in digital twins to improve a prefabricated bridge deck assembly process. The salad game in Ng and Hall [20] facilitates integrated design processes to stimulate systemic innovation. 5% aim to explore acceptability amongst players. For example, Hung et al. [31] and Ng and Chen [7] used gamification to explore people's perceptions. 5% were designed to perform seismic damage assessment, while 3% were aimed at boosting business-or-finance-related activities. Surprisingly, only 3% promote a clean and green built environment.

Digital Features: Furthermore, in response to emerging needs in digital transformation in AECO, this work reveals the trends of 23 digital and technological features in recent digital game development. Based on the literature review, 30% of the gamification research developed a digital twin such as Jang et al. [33]; while 29% comprise gamified interactions such as Hardy et al. [29]. 29% use VR, 13% use AR and 2% use Mixed Reality (MR) features, respectively. 27% include BIM such as Kastner et al. [21]. 15% include virtual site or virtual walkthrough such as Zhang et al. [45], Only 6% of the games include customised or personalised and only 2% are games about robotics. For example, Hu et al. [30] developed a customised experience in the archaeological site museum through gamification.

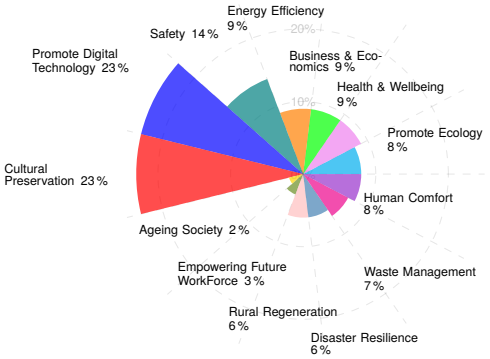

Figure 2. Recent trends in games relevant to the concepts in Society 5.0 .

Society 5.0 Concepts: To answer RQ2, this work identifies 13 Society 5.0 concepts that can be found in recent game developments based on the reviewed literature. Amongst all, 23% of the games have been developed for cultural preservation and promoting digital technologies, respectively. Games about safety in AECO are also relatively popular, such as Harichandran et al. [22]. Energy efficiency, health and wellbeing, and human comfort can also be found in around 8-9% of the publications reviewed. Games that simulate business related activities can be found in 9% of the games. For example Zielke et al. [46] developed a serious digital game about lean-based logistics to improve efficiency and therefore cost effectiveness. Very few games explore future workforce and ageing society respectively.

Five Dimensions in Society 5.0: To achieve OB2, this work further investigates a more detailed overview of the five dimensions in Society 5.0 as described in Section 1. The differentiation of the recent games are relatively well distributed across these dimensions. 33% of the games explore *human-centred values*; 28% explore *cyber-physical intelligence* through, for example, digital twins in the game development such as Voinea [41]. 27% delve into *socio-technical embeddedness*, while 23% look at *societal challenge orientation*, respectively. 20% explore *system-level impact potential*.

4 Discussions about Games for Society 5.0

The analysis of heatmap-based co-occurrence patterns in Figure 3 provides a systematic overview of how current

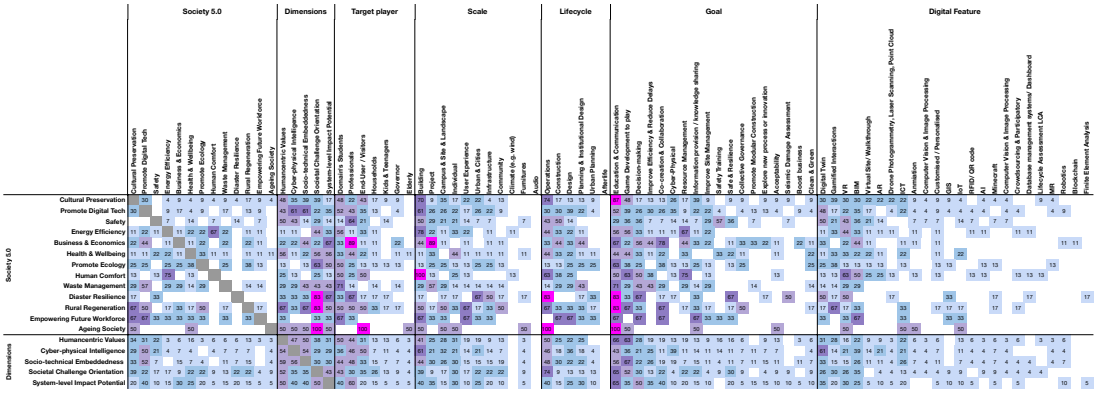

Figure 3. Heatmap of row-normalised conditional co-occurrence percentages across game features, Society 5.0 concepts and the five dimensions. Each cell shows the proportion of articles with the row feature that also exhibit the column feature, rounded to the nearest integer. The number in each cell refers to the percentage of the correlations. For example, amongst all 23 games about cultural preservation, 16 of them, i.e. rounded-up to 70%, involves gamification of buildings.

digital game-based developments in the AECO sector align with the broader aspirations of Society 5.0. While certain themes such as safety training, cultural preservation, and digital technology promotion are well represented, other critical dimensions remain underexplored. This reveals both the strengths and the limitations of current gamification practices in supporting a more human-centred and system-oriented built environment. This work achieves OB3 to discuss potential game developments to foster Society 5.0 in AECO.

4.1 Dominant Clusters and Underexplored Needs

Amongst the most prominent trends, safety-related games exhibit strong integration across multiple lifecycle stages, particularly construction and operations. These games frequently use digital features such as gamified interactions and immersive environments, with the primary goal of supporting safety training and hazard awareness. This is reflected in the heatmap, where the 'Safety' row shows relatively high co-occurrence values for the 'Construction' lifecycle stage (50%), as well as 'Gamified Interactions' (21%) and 'VR' (43%) amongst digital features. Cultural preservation is another area of significant focus, with many games using VR, digital twins and walkthroughs to enhance user experience in heritage contexts. Similarly, promoting digital technology is a recurring theme, often linked to BIM, gamified learning and educational communication. These clusters suggest a tendency to deploy games in domains where the benefits of technology can be clearly demonstrated, risks are manageable and regulatory constraints are lower.

Nevertheless, despite the emphasis on human-centredness in Society 5.0, certain societal needs are noticeably absent. The concept of ageing society, for instance, is scarcely addressed in the reviewed games. Very few applications are designed with elderly users, children or general households in mind. Most games target students and professionals, thereby limiting their societal reach. Similarly, lifecycle stages such as the end-of-life stage of buildings, covering topics such as *system-level impact* and *socio-technical embeddedness* in deconstruction, reuse and circular design, receive almost no attention, despite their importance for sustainability and long-term planning. These gaps point to a missed opportunity for games to contribute to inclusive design, intergenerational equity and circular economy transitions. Several factors may explain these gaps: recruiting vulnerable populations (elderly, children, non-expert households) poses ethical and methodological challenges unfamiliar to technically oriented AECO teams; the end-of-life stage lacks commercial incentive relative to design or operations; and disciplinary silos between AECO and social science or gerontology limit cross-pollination of methods. To address this, cross-disciplinary co-design workshops involving diverse end-users, partnerships with care facilities and community organisations, as well as policy-driven agendas linking circular economy mandates to gamification could broaden both target audiences and thematic scope.

4.2 Mechanics and Embeddedness

The analysis also highlights the importance of game goals and mechanics in shaping their alignment with Society 5.0 dimensions. While a majority of the games are developed for educational and communicative purposes, only a minority are designed to be engaging or enjoyable in a conventional sense. This suggests that many academic games prioritise knowledge transmission over player experience, which may hinder their impact. Interestingly, games developed for decision-making and co-creation tend to correlate more strongly with dimensions like *system-level impact*. These findings imply that the transformative potential of games lies not only in their content or digital features, but also in how they frame interaction, collaboration and agency. The heatmap supports this: 'System-level Impact Potential' co-occurs more strongly with 'Professionals' (60%) than 'Domain's Students' (40%) as target players, and shows relatively strong co-occurrence with the Society 5.0 concept of 'Business & Economics' (30%) compared to other concepts.

Socio-technical embeddedness, in particular, emerges as

a critical but underutilised dimension. It is most effectively realised in games that involve collective governance, participatory planning and stakeholder negotiation, especially at urban, community or site scales. However, many games still treat social contexts, institutional structures and power dynamics as external conditions rather than integral parts of gameplay. Even when advanced technologies such as VR or BIM are used, their contribution to embeddedness is limited unless supported by mechanics that model real-world complexity, such as role-based decision-making or scenario-based negotiation.

To support the broader transformation envisioned in Society 5.0 and Construction 5.0, future game development must go beyond technology demonstrations or visual simulations. There is a clear need for games that support participatory and experiential learning, that model trade-offs and systemic consequences, and that engage a broader spectrum of users beyond students and professionals. Addressing the end-of-life stage of buildings, designing for inclusivity and accessibility, and embedding socio-technical complexity into gameplay will be essential steps. Only by expanding the scope, depth, and diversity of game-based applications can the AECO sector fully leverage gamification as a tool for human-centred, sustainable, and system-level innovation.

4.3 Limitations and Future Research Directions

This review is restricted to Scopus-indexed peer-reviewed publications from 2021-2025. Industry-developed games, commercial applications and grey literature are excluded. The findings may under-represent applied solutions that influence practice but fall outside the academic literature. This study has several limitations that should be considered when interpreting the findings. First, the analysis is based on thematic co-occurrence and correlation patterns derived from a systematic review. While this approach enables a structured comparison across a large body of literature, it does not assess the depth, quality or effectiveness of individual game implementations. Moreover, recent AECO game developments rarely engage explicitly with the fourteen forms of fun. As such, the results indicate patterns of emphasis rather than evidence of impact or causal relationships between game design features and societal outcomes. Second, the classification of game features, Society 5.0 concepts, and the five dimensions necessarily involves a degree of interpretive judgment. Although a systematic and consistent coding framework was applied, some dimensions, particularly *socio-technical embeddedness* and *system-level impact potential*, are conceptually broad and may be operationalised differently across studies. The resulting heatmap therefore reflects relative emphases rather than definitive or exhaustive categorisations. Finally, each game was treated as a single unit of analysis, without accounting for differences in maturity, scale of deployment, duration of use or institutional embedding. Early-stage prototypes and long-running platforms are weighted equally, which may obscure important variations in adoption, learning outcomes or long-term influence.

Although this study provides a structured overview of how digital games relate to Society 5.0 concepts in the built environment, the analysis is primarily based on thematic correlations and does not evaluate the depth or effectiveness of individual implementations.

Future studies should move beyond the current concentration on technology demonstration, safety training and cultural preservation. They should explore how games can support more complex social challenges. In particular, there is a strong need to address under-represented themes such as ageing society and inclusive participation, by designing game-based applications for elderly users, households and non-expert stakeholders. Sustainability oriented games should also evolve from technically focused simulations toward participatory and experiential formats that allow players to engage with environmental trade-offs, long-term impacts, and collective responsibility. Moreover, the near absence of afterlife stage applications highlights an important opportunity for future research to develop games that address deconstruction, reuse, and circular economy strategies. Finally, expanding game-based approaches towards decision-making, governance and system-level exploration may enhance their potential to support the broader socio-technical transformation envisioned in Construction 5.0 and Society 5.0.

5 Conclusions

This paper presented a systematic review of 98 digital games in the AECO sector, analysing their alignment with the five dimensions of Society 5.0. The results reveal that while current games often focus on safety, cultural heritage and digital technology promotion using tools such as VR, BIM and digital twins, critical areas like ageing society, inclusive participation and the afterlife stage of buildings remain largely overlooked. Most games are developed for students and professionals, with limited engagement of diverse or vulnerable user groups. Moreover, while many games employ advanced digital features, few fully support *socio-technical embeddedness* or *system-level impact*, often lacking participatory or collaborative mechanics. To better support the goals of Society 5.0 and Construction 5.0, future gamification efforts should go beyond education and demonstration. There is a clear opportunity to design more inclusive, participatory, and systems-oriented games that engage broader audiences and address complex societal challenges in the built environment.

Abstract

This study examines the emerging role of Artificial Intelligence (AI) and blockchain in construction supply chain research through bibliometric and thematic analysis of the existing literature. Using VOSviewer, the study identifies key research trends, thematic clusters, and knowledge structures related to supply chain transparency, automation, optimisation, and adoption barriers. The analysis highlights interconnections between blockchain-enabled traceability, supply chain management, and AI-driven optimisation in construction projects.

The study also synthesises reported applications, including blockchain for secure transaction tracking and smart contract automation, and AI for predictive analytics in resource planning and risk management. Findings indicate growing scholarly attention to the complementary role of AI and blockchain in improving transparency, coordination, and decision-making across construction supply chains, while highlighting persistent challenges such as implementation costs, regulatory uncertainties, technological integration, and organisational resistance.

By mapping the current research landscape, this study provides a structured overview of key themes and emerging research directions, offering insights for researchers and practitioners advancing digital transformation in the construction industry.

Keywords –

Artificial intelligence; Blockchain technology; Construction supply chain; Thematic review; Bibliometric analysis

1 Introduction

The construction industry, crucial for global economic growth, consistently grapples with inefficiencies, transparency issues, and delays in supply chain processes, leading to significant cost overruns and reduced productivity. These technologies offer promising solutions to long-standing issues in the construction supply chain, including inefficiencies, delays, and a need for more transparency. This study aims to provide a comprehensive analysis of how AI and blockchain can be applied to construction supply chains, focusing on research gaps and opportunities for practical implementation.

Traditionally reliant on labour-intensive methods prone to human error, the industry has been slow to adopt new technologies. AI technologies, including machine learning and predictive analytics, enhance project planning and resource allocation by analysing historical and real-time data to anticipate delays, optimise logistics, and reduce material wastage. For instance, AI-driven predictive maintenance can forecast equipment failures, preventing costly downtime (Zheng et al., 2023; Wang et al., 2020).

Blockchain technology provides a decentralised ledger system that enhances transparency and traceability across supply chains by recording transactions and material movements, fostering stakeholder trust. Smart contracts automate agreements, streamline procurement, and support timely payments (Cheng et al., 2021). While integrating AI and blockchain can improve decision-making, reduce operational costs, and enhance project reliability, challenges such as high implementation costs, skills shortages, and regulatory barriers hinder adoption. This study reviews recent literature to identify key trends, benefits, and challenges in construction supply chains.

2 Literature Review

Integrating AI and blockchain technology in construction supply chains is a relatively new study area. However, it holds immense potential for transforming the construction industry's operations. Both technologies

have significantly improved efficiency, transparency, and decision-making when applied individually. However, their combined potential still needs to be explored in current research. This study will explore the role of AI and blockchain in construction supply chains, examining critical research gaps, previous studies and recent technological advancements.

2.1 Previous Work and Study Gaps

Research into using AI and blockchain technology within construction supply chains has evolved considerably in recent years. This field of study addresses critical challenges in construction, such as inefficiencies in resource management, transparency issues and the need for better project coordination. While construction has historically been slower to adopt advanced technologies than manufacturing, the sector's increasing demand for productivity, cost reduction, and adherence to regulatory standards has led to growing interest in leveraging AI and blockchain to enhance supply chain processes. Studies have explored AI and blockchain separately, focusing on their respects and challenges, with only a few addressing their combined potential.

2.2 AI in Construction Supply Chains

The application of AI in construction primarily centres on improving project planning, resource optimisation, and risk management. Researchers have explored how machine learning algorithms can analyse vast datasets to forecast project timelines, identify resource bottlenecks, and predict delays. Elghaish et al. (2023) reviewed predictive analytics in construction supply chains, emphasising how AI-driven forecasting tools enable managers to plan proactively and allocate resources more effectively, reducing the likelihood of costly overruns.

Other studies have highlighted AI's potential to streamline project monitoring and control. Technologies such as drones, real-time sensors, and AI algorithms allow continuous tracking of construction progress against predefined benchmarks. Hamledari and Fischer (2020) showed that AI-powered reality capture technologies provide real-time project updates by comparing site data with project plans, enabling prompt responses to deviations and improving site efficiency.

AI's role in resource optimisation has also received significant attention in construction research. Predictive algorithms can analyse past projects to forecast material requirements, allowing firms to plan procurement schedules more precisely. Research shows AI can optimise inventory and supply chain flows, reducing wastage, streamlining procurement, and lowering costs in dynamic construction environments.

2.3 Need for Integration of AI Applications

The integration of Artificial Intelligence (AI) and blockchain technologies has increasingly been discussed in the digital transformation of construction supply chains. AI techniques such as machine learning and predictive analytics can analyse historical and real-time project data to forecast material demand, optimise inventory, and anticipate supply chain disruptions. However, the effectiveness of AI-based systems depends on reliable and trusted data exchange among stakeholders, which remains challenging due to fragmented project structures and limited transparency.

Blockchain has been proposed as a complementary solution due to its ability to provide secure, transparent, and tamper-resistant data records across decentralised networks (Turk and Klinc, 2017). Studies show that blockchain can enhance supply chain traceability, strengthen stakeholder trust, and automate contractual transactions through smart contracts (Li et al., 2019). When integrated with AI analytics, blockchain can provide a secure infrastructure for sharing predictive insights and supporting collaborative decision-making across project participants.

Another promising area of integration is quality assurance and compliance monitoring. AI-based computer vision and sensor analytics can detect material defects and monitor construction processes in real time, while blockchain can maintain immutable records of inspection results and quality certifications for audit and dispute resolution. Despite this potential, existing research largely examines AI and blockchain separately, leaving limited exploration of integrated AI–blockchain frameworks for construction supply chains.

3 Methodology

This study adopts a bibliometric and thematic review approach to analyse the development of research on Artificial Intelligence (AI) and blockchain in construction supply chains. Relevant literature was identified through systematic searches in major academic databases, including Web of Science, Scopus, and Google Scholar, focusing on peer-reviewed publications published between 2010 and 2025. Keywords related to artificial intelligence, blockchain, construction and supply chain were used to retrieve relevant studies.

The inclusion criteria were articles published in peer-reviewed journals; studies focusing on Artificial Intelligence (AI) and blockchain applications within construction supply chains; and papers discussing technological applications or implications related to supply chain efficiency, transparency, automation, or management. The exclusion criteria were articles not published in English; studies not directly related to

construction supply chains; and papers without substantive discussion of AI or blockchain in the construction context. Following the initial search, duplicate and irrelevant records were removed through a screening process based on title, abstract, and relevance to the study scope A total of 412 records were initially identified through database searches in Google Scholar, PubMed, and Web of Science. After removing duplicates, 368 records remained and were screened based on their titles and abstracts.

Following this screening process, 283 records were excluded due to lack of relevance, leaving 85 full-text articles assessed for eligibility. Of these, 46 articles were excluded based on the predefined exclusion criteria, resulting in 39 studies being included in the final bibliometric analysis. The final dataset was analysed using bibliometric mapping techniques with VOS viewer to identify publication trends, keyword co-occurrence networks, and thematic clusters within the literature. These bibliometric insights were complemented by a narrative synthesis of selected studies to interpret emerging research themes, technological applications, and reported challenges associated with AI and blockchain adoption in construction supply chains. This approach enables the study to systematically map the knowledge structure, research trends, and thematic evolution of AI and blockchain applications in construction supply chain research.

3.1 Quantitative analysis

The quantitative analysis examines case studies of construction projects implementing AI and blockchain technologies, focusing on metrics such as project delivery times, cost reductions, and supply chain efficiency to identify the tangible benefits of these digital tools in construction supply chain management. Evidence from the literature suggests that AI-enabled predictive analytics and blockchain-based platforms can enhance decision-making, coordination, and resource allocation across project supply chains. For instance, the case study by Elghaish et al. (2023), which analysed projects using AI-driven predictive analytics for resource planning, reported a 20% reduction in project delivery times and a 15% decrease in material waste compared with projects that did not implement AI. These improvements were attributed to AI's ability to accurately forecast resource requirements and enable just-in-time delivery of materials and equipment, thereby reducing inventory costs and minimising idle time on-site.

Similar benefits of AI-enabled predictive analytics in construction have been highlighted in broader studies on AI adoption in construction management, which report improvements in productivity, scheduling accuracy, and resource planning efficiency (Abioye et al., 2021). In addition, blockchain-based supply chain systems have been shown to improve transparency and coordination among project stakeholders, contributing to more efficient supply chain operations (Perera et al., 2021). However, empirical studies providing detailed quantitative performance metrics for integrated AI and blockchain applications in construction supply chains remain limited. Therefore, the reported figures should be interpreted as illustrative evidence rather than universally generalisable outcomes, highlighting the need for further empirical case studies and industry validation.

3.2 Qualitative analysis

The qualitative analysis is conducted using a desktop-based approach. This approach utilises insights from existing literature, case studies and industry reports rather than primary data collection through interviews and surveys. This approach allows for a comprehensive examination of the documented experiences, perspectives, and challenges associated with adopting AI and blockchain technologies in construction supply chain.

The qualitative analysis focuses on synthesising findings from multiple sources to understand the real-world applications and perceived barriers to implementing AI and blockchain in construction. Studies indicate that traditional practices and a lack of digital expertise among construction professionals contribute to a cautious approach toward technological transformation. This study thus contextualises AI and blockchain adoption within the construction industry, synthesising existing research to conclude how these technologies can address operational inefficiencies while acknowledging barriers to their widespread adoption.

4 Analysis of Network Visualisations

The two VOSviewer network visualisations provided are bibliometric analyses based on research related to AI, blockchain and construction supply chains. Both maps, created at different resolution levels, offer insights into the dominant themes, clusters, and connections within the literature "Influences of AI and Blockchain Technology on the Construction Supply Chain". The first map, with a resolution of 1.00, presents a broad view of relationships across various keywords. In contrast, at a reduced resolution of 0.80, the second map focuses on fewer but more robust connections, highlighting the core themes and indicating critical gaps in the literature.

4.1 VOSviewer First Mapping

Figure 1. offers visualization of five primary clusters, each represented by a different colour, indicating major thematic areas and subfields within literature.

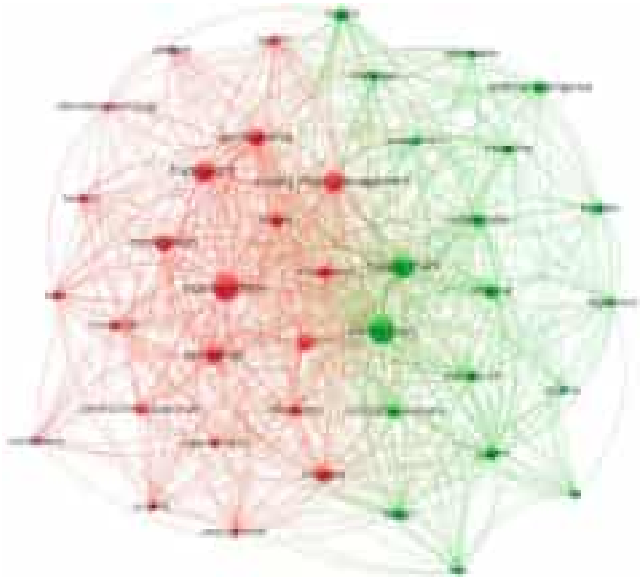

Figure 1. VOSviewer Network Visualisations at Resolution 1.00

4.1.1 Clusters and Key Themes

Red Cluster (Blockchain and Supply Chain): The red cluster centres on "blockchain" and "supply chain," suggesting that blockchain's applications within supply chain management are a focal point in the literature. This cluster includes terms like "big data," "IoT" (Internet of Things), "digital twin," and "Industry 4.0," highlighting that blockchain is often discussed in the context of digital transformation technologies that enhance supply chain transparency, traceability, and data security. The term "sustainability" in this cluster emphasises blockchain's potential to support sustainable supply chains, which is particularly relevant in construction, where resource management and waste reduction are critical concerns.

Green Cluster (Management and Technology Implementation): This cluster is anchored by terms such as "management," "innovation," "trust," and "coordination," with a focus on the operational and practical aspects of adopting AI and blockchain in construction. The frequent connection to the "construction supply chain" reflects an interest in how these technologies affect management processes, particularly in coordinating complex projects with multiple stakeholders. This cluster underscores the literature covering technical and human factors, like stakeholder trust and collaboration, necessary for successful implementation.

Blue Cluster (Construction and Integration): The blue cluster contains terms such as "integration," "construction," "information," and "supply chain management," suggesting a focus on incorporating digital technologies, like AI and blockchain, into existing construction processes. The term "integration" is particularly prominent, implying that researchers are examining the difficulties and strategies of embedding new technologies in traditional, often fragmented, construction supply chains.

Yellow Cluster (AI and Optimisation): This cluster is built around "artificial intelligence," "optimisation," "performance," and "model." It highlights the literature's interest in AI's ability to optimise performance and efficiency within construction supply chains. AI is commonly discussed in terms of predictive analytics and resource allocation, which are vital for minimising project delays and enhancing productivity in construction.

Purple Cluster (Adoption and Information Technology): The purple cluster includes terms such as "adoption," "information technology," and "barriers," reflecting an emphasis on understanding the obstacles to implementing AI and blockchain. The presence of terms like "information technology" and "barriers" indicates that technological and infrastructural limitations are primary concerns in the literature.

4.1.2 Central Nodes and Connections

Key terms such as "blockchain," "supply chain," "management," and "artificial intelligence" appear as central nodes with dense interconnections. "Blockchain" and "supply chain" are heavily connected, suggesting blockchain's potential to enhance supply chain management is a central theme. "Management" also shows high connectivity, indicating that operational and managerial aspects are widely explored within the context of technology adoption in construction. Additionally, "artificial intelligence" is well-connected, especially with "optimisation" and "performance," showing its application in improving efficiency within construction processes.

4.1.3 Overall insight

Dominant Research Themes: The VOSviewer network visualisation highlights distinct clusters representing dominant research themes in AI, blockchain, and construction supply chains. In the first mapping, the red cluster centred on blockchain and supply chain forms one of the most densely connected areas, with strong linkages to IoT, big data, digital twin, and Industry 4.0. This indicates that blockchain research in construction is largely framed within broader digital transformation efforts to improve transparency, traceability, and data security across supply chains. In contrast, the yellow cluster centred on artificial intelligence connects strongly with optimisation, performance, and model, reflecting AI's focus on predictive analytics and operational efficiency in construction projects.

The presence of these clearly defined thematic clusters suggests that the literature has developed around specific technological capabilities rather than integrated digital supply chain systems, indicating that research on AI and blockchain remains largely compartmentalised.

Fragmented Integration Between Technologies: Although both technologies appear as central nodes in the network, the visualisation shows relatively limited direct linkages between AI-related keywords and blockchain-related keywords. Instead, AI terms are primarily connected to optimisation and performance-oriented research, while blockchain terms are strongly associated with supply chain transparency and traceability. This structural separation suggests that the two technologies are frequently studied as independent technological solutions rather than as integrated systems within construction supply chains. The limited co-occurrence of keywords such as integration, framework, or combined systems further supports this interpretation. Consequently, the bibliometric structure indicates that while both technologies are recognised as important digital innovations in construction, research exploring their combined application remains relatively underdeveloped, highlighting a gap in integrated AI–blockchain supply chain studies.

Practical Implementation and Adoption Challenges: The network visualisation also reveals clusters related to management, coordination, trust, and barriers, particularly within the green and purple clusters. While these terms indicate that the literature acknowledges organisational and technological challenges associated with adopting AI and blockchain, their relatively weaker connections compared to core technological terms suggest that practical implementation issues receive less attention than conceptual technological benefits. In addition, keywords associated with empirical application such appear less central within the network. This pattern indicates that although the theoretical potential of AI and blockchain in construction supply chains is widely discussed, empirical studies demonstrating real-world implementation remain limited. The visualisation therefore supports the conclusion that future research should place greater emphasis on implementation frameworks, case-based evidence, and practical strategies for integrating AI and blockchain technologies within construction supply chains.

4.2 VOSviewer Second Mapping

Figure 2. offers the second VOSviewer map, with a reduced resolution removes weaker links and secondary themes, providing a distilled view of the literature's core focus areas. The clustering has been consolidated, highlighting fewer but stronger relationships between keywords and reinforcing the most central themes in AI and blockchain research related to construction.

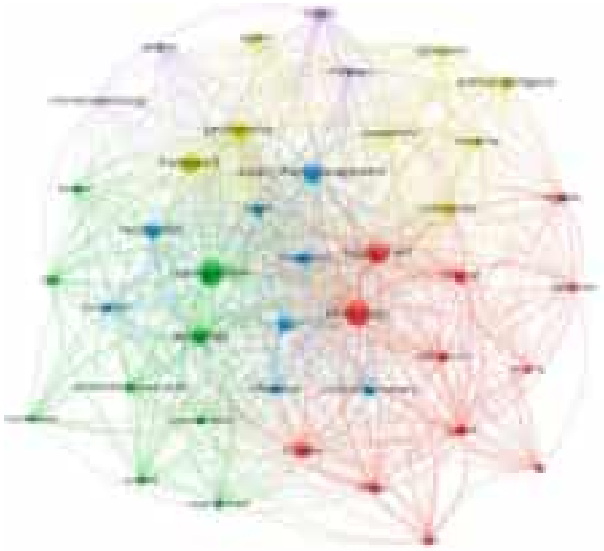

Figure 2. VOSviewer Network Visualisations at Resolution 0.8

4.2.1 Clusters and Key Themes

Red Cluster (Management, Technology, and Performance): This cluster consolidates terms around "management," "technology," "framework," and "performance." The intense focus on management and technological frameworks indicates that much research concentrates on understanding AI and blockchain's organisational impacts. This consolidation reveals that while managerial aspects are well-studied, the interaction between blockchain, AI and specific construction management practices is less pronounced.

Green Cluster (Blockchain, Supply Chain, and AI): The green cluster centres around "blockchain," "supply chain," and "artificial intelligence." AI and blockchain are closely connected in this reduced resolution map, suggesting that the literature identifies these technologies as complementary tools for optimising supply chain management. However, terms like "integration" and "implementation" are less prominent in this simplified view, pointing to a possible gap in research focused on applying these technologies in real-world construction.

Consolidation of Key Nodes The reduced resolution places even greater emphasis on "blockchain," "supply chain," and "management" as central nodes, suggesting that these are the predominant themes driving research. Blockchain’s link to the "supply chain" remains strong, reinforcing its role in enhancing transparency and trust in construction projects. The increased emphasis on these connections also suggests that, at a fundamental level, the literature is more focused on broad themes of blockchain's role in supply chain improvement and AI’s optimisation potential than on specific case applications in construction.

4.2.2 Overall insight

Research Themes and Structural Patterns: The VOSviewer keyword network reveals several prominent thematic clusters centred on blockchain, artificial intelligence, and construction supply chain management. In the higher-resolution map (1.00), strong linkages are observed between blockchain and terms such as supply chain, IoT, and digital twin, indicating that blockchain research in construction is primarily associated with improving transparency, traceability, and data sharing across project stakeholders. In contrast, AI-related terms cluster around optimisation, performance, and resource allocation, suggesting that AI research is mainly directed toward predictive analytics and operational efficiency. The separation of these clusters indicates that the literature tends to examine AI and blockchain as distinct technological approaches rather than as components of an integrated digital supply chain system. This structural pattern suggests that although both technologies are widely recognised as key enablers of digital transformation in construction, their combined application within construction supply chains remains relatively underexplored in existing research.

Barriers and Adoption Challenges: The comparison between the two visualisations also highlights differences in the prominence of adoption-related terms. In the higher-resolution map, keywords such as trust, coordination, and barriers appear more clearly connected to the broader network, indicating that the literature acknowledges organisational and technological challenges associated with adopting AI and blockchain in construction supply chains. However, in the lower-resolution map (0.80), these terms become less visible and exhibit weaker connections within the network. This pattern suggests that while barriers to adoption are recognised within the literature, they may receive less sustained analytical attention compared with themes related to technological capabilities or optimisation benefits. As a result, the bibliometric structure indicates that research has focused more heavily on conceptual technological potential than on systematically addressing the organisational, regulatory, and operational challenges associated with implementation.

Gap in Practical Integration and Implementation: Another notable observation from the network visualisations is the limited prominence of terms directly associated with integration and real-world implementation, such as implementation, framework, or deployment. These keywords appear with relatively lower occurrence frequencies and weaker link strengths compared with dominant technological terms such as blockchain, AI, and supply chain. This structural pattern indicates that much of the existing literature focuses on conceptual discussions of technological capabilities rather than empirical demonstrations of how these technologies can be integrated into operational construction supply chains. Consequently, the visualisation suggests that while the theoretical benefits of AI-driven optimisation and blockchain-enabled transparency are well established, practical frameworks for implementing these technologies together within construction supply chains remain limited. This gap highlights an important opportunity for future research to explore integrated implementation strategies and case-based evidence supporting AI–blockchain adoption in construction practice.

5 Emerging Themes

The following section analyses key trends and themes emerging from the bibliometric analysis.

5.1 Transparency and Traceability

Blockchain technology's primary advantage in construction supply chains is its unparalleled transparency and traceability. It records every transaction in an immutable, tamper-proof ledger, ensuring that all project activities, from procurement to delivery and payment, are documented precisely. This transparency can significantly reduce risks in construction, where delays, miscommunication, and disputes are common.

As mentioned previously, blockchain can be used to track the origin of materials, ensuring compliance with environmental regulations and certifications such as LEED. Wang et al. (2020) demonstrated how blockchain could track precast components, from manufacturing to installation, providing real-time visibility into their status and ensuring that all quality standards were met. This level of traceability is critical for large-scale construction projects where multiple suppliers are involved and materials are sourced from different regions.

Additionally, blockchain's transparency helps build trust among stakeholders. When all parties in a construction project have access to the same verified information, disputes over deliveries, payments, and project milestones are less likely to occur. Smart contracts further enhance this by automating payments when specific conditions, material delivery or project completion, are met Yoon et al. (2022). This drastically reduce delays caused by payment disputes, improve cash flow, and ensure projects remain on schedule.

5.2 Automation and Efficiency

AI has the potential to automate many repetitive and time-consuming tasks in construction supply chains, including scheduling, resource allocation, and material procurement. By leveraging machine learning algorithms, AI can analyse historical and real-time project data to predict future trends and optimise supply chain decisions.

One area where AI has demonstrated significant potential is project scheduling, where AI-powered project management tools can analyse project scope, timelines, and resource availability to generate optimised schedules that minimise delays and improve overall efficiency. Similarly, AI can support procurement by predicting material needs based on project progress, enabling timely ordering while reducing excess inventory and costs.

When integrated with blockchain, these AI-driven capabilities can be further enhanced through secure data sharing and automated transaction execution. For example, AI-generated predictions such as forecasts of material demand or schedule adjustments can be recorded on blockchain-based distributed ledgers, ensuring transparency, traceability, and data integrity across project stakeholders. In addition, smart contracts can interface with machine learning outputs to automatically trigger procurement orders, verify supplier deliveries, or release payments once predefined project milestones are achieved. This integration enables more reliable information exchange, reduces manual intervention in supply chain processes, and improves overall operational efficiency in project delivery.

5.3 Stakeholder Engagement

The construction industry is known for its fragmentation, with multiple stakeholders, including contractors, subcontractors, suppliers and clients, often working in silos. This lack of collaboration can lead to miscommunication, delays, and cost overruns. Blockchain and AI technologies can help address these challenges by fostering greater cooperation and ensuring all stakeholders access the same information.

Blockchain's decentralised ledger provides a single source of truth for all project stakeholders, ensuring that everyone is working from the same set of verified data. This transparency reduces the likelihood of disputes over project milestones, material deliveries, and payments, as all parties can access a consistent and trustworthy record of transactions. By enabling real-time data sharing, blockchain enhances collaboration among stakeholders, helping to minimise delays and miscommunication that can arise from discrepancies or incomplete information Wang et al. (2020), Elghaish et al. (2023).

AI can also improve collaboration by providing real-time insights into project progress and potential risks. AI can also analyse data from previous projects to identify patterns and suggest best practices for future projects, helping stakeholders make more informed decisions Hamledari et al. (2021).

5.4 Smart Contracts

Another significant theme in the literature is the use of smart contracts to automate processes in the construction supply chain. Smart contracts are self-executing contracts where the terms of the agreement are written directly into code. Once certain conditions are met, such as the completion of a project milestone, the smart contract automatically executes, triggering payments Yoon et al. (2022). In construction, smart contracts can use intelligence to streamline procurement processes, ensuring that payments are released as soon as materials are delivered and verified. This reduces the need for manual interventions and helps ensure that suppliers are paid on time, improving cash flow and reducing delays caused bypayment disputes Wang et al. (2020). Smart contracts can also automate compliance checks, ensuring all project requirements are met before payments are released Elghaish et al. (2023).

6 Discussion

While the potential benefits of AI and blockchain in construction supply chains are well-documented, several barriers exist to their widespread adoption such as high implementation costs, regulatory challenges, and resistance to change.

6.1 High Implementation Costs

One of the main barriers to adopting AI and blockchain in construction is high cost of implementation. Both technologies require significant upfront investments in hardware, software and training costs can be prohibitive if the return on investment (ROI) is not immediately apparent Yoon et al. (2022). However, long-term benefits of AI and blockchain such as improved efficiency, reduced delays and enhanced transparency can offset initial costs. For example, blockchain can help construction firms save time and money by automating procurement processes and reducing likelihood of payment disputes. Similarly, AI's ability to predict risks and optimise resource allocation can lead to significant cost savings by preventing delays and material waste Elghaish et al. (2023).

6.2 Regulatory Challenges

Another significant barrier to the adoption of blockchain in construction is the need for clear regulations surrounding the use of smart contracts. While intelligent contracts offer numerous advantages—such as automating payments and compliance checks—the legal framework for their use in construction is still underdeveloped. For example, there are questions about the enforceability of smart contracts in different jurisdictions, particularly when resolving disputes Yoon et al. (2022). Blockchain’s decentralised nature raises concerns about data privacy and security. Construction firms must comply with regulations such as the General

Data Protection Regulation (GDPR) when using blockchain to store and share data. Failure to comply can result in significant penalties, making it essential for firms to work closely with legal experts to ensure their use of blockchain is compliant Elghaish et al. (2023).

6.3 Resistance to Change

The construction industry traditionally needs to adopt new technologies faster, but management and workers often resist change. Many construction firms are risk-averse, preferring to stick with traditional methods rather than invest in new technologies that they perceive as unproven. There is also a fear that adopting AI and blockchain could lead to job losses, particularly among administrative and clerical staff whose roles could be automated Hamledari et al. (2021). To overcome this resistance, construction firms must demonstrate the tangible benefits of AI and blockchain. By providing training and education programs, firms can help workers understand how these technologies can improve rather than replace their jobs. By automating administrative tasks, AI and blockchain can free workers to focus on more value-added activities Elghaish et al. (2023).

7 Conclusion

Integrating artificial intelligence and blockchain technology into construction supply chains holds enormous potential to revolutionise the industry. These technologies offer solutions to many challenges that have plagued the construction sector. AI's predictive capabilities enable construction firms to optimise project planning, resource allocation, and risk management, while blockchain ensures transparency, traceability, and security across the supply chain. However, despite the apparent benefits, significant barriers exist to the widespread adoption of AI and blockchain in construction. These include high implementation costs, regulatory challenges, and resistance to change. Overcoming these barriers will require a concerted effort from industry stakeholders and a deeper understanding of integrating these technologies into existing supply chain management practices. Future research should focus on real-world case studies that demonstrate practical implementation of AI and blockchain in construction. These studies would help build confidence in these technologies and encourage broader adoption across the industry. Additionally, research should explore how AI and blockchain can be integrated with other emerging technologies, such as the Internet of Things (IoT) and Building Information Modelling (BIM) to create fully digitalised and interconnected construction supply chains. Finally, construction firms must work closely with regulators to ensure blockchain and smart contracts are legally enforceable and compliant with data protection laws. By addressing these challenges, construction industry can fully leverage the benefits of AI and blockchain to create more efficient, transparent and collaborative supply chains.

Abstract –

Factories are a key part of industrial value creation and have a significant impact on the environment throughout the entire supply and production chain. Therefore, a sustainability assessment of both the building and the production system requires a holistic, interdisciplinary perspective on the factory system, which cannot be achieved using conventional methods employed for other building types. This study therefore addresses a research gap concerning the automated integration of Building Information Modeling (BIM) and Life Cycle Assessment (LCA) in the context of factory planning. The objective is to address the key challenge of linking multiple data sources for the very different interdisciplinary requirements. Hence, based on literature current approaches for both building LCA and factory planning processes are analyzed, and a factory-specific openBIM workflow for ecological assessment is proposed and implemented using Desite md. To meet the requirements of the various disciplines involved in the factory planning project, the workflow considers processes at both the disciplinary and coordination levels. To integrate the databases containing the energy demand and LCA profiles of the machinery and building materials used, the implemented approach connects individual production system databases, as well as building-specific databases such as the German ÖKOBAUDAT. The findings demonstrate the current potential and challenges of applying the workflow in Desite md, revealing practical insights for assessing the ecological sustainability of factory buildings. Ultimately, this supports factory operators in making more sustainable decisions during the design phase, leading to significantly more sustainable building operations.

Keywords –

Building Information Modeling (BIM), Life Cycle Assessment (LCA), sustainability, openBIM

1 Introduction

The environmental sustainability of industrial value chains is gaining relevance in light of advancing climate change, stricter legal frameworks and growing social expectations [1–3]. In the context of factory planning in particular, there is considerable potential to reduce environmental impacts across all life cycle phases [4]. In practice, Life Cycle Assessments (LCA) of factories, including the building, technical building systems (TBS) and production equipment, are challenging due to the extensive effort required to capture all environmentally relevant factors and their interactions over the entire life cycle [5]. In contrast to the planning of conventional buildings, factory planning requires a multidimensional approach that takes into account not only the building and TBS, but also production processes [6]. Another significant difficulty stems from the substantial amount of data generated by the project's interdisciplinary nature and the requirement for consistent documentation and traceability of results within such a complex system as a factory [7]. Building Information Modelling (BIM) offers the possibility of capturing, linking and systematically evaluating information across domains [8]. This raises the central research question of how a BIM-based approach to the ecological sustainability assessment of factories is designed so that it serves as a basis for sustainable decisions throughout the entire life cycle of the factory. Although various ecological assessment approaches exist [9, 10], they primarily address conventional buildings. Existing methods for production facilities consider only the production system and are not yet fully digitally integrated [11, 12]. Consequently, this study aims to develop a holistic, BIM-supported methodology for life cycle–based ecological sustainability assessment of factory planning projects.

2 Background and related works

2.1 BIM-based LCA

Several approaches to integrating BIM and LCA already exist for building construction and infrastructure projects. The predominant classification of these approaches was defined by WASTIELS AND DECUYPERE, who identified five overarching strategies for integrating BIM and LCA. The first strategy involves the manual export of the bill of quantities to a spreadsheet, wherein the LCA is calculated either directly or in a LCA software. Materials and quantities are manually linked to corresponding LCA profiles, representing the current state of practice [13]. The second strategy adopts an openBIM approach by exporting an Industry Foundation Classes (IFC) file to LCA software, transferring geometry, material names, and Global Unique Identifiers, after which materials are manually associated with LCA profiles. The third strategy, also based on openBIM, introduces an intermediate BIM viewer to link materials to LCA profiles, prior to performing the assessment in a LCA software. The fourth strategy employs a closed BIM approach, in which a plug-in within the native BIM authoring environment links BIM objects to LCA databases and visualizes results directly in the 3D model. Finally, the fifth strategy entails the direct allocation of LCA data to BIM objects, facilitated by either database identifiers or explicit indicator values. This approach finds application in both openBIM and closedBIM workflows, employing either plug-ins or IFC-based LCA software [14]. There is an absence of research approaches integrating BIM-LCA in factory planning, which is necessary because current approaches do not allow for an integration of the production system and are not addressing key requirements of factory planning. The key requirements of this use case are outlined in the subsequent subchapter.

2.2 Requirements for a BIM-based LCA workflow for factories

Factory planning is highly interdisciplinary and presents specific requirements for integrating BIM and LCA. In factory planning projects, up to 100 different disciplines may be involved. These disciplines can be divided primarily into the domain of factory planning (e.g. layout or logistics) as well as the domain of object planning (e.g. architecture, TBS). Their collaboration requires an error-free exchange of large and heterogeneous data sets [15–17]. This heterogeneity is mainly caused by discipline-specific data formats, software applications and modeling logics [16, 17]. In addition, several of these disciplines are required to collaborate within a shared or coordinated model environment rather than exchanging data sequentially, in order to enable a holistic sustainability assessment across building-related and process-related elements. Consequently, technical interoperability constitutes a central requirement for a BIM–LCA workflow. Standardized data exchange via open formats, such as IFC, is required for enabling an interdisciplinary flow of information.

In addition to technical interoperability, a suitable workflow must consider the existing IT systems of the parties involved in the planning process. Especially in small and medium-sized enterprises (SMEs), IT infrastructures are often centralised, inflexible, and modernised only incrementally [18, 19]. This is largely due to high software and implementation costs [20, 21]. This challenge intensifies in factory planning because individual planning tasks are often outsourced to external offices while the manufacturing company retains overall coordination [22]. Therefore, a BIM–LCA workflow must integrate with existing software portfolios and operate without fundamentally restructuring the IT landscape to be practical, particularly for SMEs.

Another key requirement is the integration of LCA datasets for factory-specific objects. While standardized and high-quality environmental product declaration (EPD) databases such as ÖKOBAUDAT are already available for the building perspective [23], data availability for the process perspective is highly individualized. Factories differ from other types of buildings, especially due to the integration of production equipment and associated media supply systems. These systems significantly contribute to the overall environmental impact [24, 25]. Accordingly, a suitable BIM–LCA workflow must support the simultaneous integration of multiple and heterogeneous LCA data sources to ensure that all relevant factory elements can be assigned appropriate environmental profiles. This includes the combination of standardized databases for building-related components with non-standardized, manufacturer- or project-specific datasets for production-related elements. Hence, the integration of factory-specific LCA data cannot rely on a single database but requires a flexible data integration concept that accommodates diverse data structures and levels of detail.

Finally, the project-based nature of factory planning requires flexibility in influencing the underlying calculation principles of the LCA. Each factory represents an individual planning project [26], meaning system boundaries, input-output flows, service lives of individual factory elements, and the temporal scope of the assessment must be defined on a project-specific basis [25, 27, 28]. Therefore, a BIM–LCA workflow must allow for the adaptation of the calculation logic and must not rely exclusively on proprietary default assumptions of LCA software, as this could otherwise lead to simplified or non-representative results [29].

In conclusion, the existing strategies are only suitable for implementation in factory planning to a limited extent. Consequently, to address the factory-specific requirements, a new workflow for BIM-based LCA for factory buildings is proposed in the following section.

3 OpenBIM Workflow for the LCA of a Factory

This workflow builds on the fundamental elements of BIM-LCA strategies that have been established in the construction sector but extends them to meet the requirements of factory planning, so that a holistic LCA of a factory can be performed during the various stages of the planning phase. This ultimately results in enhanced decision-making processes with regard to sustainability, thereby optimizing the entire life cycle of a factory.

3.1 Sustainability assessment

Prior to the development of the workflow, it is necessary to outline the general conditions for the environmental sustainability assessment of a factory, which include the considered life cycle phases and ecological indicators.

This workflow considers the whole life cycle of the factory and is based on the life cycle modules used in the construction industry, that are defined in EN 15978 [30]. Based on this standard the following life cycle modules are included: the production stage (A1–A3) covering raw material extraction, transport, and manufacturing; the construction process stage (A4–A5) addressing transport to site and construction activities; the use stage (B1–B7) comprising operation, maintenance, replacement, and operational energy and water use; and the end-of-life stage (C1–C4) including deconstruction, waste processing, and disposal [30].

The ecological impact of a factory system can be measured using various midpoint indicators, as in a typical LCA. This workflow emphasizes the most critical indicators for factories but can be expanded to include more. An analysis of German certification systems like German Sustainable Building Council [31] and Assessment System for Sustainable Building [32], as well as research approaches from Gebler [33] reveals that the environmental indicators global warming potential (GWP), ozone depletion potential (ODP), acidification potential (AP), eutrophication potential (EP), ozone creation potential (POCP), renewable primary energy demand (PERT), and non-renewable primary energy demand (PENRT) are classified as relevant or necessary across all approaches considered. Therefore, it can be concluded that these indicators can act as a basis for ecological assessment in the context of factory planning.

Furthermore, the selected indicators are suitable for incorporation into a BIM-LCA because they can be accessed in standardized life cycle assessment databases, such as ÖKOBAUDAT [34, 35].

3.2 Interoperability and openBIM

In order to meet the requirement of open data exchange and thus facilitate a comprehensive evaluation of the coordination model, the openBIM approach is employed. This approach ensures interdisciplinary information exchange via standardized data formats, particularly IFC [36]. While WASTIELS AND DECUYPERE identify three openBIM strategies, this workflow integrates the fifth strategy, which involves the semantic enrichment of BIM objects and their export to IFC, with the third strategy, which incorporates a BIM viewer. While many LCA software applications support importing IFC files, several studies demonstrate that differences in data structures between BIM and LCA systems often result in inefficient data exchange or lead to functional limitations [18–20]. Hence, utilizing a BIM viewer as a substitute and implementing the LCA calculation there can result in enhanced interoperability and minimal disruption to the BIM-based planning workflow. Additionally, implementing a BIM viewer fulfils the requirement for seamless integration with existing software portfolios, since BIM viewers are widely used for BIM-based planning.

In this workflow the semantic enrichment entails the addition of unique identifiers (ID) of LCA datasets to BIM objects, as opposed to the assignment of indicator values. Specifically, this implies that the materials contained in the respective discipline models are assigned corresponding IDs from environmental databases, for example the Universally Unique Identifier (UUID) in the ÖKOBAUDAT. This method reduces the impact on the quantity of data contained within the BIM model since fewer attributes need to be assigned.

Due to the large number of disciplines involved in factory planning projects, this workflow suggests a mapping process in which planners add the IDs to their discipline models in their authoring tools. Once this assignment has been done manually, the corresponding LCA indicator values can be automatically linked to the individual components in the model. A key advantage of this process is that the challenge of assigning the right data set is already solved at the level of the individual discipline models. The early and automated assignment of LCA IDs within the respective BIM objects ensures the consistency of the environmental data basis before the discipline models are merged into an overall coordination model. This is especially true in the context where the disciplines of factory and object planning interact, and a lack of expertise exists among sustainability experts to map the LCA data sets for both domains. Furthermore, as the transition to standardized, semantically enriched

object libraries in BIM authoring tools continues, this effort can be minimized in the future [37].

3.3 Integration of multiple databases

Due to the different planning domains described in section 2.2, the integration of various databases is required. The following section explains which databases are considered in this workflow.

This workflow focusses on the database ÖKOBAUDAT as an environmental database for the domain of building and technical building systems. The ÖKOBAUDAT is the official database for German sustainability certification systems and comprises over 2,100 data sets that have been specially prepared for construction products [35, 38]. As a material-based database, the ÖKOBAUDAT provides specific environmental factors for individual materials, allowing for precise life cycle assessments based on material-specific data [39].

In contrast to the construction sector, there are no established environmental databases for production equipment in the factory planning domain. Therefore, manufacturer-specific EPDs are critical for ensuring consistent and robust LCAs in factory contexts. Instead of a standardized database, company-specific databases or Excel spreadsheets are used to assess the necessary data for evaluating the production system. Enterprise resource planning (ERP) systems, such as SAP, can also provide important data on machines and their media usage [11]. An ERP system is a business management software solution that aims to automate and integrate a company's central business processes and link them via a company-wide database. It enables access to real-time information, avoids data redundancy and ensures data integrity by providing a single source of truth. [40] Manufacturing companies use ERP systems as central data repositories for managing project-related information. This system stores and provides structured access to general project information and environmental data, technical parameters, cost overviews, maintenance intervals and measures, as well as process management information [11]. These data are necessary for sustainability assessments. For this reason, integrating different databases and ERP systems is recommended for this workflow to meet the aforementioned requirement of integrating databases from both planning domains. Although the implementation described below primarily uses CSV files, a direct connection via Application Programming Interfaces (API) is planned for future work to ensure accuracy.

3.4 Integration in planning process

Having described the theoretical basis of the key elements of the workflow in previous sections, this section summarizes the complete workflow and its integration into the planning process. The foundation of this workflow is based on existing standards and guidelines.

In accordance with the guideline of the Association of German Engineers [41], planners assign the ID parameter to match the LCA data sets of their BIM objects, as explained in chapter 3.2. After enriching the model, planners are responsible for conducting plausibility and validation checks to ensure that all BIM objects are assigned the correct LCA datasets. This includes verifying the completeness and correctness of the required datasets. Subsequently, the BIM coordinators of each discipline upload the approved IFC files to the Common Data Environment (CDE) [41]. The overall BIM coordinator is responsible for merging the IFC files in a coordination software (e.g., Desite md) and performing the second validation step. This involves a rule-based model check within the coordination software that detects missing attributes, such as IDs, and documents them in the form of a report. These reports are serve as the foundation for the corrective measures by the involved planners. Subsequent to validation and quality testing, a holistic LCA calculation is performed based on the enriched coordination model by the LCA expert. Consequently, the overall coordination model is automatically linked to the databases via an API within the coordination software. Based on this, the rule-based LCA calculation is performed. Figure 1 provides a graphical summary of the workflow.

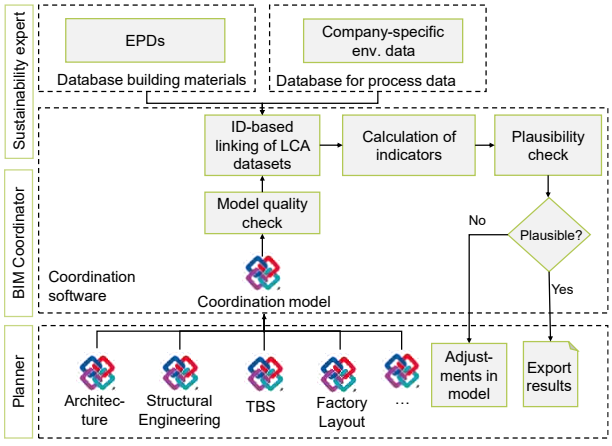

Figure 1 BIM-based factory sustainability assessment

3.5 Modelling requirements

For this workflow to be executed, it is essential that certain modeling requirements are met. First, the aforementioned ID is written as a shared parameter and, in the context of IFC data exchange, is assigned to a user-defined Pset, such as 'Pset_LCA'. It should also be noted that the UUIDs are version-dependent and that both the

UUID and the version number (e.g. as LCA_Version) must be stored in the model during the mapping process. In addition, the type and material information should be assigned for the purpose of simplifying the plausibility check later on.

While this procedure applies to all elements of the object planning domain, additional aspects must be considered for the technical building equipment. According to the findings of GENOVA [42], the technical elements can be divided into two main categories: technical routing and technical devices. The technical routing system covers all components such as pipes, air ducts, electrical cables, lighting systems and cable trays and their fittings. These are typically characterised by the fact that they are generated by extruding a cross-section along a line path. These elements are usually not represented in detail geometrically, while the information content is nevertheless retained in full. However, a technical deficit arises from the fact that, for example, authoring tools like Revit do not allow direct access to volumetric geometry data for these components. This makes it considerably more difficult to calculate material masses. A practical solution is to determine the area resulting from the thickness of the pipe and the circumference and multiply it by the length of the corresponding reference line. Based on this, mass values of the components can be calculated [42]. The second category, technical devices, includes all industrially manufactured products installed in a building whose dimensions and material composition are usually specified by the manufacturer per piece. The correct reference flow of the matched LCA data set should therefore be automatically read out so that no errors occur in the calculation and the correct unit is assigned.

In the scenario where SAP is used as the company-specific data repository and therefore needs to be integrated with BIM, the BIM objects, along with their properties such as dimensions and material definitions, are assigned to the corresponding SAP identifiers and attributes. This data mapping process between BIM and SAP is carried out using a classification system. The use of classification systems supports the assignment of BIM data to corresponding structures in the SAP system [43]. The classification system must be adapted for factory planning, as established classification systems are designed for building construction in accordance with the ISO 12006-2 standard [44]. For this purpose, it is recommended that the ECLASS classification system is used. ECLASS is an internationally recognized standard for the uniform description and structuring of products, machines, components and services [45, 46].

For a consistent BIM-SAP link, it is necessary to store the ECLASS codes as type parameters in the BIM model. This makes it possible to uniquely identify, for example all CNC milling machines in the model using an eight-digit code. When exporting to IFC, these parameters must be assigned in IfcClassificationReference [47]. The ECLASS codes and versions stored in the SAP system can be exported in the form of structured data records (e.g. as CSV or Excel files). These usually contain the material number, the equipment ID, a textual product description, the associated ECLASS code and the ECLASS version used. Integration with the BIM model is achieved by mapping the data exported from SAP to the model objects available in the authoring software.

4 Implementation

For the exemplary implementation of the calculation part of the workflow, Desite md and therein WebForms are used to demonstrate the automatic linking of LCA data sets and BIM objects based on their common ID for elements of the building as well as the production system.

For this purpose, two types of databases are integrated: the ÖKOBAUDAT and a spreadsheet-based database containing LCA data for production equipment, both provided in CSV format. The ÖKOBAUDAT is available as a CSV file on their website. [35] The second CSV acts as examples of ERP system exports or other company-specific data that could be queried via an API in the future. The CSV requirements and IFC export information can be found here [48].

The internal functioning of the WebForm is based on a multi-stage processing sequence. This sequence includes reading the CSV files, recognizing and aggregating the relevant data records, mapping them to the model objects, and assigning the sustainability indicators via the Desite md API. The logic is controlled entirely by JavaScript, while the user interface is implemented in HTML. Both components interact closely with each other via the Desite md API, so that all data is processed directly in the model. The script links the environmental indicators from the ÖKOBAUDAT with the corresponding component instances in the model in Desite md. This is based on reading the UUIDs from the ÖKOBAUDAT and the associated identification attributes in the model. The relevant field names for identification and assignment parameters can be defined by the user directly in the user interface. This allows the script to be flexibly adapted to different model structures, data exports and attribute names.

First, the UUID column is searched for the ID in the model and the indicator columns for example for GWP and PERT are identified. In the next step, the BIM objects are read into Desite md. Here, either all objects or only the currently selected elements can be processed, so only a selection of relevant objects can be evaluated as well. Objects without valid identification are given the status ‘no match’. If there is a valid match, the corresponding sustainability values are assigned to the BIM objects. The

process is the same for the production system, except a company-specific equipment ID is used to link the database.

During processing, a tabular overview of the processed objects is created. This overview contains not only object names and IDs, but also the mapping status and all transferred sustainability indicator values, their reference units, and the indicator totals. Since the reference unit of the LCA data set is identified automatically, the indicator total is calculated by automatically multiplying the indicator value by the correct unit of measurement. In addition, several key figures are calculated automatically. These include the total number of objects in the model, the number of objects with a valid UUID, the number of objects without a match, and the sum of the calculated GWP values, separated by buildings and production equipment, as well as the total. While there are 4,202 objects in the tested model, 14.8% of them are unmatched. This is because some of the objects, such as rooms or small parts of the façade, do not have a UUID. The result can be saved as a CSV file using the export function. The key figures are then written back to each BIM object as attributes and are therefore suitable as a basis for variant comparisons, optimization and heatmap visualizations.

To test and evaluate this WebForm, an example model containing objects of building construction and production equipment is used.

The result is an evaluation of the entire factory, including the building and the production equipment. For this evaluation, multiple databases are linked to the BIM model, allowing the results to be written back to the BIM objects.

4.1 Discussion

The results of this study are to be interpreted with consideration of the following limitations, which also represent potential for further research. First, there is currently insufficient availability of environmental datasets to consistently establish one-to-one links between BIM objects and LCA data using unique identifiers, such as UUIDs. Consequently, future work will require a mixed linking approach combining identifier-based assignment with direct assignment of LCA indicator values to BIM objects. Second, component service lives are not yet integrated into the assessment framework. As a result, the replacement of building elements and technical components over the life cycle is not yet accounted for. Addressing this limitation will require either an enrichment of the underlying databases with service life information or the introduction of classification-based matching using external databases for typical life spans of different construction and equipment types. Third, energy demand is considered exclusively at the level of production equipment. Energy consumption associated with technical building systems beyond machinery is not included, leading to an unrealistic representation of operational impacts. Nevertheless, this exemplary implementation indicates the potential and feasibility of the proposed workflow.

Despite existing limitations, the workflow fulfills the initially outlined requirements by enabling a holistic assessment of a factory, including the building and the production system. Additionally, the logic can be transferred and expanded to various factory elements. Overall, the proposed LCA data set matching workflow based on unique identifiers in the IFC model can significantly reduce the effort required for a factory sustainability assessment.

5 Conclusion

This work introduces a semi-automated openBIM workflow for the LCA of factories, integrating building construction and production systems within a digital process. By embedding LCA-relevant information directly into BIM objects through standardized identifiers, the workflow enables a consistent linkage between planning models and environmental datasets. The exemplary implementation using Desite md and WebForms illustrates the technical feasibility of identifier-based data linking for both building components and production equipment using a BIM viewer. However, the workflow must be tested on several different, more complex BIM models as a next step. Future work also requires incorporating component service life data into the employed databases and integrating technical building systems. Implementing these changes will improve the accuracy and comprehensiveness of the proposed workflow and build on the demonstrated potential and feasibility of this study.

Methods for finding photos of parts of buildings in virtual space

Ishida Kosei[1]

[1]Associate Professor, Department of Architecture, Faculty of Creative Science and Engineering, Waseda University, Doctor of Engineering
k_ishida@waseda.jp

Abstract

We created a support system for inspecting the exterior appearance by loading a three-dimensional photogrammetric model into a virtual space. This system shows a photograph of what the observer sees in virtual space.

To realize this system, we devised a method to represent buildings as voxels, check whether the voxels are reflected from shooting points in virtual space, and register shooting points as voxels. The system allows the viewer to scan the voxel in front of their line of sight in virtual space and then displays a photo of the shooting point registered to the voxel.

We created software that implements this mechanism and confirmed that the necessary photos can be obtained promptly.

Keywords –

Photogrammetry; 3D model; Voxel; Inspection; VR

1 Introduction

The technology for creating three-dimensional (3D) models based on photographs is used in various situations in Japan. Many people use 3D maps, such as Google Maps daily. Three-dimensional models created using photogrammetry are essential for building inspections and patrols. Research is also being conducted on the technology to perform inspections in a virtual space.

Inspection using photographs confirms the disaster situation. Research has been conducted to predict earthquake damage using images and photometry [1]. In addition, to reduce the environmental impact, there are methods for checking the status of heat loss using photographs and thermography [2][3]. We considered the digitalization of buildings by combining UAV, photogrammetry, and BIM [4]. Photogrammetry and deep learning have been used to detect cracks and perform exterior inspections of buildings [5]. Similarly, this method has been applied to the external inspection of bridge piers [6]. Photogrammetry has been used to survey the occupancy status of buildings [7]. Furthermore, some studies have been conducted on visual inspection of tunnels [8] and remote inspection of wind power generators [9]. Photogrammetry has also been used for inspecting dam bodies [10].

However, as the surface texture of 3D models created using photogrammetry is rough, referring to an original photograph is often desirable. Because photogrammetry uses various photographs, it is often difficult to identify a desired photograph. Therefore, we aimed to develop a technology that would allow us to smoothly obtain detailed photographs of parts of 3D models.

2 Methods for finding photos of parts of buildings in virtual space

2.1 Procedure to search for photos that depict parts of buildings in virtual space

We plan to create a system to search for photographs of 3D models of buildings prepared in virtual spaces. Because this 3D model was created using photogrammetry, an original photograph exists. We devised a method to search for photos of a specific part of a building's surface while observing the exterior of the building in a virtual space. A conceptual diagram of this concept is shown in Figure 1.

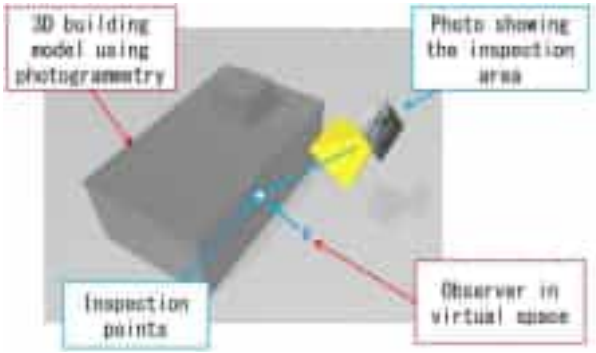

Fig 1 Conceptual diagram for finding a photo of a specific part of a building's surface in virtual space

The following procedure shows how to search for photographs depicting parts of buildings in a virtual space.

(1) Load the 3D model created using photogrammetry and photographic points.
(2) Replace the 3D model with voxels using photogrammetry
(3) Set up a camera at a shooting point in the virtual space and find all voxels within the range of the camera view.
(4) Record all shooting points on the voxel side.

2.2 Registration of shooting points to voxels indicating buildings

As described in Section 2.1, the buildings were made into voxels, and photographic points were registered for these voxels. When observing a structure in a virtual space and looking for a photograph of a part of a building, one can search based on the shooting points registered in the voxels.

Subsequently, we explain how to register shooting points for each voxel of this building.

This voxel registration method is straightforward: it reproduces the camera's shooting point and direction in the virtual space, captures a photo from the camera in the virtual space, and searches for voxels that can be observed from the camera. This approach is currently being implemented.

Figure 2 shows a photograph of the registered camera shooting points on the voxels of the building.

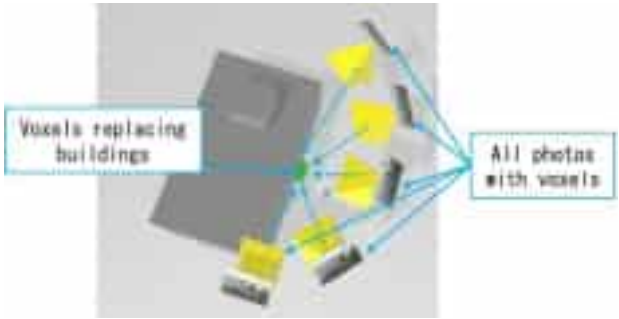

Fig 2 Image of registering camera shooting points to building voxels.

To register shooting points to voxels, the system reproduces the actual angle of view of each camera in the virtual space. We implemented a ray-casting approach where rays are emitted from the camera position with a sampling interval of 50 pixels in both horizontal and vertical directions across the image plane. This process identifies all visible voxels for each photograph and records the relationship in a pre-computed lookup table. By shifting the computational burden to this pre-processing stage, the system ensures high performance during real-time interaction.

2.3 Method for an observer in virtual space to search for photos of parts of a building

We explain how an observer can search for a photo that shows the observation point of a building in a virtual space using a 3D model in which photo points are registered in the voxels of the building.

When an observer in a virtual space observes a part of a building, the ray is irradiated in the direction of the center of their line of sight. Next, a list of photograph shooting points associated with the voxel hit by the ray is obtained. This list of photo points shows the parts of the building being observed so that one can efficiently search for photos used during photogrammetry.

Figure 3 shows how to search for the original photo when observing a building in a virtual space.

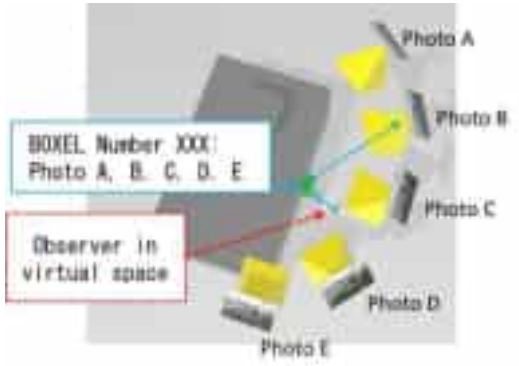

Fig 3 Searching for the original photo when observing a building in a virtual space.

3 Development of the finding system for photos of parts of buildings in virtual space

3.1 Creating a 3D model using photogrammetry

We create a system to search for photos in a virtual space, as described in Section 2. To achieve this, we created a 3D model using photogrammetry. The photograph used is shown in Figure 4. We cut the aerial videos captured using a drone into 960 still photographs.

Figure 5 shows the 3D model created using this photograph. Bentley context-capture photogrammetry software was used.

Fig 4 Examples of photos used to create 3D models

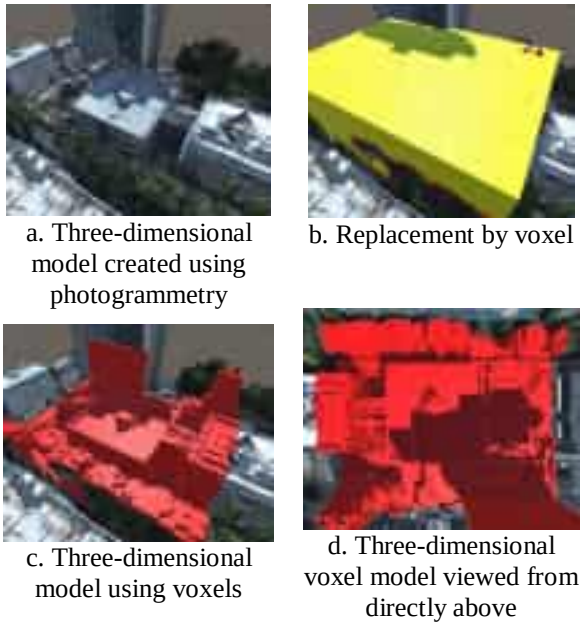

Fig 5 Three-dimensional model created using photogrammetry.

3.2 Replace the 3D model by photogrammetry with voxels

Subsequently, the 3D model created using photogrammetry was replaced with voxels. Using voxels with a side length of 1 m, the shape of the building and its surroundings was reproduced. We created a 3D model using voxels by the following steps:

(1) Place a 1 m-sized cube (voxel) at the location where the 3D model created using photogrammetry exists.
(2) If the 3D model and 1 m size voxel overlap, place the voxel.

Figure 6 illustrates the procedure used to replace the voxels. The system placed 1 m-sized cubes without gaps, as shown in Figure 6b, in a space containing the 3D model shown in Figure 6a. The yellow cubes represent space, and the red cubes represent voxels placed in the 3D model. Figures 6c and d show the results of replacing the 3D model with voxels.

b. Replacement by voxel

c. Three-dimensional model using voxels

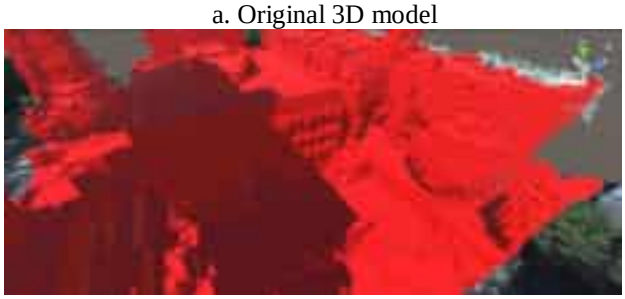
d. Three-dimensional voxel model viewed from directly above

Fig 6 Results of replacing a 3D model of a building created using photogrammetry with voxels

3.3 Set up a camera at a shooting point in virtual space and find all voxels within the range that the camera can see

Next, our system searches for voxels of buildings that are visible from the point where the photo was captured. The procedure is as follows:

(1) Reproduce the photographing point and direction of a photograph in a virtual space
(2) A camera that reproduces the actual angle of view in the virtual space is created and installed at the shooting point.
(3) The shooting range is irradiated with rays to clarify the range seen from the camera in the virtual space.
(4) The photo number in the voxel hit by the ray is recorded.



We used the data estimated using photogrammetry software for the camera shooting point and direction.

Figure 7 shows a situation in which the range

captured by the camera in the virtual space is confirmed. Figure 7b shows the range observed by the camera in the virtual space. Figure 7c shows a situation in which a ray is irradiated to investigate the range that the camera is viewing.

b. Result after replacing the building with voxels

c. Situation where Ray is emitted from the camera

Fig 7: Range visible from a camera in virtual space is being investigated.

Figure 8 shows a situation in which the camera in the virtual space is moved to other shooting points, and the shooting range is investigated from each shooting point.

3.4 Record all the shooting points that you can see on the voxel

The number of photographs captured for each voxel was recorded by repeatedly searching for voxels within the visible range of the camera. In this section, we present the results of recording the shooting points in the voxels of buildings using the proposed system. Figure 9 shows the number of photographs captured for each voxel. The blue voxels indicate images captured at 50 or more locations. Figure 10 shows the number of photographs recorded for each voxel.

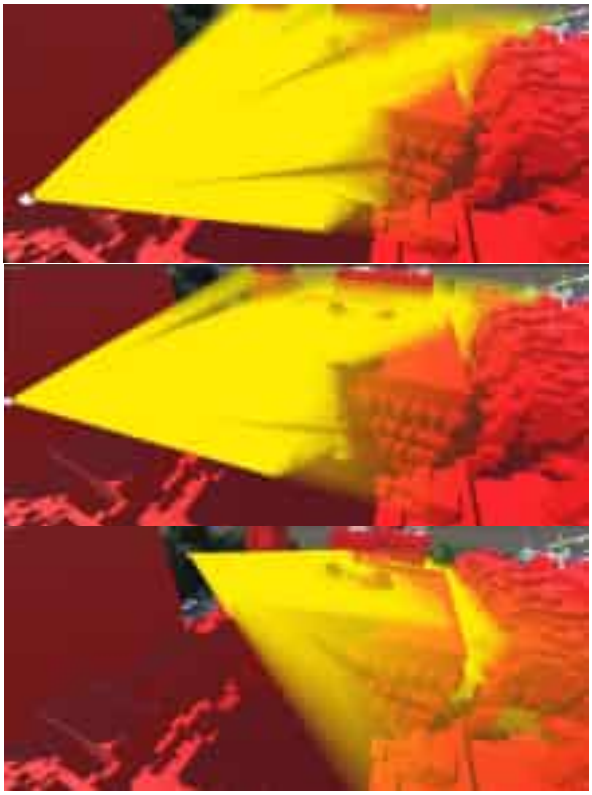

Fig 8 Situation where the shooting range is being investigated from each shooting point

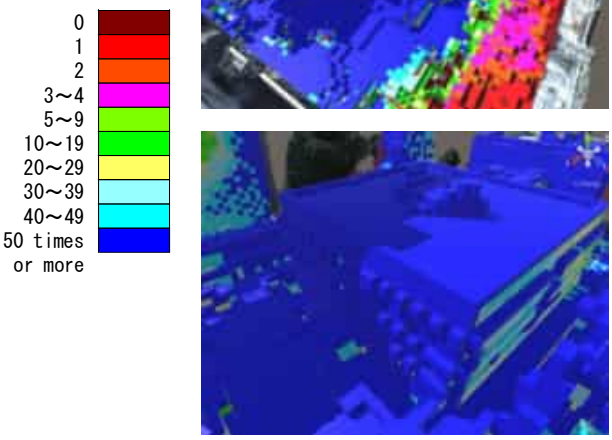

Fig 9 Number of times a voxel appeared in a photo.

Fig 10 Results of recording the number of photo shoots for each voxel

The proposed system was implemented as a Unity-based WebGL application. During the inspection in virtual space, when an observer's gaze hits a voxel, the system retrieves the associated photo list near-instantaneously. Since the spatial relationship is already indexed in a pre-built data structure, the retrieval complexity is $O(1)$, allowing for a seamless transition from the 3D model to original high-resolution photographs without any noticeable latency.

4 System for an observer in virtual space to search for photos of parts of a building

4.1 Building a system to search for photos of building surfaces in virtual space

Using the method described in Section 3, we registered the shooting points within the voxels. Next, we created a system that smoothly searched for photos captured at the observation points while observing a 3D model in a virtual space.

First, a 3D model created using photogrammetry was loaded, and then the point at which the photo was captured was reproduced in the virtual space. Finally, the voxels described in Section 3 were placed. This voxel was placed in a transparent state—place voxel as shown in Figs. 11 and 12.

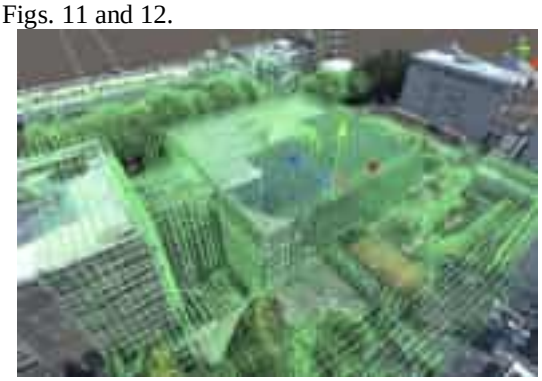

Fig 11 Result of placing transparent voxels

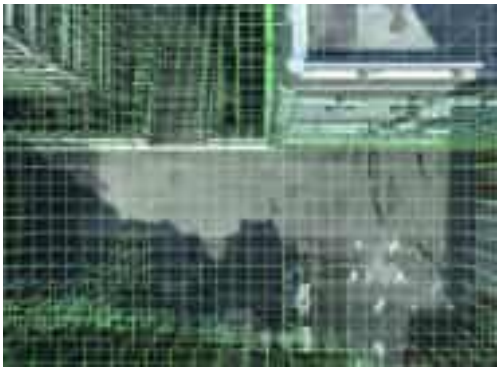

Fig 12 Close-up view of the result of placing transparent voxels

4.2 Search results for all photos depicting observation points

Based on the results obtained thus far, we created a system that shows all the photographs captured at the observation point when a building is observed in a virtual space.

Figure 13 shows the results of running the created system. In Figure 13, the voxel where the observer is looking in the virtual space is displayed, all shooting points registered to this voxel are shown, and a line is drawn between the voxel and the shooting point.

Fig 13 Result of the observation system execution

Figure 14 shows the viewpoint of the observer in the virtual space. In particular, voxels viewed by the observer are shown. The purple line extends to the shooting point that captures the voxel ahead of the line of sight.

Fig 14 Observer's perspective

Figure 15 shows an example of acquiring voxel numbers on a building surface as observed by an observer. By accepting this voxel number, a list of photographs showing the voxels can be obtained, as shown in Figure 16. A photo number can be obtained by selecting any photo from the photo list. Next, as shown in Figure 17, the directory in which the photo was stored was obtained based on the photo number, and the photograph was displayed. The desired photograph is shown in Figure 18.

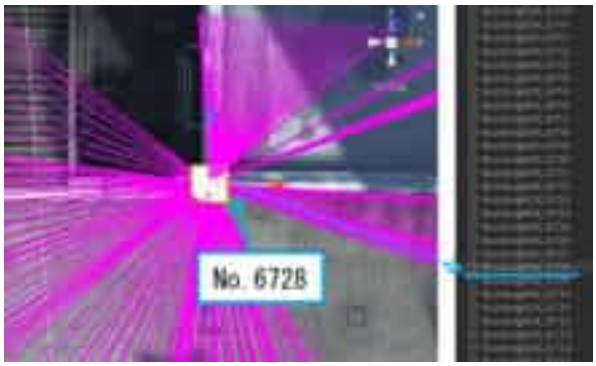

Fig 15 Example of obtaining the number of the voxel ahead of the line of sight

Fig 16 List of photo numbers that capture the voxel ahead of your line of sight

Fig 17 Situation to obtain photo storage directory from photo number

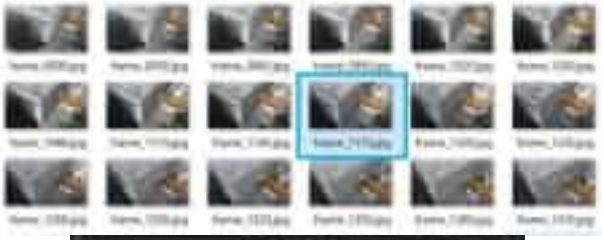

Fig 18 Example of displaying the desired photo

We selected a voxel size of 1 m for the building representation. This resolution is strategically determined based on the practical requirements of building exterior inspections, such as identifying cracks or concrete spalling. A 1 m grid provides a sufficient level of detail to localize defects on a building scale while ensuring that each voxel is covered by an adequate number of overlapping photographs from various drone shooting positions, which is essential for a reliable photogrammetric inspection.

5 Conclusion

We created a system that searches for all photographs captured from observation points when a 3D model created using photogrammetry is observed in the virtual space. Using the developed system, we obtained an original photograph of the location observed in virtual space. This results in more efficient inspections using building models in a virtual space.

A Spatial Multi-Criteria Framework for Assessing Last-Mile Delivery Resilience in Modular Construction Supply Chains: A Network-Based Analysis of Lille

Saad EL BABIDI[1] **and Zoubeir LAFHAJ**[1]

[1]École Centrale de Lille, University of Lille, France

saad.el-babidi@centralelille.fr, zoubeir.lafhaj@centralelille.fr

Abstract -

The resilience of construction supply chains has become a critical issue in dense urban environments, particularly for modular construction systems that rely on large and time-sensitive deliveries. While existing studies have extensively addressed construction logistics and supply-chain resilience at strategic and regional levels, the last-mile delivery phase within urban areas remains insufficiently analyzed. This paper proposes a spatially explicit methodological framework to assess last-mile delivery resilience for modular construction in urban contexts. The framework is based on a grid-based, multi-criteria analysis integrating road access suitability, truck-feasible network redundancy, and urban morphology operability. The city of Lille was selected as a representative dense European urban last-mile context and was discretized into a regular grid to ensure spatial comparability and reproducibility. Open geospatial data were used to model road networks and urban form, and normalized indicators were computed for each grid cell. The results showed that, although large portions of the study area remained physically accessible for modular deliveries, the truck-feasible road network exhibited very low redundancy, indicating a high sensitivity to local disruptions. Urban morphology was found to be a secondary limiting factor compared to network structure. The proposed framework enabled the identification of structurally fragile zones and critical corridors, providing a basis for targeted operational, territorial, and regulatory recommendations to improve last-mile delivery resilience for modular construction.

Modular construction; Last-mile delivery; Supply-chain resilience; Urban road networks; GIS-based multi-criteria analysis

1 Introduction

Urban construction systems increasingly face constrained spatial conditions, environmental requirements, and regulatory frameworks. In response, modular construction has gained growing attention as an alternative to conventional methods due to its potential to improve productivity, quality, and sustainability by shifting a significant share of activities from on-site execution to off-site manufacturing [1, 2]. This shift, however, increases project dependency on reliable logistics and precise delivery operations, particularly in dense urban environments.

In this context, the last mile of the construction supply chain—defined as the final segment connecting the urban transport network to the construction site—plays a critical role in project performance. Modular construction relies on transporting large and often oversized components under strict sequencing and time constraints, making last-mile accessibility and reliability decisive factors. Unlike other time-critical construction deliveries such as ready-mixed concrete or crane-assembled components, modular systems impose a compounded constraint: components are dimensionally fixed and non-substitutable, assembly sequences are predetermined and cannot tolerate partial or delayed deliveries, and off-site fabrication schedules are decoupled from the site, eliminating any on-site buffering capacity. A single delivery failure in a modular sequence thus propagates directly to installation downtime, with no on-site workaround available. Urban freight studies consistently identify last-mile operations as the most complex and disruption-prone segment due to congestion, access restrictions, and competition for limited urban space [3], with similar constraints observed in urban construction logistics, where delivery failures directly affect on-site productivity and installation schedules [4].

Supply-chain resilience has been widely studied in manufacturing and logistics and, more recently, in construction, emphasizing the ability of systems to absorb, adapt to, and recover from disruptions. Research on modular and prefabricated supply chains highlights transportation and logistics as critical determinants of resilience [2, 5]. However, most contributions remain project-centric or conceptual and rarely translate resilience principles into spatially explicit indicators applicable at the urban scale.

In parallel, geographic information systems (GIS) and multi-criteria decision analysis (MCDA) have been widely used in urban planning and infrastructure assessment to integrate heterogeneous spatial data within transparent and reproducible frameworks [6, 7]. Three GIS capabilities

are central to the present framework: (i) network analysis, enabling graph-based computation of route redundancy and alternative-path availability; (ii) spatial overlay operations, allowing heterogeneous data layers (road hierarchy, building density) to be aggregated over a common grid; and (iii) grid-based spatial discretization, ensuring that indicators are comparable and transferable across different urban contexts. Despite their potential, these methods have seldom been applied to characterize last-mile delivery resilience for modular construction, particularly through indicators explicitly accounting for road-network structure and redundancy.

As a result, a methodological gap persists at the intersection of modular construction, last-mile logistics, and urban system resilience: spatially explicit and network-informed frameworks capable of assessing last-mile delivery resilience using interpretable and transferable indicators remain limited. To address this gap, this paper proposes a GIS-based, network-informed multi-criteria framework integrating three complementary dimensions: road access suitability, truck-feasible network redundancy, and urban morphology operability. Indicators are computed over a regular spatial grid to enable comparability and transferability across urban contexts. The city of Lille (France) is used as a pilot case representative of dense European urban environments with pronounced last-mile constraints for construction logistics.

The remainder of the paper is organized as follows. Section 2 reviews relevant literature. Section 3 presents the methodology and data sources. Section 4 reports the results for the Lille case study, Section 5 discusses the findings and recommendations, and Section 6 concludes and outlines future research perspectives.

2 State of the Art

This section reviews prior research at three nested levels: (i) supply-chain resilience in construction and modular/prefabricated delivery systems, (ii) last-mile logistics and construction logistics constraints in dense urban environments, and (iii) spatially explicit assessment methods (GIS-based indicators and multi-criteria approaches) enabled by open geospatial data. The review follows a funnel logic from general concepts to the specific gap addressed by this paper.

2.1 Supply-chain resilience in construction and modular systems

Supply-chain resilience is commonly defined as the capability of a supply network to anticipate, absorb, adapt to, and recover from disruptions while maintaining essential functions. In construction, resilience discussions have intensified due to increasingly complex procurement structures, fragmented stakeholders, and exposure to shocks (supply shortages, transport disturbances, regulatory changes). Recent synthesis works highlight that disruption research remains fragmented and that resilience operationalization often lacks consistent and measurable indicators comparable across contexts [8, 9].

Modular and prefabricated construction systems strengthen the coupling between manufacturing, transportation, and on-site assembly, thereby increasing sensitivity to delivery reliability and urban access constraints. Quantitative and conceptual contributions have addressed modular logistics through optimization models, buffering and sourcing strategies, and conceptual frameworks. For instance, two-stage stochastic programming has been used to optimize modular logistics decisions across manufacturing–inventory–transportation under demand variability, illustrating the value of mathematical decision-support primarily at the project planning level rather than at an urban last-mile territorial scale [10]. Systematic works further emphasize disruption drivers (including transportation and procurement as critical levers) and resilience mechanisms (e.g., redundancy, flexibility, collaboration, digitalization), yet rarely translate these concepts into spatially explicit indicators supporting local last-mile deployment [1, 2, 5].

2.2 Last-mile logistics and construction logistics in dense cities

Last-mile logistics is widely characterized as the most complex and least efficient segment of urban supply chains due to high uncertainty, limited space, conflicts with other urban functions, and dynamic regulatory constraints. Literature reviews highlight recurring barriers such as congestion, limited curb space, access restrictions, and the need to balance economic, environmental, and social performance [3]. Cities nevertheless often under-integrate last-mile logistics into planning despite its growing impact, calling for locally adapted operational and regulatory instruments [11].

Construction logistics intersects with city logistics but exhibits distinct characteristics: heavy and oversized deliveries, temporal criticality aligned with installation windows, safety constraints, and site-interface limitations. Empirical studies on construction logistics centers (CLCs) show that logistics strategies (consolidation vs. just-in-time deliveries) significantly influence delivery patterns and disturbances, while implementation barriers remain substantial [4, 12]. Despite these advances, most last-mile research still focuses on retail and e-commerce flows, whereas construction logistics studies often remain project-centric. Modular construction, whose installation is delivery-dependent and schedule-critical, therefore requires last-mile analysis that is both urban-system oriented

and operationally grounded.

2.3 Spatially explicit assessment and GIS-based multi-criteria approaches

Supply-chain resilience and accessibility challenges in dense urban contexts are increasingly addressed through GIS-based indicators and multi-criteria decision analysis (MCDA), enabling heterogeneous data layers (transport, morphology, constraints) to be integrated into comparable territorial scores [6, 7]. In parallel, network science provides measures (e.g., redundancy, alternative routing potential) to describe transport network robustness under disruption. However, in construction logistics, and particularly in modular last-mile delivery, these approaches are still rarely instantiated as reproducible indicator sets supporting urban zoning and actionable recommendations. Data availability constitutes a practical challenge: OSM, widely used for road-network extraction, reaches sufficient quality for urban analytical uses when limitations are explicitly acknowledged, though quality varies by geography and feature type [13, 14].

2.4 Synthesis of gaps and positioning of this paper

Three gaps emerge: modular supply-chain studies rarely operationalize last-mile constraints spatially [2, 5]; urban last-mile research targets retail flows rather than construction [3, 11]; and GIS-MCDA frameworks lack a bridge to modular last-mile resilience metrics.

3 Methodology and Data

A spatially explicit, network-informed multi-criteria framework was developed to assess urban last-mile delivery resilience for modular construction. The framework integrated (i) road access suitability, (ii) truck-feasible network redundancy, and (iii) urban morphology operability into normalized indicators computed over a regular grid. The approach followed established principles from GIS-based multi-criteria analysis and urban freight/logistics assessment, while explicitly operationalizing network redundancy as a resilience property [3, 7, 4].

3.1 Study area and spatial discretization

The city of Lille (France) was selected as a pilot case representative of dense European urban conditions where modular construction deliveries face significant last-mile constraints. The study area was defined as a polygonal extent within which all computations were performed.

The area was discretized into a regular grid of square cells of side length $\Delta = 250$ m. Let $\mathcal{G} = \{g_1, \ldots, g_N\}$ denote the set of grid cells, with $A_g = \Delta^2$ the area of a cell. A grid-based formulation was adopted to ensure spatial comparability and transferability across cities, as commonly required for spatial decision-support and multi-criteria mapping [7].

3.2 Open data sources and preprocessing

OpenStreetMap (OSM) data were used for road and building layers to ensure transparency and reproducibility, while explicitly acknowledging quality and fitness-for-use limitations [14, 13].

Road geometries and attributes (including the `highway` classification) were extracted and clipped to the study boundary. Building footprints were extracted using OSM `building` tags and filtered to retain polygonal geometries. All layers were re-projected to a metric coordinate reference system (Lambert-93 EPSG:2154) to enable consistent length and area computations.

3.3 Road-network representation and truck-feasible subnetwork

The road network was represented as a graph $\mathcal{N} = (V, E)$, where V denotes intersections and E road segments. Each edge $e \in E$ had a geometric length L_e and an OSM road class $h(e)$.

Truck feasibility was operationally defined based on OSM road classes by excluding residential, service, and pedestrian roads, consistent with typical heavy and oversized vehicle constraints in urban construction logistics. This filtering approximates the access constraints applicable to the standard semi-trailer configuration used for modular deliveries in France: total length 16–18 m, width 2.5 m, maximum authorized gross weight 44 tonnes. Such vehicles are structurally incompatible with residential and service roads due to geometric (turning radius, lane width) and load-bearing constraints. Vertical clearance restrictions (e.g., overpasses, underpasses) were not modeled at this stage, as OSM does not systematically provide `maxheight` attributes across the study area; this constitutes an explicitly acknowledged limitation (Section 6).

A truck-feasible subnetwork $\mathcal{N}_T = (V_T, E_T)$ was derived by retaining edges satisfying a feasibility rule $\phi(e) = 1$ based on road class and intended modular delivery constraints. This subnetwork enabled redundancy analysis under truck-feasible conditions, which is central to resilience assessment [2, 5].

3.4 Indicator definition and mathematical formulation

Three criteria were computed per grid cell $g \in \mathcal{G}$ and normalized to $[0, 1]$ for comparability. Their selection was grounded in the specific constraints of modular last-mile delivery. C1 (road access suitability) captures the physical compatibility of the road environment with oversized

vehicles—the necessary entry condition for any modular delivery. C2 (truck-feasible network redundancy) directly operationalizes resilience as the availability of alternative routing options under disruption, which is the defining structural vulnerability of modular logistics in dense urban networks. C3 (urban morphology operability) captures site-interface constraints related to building density, conditioning on-site maneuvering and staging capacity. Other potential factors—including real-time traffic, time-window regulations, and low-emission zones—were excluded because they require dynamic or proprietary data unavailable across cities; their influence is partially captured through road hierarchy classification and acknowledged in Section 6.

3.4.1 C1: road access suitability

C1 quantified the suitability of the local road environment for modular deliveries using road hierarchy as a proxy for capacity and maneuverability. Each road segment e intersecting grid cell g was assigned a suitability score $s(h(e)) \in [0, 1]$ based on its road class $h(e)$. Let E_g denote the set of edges intersecting g and $L_{e,g}$ the length of edge e within g.

The raw suitability score was defined as the length-weighted mean:

$$C1^{raw}(g) = \frac{\sum_{e \in E_g} s(h(e))\, L_{e,g}}{\sum_{e \in E_g} L_{e,g} + \varepsilon}, \tag{1}$$

where $\varepsilon > 0$ avoided division by zero. This formulation ensured proportional contribution of longer segments and boundedness in $[0, 1]$ prior to normalization.

3.4.2 C2: truck-feasible network redundancy

C2 operationalized local redundancy of the truck-feasible network as a resilience property using two complementary proxies: (i) truck-feasible edge-length density and (ii) branching opportunity density [8].

Let $E_{T,g}$ denote the set of truck-feasible edges intersecting cell g and define the edge-length density:

$$\rho_L(g) = \frac{\sum_{e \in E_{T,g}} L_{e,g}}{A_g}. \tag{2}$$

Let $V_{T,g}$ be the set of truck-feasible nodes within g, with degree $\deg_T(v)$ in $\mathcal{N}_T$. Define the branching node set $B_g = \{v \in V_{T,g} : \deg_T(v) \geq 3\}$ and branching density:

$$\rho_B(g) = \frac{|B_g|}{A_g}. \tag{3}$$

The raw redundancy score was computed as:

$$C2^{raw}(g) = \left(\frac{\rho_L(g)}{\max_{g' \in \mathcal{G}} \rho_L(g') + \varepsilon} \right) \left(\frac{\rho_B(g)}{\max_{g' \in \mathcal{G}} \rho_B(g') + \varepsilon} \right), \tag{4}$$

yielding high values only where sufficient truck-feasible infrastructure and multiple branching opportunities coexist.

3.4.3 C3: urban morphology operability

C3 characterized urban operability using building footprint density as a proxy for spatial constraints. Let $\mathcal{P}_g$ denote the set of building polygons intersecting grid cell g, and $A_{p,g}$ the area of polygon p within g. The built-up ratio was defined as:

$$\beta(g) = \frac{\sum_{p \in \mathcal{P}_g} A_{p,g}}{A_g}. \tag{5}$$

Higher built-up ratios implied tighter spatial conditions; operability was therefore defined via inversion and normalization (see Section 3.5).

3.5 Normalization and direction harmonization

All criteria were mapped to a common scale $[0, 1]$ using min–max normalization:

$$\mathcal{N}(x(g)) = \frac{x(g) - \min_{g' \in \mathcal{G}} x(g')}{\max_{g' \in \mathcal{G}} x(g') - \min_{g' \in \mathcal{G}} x(g') + \varepsilon}. \tag{6}$$

Final normalized indicators were defined as:

$$C1(g) = \mathcal{N}(C1^{raw}(g)), \tag{7}$$

$$C2(g) = \mathcal{N}(C2^{raw}(g)), \tag{8}$$

$$C3(g) = 1 - \mathcal{N}(\beta(g)). \tag{9}$$

Higher values therefore always corresponded to more favorable conditions for modular last-mile delivery resilience.

3.6 Linking the three criteria for zoning and decision support

To support interpretable zoning while avoiding black-box indices, a transparent composite score was optionally defined:

$$R(g) = w_1\, C1(g) + w_2\, C2(g) + w_3\, C3(g), \quad \sum_{i=1}^{3} w_i = 1,\ w_i \geq 0. \tag{10}$$

A baseline equal-weight configuration $w_1 = w_2 = w_3 = \frac{1}{3}$ was adopted as the epistemically neutral prior: in the absence of empirical weighting evidence (e.g., expert survey

data or revealed logistics preferences for the Lille context), equal weights avoid introducing arbitrary priorities that cannot be validated against field data at this pilot stage. A sensitivity check varying each w_i within [0.10, 0.60] confirmed that the spatial ranking of the most critical zones remained stable under all tested configurations [7].

3.7 Implementation and replicability

All steps (data extraction, preprocessing, spatial overlays, indicator computation, normalization, and visualization) were implemented in Python using open-source geospatial and network libraries. The workflow was fully scripted to ensure reproducibility given the same boundary definition, grid resolution, and OSM data snapshot.

4 Results

This section presents the results of the spatial multi-criteria analysis applied to the city of Lille. Results are reported separately for each criterion in order to distinguish the respective effects of road access suitability, truck-feasible network redundancy, and urban morphology operability on last-mile delivery resilience for modular construction. Both spatial patterns and statistical distributions are presented.

4.1 Road access suitability (C1)

Criterion C1 quantified the physical suitability of the local road network for modular construction deliveries based on road hierarchy and length distribution. Figure 1 shows the spatial distribution of C1 values across the 250 m grid covering the study area.

The results revealed a strong spatial heterogeneity in road access suitability. Grid cells located along major urban corridors and near primary road infrastructures exhibited high C1 values, indicating favorable access conditions for heavy and oversized vehicles. In contrast, dense residential areas characterized by a predominance of local and service roads were associated with low C1 values.

From a statistical perspective, the distribution of C1 values was highly asymmetric, with a large proportion of grid cells exhibiting very low access suitability. The median C1 value was equal to zero, reflecting the structural predominance of constrained road segments in the urban fabric. High C1 values were limited to a small number of grid cells, mainly aligned with major transport axes.

4.2 Truck-feasible network redundancy (C2)

Criterion C2 assessed the redundancy of the truck-feasible road network by evaluating the availability of alternative routes and branching opportunities within each grid cell. The spatial distribution of C2 values is presented in Figure 2.

Figure 1. Spatial distribution of road access suitability (C1) for modular construction last-mile delivery in Lille (250 m grid). Normalized scale 0–1: $C1 < 0.2$ (red) indicates low suitability (predominantly residential and service roads); $C1 > 0.8$ (green) indicates high suitability (primary arterial corridors); intermediate values reflect mixed road-class environments.

The results showed that network redundancy was extremely limited across most of the study area. A very large majority of grid cells exhibited C2 values close to zero, indicating the absence of locally available alternative truck-compatible routes. Higher C2 values were observed only in a small number of locations, generally near major intersections and high-capacity road segments.

The statistical distribution of C2 values was strongly skewed toward zero, with a mean value close to zero and very limited dispersion. This pattern is also structurally expected from the multiplicative formulation of C2 (Eq. 4): high values require both truck-feasible edge-length density and branching node density to be simultaneously non-negligible within the same cell, a condition that is intrinsically rare in a dense urban network where the truck-feasible subnetwork is sparse by construction. This distribution highlighted a structurally fragile last-mile network configuration, in which physical access did not necessarily imply resilience to disruptions such as road works, congestion, or temporary access restrictions.

4.3 Urban morphology operability (C3)

Criterion C3 evaluated the operability of the urban morphology by analyzing building density and footprint concentration as proxies for on-site spatial constraints. Figure 3 presents the spatial distribution of C3 values over the study area.

The results indicated generally high C3 values across the majority of grid cells, reflecting favorable urban morphology conditions for last-mile construction operations.

Figure 2. Spatial distribution of truck-feasible network redundancy (C2) in the Lille last-mile context. Normalized scale 0–1: $C2 < 0.2$ (dark red) indicates no or negligible locally available alternative truck-compatible routes; $C2 > 0.8$ indicates high redundancy, observed only near major high-capacity intersections. The near-zero distribution reflects both the structural scarcity of truck-feasible routes from road-hierarchy filtering (Section 3.3) and the multiplicative formulation of C2, which requires simultaneous non-negligible edge density and branching density (Section 3.4.2).

Lower C3 values were mainly concentrated in areas characterized by high building density and compact urban forms.

The statistical distribution of C3 values showed a concentration toward high operability levels, with a high mean value and limited dispersion. This pattern suggested that, at the city scale, urban morphology imposed fewer constraints on modular construction last-mile operations than road access and network structure.

Figure 3. Spatial distribution of urban morphology operability (C3) in the Lille study area. Normalized scale 0–1: $C3 < 0.2$ indicates low operability (dense, compact built-up areas with high building footprint coverage); $C3 > 0.8$ indicates high operability (sparse or open urban fabric with low building coverage).

4.4 Statistical distribution of resilience indicators

Figure 4 presents the statistical distributions of the three normalized criteria (C1, C2, and C3) computed over the 250 m grid covering the city of Lille. The distributions highlight strong contrasts between access suitability, network redundancy, and urban morphology operability in the last-mile delivery context.

C1 showed a highly asymmetric distribution with a median of zero, confirming the structural predominance of constrained roads, while approximately 25% of cells exceeded moderate suitability along major corridors. C2 was strongly skewed toward zero, more than 90% of cells exhibited near-zero redundancy, revealing a structurally fragile network where most locations depend on a single truck-compatible route. C3 concentrated toward high values (median > 0.80), indicating that urban morphology imposed fewer constraints than network structure. Together, these distributions confirm that last-mile resilience in Lille is primarily limited by network-related factors.

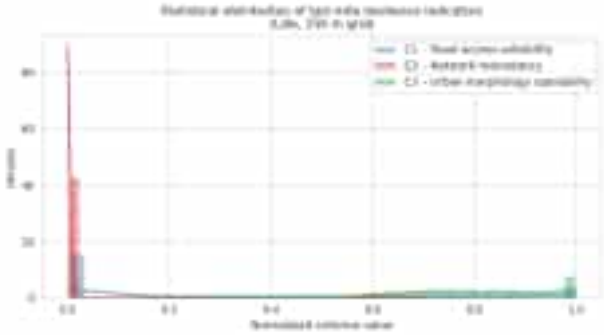

Figure 4. Statistical distributions of road access suitability (C1), truck-feasible network redundancy (C2), and urban morphology operability (C3) across the Lille study area (250 m grid, kernel density estimates).

5 Discussion and Recommendations

5.1 Network structure as the primary driver of last-mile resilience

The results demonstrated that last-mile delivery resilience for modular construction in Lille was primarily governed by road network structure rather than by local accessibility alone. Although road access suitability (C1) exhibited marked spatial heterogeneity, truck-feasible network redundancy (C2) remained extremely low across the majority of the study area. This interpretation is directly supported by the near-zero median values of C2 and its very limited dispersion (Figure 4), in contrast with the extended upper tail observed for C1 along major corridors.

The near-zero values observed for C2 in most grid cells reflected a structural dependence on a limited number of truck-compatible routes. Such configurations increased sensitivity to localized disruptions, including road works, congestion, and temporary access restrictions. This vulnerability is consistent with the spatial pattern of C2 (Figure 2), where higher redundancy is confined to a small number of cells near major intersections and high-capacity segments. These findings are consistent with resilience theory in urban systems, which emphasizes redundancy and alternative paths as key properties for disturbance absorption and recovery. In dense European urban contexts, historical road hierarchies and planning priorities have often concentrated freight traffic on a small number of corridors, thereby limiting redundancy at the local scale.

5.2 Limited influence of urban morphology in dense last-mile contexts

Urban morphology operability (C3) exhibited generally high values across the study area, with limited dispersion compared to access- and network-related criteria. This result is directly supported by the concentration of C3 toward high values (median exceeding 0.80 in Figure 4) and by the spatial distribution in Figure 3, where low operability is limited to compact and highly built-up areas. These patterns suggested that spatial constraints related to building density and footprint concentration were not the dominant limiting factors for last-mile modular construction operations in Lille.

This finding can be explained by the fact that conventional construction practices already operate under constrained urban conditions, relying on regulated temporary occupation of public space, staged deliveries, and adaptive on-site logistics. As a result, morphology-related constraints can often be operationally mitigated at the site interface, whereas limitations imposed by road network structure are more difficult to compensate. The results therefore indicated that, in dense urban environments, improving last-mile resilience requires a stronger focus on network-level characteristics rather than solely on site-scale spatial availability.

5.3 Distinguishing accessibility from resilience in modular construction logistics

A key outcome is the distinction between accessibility (C1, nominal conditions) and resilience (C2, functionality under disruption). The divergence between these criteria—heterogeneous C1 versus near-zero C2 in over 90% of cells—shows that accessibility alone is insufficient as a resilience indicator (Figure 4). For modular construction, where alternative routes are non-negotiable given dimensional constraints, the framework formalizes this distinction spatially, addressing a gap in existing supply-chain resilience studies.

5.4 Operational, territorial, and regulatory recommendations

Based on the identified spatial patterns, several recommendations can be derived. At the operational level, delivery planning for modular construction should explicitly account for local network redundancy, rather than relying solely on shortest-path or nominal access criteria. In practice, low-C2 areas (Figures 2 and 4) should be treated as disruption-sensitive zones where contingency routing, time-buffering, and coordination with on-site installation windows become critical. Identifying critical corridors and intersections can support more robust routing strategies and contingency planning.

At the territorial level, targeted interventions on the few high-C2 links and junctions may yield significant resilience improvements without extensive network modifications. At the regulatory level, urban access policies and temporary road occupation permits could be adapted to reflect network resilience considerations. Coordinated scheduling of road works and construction activities along critical corridors may reduce cumulative disruption effects, particularly in contexts where redundancy is structurally low (C2 near zero across most cells). More broadly, integrating last-mile resilience diagnostics into urban planning and construction permitting processes could support the deployment of modular construction systems in dense cities.

6 Conclusion

This paper proposed a GIS-based, network-informed multi-criteria framework to assess last-mile delivery resilience for modular construction in dense urban environments, integrating three complementary indicators: road access suitability (C1), truck-feasible network redundancy (C2), and urban morphology operability (C3), demonstrated on the city of Lille.

The results revealed that favorable access for modular deliveries was concentrated along a limited number of major corridors (C1), while truck-feasible network redundancy (C2) emerged as the most critical limiting factor, with near-zero values across most of the study area. Urban morphology operability (C3) remained comparatively favorable. These findings emphasize that accessibility alone does not guarantee last-mile resilience, and that road network redundancy plays a decisive role for modular construction logistics.

Several limitations must be acknowledged: reliance on open geospatial data with possible local inaccuracies; road-class filtering without explicit modeling of vertical clearance or axle load restrictions (reference configuration: semi-trailer, 16–18 m, 44 t); exclusion of regulatory

constraints such as time windows and low-emission zones; and a static spatial scope that does not capture temporal variability.

Future research should incorporate regulatory and temporal dimensions, empirical validation using real logistics data, vehicle-specific network filtering, and application to other urban contexts to support transferable guidelines for modular construction last-mile resilience.

Abstract -

Underground utility information is frequently incomplete, inconsistent, or of uncertain confidence, leading to safety risks, rework, and inefficiencies during construction and maintenance activities. Although existing standards, sensing technologies, and digital platforms define data quality concepts and investigation methods, their application within construction workflows remains fragmented and largely project-specific. In particular, limited guidance exists on when utility data should be collected across the construction lifecycle and how confidence in existing information should inform construction decisions. This paper proposes an event-based utility data collection approach that aligns subsurface information acquisition with recurring construction and maintenance events. It integrates lifecycle events, utility data categories, technology classes, and confidence considerations to support transparent, confidence-aware decisions on investigation, escalation, and opportunistic data capture. A visual representation and supporting tables illustrate how construction methods and access conditions influence achievable confidence and data availability, while highlighting construction and maintenance activities as high-value opportunities for reliable data capture. By providing an operational structure for applying existing standards in real construction contexts, the proposed approach supports coordinated decision-making, reduces reliance on ad-hoc investigations, and enables incremental improvement of utility information over time, contributing to safer construction practices and more reliable long-term subsurface asset management.

Keywords -

Underground utilities; Subsurface utility engineering; Construction lifecycle; Data collection framework; Utility data confidence; Event-based data capture; Infrastructure asset management; Utility mapping

1 Introduction

Underground utilities constitute a critical yet largely invisible component of the built environment. Utilities such as water, sewerage, gas, electricity, and telecommunication networks are routinely affected during construction and maintenance activities, resulting in service disruptions, safety hazards, schedule delays, and cost overruns [1]. Despite advances in sensing technologies and digital information systems, utility strikes and subsurface conflicts remain prevalent, particularly in dense urban corridors where multiple assets coexist within constrained space [2].

A key reason for these recurring issues is the misalignment between construction workflows and subsurface information practices [3]. Construction and asset management progress through interconnected stages, planning, design, installation, operation, maintenance, and decommissioning, yet underground utility information is commonly treated as static, captured once and reused irrespective of subsequent interventions [4]. As a result, critical construction decisions are often made using outdated or low-confidence information, while opportunities to improve data quality during direct interaction with the subsurface are frequently missed.

In practice, subsurface utility information is fragmented across organizations and project phases. Planning teams rely on legacy records and GIS databases; designers commission selective investigations; contractors expose utilities during construction; and maintenance crews uncover assets during routine and emergency maintenance works. These repeated encounters are rarely coordinated through a unified, lifecycle-oriented data logic, and records are infrequently updated after sites are reinstated, perpetuating uncertainty and rework across successive projects [1]. These challenges manifest differently across greenfield and brownfield contexts: while greenfield projects face uncertainty due to limited baseline records, brownfield environments are dominated by legacy utilities of unknown location, condition, and confidence, making coordinated construction particularly risk-prone.

At the same time, the construction sector has widely adopted detection, surveying, and documentation technologies such as ground-penetrating radar, electromagnetic locating, GNSS surveying, laser scanning, etc., [2, 5]. While these technologies have improved detection and documentation capabilities, their use remains largely project-driven and reactive rather than integrated across the asset lifecycle. Decisions regarding when to investigate, how far to escalate verification, and what information to capture are typically left to individual project teams, leading to inconsistent outcomes across projects and jurisdictions [4].

These observations indicate that subsurface utility challenges are not only technological but also procedural, highlighting the need to align utility data collection with construction and maintenance events while explicitly accounting for information confidence. This paper addresses this need by proposing an event-based utility data collection framework that operationalizes existing standards and technologies within real construction workflows. It focuses on defining when, how, and under what construction conditions subsurface utility data should be captured to maximize long-term data value, safety, and reliability.

2 Background and related works

2.1 Persistent challenges in subsurface utility data

A consistent finding across subsurface utility research is that existing utility records are frequently inaccurate, incomplete, outdated, or of unknown confidence. Comparative studies demonstrate that traditional utility records, including as-built drawings and One-call systems (Call before you dig), often significantly under-represent underground infrastructure and exhibit substantial positional inaccuracies when compared with Subsurface Utility Engineering (SUE) investigations [1]. Empirical evidence indicates that conventional records may represent up to 160% less utility infrastructure than identified through systematic investigation, and that only a minority of mapped utilities fall within acceptable positional tolerances [3].

Similar challenges are reported across transportation projects, airports, and dense urban developments, where the depth information is missing, reference systems are inconsistent, and records reflect as-designed rather than as-built conditions [6, 2]. These shortcomings result in increased project costs, repeated site investigations, and heightened safety risks during excavation [7, 8]. The literature consistently identifies fragmented data capture practices and the absence of systematic updating mechanisms as key contributors to poor data quality [4].

2.2 Quality-based approaches and SUE

Subsurface Utility Engineering (SUE), formalized through standards such as ASCE 38 and complemented by ASCE 75 and PAS 128 with PAS 256, is widely recognized as a structured engineering approach for improving subsurface utility data quality using defined quality or confidence levels. Higher SUE quality levels are associated with increased positional accuracy, improved completeness, and reduced risk of utility conflicts during construction [9].

A key strength of these standards lies in its explicit linkage between investigation methods and achievable confidence, enabling informed engineering decisions during planning and design. However, prior studies note that such standards are predominantly applied during pre-design and design stages as a project-specific investigation and provides limited guidance on systematically capturing and updating utility data during installation, repair, diversion, or replacement activities [1].

2.3 Utility investigation technologies

A wide range of technologies and methods has been investigated for subsurface utility detection and documentation. Non-destructive geophysical methods, including ground-penetrating radar and electromagnetic locating, are widely used to detect buried utilities under varying site and soil conditions [5]. Geospatial surveying technologies such as GNSS, total stations, and terrestrial laser scanning enable accurate spatial referencing of exposed utilities and support integration with digital records [2].

Intrusive verification methods, including trial trenches and vacuum excavation, remain the most reliable means of achieving high-confidence positional and depth information, particularly where non-destructive methods are constrained. While the technical performance of investigation technologies is well documented, studies consistently note that achievable accuracy is limited by soil conditions, congestion, and utility material, and that investigation methods are rarely sequenced or escalated within construction workflows [5, 2]. Consequently, technology selection remains reactive and project-specific rather than embedded within a lifecycle-oriented strategy.

2.4 Data uncertainty and digital integration

Prior studies emphasize that uncertainty is an inherent characteristic of subsurface utility data and must be explicitly represented to support risk-informed decision-making [10]. Probabilistic mapping and uncertainty-aware visualization approaches acknowledge that complete information is rarely achievable and instead aim to represent confidence envelopes around detected utilities [11].

Parallel work on BIM–GIS, CAD-GIS integrations, digital twins, and augmented reality seeks to improve coordination and situational awareness for utility management [12, 13]. While these platforms offer substantial potential, their effectiveness is highly dependent on the quality and confidence of input data. Many such approaches implicitly assume the availability of reliable baseline utility data or the feasibility of systematic data collection independent of construction activities. In practice, this assumption is rarely valid for legacy infrastructure, limiting their effectiveness in real construction contexts.

2.5 Lifecycle and event-based data capture

A smaller but critical body of literature explicitly argues that subsurface utility data quality should be improved incrementally across the asset lifecycle, rather than through

large-scale resurveying efforts [14, 1]. These studies highlight the impracticality of repeated full exposure and advocate leveraging recurring construction and maintenance events, such as installation, diversion, repair, and replacement, as high-value data capture opportunities. While this work establishes the importance of lifecycle-based improvement, it does not provide a detailed operational structure defining event priorities, data requirements, technology applicability, or confidence management over time.

3 Research gap and objectives

Despite advances in underground utility data standards, sensing technologies, and digital platforms, construction practice still lacks a clear operational structure for aligning utility data collection with recurring construction and maintenance events. Existing approaches define data quality concepts, investigation methods, and uncertainty representation; however, their application across the construction lifecycle remains fragmented and largely project-specific. In practice, decisions regarding when to undertake additional investigation, which methods are appropriate under given access conditions, and how confidence in existing information should influence construction activities are often left to individual judgement. As a result, high-confidence data capture opportunities during routine construction and maintenance activities are frequently missed, perpetuating uncertainty and repeated investigations.

To address this gap, this study proposes an event-based utility data collection framework that situates utility information acquisition within construction workflows. The framework integrates lifecycle events, utility data categories, technology classes, and confidence considerations into a single construction-oriented structure. Specifically, it aims to (i) align utility data categories and applicable technology classes with key lifecycle events, and (ii) support transparent, confidence-aware decisions related to verification, escalation, and opportunistic data capture during construction and maintenance activities.

4 Methodology and framework development

This section summarizes the methodological approach used to develop the event-based subsurface utility data collection framework. The framework is conceived as a structuring and decision-support artefact that synthesizes concepts from existing utility data standards (e.g., ASCE 38-22, ASCE 75-22, PAS 128, PAS 256), investigation methods, and construction practice into a coherent, construction-oriented logic suitable for application within real work zones.

The framework was developed based on the premise that physical access to underground utilities is governed primarily by construction and maintenance events rather than by continuous monitoring or isolated survey campaigns. Accordingly, methodology adopted an event-based perspective: recurring lifecycle events are treated as the primary opportunities for interaction with subsurface assets and for capturing durable data.

Framework design was guided by five principles: (i) construction-centricity, aligning with real workflows; (ii) lifecycle orientation, treating utility information as an evolving asset; (iii) spatial anchoring, applying the framework to defined work zones containing multiple utilities; (iv) confidence awareness, explicitly accounting for information reliability; and (v) technology neutrality, grouping methods by functional capability rather than specific tools. These principles ensure compatibility with existing standards while maintaining adaptability across project and regulatory contexts.

Eight representative lifecycle events (E1–E8) were identified through synthesis of typical planning, construction, and operational workflows in utility-dense environments. These events span records review, reconnaissance, non-intrusive investigation, intrusive verification, open-cut and trenchless installation, maintenance or repair, and decommissioning. Events are non-linear and non-mandatory, reflecting construction practice in which activities may recur, overlap, or be bypassed depending on project intent and risk.

To support standardized capture, utility information requirements were synthesized into six high-level categories: P (positional & geometric), M (material), F (functional), C (condition & performance), S (survey metadata), and L (lifecycle metadata). Investigation methods were abstracted into five technology classes (T1–T5) reflecting record sources, optical/visual methods, geospatial surveying, geophysical/NDT, and intrusive verification.

A key methodological distinction is made between *current confidence*, representing the reliability of existing information for a given utility within the spatial extent, and *achievable confidence*, representing the maximum reliability attainable during a given event using appropriate methods. This distinction underpins the framework's escalation logic: construction or maintenance activities should proceed only when current confidence is appropriate for the intended action; otherwise escalation to earlier or more invasive events is recommended.

Finally, events involving physical exposure of utilities, such as intrusive verification, open-cut installation, maintenance repairs, and decommissioning, are explicitly identified as high-value data capture opportunities. During these events, comprehensive utility information can be obtained with minimal additional effort relative to the con-

struction activity itself. The framework therefore adopts an opportunity-based perspective that promotes systematic capture and recording whenever exposure occurs, supporting incremental improvement of utility records over time and reducing reliance on repeated standalone investigations.

5 Event-based utility data collection framework

This section presents the proposed event-based utility data collection framework and articulates its conceptual structure and decision logic. The framework integrates lifecycle events, utility data categories, technology classes, and confidence considerations into a construction-oriented model for subsurface utility data acquisition. The visual representation formalizes relationships between construction events, data availability, and achievable confidence, providing a structured basis for transparent and auditable decision-making across construction and maintenance contexts.

5.1 Framework overview and representation

Figure 1 illustrates the framework for a defined spatial extent (e.g., road segment, project corridor, or work zone), which constitutes the unit of application. Within this spatial extent, multiple underground utilities may coexist, each characterized by different levels of data availability and confidence. The framework is therefore spatially anchored rather than asset-isolated, reflecting real construction conditions in which decisions affect all subsurface assets within the work area.

The outer ring denotes eight recurring lifecycle events (E1–E8), derived from synthesis of construction workflows reported in literature, subsurface utility standards, and typical installation, maintenance, and diversion practices, and representing repeatable opportunities to consult, verify, or capture utility information. Events are nonlinear and may be entered, skipped or revisited depending on project intent, access and risk. The inner region groups utility information into six high-level categories (P, M, F, C, S, L); implementers should rely on Table 1 for attribute-level definitions and capture templates. The figure marks exposure-based events as high-value data capture opportunities (starred) where the highest achievable confidence is typically attainable.

When used, the framework encodes a simple decision logic: practitioners populate a side-panel register with existing information and assign current confidence per utility; they define the planned activity and its required confidence; they consult Table 2 to identify technology classes and events that can raise achievable confidence; and they escalate to those events when current confidence is insufficient. This logic is intentionally generic and auditable and supports selective escalation rather than prescriptive sequencing.

5.2 Utility data categories

Table 1 formalizes the six data categories used throughout the framework. The attributes listed are representative and not intended to be exhaustive or restrictive. This consolidated category structure is intended for attribute dictionaries, data capture templates, contractual clauses and permit conditions, and provides a consistent lens for linking data requirements to construction events. These categories define what information may be captured; when and how it is captured depends on lifecycle events and access conditions.

5.3 Lifecycle events and data capture capability

Each lifecycle event (E1-E8) provides a different degree of physical or informational access to underground utilities and therefore supports different subsets of abovementioned data categories. Early events such as record review and reconnaissance primarily support baseline understanding and risk screening, with limited achievable confidence. Non-intrusive investigation events enable indicative detection and alignment estimation but remain constrained by site conditions and utility characteristics.

Events involving direct exposure, such as intrusive verification, open-cut installation, maintenance repairs, and decommissioning, offer the highest achievable confidence across multiple data categories. These events allow direct measurement and observation of geometry, material, condition, and installation context. The framework explicitly identifies such exposure-based events as high-value data capture opportunities, encouraging systematic recording rather than incidental documentation.

Open-cut and trenchless construction methods are treated distinctly. Open-cut installation inherently enables comprehensive data capture prior to backfilling, whereas trenchless installation significantly restricts post-installation verification. Consequently, the framework emphasizes achieving sufficient confidence through earlier events before undertaking trenchless works.

5.4 Confidence Assessment and Escalation

A core feature of the framework is the distinction between achievable confidence and current confidence. Achievable confidence represents the maximum reliability that can reasonably be attained during a given event using appropriate methods. Current confidence represents the reliability of existing information for a specific utility within the spatial extent, based on available records, prior investigations, and documented exposures. Current

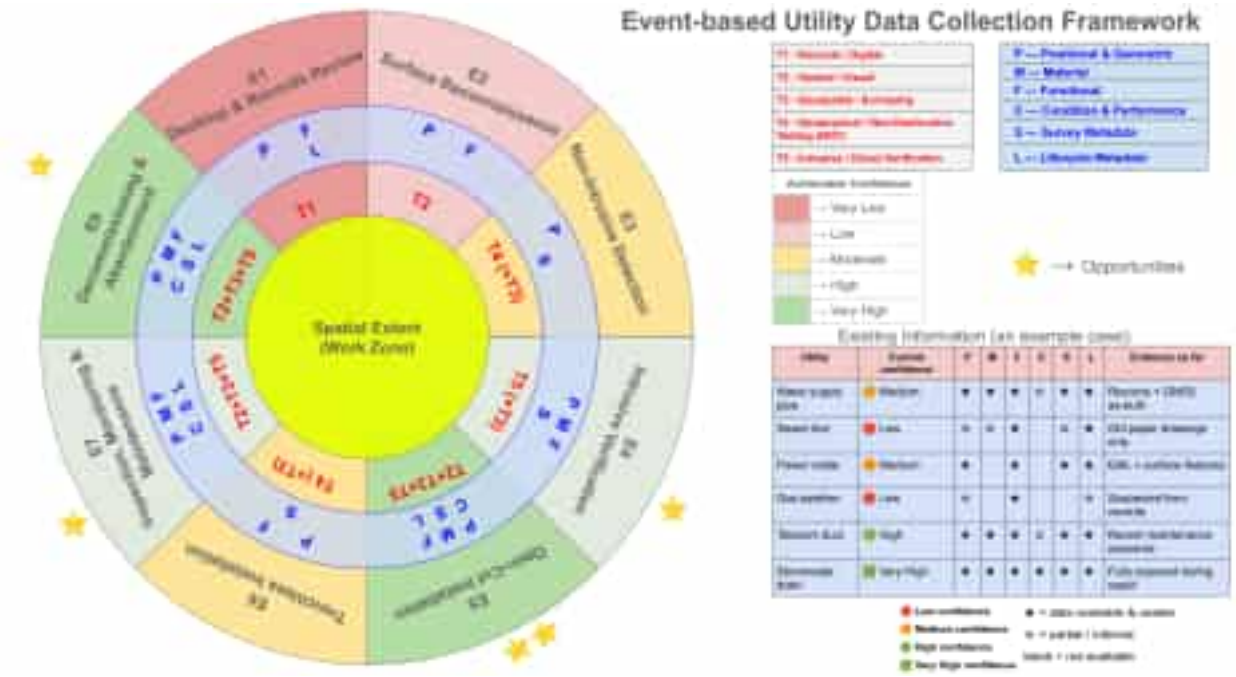

Figure 1. Event-based utility data collection framework

Table 1. Utility data categories and representative (non-exhaustive) attributes

Data Category	Example Attributes / Parameters
P - Positional & Geometric	Horizontal coordinates (X, Y), elevation/depth, spatial reference system, alignment, length, diameter, horizontal and vertical profile,burial depth, network connectivity, proximity to other utilities
M - Material	Material type (PVC, steel, concrete), wall thickness, grade/specification, lining/coating type, corrosion protection, backfill/bedding type, manufacturer, applicable material standards, installation age
F - Functional	Asset type (water pipe, gas pipe, duct, etc.,), service type, design capacity, pressure rating, flow direction, load class, operating limits, functional role in network, redundancy or criticality, control function (e.g., valve)
C - Condition & Performance	Condition rating, structural integrity score, corrosion level, deformation, leakage/blockage status, hydraulic/performance metrics, failure history, remaining useful life, inspection findings, inspection frequency/last inspection date
S - Survey Metadata	Survey method (e.g., GPR, GNSS, etc), instrument, survey date, surveyor/organization, accuracy, resolution, QA/QC status, detection limitations, standards compliance, data format/encoding
L - Lifecycle Metadata	Installation date, construction method (open-cut or trenchless), project/contract ID, ownership, operation start date, maintenance/repair/upgrade history, decommissioning date, regulatory compliance, replacement cost, asset status, risk/criticality score, warranty

confidence may be assessed using established quality classification systems such as SUE quality levels defined in ASCE 38-22, or equivalent local practices where available. Where formal classifications are not available, confidence may be assigned based on the data source, investigation method, and recency of verification.

Construction and maintenance decisions are informed by comparing these two measures. Where current confidence is sufficient for the intended activity, work may proceed. Where it is insufficient, the framework supports escalation to earlier investigation events until acceptable confidence is achieved. This logic is particularly critical for trenchless works and high-risk excavations, where post-construction verification is limited or impossible. Importantly, the framework does not mandate escalation through all events; it provides transparent guidance on when escalation is justified.

5.5 Technology classes and applicability constraints

Investigation and documentation methods are grouped into five functional classes (T1–T5). Table 2 lists representative methods as sub-rows, summarizes where each method typically performs well, and identifies known limitations (for example, material dependency of GPR and tracer-wire reliance for EML). This abstraction allows technology constraints to be considered at the decision level without embedding site-specific optimization into the framework.

Where different technology classes provide conflicting information, a simple precedence logic is applied. Geo-

Table 2. Technology tiers for subsurface utility data collection and applicability

Tier	Typical Methods / Data Sources	Works Well For	Known Limitations
T1 – Records	GIS databases & utility atlases	Baseline topology, planned layouts, design intent, ownership context	Often incomplete or outdated; may represent design not as-built
	As-built drawings & owner records	Approximate alignment, Material specifications, installation dates, and historical context	Fragmented across agencies; inconsistent georeferencing; unknown coordinate datums
	Historical maps & archived plans	Identifying legacy or abandoned utilities	Poor accuracy; unknown reference systems; unverified current existence
T2 – Optical / Visual	Photos, video logs, & field documentation	Chronological record of exposed assets, materials, and construction activities	Unstructured; lacks spatial reference; no subsurface detection
	UAV & aerial imagery	Surface context, obstructions, site topography, and progress monitoring	Cannot detect buried utilities; weather/lighting dependent; requires airspace clearance
	CCTV & pipeline inspection	Internal condition (corrosion, cracks, blockages) of accessible pipelines	Limited to pipe interiors; lacks external positional data
T3 – Geospatial / Surveying	GNSS (RTK / PPK)	Centimeter-level positioning of exposed utilities and survey control	GNSS-denied environments; multipath errors; requires clear sky view
	Total station survey	Millimeter-level precision for exposed utility geometry	Line-of-sight constraints; limited range
	Laser scanning (TLS/MLS)	High-density 3D capture of exposed infrastructure (TLS) or rapid corridor mapping (MLS)	Requires exposure; setup effort (TLS); reduced accuracy in cluttered environments (MLS)
T4 – Geophysical / NDT	Ground penetrating radar (GPR)	Detection of shallow utilities; non-metallic pipes	Performance dependent on soil conditions; interpretation uncertainty
	Electromagnetic locating (EML)	Tracing metallic utilities and plastic pipes with tracer wire	Ineffective without intact tracer
	Acoustic leak detection	Identifying pressurized leaks in utility networks	Ineffective for gravity or low-pressure systems
	Fiber-optic & strain sensing	Distributed monitoring of instrumented pipelines	Requires pre-installed sensors; does not locate unmapped utilities
T5 – Intrusive / Verification	Vacuum excavation (hydrovac)	Non-destructive exposure for verification and safe clearance	Cost and access constraints
	Test pits & trenches	Direct confirmation of position, depth & material	High disruption; reinstatement required
	Boreholes	Stratigraphy and groundwater assessment for design planning	Risk of utility strikes; limited lateral information
	Manhole & chamber surveys	Direct measurement of invert elevations, pipe sizes, and connectivity	Limited to existing access points; confined space hazards

physical survey results (T4) are treated as the primary source for positional attributes (P) within the surveyed area, as they reflect physical detection rather than historical records (T1). Record-based sources (T1) remain relevant for material (M) and functional (F) attributes not directly inferred from geophysical methods. Such discrepancies are recorded in survey metadata (S) and act as a trigger for escalation to intrusive verification (E4/T5) where conflicts occur within the planned work zone.

5.6 Framework use and interpretation

The framework is intended to be applied iteratively. For a given spatial extent, users first assess existing information and current confidence, define the intended construction or maintenance activity, and identify the required confidence level. The framework then guides whether existing information is sufficient, whether escalation is warranted, and which events represent high-value opportunities for durable data capture.

By structuring utility data collection around construction and maintenance events, the framework supports incremental improvement of subsurface information over time. It enables authorities, designers, and contractors to move beyond static records and ad-hoc investigations toward a coordinated, confidence-aware approach aligned with real construction workflows.

5.7 Illustrative application scenarios

To illustrate how the framework supports decision-making, Table 3 summarizes representative, illustrative scenarios. These scenarios demonstrate how the framework guides escalation, technology classes, and opportunistic data capture under different construction intents and site conditions. These examples provide operational clarity without prescribing rigid procedures.

6 Discussion and Implications

This study proposes an event-based utility data collection framework that reframes subsurface information management as a construction- and maintenance-driven process, rather than a one-time or pre-design activity. The primary contribution lies not in introducing new sensing technologies or data standards, but in operationalising when, under what construction conditions, and with what confidence utility data should be acquired within real construction workflows.

Existing standards and guidance have established data quality concepts, investigation methods, and documentation requirements, significantly improving awareness of subsurface uncertainty. The proposed framework complements these efforts by providing an explicit operational layer that links such guidance to recurring lifecycle events. By distinguishing between current confidence and

Table 3. Illustrative application scenarios

Scenario	Context	Framework Application	Expected outcome
Baseline understanding and risk screening for planned works	Planned surface works (e.g., resurfacing) in a utility-dense corridor using primarily GIS and legacy as-builts	Framework applied at corridor level. Assessment begins at E1 with current confidence assigned per utility. Low-confidence utilities are flagged, and escalation to E2 or E3 is triggered only where construction risk or congestion justifies it.	Selective escalation improves confidence where needed, avoiding unnecessary investigations and supporting construction safety.
New utility installation - open-cut	Open excavation for new line installation	Baseline from E1; open-cut treated as opportunistic high-value capture event (E5). Comprehensive as-built data captured using T2, T3, T5 during exposure before backfilling	High-confidence as-built update eliminates need for future E2–E4 investigations in this zone
New utility installation - trenchless (HDD)	New HDD installation beneath a road where post-installation verification is limited	Trenchless installation (E6) require pre-construction escalation to E3/E4 to verify existing utility positions, as post-installation correction is not feasible	Prevents utility strikes and alignment errors that cannot be rectified after drilling
Maintenance and repair as opportunistic capture	Routine or emergency maintenance requiring temporary exposure of utilities	Maintenance (E7) treated as opportunistic capture event. Exposed utility attributes systematically recorded using T2, T3, T5 and integrated into authoritative records to update confidence	Maintenance events incrementally improve authoritative records at marginal cost.
Multi-utility coordination in brownfield corridors	Fragmented ownership, inconsistent records, conflicting stakeholder data	Framework applied at spatial-extent level. Current confidence is assessed per utility; missing or conflicting records are treated as low confidence, triggering selective escalation to E3/E4. Confidence is updated per utility to support coordinated decision-making across stakeholders.	Improved coordination, reduced disputes, and increased corridor-level confidence.
Incremental information improvement over time	Authority lacks resources for comprehensive resurveying	Framework is institutionalized to require data capture at high-value events such as E4, E5, and E7. Each intervention incrementally updates records and confidence without dedicated survey campaigns	Progressive update of utility information supports long-term asset management & reduces repeated investigations.

achievable confidence, the framework supports transparent and defensible escalation decisions without assuming that higher investigation levels are always necessary.

Importantly, the framework does not prescribe rigid sequences or mandatory investigations. Instead, it formalizes a decision logic that allows events to be skipped, revisited, or escalated based on construction intent, access conditions, and risk. This flexibility reflects real construction practice and avoids the inefficiencies associated with uniform or overly conservative investigation requirements.

From a construction perspective, the framework supports risk-informed decision-making by clarifying when existing information is sufficient and when escalation is justified, particularly for high-risk activities such as trenchless installations. For asset owners and authorities, it provides a consistent basis for defining permit conditions, inspection requirements, and data capture obligations without prescribing specific technologies or vendors.

A key practical implication is the explicit recognition of construction, maintenance, and decommissioning activities as high-value data capture opportunities. Systematic recording during these events enables incremental improvement of utility records over time, reducing reliance on repeated standalone investigations and supporting long-term asset information quality.

The use of technology classes rather than specific instruments is a deliberate design choice. Known applicability constraints, such as material dependency of geophysical methods or access limitations for surveying, are addressed through technology applicability tables and embedded escalation logic. The framework therefore guides how technology limitations should influence decisions, rather than attempting to optimize sensor selection.

This study does not claim to eliminate uncertainty or replace engineering judgement. Site-specific conditions, contractual constraints, and safety considerations remain critical and must be addressed by practitioners. The framework has been developed through synthesis of standards, prior research, and construction practice and illustrated through representative scenarios. Large-scale field validation and quantitative assessment are identified as important areas for future work.

7 Conclusion

This paper presented an event-based utility data collection framework that aligns subsurface utility information acquisition with construction and maintenance workflows. By structuring utility data collection around lifecycle events, data categories, technology classes, and confidence considerations, the framework provides practical guidance on when data should be collected, when escalation is warranted, and when construction activities should be leveraged as durable data capture opportunities.

The proposed approach shifts utility data management from a predominantly record- or survey-driven paradigm toward a workflow-integrated, confidence-aware process. Rather than requiring comprehensive resurveying, the framework enables incremental improvement of utility information through routine construction and maintenance activities, supporting safer construction, improved coordi-

nation among stakeholders, and more reliable long-term asset records.

Future work may focus on implementing the framework within digital platforms, evaluating its application across diverse project types, and exploring automated or semi-automated support for confidence assessment and escalation decisions. Nevertheless, the framework provides a structured foundation for operationalising existing standards and technologies within real construction contexts.

Abstract –

The rapid change in global climatic conditions and the increasing number of severe climate events have urged the demand for rapid, installable, customized, and sustainable housing solutions for climate-affected and displaced populations. To address this concern, this study develops a modular housing system tailored for climate displacements that integrates prefabricated bio-panel construction with an immersive digital design and evaluation workflow. The proposed design approach is based on the Building Information Modelling (BIM) framework to enable the systematic parametric integration of architectural quality, structural coherence, environmental performance, and human-centered design criteria.

An example of a housing design deliverable is studied based on dry-assembled prefabricated bio-panel components to support rapid on-site installation, reduced construction time, and limited dependence on skilled labor. Prefabrication design logic allows individual units to operate independently or be assembled as a large housing compound, which will facilitate expandable displacement community developments across diverse climatic and geographical regions. The BIM design is integrated with the Low-Latency Mixed Reality Design Platform (LMRDP) through a customized Revit API–based workflow, enabling high-fidelity design visualization to engage users. This integration enables seamless data transfer to an almost real-time MR application deployed to an MR headset. Based on the example demonstration, this study showcases a pathway to the combined potential of modular construction, BIM, and MR to enhance early-stage design evaluation, spatial usability assessment, and user engagement to support sustainable housing solutions for climate-affected displaced populations.

Keywords –

Climate displacement; Modular housing design; Building Information Modeling (BIM); Mixed Reality (MR); WebSocket

1 Introduction

Climate change has increased the number of people to lose their homes due to floods, fires, droughts, and other natural disasters. Every year, millions of people are forced to move and become climate refugees. Many of them need safe and comfortable housing that can be quickly built and used for different lengths of time. Traditional emergency shelters are often constructed in a hurry, using materials that are not environmentally friendly and do not provide adequate living comfort.

Modern construction methods allow for the design of modular prefabricated houses that can be manufactured in a factory, easily transported, and quickly assembled on site. These systems allow buildings to be reused or relocated as needed, reducing waste and promoting sustainable construction. Previous studies show that modular and off-site construction supply chains can save time, lower costs, and improve building quality [1][2] in post-disaster situations.

This study is designed based on the climate refugees' community needs for temporary homes that are easy to build, move, energy efficient, and comfortable to live in. The design uses EcoCocon straw panels as the main material for walls and roofs. These panels provide good thermal insulation, allow the building to “breathe,” and store carbon throughout their lifetime [3]. The use of natural materials helps to create healthy indoor conditions while reducing the environmental impact of construction. Several types of modular units, including small and medium-sized residential buildings, multi-room family modules, office and technical units, as well as shared spaces such as playgrounds, are proposed. Each module can be combined with others or used separately, depending on the number of residents and the specific location.

Thus, the study presents proof of concept design and system development efforts that integrate climate-

responsive design, modular construction, and a mixed reality (MR)-based digital toolkit. Overall, the study indicates how modular construction and biomaterials can help create climate-resilient homes that are fast to build, easy to transport, and pleasant to live in. For this purpose, a digital toolkit using MR and WebSocket is developed to enhance the visualization experience. The BIM model of the housing design, with local climate data (temperature, wind, etc.) adapted to it and available cost-effective materials, is integrated into an MR environment through a self-developed low-latency MR design platform using Revit API, WebSocket protocol, and the Microsoft MRTK-3. By bridging the gap between static architectural data and immersive environments, the toolkit provides a platform for stakeholders to visualize, iterate, and optimize climate refugee housing solutions in real-time.

2 Literature review

The literature and market survey indicate that cost-effective material selection for climate refugee housing is closely linked to prefabrication, dry assembly, and lifecycle performance. Bio-based prefabricated panels, engineered timber systems, and Structural Insulated Panels (SIP) technologies are repeatedly highlighted as materials that reduce construction time, labor intensity, and waste through factory-controlled production [4][5][6]. Studies emphasize that lower embodied carbon materials, such as straw-based panels and timber products, contribute to long-term environmental savings while supporting rapid deployment [4][7]. Industrial panel systems benefit from standardization, predictable performance, and reduced on-site errors, further improving cost efficiency [6][8]. The literature emphasizes that cost effectiveness must be evaluated across the full life cycle, including transport, assembly, reuse, and potential disassembly [9][10].

Comparative analysis identifies three main material groups relevant to accelerated housing construction: bio-based prefabricated panels, engineered wood and CLT systems, and SIP or sandwich panel technologies [4][5][6]. Bio-based panels, such as straw- and hemp-based systems, prioritize low embodied carbon, carbon sequestration, and healthy indoor microclimates while remaining suitable for rapid dry assembly [4][11]. Engineered timber and CLT panels provide higher structural capacity, scalable panel dimensions, and predictable mechanical performance, enabling applications from single units to multi-story prefabrication [5][7]. SIP and sandwich panel systems focus on speed, airtightness, and high thermal resistance, offering reduced assembly time compared to conventional masonry construction [6][8].

The reviewed literature highlights that panelized and modular construction systems are well-suited to BIM-based housing design due to standardized geometries, defined tolerances, and repeatable connection logic [5][6]. Manufacturer documentation for CLT, SIP, and proprietary panel systems provides technical data that can be directly integrated into BIM workflows, supporting coordination between structure, enclosure, and building services [5][10]. Prefabrication supported by BIM improves logistics planning, panel sequencing, and quality control, reducing construction errors and material waste [7]. Standardized fastening systems, membranes, and connection components further support digital coordination and reassembly potential [7][12] [13].

The literature consistently emphasizes that temporary housing must focus on human comfort, health, and adaptability alongside technical performance. Bio-based panels are known for their positive impact on indoor air quality and hygrothermal behavior, supporting healthy indoor environments for displaced populations [4][11]. High thermal resistance, airtightness, and moisture control are identified as critical factors for maintaining comfort across different climates [6][8]. Modular panel systems allow flexible layouts and scalable unit combinations, supporting various household sizes and shared community spaces [7]. Material selection is therefore shown to influence not only environmental performance and reusability but also occupants' sense of safety, comfort, and acceptance of temporary housing solutions [9][10].

The integration of BIM and MR represents a shift from traditional, asynchronous file-based exchanges toward synchronous, model-based collaborative environments [14]. BIM parametric designs are useful for managing the prefabrication supply chains and mass customization of houses [15]. MR distinguishes itself from other immersive technologies by overlaying virtual models onto physical contexts to facilitate real-time decision-making and on-site coordination [16][17]. Current literature suggests that integrating immersive technologies with parametric BIM models allows for the simulation of complex variables, such as energy performance and material impacts, within a shared digital-physical space [18][19].

To overcome the interoperability limitations of traditional formats like IFC and gbXML, recent research emphasizes the necessity of real-time, bidirectional protocols [19]. By utilizing low-latency frameworks such as WebSocket alongside specialized toolkits like Microsoft MRTK-3, designers can establish an open-source toolkit. This integration ensures data continuity and enables multiple users to visualize, edit, and validate housing designs simultaneously, ultimately reducing material wastage and ensuring that climate-responsive shelters can be optimized based on their specific geographic and economic constraints [20][21][22].

Conventional web communication protocols, such as HTTP and TCP/IP, are reliable but limited for real-time collaboration between BIM and MR [23]. They rely on request-response models that require established and closed connections, which causes non-negligible latency [24]. In HTTP, every client's request starts a new connection. It receives the server response after transmitting header data, creating significant delays for real-time connections required by multi-BIM collaboration [25][26]. As for TCP/IP, it requires frequent handshakes and acknowledgments, making it inefficient in terms of low-latency synchronization scenarios [24].

On the other hand, the WebSocket protocol solves these problems by providing a persistent, bi-directional channel over a single TCP connection, allowing clients and servers to exchange messages and data simultaneously without repeatedly building connections [27]. Once the initial handshake occurs, both client and server can push updates instantly, which reduces latency and resource burden. The research conducted by Łasocha and Badurowicz shows that when transmitting more than 100 copies of data using the WebSocket protocol (compared to HTTP), performance can be increased by several hundred percent [24]. While latency tests run by Pandey and Gill present that under high concurrency (5,000 users), the WebSocket application maintained an average latency of 30ms, compared to an average of 120ms for the HTTP long-polling application [28].

3 BIM-based modular housing design

3.1 Conceptual design of the house in BIM

The proposed system of temporary modular housing for climate refugees is grounded in the principles of mobility, modularity, and sustainability. Its primary aim is to deliver dignified, energy-efficient housing that can be deployed quickly and adaptable in different climatic conditions and social settings.

Each unit, Residential Single, Residential Double, Residential Multi-room, Office, and technical modules, is designed as part of a flexible and adaptable assembly system. Depending on the emergency situation, modules may function as standalone units or be combined to form compact settlements. Residential units are intended for two- and four-person households, while larger multi-room and dormitory configurations allow for shared facilities such as communal kitchens and sanitary cores. The detailed floor layout of the Residential Double module is shown in Figure 1, while Figure 2 presents a three-dimensional schematic view of the module, illustrating its spatial organization and structural logic. This modular logic supports the development of scalable settlements that encourage social interaction and community cohesion.

The housing modules are conceived as self-contained units that can also be interconnected through shared energy and water infrastructure where appropriate. This approach allows communities to function semi-autonomously while maintaining resilience in situations where existing infrastructure may be disrupted by natural disasters.

The modular system enables flexible reconfiguration across different terrains, climates, and settlement scales, with units operating independently or forming larger housing clusters. To accommodate varied site conditions, the housing units are designed to be installed on pile foundations, which allow construction on uneven or challenging terrain with minimal ground intervention. Lightweight construction and dry-assembly methods allow efficient installation, dismantling, and relocation. This approach corresponds with research on modular and off-site construction, which highlights improvements in response speed, cost efficiency, and sustainability in post-disaster housing [1].

3.2 Design philosophy and architectural criteria for climate refugee value

The design philosophy is based on a human-centered and regenerative approach that addresses both immediate emergency needs and long-term recovery, with a clear focus on architectural value for climate refugees. The primary objective is to create architecture that supports dignity, safety, and a sense of identity under temporary living conditions.

Dignity and psychological comfort are addressed through architectural criteria that prioritize privacy, daylight, and ventilation. Each housing unit provides a well-ventilated and daylit interior while avoiding the repetitive uniformity typical of refugee camps. Instead, the layouts emphasize personal space and establish a

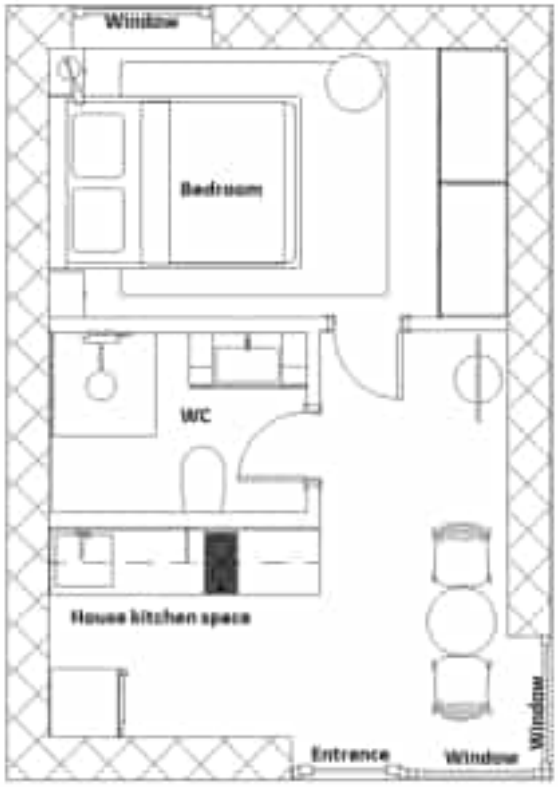

Figure 1. Detailed layout of the residential module

Figure 2. 3D view of the residential double module

hierarchy between private, semi-private, and shared zones, reinforcing residents' well-being and autonomy. Generous window openings, glazed entrance doors, and a roof-level window in the sanitary unit enhance the quality of natural light and improve overall spatial comfort without relying on artificial systems.

Furthermore, research in the fields of post-disaster architecture and humanitarian architecture emphasizes that community-oriented spatial planning, such as communal kitchens, open gathering spaces, and shared sanitation modules, can strengthen social cohesion and community-led recovery processes, transforming temporary shelters into vibrant social infrastructures. In line with this approach, the proposed modular system not only acts as a response to emergency housing needs but also as a platform for community resilience, allowing residents to regain a sense of normality, activity, and belonging in transitional conditions.

Aesthetic and spatial identity contribute to the architectural value of temporary housing by reinforcing a sense of home. The architectural expression is intentionally restrained, prioritizing functional clarity and emotional warmth. An asymmetrical roof form introduces visual variation while reinforcing a sense of shelter, while the combination of natural wood surfaces and anthracite window frames creates a familiar and calming domestic atmosphere that supports dignity and acceptance in temporary living environments.

3.3 Material selection to incorporate human aspects

Material selection is essential for addressing human needs in temporary housing for climate refugees. In addition to structural performance, materials influence indoor comfort, health, and psychological well-being. Studies in humanitarian architecture show that healthy indoor environments and natural materiality support emotional stability and adaptation of displaced populations [24][25].

Bio-based materials such as wood and straw contribute to improved indoor air quality and moisture regulation due to their breathable properties [7][9]. These characteristics help maintain stable indoor conditions and reduce dependence on mechanical systems, which is especially important in temporary and emergency housing. Research also indicates that natural materials create a more familiar and non-institutional atmosphere, positively affecting residents' mental well-being [26].

The use of EcoCocon straw-based prefabricated panels supports a human-centered design approach by combining high thermal insulation with vapor permeability and low environmental impact [3]. Thermal stability reduces stress caused by climate extremes, while renewable, low-carbon materials align with ethical and sustainability principles relevant to long-term displacement scenarios.

The structural and envelope system is based on EcoCocon straw-prefabricated panels used for both walls and roofing [4]. These panels are carbon-negative, offer high thermal insulation performance (U-value $\approx$ 0.12 W/m²K), and remain vapor-permeable while achieving a high level of airtightness. Interior partition walls are designed as lightweight gypsum board systems, allowing

flexible space planning and ease of modification over time. Construction is based on a dry-assembly process, eliminating the need for wet construction methods or heavy machinery. This enables fast on-site installation as well as straightforward disassembly when relocation is required, aligning with the project's sustainability and circularity objectives.

3.4 User experience: Contractors, owners, and Humanitarian organizations

User experience in temporary housing systems for climate refugees involves several stakeholder groups, including contractors, owners, and humanitarian organizations. For contractors, modular construction systems must ensure clear assembly logic, standardized components, and minimal reliance on specialized equipment. Prefabricated panel systems, such as straw-based EcoCocon panels, support dry construction processes, which simplify on-site work and improve construction reliability in emergencies and remote contexts [4][7].

From the owners and project coordinators' perspective, adaptability and resource efficiency are key factors. Modular housing solutions that allow reconfiguration, reuse, and relocation improve long-term value and operational flexibility. This approach also results in cost savings for owners, as the housing units are designed for repeated assembly and multiple life cycles rather than single-use deployment. Research in modular and off-site construction highlights that standardized systems reduce maintenance complexity and support scalable deployment in humanitarian housing projects [6].

Humanitarian organizations act as coordinators between residents, local authorities, and technical partners. Organizations such as Okanagan 4 Ukraine focus on community support, integration, and well-being of displaced persons through coordinated services, partnerships, and local engagement [8]. Their activities demonstrate that housing solutions must not only provide shelter but also enable social interaction, access to support services, and community-building. Therefore, ease of deployment, flexibility, and compatibility with humanitarian operations are essential design criteria for temporary housing systems.

4 Development of a digital design toolkit

4.1 Integration of BIM and MR

The integration of BIM and MR is executed through a self-developed Low-latency Mixed Reality Design Platform (LMRDP), which is discussed in detail in 4.2. The BIM model of the climate refugee housing, together with local climate data (temperature, wind, etc.), adapted to it and available cost-effective materials, is transferred to Unity using a customized Revit add-in and finally deployed to Microsoft HoloLens-2 for visualization and interaction in the MR environment. This add-in utilizes the Revit API to extract high-fidelity geometry and material data, exporting them as OBJ and MTL files to a central cloud WebSocket server.

The integration is completed within a 3D game engine (Unity), where the digital assets are reconstructed into a digital dashboard. By leveraging the Microsoft MRTK-3, the platform enables spatial awareness and hand-tracking interactions, allowing users to manipulate the model (scale, rotate, and translate) in a real-world physical context. This workflow ensures that complex architectural and environmental data from the BIM environment is not only visualized but is also interactive and actionable for on-site decision-making.

Furthermore, the toolkit integrates the digital dashboard directly into the MR application. This dashboard can link the immersive model to any web-based platform, offering the automation features of the dashboard. The interface of this digital dashboard is shown in Figure 3.

Figure 3. Digital design dashboard of the integrated BIM system in a 3D game engine

4.2 Open-source design toolkit

The LMRDP is developed as an open-source toolkit to facilitate collaborative design among architects, engineers, and humanitarian organizations. The architectural backbone of the toolkit is a Node.js WebSocket server hosted on a remote Ubuntu instance on the Amazon Web Services platform, which enables persistent, real-time communication between distributed clients. This configuration replaces traditional, asynchronous file transfers with a low-latency pipeline capable of transmitting binary data in sequential 8KB chunks, ensuring that model updates are synchronized across the design team instantly.

To lower the barrier of entry for the stakeholders, the

toolkit includes a customized "WebSocket Connector" plugin for Unity. This plugin provides a dockable interface that allows users to list, preview, and import BIM models from the server with a single click, automatically parsing the OBJ/MTL data into prefabricated Unity assets, as shown in **Error! Reference source not found.**. By providing a unified interface for real-time data exchange and environmental analysis, the LMRDP democratizes access to sophisticated design tools, allowing for the rapid development of affordable and sustainable climate refugee housing solutions in humanitarian contexts.

Figure 4. Customized Unity plugin dockable panel interface to enable WebSocket connection

4.3 Immersive user experience

The BIM model of the climate refugee housing design was imported into the Unity engine using a customized Revit add-in and a self-developed Unity plugin. This workflow allows both geometry and basic information to be transferred from Revit to a real-time 3D environment. The Unity interface was then integrated with the MRTK-3 and deployed to the MR headset (HoloLens). This setup enables MR visualization and interaction with the housing model in the real world.

The model can be visualized in Figure 5 in reality at a 1:1 scale. The virtual model of the building is aligned with the physical environment, so its size and position match real-world conditions. Users can move and rotate the model using hand gestures supported by the MR headset without any physical controllers. This makes the interaction more natural and easier to learn. Users can quickly test different positions and orientations of the building on site.

After placing the model, users can either walk around it to view the exterior from different angles or walk directly inside the building. The experience is similar to entering a real house. The interior includes key elements such as chairs, tables, WC fixtures, and a complete kitchen layout. All objects are shown at real scale. This helps users understand room size, ceiling height, and the distance between furniture items.

The immersive view allows users to better understand space and physical features. Circulation paths and room connections become easier to understand. Users can check whether the living space feels comfortable and practical. This is difficult to achieve with 2D paper drawings or screen-based 3D models. For climate refugee housing, this is especially important because such projects require efficient use of space and must provide safe and dignified living conditions.

Overall, the MR system turns the BIM model into an interactive and reality-based experience. The housing design is no longer only a digital file. It becomes a life-size virtual model that can be explored with realistic features. This enhances communication between designers, contractors, and owners. It also helps users to better understand the design layout. By combining BIM, Unity, and an MR headset, the workflow provides a practical way to evaluate spatial quality and usability at an early design stage.

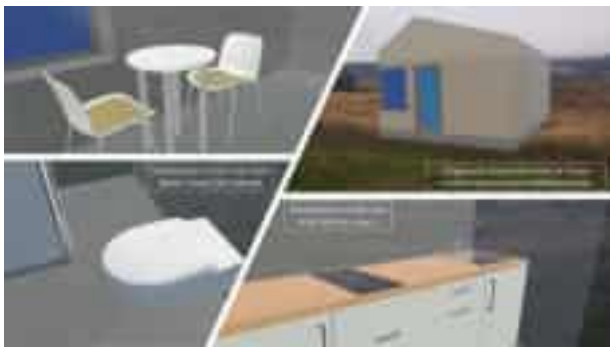

Figure 5. Visualization of the climate-displacement housing design model in MR at 1:1 scale

5 Results and discussion

The study evaluates the performance of a climate-resistant housing design in terms of adaptability to varying climatic and topographical conditions, life-cycle flexibility, and logistical efficiency. The potential outcomes of the proposed approach illustrate that the use of bio-based prefabricated panels facilitates multi-cycle reuse, simplifies transportation and assembly processes, and enhances environmental sustainability. Furthermore, the integration of modular planning and off-site fabrication improves construction efficiency while contributing to improved living conditions, including thermal comfort, spatial flexibility, and social adaptability for occupants.

The study also emphasizes that the proposed modular housing system effectively combines architectural, environmental, and human-centered criteria to meet the needs of climate refugees. The analysis indicates that the use of prefabricated bio-panel systems allows for rapid

deployment of housing, adaptation to different climatic and topographical conditions, and use over multiple life cycles. Modular logic allows housing units to function independently or as part of larger settlements, supporting scalability and flexible community formation depending on emergencies.

In addition, the research also focuses on the human aspect of design and how to make people feel safe, comfortable, and part of a community even after losing their homes. To enhance user experience in the design approach, a digital toolkit using MR and WebSocket has been developed. A high-fidelity BIM model of housing design, with local climate data (temperature, wind, etc.), is integrated into an MR environment through a self-developed low-latency MR design platform using Revit API, WebSocket protocol, and the Microsoft MRTK-3. Thus, the integration of this digital design toolkit emphasizes that the system offers clear advantages for contractors, owners, and humanitarian organizations by reducing on-site labor requirements, simplifying logistics, and enabling cost-effective reuse. These findings are consistent with existing research on modular and off-site construction, suggesting the relevance of the proposed approach for scenarios of population displacement following disasters and due to climate change.

Moreover, a detailed comparative analysis of MR-based design review against conventional methods, including user studies and quantitative performance metrics, has been conducted as part of a parallel study and will be reported separately to maintain the focus of the current work.

6 Conclusions

The increasing displacement of populations in climate-affected areas requires rapid, adaptable, and sustainable housing solutions. To address this challenge, this research developed an immersive (Mixed Reality-enabled) digital toolkit that integrates modular design principles, BIM parametric designs, and immersive visualization technologies.

The study utilized modular housing design based on prefabricated bio-panel systems as an effective response to the challenges associated with the temporary accommodation of climate refugees. The proposed approach increases construction efficiency through dry assembly methods, reduces on-site labor requirements, and allows for rapid deployment and relocation of buildings in different climatic and topographical conditions. Moreover, modular design supports the principles of reuse, scalability, and circular construction, while the choice of architecture and materials enhances indoor comfort and social well-being.

In addition, a digital toolkit using MR and WebSocket is developed to enhance the visual experience of stakeholders. The parametric housing design, including the local climate data (temperature, wind, etc.) and available cost-effective materials, is integrated into an MR environment through the low-latency MR design platform using Revit API, WebSocket protocol, and the Microsoft MRTK-3. By bridging the gap between static architectural data and immersive environments, the toolkit provides a platform for stakeholders to visualize, iterate, and optimize climate refugee housing solutions in real-time.

The proposed design workflow allows stakeholders to interact with housing designs in real time, enabling interactive exploration and collaborative decision-making, especially related to cost-effective material selection. By using MR-based solutions, the toolkit provides an intuitive and engaging platform for designing climate-resilient housing that is both cost-effective and context-sensitive.

Although the study has presented some promising outcomes, it still has some limitations. The proposed system has been evaluated at a conceptual and prototype level, and it still lacks some field implementation or stakeholder-based validation. To address these limitations, future work will focus on conducting field testing, engaging stakeholders (e.g., Okanagan 4 Ukraine, Habitat for Humanity), and performing quantitative evaluations to further evaluate the field implementation and validation of the proposed approach.
